which states that the modulus of a unidirectional fiber composite is proportional to the volume fractions (f) of the materials in the composite. The rule of mixtures can also be applied to composite strength and composite density. Beside increased mechanical performance, bioactive glass as a part of a composite may enhance the biocompatibility of the formed composite when the appropriate amount of glass is free for surrounding tissue fluids. Bioactive glass is reported to enhance osteoblast growth, proliferation, and differentiation and recent findings indicate bioactive glass as a part of tissue engineered scaffolds positively affects the formation of vascularization to the tissue engineered construct.^[13]

CONCLUSIONS

Melt spinning is an old manufacturing technique that can be used with materials that can be melted and reformed. It is mainly utilized to manufacture polymer and glass fibers. Within past decades, the introduction of new biomaterials and further developments in melt spinning and fiber processing techniques, together with the use of more accurate and comprehensive testing, all significantly influenced advancing fibers and fabrics for medical applications. Especially in the field of tissue engineering, ever-new challenges are presented for biomaterials. Many biological structures have fibers in some scale and, thus, it is likely that fibers will play an even greater role in the future in the fields of biomaterials and biomedical engineering. Further information on the subject can be found in the references.

Metallic Orthopedic Devices: Failure Analysis

Lyle D. Zardiackas

Department of Biomedical Materials Science, University of Mississippi Medical Center, Jackson, Mississippi, U.S.A.

INTRODUCTION

Failure, as defined by Webster,^[1] is paraphrased as the omission or inability to perform a function. As the function of implanted metallic orthopedic and oral maxillofacial devices may or may not be to serve as definitive substitutes for bone or other hard tissues, this definition provides an interesting dilemma in relation to failed implants. Assessment of a defect is dependent on application rather than on fracture or deterioration. It is, therefore, imperative to carefully consider the function of the device when assessing success or failure.

Prediction of the physiological loads and the biological changes, which may occur, is not possible, and success or failure of the implant is often dependent on the patient. When assessing the adequacy of a device, especially a fracture fixation device, it is important, therefore, to correlate the "failure" of the device with patient record information. In establishing intended function, it is necessary to point out that these metallic implants may be separated into two categories: (i) Fracture fixation devices are used to anatomically align the bone to promote healing and (ii) Metallic prostheses are designed for long-term replacement of bone.

BIOLOGY, STRUCTURE, AND PROPERTIES OF BONE

Although it is true that all systems change with environment and time (expand, contract, corrode, change phase, etc.), none changes with such dynamics as does a living, growing system such as bone. In addition to the bone itself, the presence and interaction of soft tissues (muscles, ligaments, tendons, blood vessels, etc.) guide and often limit the implanted device in dimension, composition, and properties, and it is the patient in whom the device is implanted who often controls success and limits the restoration of function. Failure to consider these factors, can and will, in many cases, lead to patient problems such as infection, rejection, and delayed union or non-union owing to a variety of factors including stress shielding. These factors are far more profound considerations than fracture of the implant.

Bone is elastic, anisotropic, and hard and tough in compression and tension.^[2] Outer cortical bone is dense and compact and is often compared to reinforced concrete. The inner cancellous bone consists of trabeculae and lamellae, which are tiny slender spicules. Both cortical and cancellous bones are porous; however, the former is less porous. The elastic properties of bone can be defined by Hooke's Law (elastic behavior). A thorough discussion of bone on the cellular level may be found in many texts.^[3-5]

Many biological and physiological mechanisms are activated by bone fracture, but the actual nature of the stimulus for new bone formation following trauma is unknown. However, when a bone is broken or sectioned, blood from ruptured medullary, periosteal, and adjacent soft tissue vessels extravasates so that a hematoma or clot is formed around the fractured or sectioned location, periosteal and intraosseous osteoblasts are activated, and bone stem cells form new osteoblasts. Within a short period of time, a callus, which includes cartilage and fibrocartilage, is formed between the two ends. In the case of a fracture or osteotomy, the osteoblastic activity is accelerated by mechanical internal fixation, which causes compression and tension of cortical bone.^[6] If bone receives an insufficient amount of stress or strain (stress or strain shielding), bone remodeling is hindered.^[7-8] Mineralization and demineralization, which are controlled by nutrition, activity, hormones, patient physiology, and rest, affect bone growth.

IMPLANTS FOR FRACTURE FIXATION AND JOINT REPLACEMENT

As previously stated, implants for fixation are designed to provide stabilization during healing. As the sites and patient needs are highly variable, great versatility and adaptability of these implants are required. Various sizes and types of plates, nails, screws, wires, etc., which may be further customized during surgery to meet specific anatomical conditions, have been developed; but this array of devices cannot be infinite.

Metallic prostheses are most often designed to be replacements for joints and are often thought of as permanent. They should not, however, be considered

Fig. 1 (A) Microstructure of annealed 316 L stainless steel (100x), (B) microstructure of cold worked 316 L stainless steel (100x), and (C) globular oxide (Type D) and sulfide stringer (Type A) inclusions in 316 L stainless steel (100x).

permanent but rather as definitive and will deteriorate over time because they are subject to the same physiological environment, which caused failure of the original biological joint. It is recognized that implant degradation begins once it is placed or, at least, as soon as it is loaded. Various sizes, types, and material combinations are used in the manufacture of prostheses such as hips, knees, shoulder, and temporomandibular joints. Unlike the situation with fracture fixation devices, there has been success in providing custom prostheses primarily because joint replacement is anticipated before surgery and is patient specific.

Complications arising from any one or more of the following factors may contribute to or cause fracture prior to healing of the bone:

1. Loosening of the implant owing to bone resorption.
2. Delayed union or non-union owing to biological considerations.
3. Secondary trauma at or near the original fracture site.
4. Overloading of the implant by the patient.
5. Inadequate reduction or alignment.
6. Improper implant handling during placement.

7. Implant degradation owing to biological considerations.
8. Implant wear.

Great care has been taken here to elucidate these concepts because of the use or misuse of the term “implant failure.” This terminology is used by those who are knowledgeable in the field to describe the failure of an implant to achieve its intended function owing to inadequacy of materials, design, or manufacturing defects that render the device unsuitable. Material defect levels must be compared with values defined by the appropriate specifications for the specific material by which the implant is made. The existence of manufacturing defects must be determined based upon limitations imposed by the host and surgical limitations. Additionally, the appropriate manufacturing documents for the specific device, as well as upon ASTM International^[2] and International Standards Organization (ISO) specifications, where appropriate must be examined.

Design defects are much more difficult to determine because the device must be examined based upon research including in vitro evaluation, and, most importantly, use by patients. Input from experts in

Fig. 2 (A) Grain structure of annealed Grade 4 CP Ti (100x); (B) grain structure of annealed Ti-6Al-4V alloy (200x); and (C) grain structure of annealed β -Ti15Mo alloy (100x).

biomaterials, biomechanics, and certainly from surgeons is required to evaluate the suitability of a device for its intended application. It must always be recognized that fracture of a device does not necessarily mean failure or even inadequate design, faulty material, or surgical error, and it is always a race between implant failure and bone healing. More often than not, repeated mechanical stresses on the implant beyond its design capabilities result in fracture.

The reasons for delayed union and non-union of bone are varied and numerous, and are generally not in the control of the surgeon and implant or device manufacturer; and patient non-compliance is often not easily discernible. In the case of failed prostheses, bone resorption, cement fracture, and fracture and/or wear of polymeric materials, which constitute one side of a bearing surface are often responsible for, or at least contribute to, failure of the implant.

Metals and Alloys

A number of metallic materials are currently accepted for use in implants and these are considered in depth elsewhere in this text. These materials have been found to be appropriate based upon their physical,

mechanical, electrochemical, and biological properties. Appropriate determination of such characteristics as the composition, grain structure and size, inclusions, foreign phases, mechanical properties, and corrosion susceptibility is key to the evaluation of the failure of an implant

The stainless steel used for fracture fixation devices is implant quality austenitic stainless steel supplied in the annealed or work-hardened condition (Fig. 1A and B). Examination of the microstructure for grain boundary precipitates, grain structure, and grain size is necessary, as these parameters are indicative of the acceptability of the material. Inclusion levels are rated in the longitudinal direction owing to elongation during cold working and the must be below certain concentration levels (Fig. 1C). A relatively new low nickel/high nitrogen-containing alloy has a number of interesting properties including higher strength, greater ductility, and longer fatigue life in the physiological environment.

Titanium (Ti) and Ti alloys constitute the second major metallic material used for this application. α -Ti exists at equilibrium at room temperature and the structure is transformed at 883°C from hexagonal close packed (hcp) to body-centered cubic (bcc) β -Ti. Commercially pure (CP) Ti (α) is supplied in four grades. As the grade number increases from 1 to 4, the

oxygen concentration increases, and, therefore, the strength increases. The strength of this material may also be appreciably increased by work hardening. The grain structure of CP Ti in the annealed condition is equiaxed (Fig. 2A). The α/β Ti alloys exhibit a two-phase microstructure and have increased strength as compared to CP Ti (Fig. 2B). Over the last several years, several β -Ti alloys have been introduced (Fig. 2C). These alloys have good strength and corrosion resistance with increase ductility as compared to the α/β Ti alloys.

Metals with Co and Cr as the primary alloying elements constitute the final major metallic system. These alloys are not used for fixations devices but are used for prostheses owing to their high elastic modulus, high strength (tensile and yield), high rate of work hardening with a commensurate reduction in ductility, as well as other factors. Of primary importance in their use for a fixation device is an increased probability of stress shielding of bone resulting in delayed or non-union. These alloys also form single-phase microstructures. The grains in the as-cast condition are very large, and only a few grains may be visible in a transverse section of a

casting (Fig. 3A). The structure of wrought alloys is generally equiaxed with much smaller grains than either the cast alloy or the other wrought alloy (Fig. 3B). Over the last several years, alloys with higher strength and hardness have been developed by conventional and powder metallurgical techniques. The microstructure of these alloys may have a small grain size and very fine, segregated carbides (Fig. 3C).

In addition to compositional analysis and metallurgical analysis to assure compliance with the appropriate specifications, evaluation of compliance with manufacturing documents is required. Evaluation of dimensional specifications is often impossible as the retrieved implant may have areas of corrosion, wear, or deformation caused during implantation, retrieval, handling, and/or while in the patient.

FAILURE ANALYSIS OF FRACTURE FIXATION DEVICES

It is necessary to ensure that retrieved implants are properly sterilized prior to handling, and it is often

Fig. 5 (A) Light micrograph showing longitudinal inclusions in DC plate of 316L stainless steel (100x); (B) light micrograph showing grain structure and ASTM grain size of 8.0 (100x); and (C) light micrograph showing etch pits and discontinuous grain boundary ditching in 316L stainless steel after screening test according to ASTM A262.

necessary to perform a thorough cleaning of the fracture surfaces to permit complete examination. Cleaning is generally accomplished using alcohol, acetone, or mild detergent solution in an ultrasonic cleaner and/or by the use of an enzyme if the amount of tissue is excessive.

While light microscopy is useful for the examination of these implants, it is limited by magnification and depth of field. Additionally, light microscopy is most often used for metallurgical analysis for evaluation of microstructure both prior to and after etching or

staining. Scanning electron microscopy (SEM) is used to examine areas such as fracture surfaces owing to increased depth of field at higher magnification. Often, only one of two opposing fracture surfaces needs to be examined because they are mirror images; however, if the morphological characteristics have been obscured or obliterated, examination of the opposing fracture surface is required.

In addition to examination of the implant itself, manufacturing documents, internal and appropriate

Fig. 7 (A) SEM micrograph of fracture surface of DC plate on right side of screw hole—crack initiation at upper right and (B) SEM micrograph showing striations over fracture surface in Fig. 7A.

Fig. 8 (A) SEM micrograph showing cracks on surface near area of crack initiation and (B) SEM micrograph showing multiple slip bands near screw hole.

standard specifications, patient records, and X-rays should be examined to correlate with the results of direct observations of the implant. There may be situations where all records are not available, but the structure and properties of the metal as well as the morphology of the fracture surface are often sufficient to determine the cause of failure.

Failure Analysis of Dynamic Compression Plate

Visual examination of the plate revealed that fracture had occurred transversely through the sixth screw hole

from one end of the plate (Fig. 4A). Visual and light microscopic examination of the pieces of the dynamic compression (DC) plate revealed no abnormal markings other than those that appear to have been caused by use. Examination of the screw holes showed minor-to-moderate fretting and/or fretting corrosion typical for a retrieved fixation device of this type (Fig. 4B).

To fully examine the fracture surfaces in the SEM and to provide a piece for metallurgical analysis, the plate was sectioned using an aluminum oxide blade on a high-speed metallurgical saw. The pieces were

Fig. 9 (A) Photograph of anterior cervical spine plate; (B) photograph of cephalad end anterior cervical spine plate showing wear near fracture surfaces; (C) photograph of caudal end anterior cervical spine plate showing wear near fracture surfaces; and (D) photograph of anterior cervical spine plate showing contour in plate.

Fig. 10 X-ray of anterior cervical spine plate after placement.

Fig. 11 Qualitative energy-dispersive spectroscopy of cervical anterior spine plate.

cleaned in an ultrasonic cleaner for approximately 15 min using a solution of Alconox in warm water, rinsed in water and ethanol, and dried with forced air. After instrument calibration, the small-sectioned piece was placed in the spark stand of the inductively coupled plasma (ICP) spectrometer for quantitative analysis. Three samplings were taken to determine the concentrations of the critical elements and they were found to be in compliance with ASTM and ISO specifications (Table 1).

After compositional analysis, the piece was mounted longitudinally in heat-cure transparent acrylic; the surface was polished to a final finish using 0.05 μm alumina and examined for non-metallic inclusions. Only globular oxide (Type D) inclusions were noted and rated according to ASTM E45 at a level of 1.0 thin/0.0 heavy (Fig. 5A) The sample was etched with a solution of CuCl_2 in HCl and ethanol and examined for the presence of δ -ferrite. No δ -ferrite was observed at 100x magnification.

Fig. 12 (A) SEM micrograph showing fracture surface left of screw hole on caudal section in Fig. 9C; (B) SEM micrograph of fracture surface in area of crack initiation at upper/right in Fig. 12A; (C) higher magnification of fracture surface in area of crack initiation showing fine striations; (D) higher magnification of fracture surface showing striations, wear, flutes and terraces; and (E) SEM micrograph showing cracking on anterior surface near fracture surface and screw hole.

Fig. 13 (A) SEM micrograph of fracture surface right of screw hole on caudal section; (B) higher magnification SEM micrograph of area of crack initiation at upper/left in Fig. 13A; and (C) SEM micrograph showing slip bands and cracks on anterior surface near fracture surface in Fig. 13A.

After the evaluation for δ -ferrite, the sample remounted transversely and polished to a final finish with $0.05\ \mu\text{m}$ alumina. Five^[5] Vickers microhardness (H_v) measurements were made under a 500 g load for 12 sec along the approximate midline toward each edge, at the approximate center, and at the approximate midpoints between the center and edges. These measurements resulted in a mean H_v value of 331.6, which is within the range expected for work-hardened 316 L stainless steel. The sample was etched using a solution of FeCl_3 in HCl and HNO_3 , and the ASTM grain size was determined according to ASTM E-112. The grain structure was free of carbide precipitates at the grain boundaries, the structure was twinned owing to cold working, and the ASTM grain size was determined to be 8.0 (Fig. 5B), which is within ASTM and ISO specifications. Since examination of the surface, the screw holes and the microstructure showed no signs of excess corrosion or a suspect microstructure, evaluation of intergranular corrosion was deemed unnecessary; however, should corrosion be suspect, the test for intergranular corrosion (ASTM A262) should be performed. An example of an acceptable microstructure for 316 L stainless steel after the screening test for intergranular corrosion as described in ASTM A262 is seen in Fig. 5C.

Fig. 6A is an SEM micrograph of the fracture surface on the left side of the screw hole. The chamfer for the screw head is oriented toward the top/right of the micrograph and chevron marks and clamshell marks are visible. The orientation of these marks shows that the main crack front, which resulted in fracture on this side of the screw hole, was initiated at the upper/right near the intersection of the screw hole and lateral side of the plate and the crack propagated toward the lower/left. The morphology near the site of crack initiation, seen at higher magnification in Fig. 6B, is typical of that seen over most of the fracture surface. Worn and smeared metal, secondary cracking, as well as striations, indicative of crack propagation

owing to Stage II fatigue, were noted. Many of these striations were very closely spaced ($<0.5\ \mu\text{m}$) indicating high-cycle fatigue, but the varied striation spacing indicates a variable load spectrum with both high- and low-cycle Stage II fatigue crack propagation resulting (Fig. 6C). Shear dimples, indicative of Stage III fatigue (overload), were observed at the lower left (Fig. 6D). This morphology indicates that final overload fracture on this side of the screw hole occurred in this area.

The fracture surface on the right side of the screw hole shows orientation of the chevron marks, and clamshell marks, which indicate crack initiation at the upper/left and propagation toward the lower/right (Fig. 7A). Fig. 7B shows an area at the approximate center of the fracture surface where the morphology is also indicative of Stage II fatigue under a variable load spectrum. Fig. 8A and B show the presence of additional cracks and the morphology of the crack interfaces as well as the presence of visible slip bands at and near the screw hole near the fracture surface. The morphology indicates that these cracks had formed after manufacturing and while in the patient.

Examination of the X-rays showed the position of the fracture in the bone, the condition of the bone

Fig. 14 Photograph of fractured screws.

Fig. 15 (A) Quantitative energy-dispersive spectroscopy of screw A and (B) quantitative energy-dispersive spectroscopy of screw B.

around the fracture site, and the relative position of the fracture of the plate in relation to the fracture of the bone. As further examination of X-rays and the patient record indicated a non-union, the implant eventually failed. Additionally, based upon the preceding tests and evaluations, it is concluded that the plate was produced in accordance with the appropriate metallurgical requirements and the appropriate manufacturing documents. It is concluded that the primary reason for fracture of this plate was fatigue owing to repetitive cyclical stressing by the patient, and that fracture was not related to deficiencies in the plate.

Failure Analysis of Anterior Cervical Spine Plate

Visual and light microscopic examination at up to 40x magnification revealed multiple nicks and scratches through the anodized surfaces, no generalized surface or fretting corrosion indicating occurrence after manufacturing (Fig. 9A). Wear of the posterior surface on the cephalad piece and the anterior surface on the caudal piece indicated that the cephalad section had become displaced over the caudal section after fracture (Fig. 9B and C). Additional examination of the plate and X-rays indicated that it had been contoured during

Fig. 16 (A) Microstructure of screw A and (B) microstructure of screw B.

Fig. 17 (A) SEM micrograph showing fracture surface of screw A and orientation of clamshell marks and shear lip and (B) higher magnification SEM micrograph showing striations secondary cracking and wear.

placement (Figs. 9 and 10). Prior to examination by SEM, the pieces of the plate were ultrasonically cleaned in a mild detergent solution to remove biological debris, rinsed in distilled water and ethanol, and air-dried. The anterior aspect of the cephalad section was qualitatively analyzed for major elemental composition by energy-dispersive spectrometry. The spectrum, seen in Fig. 11, shows that the only major element detected was Ti indicating that the material is CP Ti.

Fig. 12A shows the fracture surface to the left of the screw hole, the cephalad piece. Much of the fracture surface toward the posterior aspect of the plate as well as the posterior surface itself was highly worn. Wear indicates that the opposing fracture surfaces and the anterior/posterior aspects of the plate rubbed against each other during and/or after the crack had formed. The orientation of the chevron marks indicates that crack initiation was at the intersection of the screw hole and the anterior surface of the plate (upper/right Fig. 12A). The area of crack initiation is seen at higher magnification in Fig. 12B. Fine and coarse striations and wear were noted. The very fine nature of the striations ($<1\mu\text{m}$) seen at higher magnification in

Fig. 12C is indicative of high-cycle Stage II fatigue crack propagation, while coarser striations indicate higher loading during crack propagation. The area at the bottom/left in Fig. 12A showed striations, wear, and indications of tear structures often seen in fatigue of Ti (Fig. 12D). Areas near the fracture surface (Fig. 12E) show the presence of slip bands and the presence of additional cracking near the intersection of the fracture surface and both the anterior and posterior aspect.

The fracture surface to the right of the screw hole is seen in Fig. 13A. The orientation of the chevron marks, while somewhat obscured, indicates that fracture is initiated at the upper/left near the intersection of the screw hole and anterior surface of the plate. The area at the top/left of Fig. 13A, near the site of crack initiation, is seen at higher magnification in Fig. 13B. This area, as well as all other areas of this fracture surface showed striations indicative of crack propagation owing to Stage II fatigue. As with the anterior aspect on the left side of the screw hole, the presence of slip bands, some of which were opening to form additional cracks, indicates stressing of the plate after manufacturing (Fig. 13C).

Fig. 18 (A) Cracking in screw thread below fracture surface and (B) higher magnification of crack showing crack interface.

Fig. 19 (A) SEM micrograph showing fracture surface of screw B—note chevron marks; (B) higher magnification SEM micrograph showing typical fracture surface morphology; and (C) higher magnification SEM micrograph showing flutes and terraces with feather marks.

Failure Analysis of Ti Screws

The two broken screws, which were labeled A and B for identification purposes, are seen in Fig. 14. Light microscopic examination at up to 40x magnification revealed no generalized surface or fretting corrosion, and no manufacturing defects. After photographing the implants, they were rinsed in ethanol and blown dry with forced air. The heads of each screw were removed using a diamond wafering blade, and the cut surfaces of the head sections were polished to a 9 μm diamond finish and quantitatively analyzed for major alloying elements using energy-dispersive spectrometer, calibrated using a standard of CP Ti. The results as seen in Fig. 15A and B indicate that the primary element is Ti with a minor amount of iron (Fe), which is within ASTM specifications for Grade 4 CP Ti.

After compositional analysis, the heads of the screws were mounted, and polished to a final finish with colloidal silica. H_v measurements were made in three areas giving a mean value of 283.2 for screw A

Fig. 20 Photograph of fractured intramedullary (IM) nail.

and a mean value of 287.2 for screw B. These values are within the range expected for cold-worked Grade 4 CPTi. After hardness testing, the samples were etched revealing a single-phase α -microstructure with an ASTM grain size for screw A of 9.5 and an ASTM grain size between 9.5 and 10.0 for screw B (Fig. 16A and B).

The fracture surfaces and areas near the fracture surfaces of both screws were examined using SEM. Fig. 17A shows the orientation of the clamshell marks on screw A, which radiate from the area of

Fig. 21 Quantitative energy-dispersive spectroscopy of IM nail.

Fig. 22 Light micrograph showing α/β grain structure of IM nail.

initiation of the major crack front as marked with an arrow. Essentially all areas of the fracture surface, left and right of the ridge in Fig. 17A, as well as at the approximate center and at the top of the micrograph showed fine striations, secondary cracking and wear, typically seen in high-cycle Stage II fatigue crack propagation caused by patient motion (Fig. 17). Fig. 17A also shows a shear lip at the upper periphery, which is indicative of final fracture owing to overload.

The morphology of the crack in the thread immediately below the fracture surface in the region of crack initiation (Fig. 18A) as well as the crack near the head of the screw (Fig. 18B) indicates the application of significant loads after manufacturing, which led to the formation of additional cracks.

The orientation of the chevron marks, radiating from both the left and right sides of the fracture surface of screw B (Fig. 19A), indicates that two cracks were propagating and met at the ledge running from top to bottom (between the arrows). Examination of the areas at both the left and the right showed

striations, secondary cracking, and wear typical in crack propagation owing to high-cycle Stage II fatigue (Fig. 19B). Fig. 19C is typical of the morphology seen on the ledge joining the two fracture surfaces with flutes, and terraces with feather marks. This morphology is typical in fatigue fracture under a high stress intensity and/or shear of Ti. Results of examination of areas near the fracture surface and in the threads revealed no additional cracking of this screw.

These results show that the material is CP Ti with an Fe concentration well within the limits of ASTM F67, and hardness values are within the range expected for implant quality cold-worked Grade 4 CP Ti. The grain structure and grain size are within the range expected for this material. As expected, crack initiation was at or near the root of the threads and propagation was primarily high-cycle fatigue for both of the screws.

M

Failure Analysis of Intramedullary Nail

Initial visual and light microscopic examination was performed and the implant pieces were photographed (Fig. 20). A piece containing the fracture surfaces was cut from the proximal section and an additional piece was cut adjacent to the piece containing these fracture surfaces. There was significant amount of wear, which had removed the anodized layer from much of the surface of the nail and there were additional marks and gouges through the anodized surface indicating that these marks occurred after manufacturing, and no surface corrosion was observed. Examination of the fracture surfaces using light microscopy showed that the fracture surfaces were highly worn owing to rubbing against one another during and/or after fracture of the nail.

After light microscopy, fracture surfaces were ultrasonically cleaned, using a detergent in warm water, rinsed in water and ethanol, and blown dry with forced air. After polishing one of the cut surfaces with

Fig. 23 (A) SEM micrograph of distal fracture surface on one side of screw hole and (B) SEM micrograph of distal fracture on side of screw hole opposite Fig. 23A.

Fig. 24 (A) SEM micrograph showing fine fatigue striations and secondary cracks; (B) SEM micrograph of area between crack front in Fig. 24A showing orientation of shear dimples; (C) SEM micrograph showing fatigue striations and secondary cracks on proximal fracture surface; and (D) SEM micrograph showing dimples indicative of ductile tensile overload fracture.

9 μm diamond, quantitative analysis of the major alloying elements was performed using a Ti–6Al–7Nb standard. The spectrum and results, as seen in Fig. 21, show that the major elements were Ti, Al, and Nb within the levels required by ASTM and ISO specifications.

After compositional analysis, the sample was mounted and polished to a final finish with colloidal silica. Five H_v measurements were made along the diameter of the sample resulting in a mean value of 340.0, which is within the range expected for this alloy. The polished surface was etched with Kroll's reagent to reveal an α/β microstructure, with no α -case in compliance with ASTM F1295 (Fig. 22).

The fracture surfaces on both sides of the screw hole on both the distal and the proximal sections were

examined because they were all extremely worn owing to rubbing after fracture. Fig. 23A and B show fracture surfaces on both sides of the screw hole. Both clamshell marks and chevron marks indicate two different cracks initiating at the intersection of the screw hole and nail surface indicating reverse loading. Fine striations ($<1\ \mu\text{m}$) and secondary cracking indicative of crack propagation owing to high-cycle Stage II fatigue were observed (Fig. 24A). This morphology is typical of that seen over most of this fracture surface, except where the surface is highly worn and the area of overload fracture as seen in Fig. 24B. These obliterated dimples are indicative of shearing stress between the two primary crack fronts.

No further information was gleaned from examination of the fracture surface on the other side of the screw hole owing to wear; however, the opposing

Fig. 25 (A) Photograph of fractured mandibular plate and (B) X-ray showing plate in situ.

proximal fracture surface was not as significantly worn, fine fatigue striations ($<1\ \mu\text{m}$) and secondary cracking were observed (Fig. 24C). As with the fracture surface on the other side of the screw hole, final fracture was owing to ductile overload (Fig. 24D).

Review of the patient record summary, device history record, material certification documents, and X-rays indicated that the bone fracture was highly comminuted and had occurred in the central to distal third of the humerus. Fracture of the nail was seen nearly 11 mo after insertion in the area of greatest stress to the nail.

All observations indicate compliance with ASTM and manufacturer's documents and crack initiation and propagation were consistent with cyclical loading by the patient, causing fatigue fracture of the device in the area of lowest section modulus and highest stress. These findings were consistent with the patient record and the nature of the fracture of the bone.

Failure Analysis of Mandibular Reconstruction Plate

Visual and light microscopic examination of the locking reconstruction plate seen in Fig. 25A as well as examination of the patient X-rays (Fig. 25B) showed fracture between the fourth and fifth screw hole from

the posterior end of the plate in the scalloped area. Multiple nicks and scratches through the anodized surface were observed indicating that they occurred after manufacturing. The plate had been contoured through the area of fracture as well as through the two adjacent anterior and posterior scalloped areas and screw holes to achieve anatomical alignment of the mandibular arch. Fracture of the plate occurred in the area of mandibular bone resection between the ends of the posterior and anterior bone segments where the plate was unsupported and underwent maximum stress. Additionally, the X-rays indicate that the reduced cross-section region (scalloped area) through which final fracture occurred coincided with the end of the posterior mandibular bone section.

After photographing the implants, they were rinsed in ethanol and blown dry with forced air. A small piece of the plate was removed using a diamond wafering blade, and a cut surface was polished to a $9\ \mu\text{m}$ diamond finish and quantitatively analyzed for the major elements using an energy-dispersive spectrometer, which had been calibrated using a standard of CP Ti. The results as seen in Fig. 26 indicates that the primary element is Ti with a minor amount of Fe, which is within ASTM specifications for Grade 4 CP Ti.

After compositional analysis, the piece was mounted, and polished to a final finish with colloidal silica. H_v measurements were made in three areas giving a mean value of 279.8, which is within the range expected for cold-worked Grade 4 CP Ti. After hardness testing, the sample was etched revealing a single-phase α -microstructure with an ASTM grain size of 9.5 (Fig. 27).

The fracture surfaces were ultrasonically cleaned in a detergent solution, rinsed in water and ethanol, and then blown dry with forced air. Fig. 28A shows the

Fig. 26 Quantitative X-ray energy-dispersive spectroscopy of mandibular plate.

Fig. 27 Light micrograph of grain structure.

Fig. 28 (A) SEM micrograph showing distal fracture surface of mandibular reconstruction plate; (B) SEM micrograph showing oblique view of fracture surface; (C) SEM micrograph of central area of fracture surface showing fatigue striations; (D) SEM micrograph of area of fracture surface showing flutes and tear structures; and (E) SEM micrograph showing slip bands and additional cracks near fracture surface.

distal fracture surface oriented with the convex surface (buccal aspect) and the concave surface (lingual aspect) at the bottom. The nature of the fracture surface morphology indicates that the crack is initiated at the superior aspect in the area of reduced cross section between the screw holes (scallop). Fig. 28B shows the same fracture surface slightly tilted to better show the scalloped area and the orientation of the chevron marks emanating from the superior surface indicating the direction of crack propagation. While much of this fracture surface was worn, owing to repeated contact during and after fracture, Fig. 28C shows striations and wear typical of the predominant morphology seen

over most of this fracture surface. Fine striations ($< 1.0 \mu\text{m}$), secondary cracks, and wear are indicative of crack propagation owing to high-cycle Stage II fatigue. Fig. 28D shows not only striations and

Fig. 29 Photograph showing pieces of Co-Cr hip prosthesis.

Fig. 30 X-ray fluorescence analysis of hip prosthesis.

secondary cracking but also fluting and terraces with feather marks indicative of a complex state of stress, often seen in fatigue fracture of hexagonal metals such as Ti. Examination of the areas near the fracture surface and the two superior scalloped areas posterior to the fracture surface showed additional cracks and multiple slip bands indicative of relatively high stresses being placed on the plate by the patient (Fig. 28E). The presence of the slip bands and the morphology of the additional cracks initiating at or near the superior surface of the plate indicates stressing of the plate by the patient and not during manufacturing.

In conclusion, compositional analysis confirms that the material is CP Ti and the concentration of Fe is within the limits defined by ASTM F67. Further, the hardness values, grain structure and grain size are within the range expected for this material, and no manufacturing defects were detected. Crack initiation and propagation was varied and consistent with the use as identified by the patient record and X-rays.

FAILURE ANALYSIS OF PROSTHESES

The primary difference between metals used for implanted metal prostheses are that they may be cast

rather than wrought and the prosthesis is designed for long-term use. Because of the prolonged time, it may be difficult to obtain patient records and device history records. As previously stated, there are a number of factors, which may have contributed to the failure of the prosthesis other than fracture of the metal components. Another significant difference is that because the prostheses are definitive devices designed to replace bone, fracture of the metallic components has become increasingly rare.

Failure Analysis of Co–Cr Hip Stem

Fracture of the hip prosthesis discussed in the following paragraphs had occurred transversely through the stem approximately two-thirds of the distance from the distal end (Fig. 29). Prior to microstructural evaluation, a piece was cut from the stem and polished with 1 μm diamond, qualitatively analyzed using X-ray fluorescence analysis as seen in Fig. 30. The analysis indicates that the material composition is in agreement with those to be expected for implant quality casting alloy conforming to ASTM F75. This same polished sample was evaluated for Vickers hardness (H_v) and a mean value of 347.1 was

Fig. 32 (A) SEM micrograph of fracture surface of Co–Cr–Mo hip stem; (B) SEM micrograph showing saw tooth pattern on fracture surface indicative of Stage I fatigue crack growth; and (C) SEM micrograph showing fatigue striations and secondary cracking on fracture surface.

Fig. 33 Photograph of fractured tibial tray.

recorded. This value is in the range expected for cast Co–Cr–Mo alloy (ASTM F75). The inclusion content and grain structure were examined on the sample used for hardness testing. Evaluation of inclusions showed typical carbide distribution (Fig. 31A) and pores typical of castings. The sample was etched to reveal a typical cast Co–Cr–Mo alloys with large grains and dendritic grain growth (Fig. 31B).

After cleaning ultrasonically in mild detergent solution, the fracture surface was viewed from the lateral toward the medial (Fig. 32A). In addition to the fatigue striations noted in many areas of the fracture surface (Fig. 32B), of particular interest is the multifaceted appearance of much of the fracture surface. This type of morphology is consistent with planar slip in this cobalt alloy and is indicative of fatigue crack at low values of ΔK while striations normally occur at higher ΔK values. Material separation has taken place along these preferred glide planes which is typical in this alloy. Also, the small voids normally present in this type of casting should be noted. During Stage II fatigue, striations are often contained on plateaus at different levels and are joined by ledges containing striations or by tear ridges. Examination at several orientations revealed that the area above the secondary crack is not in the same plane as the area below the crack. Another view of the fracture surface, but with significant tilting can be seen in Fig. 32C, which clearly shows that the area above the crack is at a significant angle to the area below which accounts for the apparent lack of fatigue striation alignment across the crack. As the two planes are in different crystallographic directions, they are joined together by a ledge or wall containing fatigue striations.

As neither the X-rays nor the patient record were available, discussion with the patient indicated that the prosthesis had been in place for in excess of 15 yr. In addition, the patient record indicated significant fracture and deterioration of the cement as well as bone resorption. This information, along with the failure analysis, the age, and the weight of the patient

Fig. 34 Quantitative X-ray energy-dispersive spectra of Ti–6Al–4V fractured tibial tray.

indicated that fatigue of the hip stem was related to factors other than the prosthesis itself.

Failure Analysis of Tibial Tray

The fractured tibial tray, which is the subject of this fracture analysis, is seen in Fig. 33. After removal of a

Fig. 35 Light micrograph showing large grained microstructure of Ti–6Al–4V tibial tray—note microcrack (35x) at left.

Fig. 36 (A) SEM micrograph of typical fracture surface morphology; (B) higher magnification SEM micrograph showing variable striation spacing; and (C) higher magnification SEM micrograph showing striations, fluting, and terrace.

small piece of the implant, compositional analysis of major alloying elements using X-ray fluorescence analysis showed that the material was Ti-6Al-4V (Fig. 34). This piece was mounted and polished to a final finish with colloidal silica, and three H_v measurements were made resulting in a mean value of 313. The surface was then etched revealing a large grained microstructure and additional microcracks in the section (Fig. 35). This large grain microstructure indicates a cast rather than wrought tibial tray.

SEM examination of the fracture surface revealed a mixed morphology, which is typical of fatigue fracture of this alloy having a large grained microstructure. Striations, fluting, cleavage, tongues, and a saw tooth structure typical in fatigue fracture of hcp metals such as Ti-6Al-4V alloys under a variable load spectrum was observed (Fig. 36A through C).

Examination of the patient record and X-rays showed significant bone resorption below the tibial tray. No materials defects were observed and this resorption, leaving an unsupported tibial component, accounts for excessively high stresses leading to fatigue fracture.

CONCLUSIONS

It is extremely important that in none of the devices evaluated was a defect in materials, design, or manufacturing noted. This observation is most often the case. Great advances in materials and design have been made over the last several decades and while defects can occur, they are extremely rare. Analysis of any failed device requires careful attention to detail. Precise information concerning the history of the specific device is often needed to render an accurate opinion. Because implants have a direct and very personal impact on people, failure analysis information is especially important as it may lead to changes in materials, design, and manufacturing. However in most cases, failure of the device can be traced to problems with

patient biology, physiology, or failure to comply with the prescribed course of treatment. Therefore, failure analysis should not be thought of as a method to prove or disprove the adequacy of a device. Rather, the scientist should embark on the analysis with the express intent of determining: (i) If the device is faulty and (ii) What contributing factors could have led to failure if no materials, manufacturing, and/or design faults are noted.

Microcirculatory Oxygen Transport

Roland N. Pittman

Department of Physiology, Virginia Commonwealth University, and Department of Biomedical Engineering, Emergency Medicine, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

Mammalian cells require an adequate supply of energy, stored in the form of the high-energy phosphate bond of adenosine triphosphate (ATP), to carry out their various functions. Consequently, cells need a continuous supply of oxygen, as they prefer to generate ATP by the biochemical process of oxidative phosphorylation in the mitochondria. Oxygen is carried in the blood, and almost all of it (about 98%) is reversibly bound to hemoglobin in the red blood cells (RBCs). The pulmonary circulation oxygenates blood from the pulmonary artery, which has returned to the right side of the heart after giving up part of its oxygen in the peripheral tissues. The oxygenated blood from the pulmonary vein now flows into the left side of the heart, where it is pumped into the systemic circulation by the left ventricle. The oxygenated blood finally reaches the peripheral tissues through the intricate microvascular networks of the circulation, where oxygen exchange takes place between the blood and tissues across the walls of the arterioles, capillaries, and venules. Microcirculatory oxygen transport forms the subject of this article.

August Krogh, the founder of the field of microcirculatory oxygen transport, thought that most oxygen exchange occurred across the walls of the smallest microvessels, the capillaries, owing to their high surface area-to-volume ratio and the low velocity of RBCs flowing through them—conditions that maximized the opportunity for diffusive exchange. However, research over the last 30 years has indicated otherwise, because arterioles can be a major site of oxygen diffusion. There has been an increased pace of activity in this research area during the past 10 years, spurred in large part by the maturation of new methods, development of artificial oxygen carriers, and the realization of the important role played by oxygen (or rather its lack) in a number of pathophysiological situations. Based on his histological and *in situ* observations of capillaries in skeletal muscle, Krogh^[1] formulated a simple conceptual model consisting of a capillary surrounded by a concentric cylinder of oxygen-consuming tissue with uniform consumption and oxygen diffusion properties. This mathematical model has served as the basis

for most modeling in this area, although many of the simplifying assumptions of the model are not strictly valid under the most general conditions. Duling and Berne^[2] made the first systematic measurements of oxygen levels in the microcirculation and unexpectedly found that a substantial amount of oxygen was lost from the arteriolar network, prior to the loss from the capillaries.

The rapid evolution of the field of microcirculatory oxygen transport over the past 30 years has been closely linked to the development of new methods for intravital microscopy. These methods allow the direct visualization of the microcirculation and measurement of the following key oxygen transport variables in individual vessels of microvascular networks: geometric (diameter and segment length); hemodynamic (velocity, hematocrit, blood flow, and RBC flow); and oxygenation (oxygen tension and oxygen saturation). These measurements can be combined to quantify the convective flow of oxygen in microvessels, and application of mass balance for oxygen can be used to calculate the rate at which oxygen diffuses from the lumen of microvessels. This article focuses on the study of oxygen transport from the point of view of the microcirculation. The fundamental conceptual basis for the subject, the Krogh cylinder model and principles of mass transport, are emphasized. A description of the basic methods applied to measure oxygen transport variables in microvessels is presented. Results of measurements in arterioles, capillaries, and venules are summarized, along with unresolved issues and controversies associated with the measurements. Finally, future research directions involving artificial oxygen carriers, nitric oxide (NO), and pathophysiological circumstances resulting in cellular hypoxia are presented.

NEED FOR OXYGEN: CELLULAR METABOLISM

Mammalian cells need a continuous and adequate supply of oxygen to carry out their various functions. The cardiovascular system serves this need by providing blood vessels in intimate contact with the surface of most cells: the flowing blood serves a dual purpose by providing needed oxygen and by carrying

away metabolic waste products. All cells have the biochemical machinery to produce ATP. The most efficient means for producing ATP is through the process of oxidative phosphorylation. ATP is produced at several steps in the Krebs cycle and along the electron transport chain in the mitochondria. Molecular oxygen reacts with the terminal enzyme in the chain—cytochrome oxidase. As long as the partial pressure of oxygen or oxygen tension (PO_2) inside the cell is higher than about 1 mmHg, the cellular and mitochondrial oxygen consumption will not be limited by the availability of oxygen. For oxygen to reach the intracellular space and the mitochondria, it must diffuse from the RBC through several barriers imposed by the RBC membrane and plasma in the blood, the microvessel wall, the interstitial fluid, the parenchymal cell membrane, the cytoplasm, and finally the mitochondrial membrane. The PO_2 progressively decreases from the RBC to the mitochondrion, because oxygen moves by diffusion and net diffusion requires a gradient in PO_2 as its driving force. In some cells (e.g., skeletal muscle cells with oxidative fiber type), the heme protein myoglobin is present and can serve as a temporary storage depot for oxygen, and possibly as a facilitator of oxygen diffusion through carrier-mediated transport.

CARRIAGE OF OXYGEN

Oxygen is carried in two forms in the blood: 1) physically dissolved in plasma and RBC cytoplasm and 2) reversibly bound to hemoglobin molecules in the RBC. The concentration of oxygen in the dissolved form, $[O_2]_D$ in ml O_2 /ml, accounts for only about 2% of the total oxygen in blood at normal arterial oxygen saturation, and it is given by Henry's law

$$[O_2]_D = \alpha PO_2 \quad (1)$$

where α is the solubility coefficient of oxygen in ml O_2 /ml/mmHg. Most of the oxygen (about 98%) is bound to the hemoglobin inside the RBCs and the concentration of oxygen in the bound form, $[O_2]_B$, is given by

$$[O_2]_B = C_{Hb}SO_2[Hb] \quad (2)$$

where C_{Hb} is the oxygen-binding capacity of hemoglobin (1.34 ml O_2 /g/Hb), SO_2 is the oxygen saturation (or fraction of heme-binding sites occupied by oxygen), and $[Hb]$ is the hemoglobin concentration in blood (g/ml).

As RBCs flow through the circulation, the hemoglobin binds or releases oxygen according to the local PO_2 gradient. Thus, in the pulmonary circulation, there is a net uptake of oxygen by the RBCs, while in

the systemic circulation there is a net release of oxygen from the RBCs. The equilibrium relationship between SO_2 and PO_2 is the oxygen dissociation curve. Its shape is described as sigmoid and has to do with the cooperative nature of oxygen binding to hemoglobin. Hemoglobin is a tetrameric molecule composed of four polypeptide chains, two α and two β chains, each with a heme group where ligands such as oxygen, carbon monoxide, and NO can bind. The heme group consists of a porphyrin ring surrounding an iron (Fe) atom. Ferrous iron (Fe^{2+}) can reversibly bind oxygen, whereas ferric iron (Fe^{3+}) cannot. The latter oxidized form of hemoglobin is called methemoglobin, and it is not capable of binding oxygen. Hemoglobin exhibits positive cooperativity in which successive oxygen molecules bind more tightly than the previous one. A simple quantitative description of oxygen binding by hemoglobin is given by Hill's equation

$$SO_2 = (PO_2/P_{50})^n / [1 + (PO_2/P_{50})^n] \quad (3)$$

where P_{50} is the PO_2 at which the hemoglobin is 50% saturated with oxygen and n is Hill's coefficient, which describes the degree of cooperativity of binding. As P_{50} decreases, the affinity of hemoglobin for oxygen increases, making it harder for hemoglobin to release oxygen. The converse is also true: as P_{50} increases, the affinity of hemoglobin for oxygen decreases, making it easier for hemoglobin to release oxygen. P_{50} varies with temperature, pH, and partial pressure of CO_2 (PCO_2). Increases in temperature, $[H^+]$ and PCO_2 , separately or in combination, will lead to a rightward shift of the oxygen dissociation curve (i.e., to higher values of P_{50}); decreases in any of these factors will produce a leftward shift. Shifts in the curve caused by changes in $[H^+]$ and/or PCO_2 are called the Bohr effect.

CARDIOPULMONARY SYSTEM

Overall management of oxygen transport in an organism is under the coordinated control of the lungs, the heart, and the blood vessels that connect them to the systemic organs, the cardiopulmonary system. Deoxygenated blood from the peripheral tissues is directed to the right atrium, from where it passes to the right ventricle and then is pumped to the pulmonary artery, and on through the small vessels of the lung. While flowing through the pulmonary capillaries, the blood is in intimate contact with the alveolar gas spaces, where it releases carbon dioxide and picks up oxygen, both by passive diffusion. Before the blood leaves the pulmonary capillaries, it comes into equilibrium with the gas in the alveoli (i.e., both PO_2 and PCO_2 in the blood are equal to their respective partial

pressures in the alveolar gas).^[3] The oxygenated blood passes through the pulmonary vein into the left atrium and then into the left ventricle, where it is ejected into the aorta. The blood is then conducted through the arterial network to the various tissues of the body, where it flows through the microvascular networks of the individual tissues. Exchange of oxygen takes place in the microcirculation of each tissue and the deoxygenated blood is collected in the venous network and conducted back to the right atrium.

MICROCIRCULATION

Roughly speaking, the microcirculation is the collection of blood vessels that are small enough so as to require a magnified image to visualize clearly. The microcirculatory network is composed of series and parallel connections of arterioles, capillaries, and venules. The primary function of the arterioles is to control the magnitude and distribution of blood flow within the network; their walls are composed of an inner layer of endothelial cells, surrounded by vascular smooth muscle. The primary function of the capillaries is the exchange of water and small solutes; their walls are composed of a single layer of endothelial cells. The primary function of the venules is collection of the blood flowing from the capillaries; their walls are composed of an inner layer of endothelial cells surrounded by vascular smooth muscle. In regard to the exchange of oxygen, all these vessels can participate, because their walls are permeable to oxygen and PO_2 differences exist between their lumens and the interstitial fluid.^[4]

APPROACHES TO STUDYING OXYGEN TRANSPORT

Oxygen transport can be studied at various levels of organization, from the intact organism to isolated organs to isolated cells to subcellular components (e.g., mitochondria and enzymes of the electron transport chain). The combination of a small microcirculatory network (i.e., feeding arteriole, capillaries, and collecting venules) and the tissue it serves represents the smallest complete functional unit that exhibits all the features of the intact tissue. Thus, studies at the level of the microcirculation can provide a rich source of information that can be linked to behavior on a larger scale.

Mathematical modeling of microcirculatory oxygen transport can be traced back to the seminal work of Krogh,^[1] referred to earlier. Although the Krogh cylinder model has formed the basis of most modeling in this area, recent advances in computational hardware

(i.e., processor speed, memory, storage space, and parallel processing) and software design, coupled with the availability of more accurate and complete experimental data, have made it possible to create models that incorporate realistic network geometry, hemodynamic schemes, and metabolic pathways.^[5,6]

Most experimental approaches have appealed to the principles of mass balance for oxygen, in which measurements of geometry, hemodynamics, and oxygenation in unbranched segments of a network are used to compute the convective flow of oxygen (QO_2^{CONV}) into and out of the segment (Fig. 1). The difference between the rate of inflow and outflow of oxygen in the segment is equal to the rate at which oxygen diffuses (QO_2^{DIFF}) into the wall of the vessel from the lumen

$$QO_2^{DIFF} = QO_2^{CONV}(In) - QO_2^{CONV}(Out) \quad (4)$$

The diffusive flux of oxygen out of the lumen (JO_2) is the diffusive flow divided by the luminal surface area

$$JO_2 = QO_2^{DIFF} / 2\pi RL \quad (5)$$

where R is the luminal radius and L is the length of the segment. Assuming that the vessel wall does not have oxygen consumption and oxygen permeability properties different from those of most other tissues, the decrement in PO_2 across the wall (i.e., transmural PO_2) should be relatively small. This expectation is consonant with results reported by Duling and Berne.^[2] The application of this approach using the methods described in the next section yields the following expression for QO_2^{CONV} (Fig. 1):

$$QO_2^{CONV} = \pi R^2 v[Hb] SO_2 C_{Hb} \quad (6)$$

Fig. 1 Calculation of diffusive oxygen flow (QO_2^{DIFF}) or flux ($QO_2^{DIFF}/\text{luminal surface area}$) from oxygen mass balance in an unbranched arteriolar segment of internal radius, R_i , and length, L . Variables used to compute QO_2^{CONV} are R_i , v , $[Hb]$, and SO_2 . Luminal surface area is $2\pi R_i L$. Wall thickness, w , is $R_o - R_i$. Oxygen consumption of the wall of this segment is $\pi(R_o^2 - R_i^2) L M$, where M is the volume-specific oxygen uptake of the wall. (From Ref. [7].)

where v is the average blood velocity and the other symbols have been defined previously. $[Hb]$ and SO_2 are the appropriate flow-weighted average values across the vessel lumen.^[8] However, because the radial dependencies of these variables are generally unknown, measured values are averages of $[Hb]$ and SO_2 along a vertical line through the center of the vessel. Results from this approach are described below.

DEVELOPMENT OF EXPERIMENTAL METHODS

The study of microcirculatory oxygen transport requires the measurement of several geometric, hemodynamic, and oxygenation variables in the living microcirculation. The availability of an instrument to perform intravital microscopy is common to all the measurements. A research-grade microscope equipped with illumination sources for transillumination of thin tissues and epifluorescence of thin or thick tissues is needed. Microscopic images are typically viewed with a closed-circuit video camera, either analog or digital, and video monitor, with additional capability to record desired images for later observation and analysis. Recordings of video images can be made with a videocassette recorder or sequences of digital images can be stored in computer memory or on a hard drive. Geometric measurements such as vessel diameter or segment length can be made directly from the image on a video monitor or by using standard image analysis software. Hemodynamic measurements such as particle velocity and hematocrit require specialized additions to the intravital microscope. Two approaches to measuring the velocity of fluorescent particles (e.g., labeled RBCs and microspheres) using video technology include multiple flash illumination^[9] and electronic shuttering of the video camera.^[10] Both these methods provide multiple images of the moving particles. By measuring the distance moved between successive particle images of known temporal spacing, the velocity can be calculated. An alternative procedure requires the use of a dual photosensor arrangement to detect the modulation of transmitted light by the passage of RBCs past the detection region.^[11] The photometric signals at the closely spaced upstream and downstream measurement points are cross-correlated and the velocity is computed from the ratio of photosensor separation and relative time shift of the signals that produces maximum cross-correlation (so-called “dual sensor” method). The measurement of hematocrit is based on the spectrophotometric determination of $[Hb]$ in a microvessel. The optical density of blood at a wavelength that is insensitive to the oxygenation state of hemoglobin (i.e., an isosbestic wavelength) is measured and used to compute $[Hb]$ from Beer’s law of light absorption. Because RBCs scatter light, in addition to that absorbed by the hemoglobin in the RBC, it is usually

necessary to measure the optical density at a second isosbestic wavelength to correct for the contribution of light scattering to the optical density. This photometric measure of $[Hb]$ is, in general, proportional to neither tube hematocrit (volume-weighted concentration) nor discharge hematocrit (flow-weighted concentration) as discussed by Ellsworth and Pittman,^[12] owing to the nonuniform luminal distribution of RBCs. Rather, it gives the $[Hb]$ averaged over a vertical line through the center of the vessel. The measurement of SO_2 is also a spectrophotometric method requiring video images of a microvessel at two (for capillaries^[13]) or three wavelengths (for arterioles and venules^[14,15]), one of which must be a wavelength at which there is a large difference between light absorption by oxy- and deoxyhemoglobin. The measurement of PO_2 in tissues or microvessels can be carried out with polarographic microelectrodes. The recessed-tip electrodes are most appropriate for microcirculatory measurements, because they have been shown to create the least disturbance of the existing PO_2 field. Detailed descriptions of all these methods, as well as the surgical preparation of various tissues for microscopic viewing, are contained in the monograph *Microcirculatory Technology*.^[16] A more recently introduced approach to measure PO_2 relies on the ability of oxygen to quench the phosphorescence of molecules excited by a brief flash of light (phosphorescence-quenching method). The lifetime of the phosphorescence decay is inversely related to the PO_2 (Stern–Volmer relation). This method has been used to measure PO_2 in microvessels and interstitial fluid.

FINDINGS IN DIFFERENT TISSUES

The methods and experimental approaches described above have been used to investigate the transport of oxygen in the microcirculation of several different tissues in a variety of species. These studies have led to discoveries of a number of interesting and unexpected results.

Results in Arterioles

Duling and Berne^[2] reported the first systematic study of oxygen levels in the arteriolar network, using oxygen microelectrodes to measure perivascular PO_2 . Contrary to the expectation from Krogh’s work, that oxygen exchange between the blood and tissues would be the exclusive domain of the capillaries, they found a substantial and progressive loss of oxygen in the precapillary arteriolar network—a longitudinal gradient in PO_2 . Following the development of the spectrophotometric method to measure SO_2 ,^[14] subsequent work showed that the fall in perivascular PO_2 was

accompanied by a parallel fall in luminal SO_2 predictable from the oxygen dissociation curve. The simultaneous measurement of diameter, velocity, hematocrit, and SO_2 at upstream and downstream sites in unbranched arterioles allowed the calculation of convective oxygen flow at the two sites, the difference of which, by mass balance for oxygen, was the flow of oxygen from the lumen by diffusion across the arteriolar wall.^[7] It was found in resting skeletal muscle that most of the oxygen, about two-thirds, diffused from the arteriolar network and only about one-third diffused from the capillaries,^[17] corroborating the previous results of Duling and Berne.^[2] Careful comparison of the experimental results with the predictions of computational models of oxygen transport led to the finding that the apparent rate at which oxygen diffused from the arterioles was an order of magnitude higher than expected.^[18] Attempts to explain this large discrepancy have followed two different paths: 1) possible misinterpretation of incomplete data on luminal SO_2 ^[8] and 2) proposed high oxygen consumption by the arteriolar wall.^[19] There is no doubt that oxygen is lost from the arteriolar network, leading to the conclusion that there must be radial gradients in SO_2 and PO_2 .^[7] Because the measurements of SO_2 referred to above were made above the centerline of the vessel, each represented an average value along a line through the center of the arteriole. Using empirical shapes for the luminal SO_2 profiles, one can calculate the relationship between measured centerline SO_2 and the parameters used to characterize the SO_2 profile.^[8] It can be shown that reasonable values of the parameters are compatible both with the measured SO_2 and with the expected rate of oxygen diffusion from the arteriole, thereby removing the order of magnitude disagreement between experimental and computational studies. While this explanation works in principle, definitive experimental evidence in the form of actual SO_2 profiles remains to be presented. The alternative hypothesis, based on the measurement by phosphorescence-quenching of a large transmural gradient in PO_2 ,^[20] proposes that the large efflux of oxygen from the arteriolar lumen is accounted for by high oxygen consumption of the wall. This possibility is more difficult to understand, because, to account for the apparent large oxygen flux from the arterioles, the oxygen consumption of the cells in the wall must be about two orders of magnitude higher than previously reported values for vascular tissue.^[21] This circumstance appears to be unlikely and it is not clear how to otherwise reconcile the report of the large transmural PO_2 gradient with previous and widely accepted results on oxygen transport in the microcirculation. The eventual resolution of these disparate results should aid our understanding of oxygen transport in microvascular networks.

Results in Capillaries

The diameter of a capillary is typically small enough so that RBCs are constrained to flow through it in single file. The first systematic measurements of oxygen transport in capillaries were reported by Ellsworth, Popel, and Pittman.^[22] A local longitudinal gradient in SO_2 was observed, which was consistent with tissue oxygen consumption and diffusion properties of skeletal muscle, in contrast to the order of magnitude discrepancy between predicted and observed oxygen flux from the arterioles. An unexpected finding was that there was not a monotonic decrease in SO_2 from the entrance to the exit of the capillary. Rather, after an initial fall in SO_2 , there was a rise and then fall in SO_2 associated with the passage of an arteriole across the path of the capillary.^[23] This observation was later validated by computational modeling of the diffusive uptake of oxygen, from a nearby arteriole, by RBCs flowing through the capillary.^[24] A recent finding is the occurrence of fluctuations in PO_2 as RBCs and plasma gaps alternately pass an observation point along a capillary.^[25] This phenomenon of erythrocyte-associated transients in PO_2 was predicted by theoretical models from the late 1970s,^[26,27] but was only verified after the spatial (1 μm) and temporal (10 msec) resolution of the phosphorescence-quenching technique was improved to this level.

Results in Venules

Venules collect blood that has flowed through the capillaries, so that venular blood generally has a lower level of oxygenation than blood from other sites. However, in some cases the oxygenation of venular blood gradually increases from the smallest to the largest venules.^[28] Thus, it is of interest to consider potential sources of this oxygen. Because of the heterogeneity of oxygen release from the capillaries, the blood that flows into venules from different capillaries also has a similar degree of heterogeneity in respect to oxygen, and it is possible that the blood added to the venules at each successive branching order would result in an increase in blood oxygenation. In addition to this convective explanation for the increase in venular oxygenation, two potential diffusive sources of oxygen exist: 1) paired arterioles that run parallel to the venules and 2) neighboring regions of interstitial fluid with higher PO_2 than that of the venular blood.^[28] Although the case of diffusive shunting of oxygen directly between adjacent arterioles and venules in close proximity is appealing, calculations have shown that the contribution to venular oxygenation by this mechanism is negligible, except for instances where blood flow is lower than normal.^[5] The PO_2 of the

interstitial fluid that bathes all the microvessels and parenchymal cells appears to lie between the values of nearby arterioles and venules, so that it can be a source of oxygen for the venules. Because the walls of all microvessels appear to be permeable to oxygen, net diffusion of oxygen only requires for there to be a PO_2 difference between microvascular blood and a neighboring region.

EMERGING AREAS OF RESEARCH

Several research areas with a close relationship to microcirculatory oxygen transport are ripe for investigation. Three of these areas are highlighted below in this section.

Artificial Oxygen Carriers

The addition of artificial oxygen carriers or blood substitutes to the circulation can be of potential benefit when the normal complement of oxygen-carrying RBCs has been reduced, as in intentional normovolemic hemodilution or hemorrhage followed by resuscitation with crystalloids or colloids. Two major types of blood substitutes have been pursued: 1) hemoglobin-based oxygen carriers (HBOCs) that carry oxygen in the bound form and 2) perfluorocarbon emulsions (PFCs) that carry oxygen in the dissolved form.^[29]

The amount of oxygen that can be carried by a HBOC is proportional to the concentration of oxygen-binding sites in the molecule. As the name implies, HBOCs are derived from hemoglobin, typically modified by chemically cross-linking the two α or β chains of the tetramer together, preventing the tetramer from dissociating into lower molecular weight dimers. Further modifications are often made, two of the more common being polymerization of the cross-linked tetramers and decoration of the tetramer with molecules such as polyethylene glycol; these changes are made to increase the size of the HBOC.^[29] The reason for increasing the size of the HBOC is that the infusion of tetrameric hemoglobin into the circulation leads to a rapid rise in arterial blood pressure, and this pressor response can be mitigated by using larger HBOCs. The mechanism for the elevated blood pressure is under investigation, but the leading candidate is the NO-scavenging action of free hemoglobin. NO (see below) is a vascular smooth muscle relaxant produced in the endothelial cells and other places. When its concentration in the arteriolar wall decreases, a net constriction occurs, raising total peripheral resistance and arterial blood pressure. NO binds tightly to hemoglobin, so that introduction of a HBOC into the

circulation causes a rapid reduction in NO concentration, both in the lumen of microvessels and their wall, leading to vasoconstriction and a rise in blood pressure. Increasing the size of the HBOC reduces the pressor effect, presumably by making it more difficult for the HBOC to move close to the endothelial surface and reducing the ability of the HBOC to extravasate from the microcirculation and influence NO levels from the interstitial side of arterioles.

PFCs consist of submicron particles about $0.2\ \mu\text{m}$ in diameter. The amount of oxygen that can be carried by the PFC is proportional to the perfluorocarbon concentration and to the ambient PO_2 , according to Henry's law. Because PFCs do not scavenge NO, they do not exhibit the pressor response of the HBOCs. For substantial amounts of oxygen to be carried by PFCs, the ambient PO_2 must be considerably higher than that of air at sea level, and 100% oxygen is often used with PFCs to increase the amount of oxygen they can deliver.

NO and Oxygen Transport

NO is a small, diatomic, gaseous molecule that is produced enzymatically from L-arginine in the presence of oxygen. The enzyme responsible for NO synthesis is nitric oxide synthase (NOS) of which there are several isoforms, depending on the source of NO: endothelial or eNOS, neuronal or nNOS, inducible or iNOS, and mitochondrial or mtNOS. NO can influence oxygen transport in two distinct ways. First, because NO is a smooth muscle relaxant and is formed by the endothelial cells, any change in the local NO concentration will alter the diameter of the nearby resistance vessels, and hence the local blood flow responsible for the convective supply of oxygen. NO levels can increase by the action of NO-dependent vasoactive agents (e.g., acetylcholine and bradykinin) and by increases in shear stress on the endothelium. Second, because NO interacts with cytochrome oxidase and reduces mitochondrial oxygen consumption, it can also modify the demand for oxygen. Thus, NO is positioned to modulate the balance between oxygen supply and demand at the level of the microcirculation.

Pathophysiology of Oxygen Transport

As having an adequate supply of oxygen is essential to the normal functioning of all tissues, any pathological or disease state in which the oxygen supply relative to oxygen demand is reduced places a tissue in functional jeopardy. Examples of such states are cancer, diabetes, environmental hypoxia, hemodilution, hemorrhage, hypertension, inflammation, ischemia/reperfusion, sepsis, and sickle cell anemia. In most

Fig. 2 Oxygen exchange among microvessels. Current understanding of oxygen supply to tissue requires consideration of diffusive interactions among all neighboring microvessels. A microvascular network is shown, containing arterioles, venules, and capillaries, with diffusion indicated by interrupted arrows and convection of oxygen in arterioles, capillaries, and venules, indicated by appropriately shaded solid arrows. The key to understanding oxygen supply to tissue requires a consideration of the complex nature of diffusive interactions among various microvessels. (From Ref. [4].)

cases, the supply of oxygen is the limiting factor and this can be compensated for by increasing blood flow to the affected tissue or by a transfusion of RBCs or HBOC. In cases where the demand for oxygen exceeds the supply, oxygen consumption can be reduced by lowering the temperature of the affected tissue or partially inhibiting the reaction of oxygen with the electron transport chain of the mitochondria.

CONCLUSIONS

An adequate supply of oxygen to cells is critical, as almost all cells require oxygen to produce the energy that supports their function. The exchange of oxygen between the blood and tissue occurs by diffusion at

the level of microvascular networks, in particular in the arterioles and capillaries. The various possibilities for oxygen exchange are summarized in Fig. 2. Typically, oxygen is lost from the arterioles and capillaries and is acquired by the venules. The primary site of oxygen transport in a specific tissue depends on its blood flow and metabolic rate: arterioles appear to be the main site in tissues with low flow and metabolism (e.g., resting skeletal muscle), whereas the capillaries appear to be preferred in tissues with high flow and metabolism (e.g., brain and contracting skeletal muscle^[30]). Quantitative assessment of oxygen transport in arterioles has revealed a large, and as yet unresolved, discrepancy between observed oxygen flux from arterioles and that predicted by computational modeling, whereas in capillaries, there is good agreement between experimental findings and predictions. Further and more complete experimental measurements are needed to resolve the findings in arterioles.

Based on recent trends in the field, in the near future one can expect increased efforts aimed at investigating the microcirculatory mechanisms by which artificial oxygen carriers, both HBOCs and PFCs, aid in the transport of oxygen to tissues. For HBOCs, this includes optimizing the oxygen-binding properties (P_{50} and Hill coefficient) of the modified hemoglobin and understanding the mechanism responsible for the pressor effect of some HBOCs. In recognition of the roles played by NO in microcirculatory oxygen transport, there will be more research focused on direct measurement of NO with improved spatial and temporal resolution, so that its involvement in oxygen supply and demand can be delineated more clearly. There will be increased emphasis on studying microcirculatory oxygen transport in animal models of disease and other pathological conditions, so that detailed mechanisms can be elucidated for future applications to clinical medicine.

ACKNOWLEDGMENTS

The research of the author, which is included in this article, was supported in part by grants HL18292 and HL79087 from the National Heart, Lung, and Blood Institute of the National Institutes of Health. The author thanks Dr. Aleksander S. Popel and Dr. Aleksander S. Golub for discussions that have helped to clarify many of the areas covered in this article.

Microcomputed Tomography and Its Applications

INTRODUCTION

Microcomputed tomography, commonly referred to as μ CT, is a relatively new field in the area of non-destructive imaging. Like conventional computed tomography, μ CT is based on the collection of the projections of X rays through a specimen and the application of tomographic principles to reconstruct the 3-D structure of the specimen. The term micro denotes a scanning system that is much higher in resolution than conventional clinical scanners. Clinical tomographic scanners may have resolutions on the order of a millimeter or less. However, high-resolution μ CT scanners may have resolutions below five microns. This difference in resolution is what separates μ CT from conventional CT scanners. In this article, micro-computed tomography will refer to tomographic scanners that can produce images with resolutions higher than 100 microns.

With the large increase in system resolution in microcomputed tomography, there is also a concomitant decrease in the field of view that can be imaged. Historically, this has limited the use of these scanners to research areas for examination of various materials, biopsied biological tissue, or the direct examination of small animal models. Also, there are differences in the source-detector gantry. In μ CT systems where a non-living specimen is being examined, it is more convenient to rotate the specimen and keep the source and detector in a fixed position. Because there is less chance of the source and detector becoming misaligned, more precise measurements are possible.

Over the past two decades, a large variety of μ CT scanners have been designed for various uses. A primary application for μ CT is the examination of biopsied human samples or small animal models for medical and pharmaceutical research. Other applications include the examination of geological specimens for impurities and the creation of physical models through rapid prototyping methods. Most of these systems use conventional X-ray tubes to produce polychromatic radiation. However, synchrotron radiation is used for

very high-resolution imaging. These instruments produce monochromatic radiation using a large particle accelerator and are limited to a handful of laboratories around the world.

BACKGROUND

The mathematical foundation for using projection data to reconstruct an image stems back to 1917, when Dr. Johann Radon developed the Radon transform. This transform provided the mathematical framework for the reconstruction of 3-D images from a set of X-ray projection data. The first practical application of image reconstruction based on X-ray projections was attributed to Godfrey Hounsfield and Allen Cormack, who shared the Noble Prize in 1979 for their independent discovery.^[1,2] Shortly after this time, researchers began to explore the idea that computerized tomography could be realized at high resolution, allowing the unique examination of both human biopsies and small animal models. In 1980, William Oldendorf outlined some of the possible applications of high-resolution computerized tomography.^[3] The idea of using a fan beam collimator with a fixed source and detector was first introduced, which allowed the specimen to rotate in order to examine tissue in situ. This concept is now widely used in μ CT for the examination of bone biopsies for structural changes in the cancellous bone.

In 1984, Kujoory et al. created a unique system for high-resolution CT of a rat nephrogram.^[4] In their system, a horizontal fan beam of X rays was illuminated through the specimen, then through a slit collimator onto an X-ray film cassette that was continuously translating the film. The specimen was located on a turntable that had two fixed lead markers, allowing the center of the projection to be easily defined. The film cassette was then digitized offline. To avoid lengthy reconstruction times, several digitized points were averaged together, giving an effective detector resolution of 133 microns with a beam height of approximately 1 mm. Overall, this resulted in their

ability to obtain 1-mm-thick coronal sections through the rat with a lateral resolution of 150 μm . In the same year, Seguin et al.^[5] published results showing that they had achieved 50 μm resolution for a single CT slice. The advantage in their system was their use of a digital detector using an integrated array of silicon photo-diodes placed behind a scintillator.

The next improvement in μCT scanners occurred in 1989, when Feldkamp et al. published their work on the measurement of trabecular bone via 3-D computerized tomography.^[6] This scanner used cone beam tomography based on a practical algorithm developed by Feldkamp several years earlier.^[7] The system resolution was 50 microns, but this was achievable in all three dimensions (isotropic resolution). An image intensifier converted the signal to visible light, followed by a vidicon camera and frame grabber to convert the signal to a digital array. This configuration allowed the first utilization of direct 3-D measures to quantify aspects of the bone architecture derived from 3-D μCT data. Notably, Odgaard et al. had previously applied some of these architecture measures from 3-D bone samples obtained through serial sectioning.^[8]

In 1995, Kinney et al. showed the power of using synchrotron radiation for the examination of in vivo bone samples from a rat hind limb.^[9] In this study, they performed longitudinal imaging of the tibias of rats. The high-quality images clearly show the loss of trabecular bone after ovariectomy. The high photon count and the use of monochromatic radiation have led to much wider use of this technique for the examination of bone.^[10,11] Most notably, Ritman et al. have done extensive work in the examination of vascular structure through the use of synchrotron imaging.^[12] Nuzzo et al. showed a high correlation between synchrotron imaging and other modalities (backscattered SEM, micro-radiography) for assessing mineralization.^[13]

In 1997, Scanco Medical (Bassersdorf, Switzerland) produced the first commercial system for non-destructive evaluation of bone architecture.^[14] Unlike Feldkamp's system, the Scanco $\mu\text{CT}20$ used only a 1-D detector and created single-slice reconstructions and then stacked these slices to obtain a 3-D data set. Similar to Feldkamp's system, the generated data was isotropic by matching the slice separation to the in-plane resolution. The Scanco $\mu\text{CT}20$ system included extensive analysis software for a broad suite of 3-D imaging measurements, which were automatically calculated and stored in a database. Hildebrand and R uegsegger developed direct measures of trabecular thickness, trabecular number, and trabecular separation.^[15] Hildebrand and R uegsegger also developed a novel approach for calculating the ratio of plates to rods using a method called structure model index (SMI).^[16] This measurement provides a quantitative measure of how plate- or rodlike a structure is, yielding

a value of zero for a fully platelike structure to a value of three for a complete rodlike structure.

As technology continues to improve, μCT is becoming more common in both academia and industry. Today there are several commercially available systems including in vivo instruments for examining small animal models.^[17,18] Most scanners today are of the cone beam type, allowing for much faster scan times and lower dose to the animal under investigation. The improvement of 2-D detector arrays and faster electronics has allowed high-resolution scans exceeding 1 gigabyte of data to be acquired in only a few minutes.

BASIC X-RAY AND COMPUTERIZED TOMOGRAPHY THEORY

Since μCT is very similar to conventional CT, a short theoretical framework is presented for computerized tomography. This provides an overview of the generation of X rays and their attenuation in material, as well as the theory behind image reconstruction. More thorough discussion of tomographic theory and the physics of X-ray generation can be found in several excellent books.^[19,20]

In general, most μCT systems have a similar design. Typically, they generate X rays with a microfocal X-ray tube. The X rays are usually filtered to remove very low-energy X rays. The X rays pass through and are attenuated by the specimen, which is mounted on a spindle and rotated to collect different projections. The X rays pass through a scintillator, which converts the X rays into visible light, which is then fed into a solid-state detector (e.g., CCD array). The data are allowed to collect in the detector for a certain amount of time, referred to as the integration time, and then read out and stored on the computer. A fine stepper motor is used to rotate the sample to collect the projections at precise positions. The set of projections is then processed on a computer workstation to produce the cross-sectional image data. The spindle is translated and the projection data are collected for the next stack of data. The whole set of cross-sectional images then makes up the complete 3-D image array. The value stored in a pixel of a CT image is ideally only determined by the local attenuation coefficient of the material at that pixel's location. The components of computerized tomography are described in greater detail later in this article.

GENERATION OF X RAYS

A typical X-ray tube consists of a negatively charged cathode and a positively charged anode. A heated

filament at the cathode and a large voltage potential established between these two ends results in the high-speed flow of electrons from the cathode to the anode. As the electrons strike the anode surface, they are deflected in different ways and their kinetic energy is converted to radiation through the emission of photons. Most of this emitted radiation is in the form of heat (~ 99%). The remaining energy is transmitted as X rays, which will have a wide variation in wavelength (energy) because of the variation in random interactions with the electron beam and the anode surface. A focusing cup is used at the cathode to keep the electron beam focused on a small area in the anode target. The effective focal spot size of the X-ray tube is a function of the focusing cup, the angle of the anode surface with the cathode, and the number of electrons striking the surface of the anode. Modern μ CT scanners can obtain a focal spot size of five microns.

Generated X rays are of two types. The most common type is called Bremsstrahlung X rays (also called general radiation). This type of radiation is a result of the deflection of an electron as it approaches the nucleus of an atom on the anode. The coulomb field of the electron interacts with the electromagnetic field of the atom, and part of the energy of the electron is converted to Bremsstrahlung and emitted as an X ray. Therefore, the resulting energy is, on average, less than the maximum keV of the system, resulting in a broad spectrum of all emitted X rays. The second type of radiation produced is called characteristic radiation. This radiation is produced when the electron bombardment causes an electron to be ejected from the inner orbits of the target atoms. Depending on the binding energy of that electron shell for that type of atom, a photon of a very specific energy is released as the electron space is refilled. Therefore, the energy is considered characteristic for an atom's electron shell. It is common for μ CT systems to use aluminum filters in front of the source to suppress the low-energy X rays where many characteristic X-ray spikes tend to appear in the transmitted X-ray energy spectrum.

ATTENUATION OF X RAYS

Although there are several ways that X rays can be attenuated, the two most common in medical imaging are: 1) photoelectric effect; and 2) Compton scattering. In the photoelectric effect, the X ray striking an atom within the specimen is attenuated by the transference of energy to eject a tightly bound electron from orbit. The photoelectric effect is more dominant when the impending X ray is of an energy just slightly greater than the binding energy of the electron. Also, it is more likely to occur when the atomic number of the element in the specimen is high. The photoelectric effect

provides good contrast in tissues having elements of different atomic numbers (e.g., compact bone vs. marrow).

Compton scattering is similar to the photoelectric effect in that it also results from an X-ray photon ejecting an electron from its orbit. The difference is that in Compton scattering, the electrons are loosely bound so they need virtually no energy to be ejected. However, the kinetic energy of this recoil electron causes an attenuation of the original photon. Also, the direction of the scattered photon is changed from its original forward direction. The higher the energy of the photon, the less the photon will scatter. Since the angles of the photons are small and much of the energy is retained by the photon, it is possible that the X-ray photon could pass into the wrong detector element, causing noise. This effect can usually be mitigated by the presence of an X-ray absorbing collimator in front of the detector to block stray photons. In bone, Compton scattering is the dominant attenuator at 60 keV and higher, while the photoelectric effect is dominant between 20 and 60 keV.

For a given thickness of known material, a certain percentage of photons will be absorbed. Therefore, the number of X rays reaching the detector after passing through a material of thickness x with an attenuation coefficient of μ can be described by the exponential equation:

$$I = I_0 e^{-\mu x} \quad (1)$$

I_0 is usually measured through air during the scan, since μ (air) is (virtually) 0. This, coupled with the dark current measure (detector signal with the X-ray shutter closed), allows accurate measurement of the relative X-ray attenuation of a given projection. This attenuation is a function of not only material composition and material density, but also of X-ray beam energy.

When polychromatic radiation is used, an artifact called beam hardening is introduced into the imaging reconstruction. This is due to the preferential absorption of low-energy (soft) X-ray photons as the X rays pass through the sample, since attenuation is higher for lower X-ray energy, given the energy range and materials used in μ CT. As the X rays reach the center portion of the specimen, many of the low-energy X rays have been attenuated, and the beam has a mean keV that is higher, resulting in less attenuation of photons. After reconstruction, this artifact appears as a cupping effect in the center of the image. Beam-hardening is more pronounced when there is substantial attenuating material on the periphery of the image (such as the skull surrounding the brain). Synchrotron avoids this problem by using monochromatic energy. This allows the quantification of small changes in density using this type of instrument.

COLLECTION OF PROJECTION DATA

In CT imaging, the projection data are collected over many angles at a single point along the length of the specimen. The specimen (or the gantry) is translated to a new position and the collection of projection data is repeated. After translating the entire specimen length, the reconstructed data are stacked together to yield the final 3-D image. The projection data can be collected as parallel beams, fan beams, or cone beams. Parallel beam was the first technique developed and it is the simplest to reconstruct. A collimated beam is passed through the specimen in a given direction to create a set of projection points representing a single projection. The source detector is then rotated a small increment (or the specimen is rotated) and another projection is collected. This is repeated for a 180-degree arc about the specimen (slightly greater for fan- or cone-beam projection). In many μ CT systems, the specimen is rotated a full 360 degrees to obtain a field of view that is twice the size of the detector. This is achieved by placing the specimen's axis of rotation along one edge of the detector. Therefore, at any one time, a projection of one-half of the object is created. After 360 degrees of rotations, both halves of the specimen have been subjected to projections over 180 degrees, allowing the reconstruction of the entire specimen.^[21] In theory, the number of projections used should be greater than the number of sample points for every projection by a factor of $\pi/2$ ^[22] (e.g., for a 512×512 image, one should use approximately 800 projections). However, due to mechanical limits of the stepper motor, it is common practice in μ CT to have the projections and the number of sample points per projection be roughly equivalent, with little image degradation.

Using fan-beam geometry, a line of projection data can be collected without translating the source. Unlike parallel projection, the X rays for an entire projection are emanated from a single point (depending on the focal spot size of the X-ray tube, the width of this point will change). A one-dimensional array of detectors is used to collect the data. Collimation is used at the source to limit the slice thickness, and at the detector end to limit scatter. One advantage of using a fan of X rays is that the image can be magnified by moving it closer to the source. If a 2-D detector is used in this collection scheme, it becomes cone-beam geometry. This technique, because of its rapid ability to acquire 3-D data, is generally used in most modern μ CT scanners. Cone angle is limited to insure that the X rays from every projection pass through each point in the 3-D volume of interest.^[23] Although collimation and reconstruction become more difficult for cone-beam geometries, the acquisition time is decreased by a magnitude, while maintaining high image quality.

IMAGE RECONSTRUCTION

Given a 2-D image, I , there is known relationship between the 1-D Fourier transform of a projection through I , at angle α , ($P_\alpha(I)$) and the corresponding 2-D Fourier transform of I , $F\{I\}$. $P_\alpha(I)$ will form a line, passing through the origin, at angle α , in $F\{I\}$. This is referred to as the Fourier Slice Theorem and can be easily derived mathematically.^[24] By rotating the projection angle, we can begin to fill in spatial frequency information in all directions. This becomes a series of radial lines passing through the origin of fourier space. At low frequencies, where all the radial lines are converging, we have an abundance of information. At high frequency, we have a deficit of information. If the entire fourier space was completely filled in, we could transform back to image space and have the reconstructed image, with no loss of information. To fill in the fourier space, we must apply a weighting scheme that emphasizes the high-frequency information, so as to approximate an interpolation of this region of fourier space. This interpolation process can be visualized as a replacement of the lines in the fourier space with pie wedges, so that they neatly fill the fourier space.^[24]

The most common way that the fourier space is interpolated and transformed back into an image is through a reconstruction method referred to as convolution-backprojection. Since a multiplication in fourier space corresponds to a convolution in real space, the weighting is done by convolution of the projection data in real space. The final step is called backprojection, which sums the weighted projections together by smearing of the data along the direction of the projection. Many modern μ CT units utilize some form of convolution-backprojection for image reconstruction. However, many sophisticated improvements have been made to the basic algorithm to handle parallel, fan-beam, and cone-beam reconstruction.

PRECISION AND ACCURACY OF MICRO-CT

To determine the accuracy and precision of the micro CT instrumentation, Chmielewski et al. developed two phantoms and methods to perform a series of repeated measurements on a Scanco μ CT20 scanner.^[25] The first phantom consisted of a single 128.13-micron-diameter aluminum wire. This wire was measured by both μ CT and light microscopy, which was calibrated with a NIST traceable standard. The mean diameter measured on the μ CT system was 125.5 microns, with a standard deviation of 0.7 microns, resulting in only a 2.1% error from the calibrated microscopy measurement. The length of the wire measured by μ CT had only a 0.3% error from the calibrated microscopy

Fig. 1 Aluminum tube phantom used to validate the μ CT scanner accuracy.

measurement. These results confirm a high degree of accuracy of this instrument for measuring changes in structure. To measure the precision of the instrument, a second aluminum phantom was used. This phantom consisted of eight concentric aluminum tubes (250-micron-diameter) with a ninth tube directly in the center, as shown in Fig. 1. Repeat measures showed a very high reliability in the precision as well. The total volume measured across the tubes had a coefficient of variation of approximately 2% with repositioning of the same specimen over multiple scans. The total surface area measurement of the tubes had a coefficient of variation of less than 0.5%. The physical phantom measurements provided a means of monitoring the precision of the image data across entire studies and showed there was little drift over the measurements over an entire year.

Muller et al. reported high correlations between micro CT measurements with conventional histomorphometric measures.^[26] Bone volume/total volume, bone surface/total volume, and trabecular separation all exhibited regression coefficients above 0.9. The mean percentage differences in absolute differences between the μ CT and histology measurements ranged between 2.5 and 6.1%. The combination of high regression and low error between conventional histomorphometry and μ CT provide further evidence of the accuracy and precision of this modality.

3-D MEASUREMENTS WITH μ CT

With the advent of 3-D μ CT, parameters such as trabecular thickness and separation can be estimated directly from the 3-D data.^[15] Using only 2-D slices, these important parameters of bone change could only be estimated based on a simple model that all components of the measured trabeculae form simple rods

or plates.^[27] Unfortunately, this model is somewhat weak because bone fits neither of these simple descriptions. Furthermore, if the morphometry of bone is shifting between a rodlike structure to a more platelike structure, it could lead to a misrepresentation that these trabecular measurements are changing when in fact they are not. Beyond these measurements, the 3-D data afforded by μ CT technology allow additional measurements such as connectivity density (# of connections/mm³), degree of anisotropy (the orientation of the trabecular architecture), and cortical porosity (% of holes in the cortical bone) and cortical thickness.

Another advantage of 3-D μ CT is that it can serve as input to a finite element model. A finite element model allows virtual mechanical testing of a sample based on its 3-D data set. Micro CT provides both density information as well as high-resolution structural data, making ideal input for such a system. The voxels in the 3-D data set are replaced by brick elements. These brick elements have a modulus of elasticity and a Poisson ratio associated with each element. The modulus of elasticity can often be derived from the CT values and represents the stiffness of the brick element in each direction. In the finite element model of bone, one side of the model is generally constrained and an opposing side is displaced a predetermined distance. Based on the material properties of the brick elements, this introduces displacements in each of the elements. The displacement of each element is governed by a set of equilibrium equations. The simultaneous solution of these equations produces a strain distribution across the specimen. The resulting distribution can then be compared against known maximum strains for the material in question, allowing prediction of regions susceptible to fracture.^[28]

APPLICATIONS OF MICRO-CT TECHNOLOGY

Microcomputed Tomography in Osteoporosis Research

Osteoporosis is a widespread disease affecting mainly the elderly, where the bone becomes fragile and prone to fracture. By the definition provided by the World Health Organization at the Consensus Development Conference in 1991, osteoporosis is a skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility and susceptibility to fracture.^[29] The idea that the microarchitecture of the bone plays an important role in the likelihood of fracture has led to great interest in quantifying changes in this complex structure using μ CT technology.

To better illustrate the changes in cancellous bone that occur with disease progression, contrast the change in trabecular structure between a normal 52-year-old woman and an osteoporotic 84-year-old shown in Fig. 2. These images are computer renderings of data collected on a benchtop μ CT scanner (μ CT20, Scanco Medical, Bassersdorf, Switzerland). It is evident from these images that there is not only a change in overall bone mass, but also a change in the architecture of the bone. The osteoporotic bone has much thinner rods with more perforations. Also, there is a preferential loss of horizontal trabeculae, which run perpendicular to the load direction in the vertebra. It is believed that the absence of these horizontal trabeculae leads to buckling effect of the vertical trabeculae during normal loading, leading to fracture.^[30]

In recent years, there has been an increasing number of compelling results demonstrating the importance of architectural examination of the bone through the use of μ CT technology to provide insights into osteoporosis treatment. In the ovariectomized minipig vertebrae, we showed that there was a preservation of architectural parameters in risedronate-treated animals, independent of bone density.^[31] Ulrich et al. showed the relative contribution of trabecular architecture to mechanical strength through the examination of iliac crest biopsies taken from a wide

Fig. 2 μ CT rendering of female vertebral cores from (A) osteoporotic 84-year-old and (B) normal 52-year-old.

age range of patients.^[32] Using paired iliac crest biopsies, we have also used μ CT technology to show that risedronate preserved trabecular bone in both an early postmenopausal group of women as well as an older osteoporotic group of women^[33,34] Micro-CT studies of iliac crest biopsies before and after treatment with PTH^[1-32] a bone anabolic agent, showed an improvement in bone architecture through an increase in trabecular connectivity and cortical thickness.^[36] These important μ CT studies had illustrated differences between antiresorptives like risedronate, and bone anabolics like PTH^[1-32] in their effect on bone microarchitecture and their mechanism of action for reducing the probability of fracture.^[35]

TRABECULAR BONE ARCHITECTURE ASSESSMENT AS A NOVEL SCREEN IN ANABOLIC RESEARCH

Due to the high resolution of the images acquired with μ CT, it is particularly well-suited for the examination of trabecular architecture in small animal models. We compared treatment effects of two bone anabolics, hPTH^[1-32] and Fluprostenol (a prostaglandin FP receptor agonist) in a severely osteopenic rat model.^[37,38] As shown in Fig. 3, three-dimensional μ CT showed that both agents significantly increased trabecular bone volume in the lumbar vertebra compared to the ovariectomized group (Fluprostenol: 45.3%, PTH: 55.6%, Final Ovx: 24.4%). However, the therapy-induced changes in trabecular architecture were greatly different for the two therapies, as can be visualized in Fig. 3. While PTH caused extensive trabecular thickening (Fig. 3D), the formation of new trabecular bone is visually evident with Fluprostenol (Fig. 3C) and resulted in trabecular bone similar to the normal intact group (Fig. 3A). This is best reflected by the changes in connectivity density measured between the two anabolic agents. In the high-dose Fluprostenol group, the connectivity density was more than twice that found in the PTH group (Fluprostenol: 84.5 conn./mm³, PTH: 37.4 conn./mm³). This study underscores the importance of being able to measure beyond just bone mass and examine the complete 3-D trabecular architecture of the bone.

3-D IMAGING OF VESSELS FOR THE UNDERSTANDING OF ANGIOGENESIS

The visualization and quantification of new blood vessel formation is important in pharmaceutical drug development of angiogenic drugs as well as understanding the natural occurrence of angiogenesis

Fig. 3 μ CT rendering of rat vertebra cross section of (A) normal, (B) ovariectomized, (C) fluprostenol, and (D) PTH-treated vertebrae.

in the body. In pharmaceutical research, the rat hind limb ischemia model is commonly used to measure the efficacy of proangiogenic compounds.^[39] In this model, the femoral artery of the rat is ligated, which causes ischemic regions to develop distal to the ligation. Angiogenic compounds are administered to the animal for a fixed number of days. Prior to euthanasia, the rat is injected with microspheres at a fixed rate. The tissue of the ischemic region is then examined and the count of the microspheres embedded in the tissue provides an accurate assessment of the flow of blood in the ischemic region. Changes in blood flow rates are then the endpoints for efficacy of the compound. However, although this is an important endpoint, it does not address whether the increased blood flow is a result of new collateral growth around the ligation, or a remodeling of existing vessels to increase their flow.

Micro CT technology provides an excellent method of visualizing and quantifying vascular changes in small animal models.^[12] The natural X-ray attenuation of the vessels is very low, therefore, a contrast agent needs to be injected into the vessels prior to imaging with μ CT. For the experiments in our lab, we have chosen the use of Microfil[®] as a contrast agent. The contrast agent is injected into the aorta, postmortem, while maintaining physiological blood pressure. Once the Microfil[®] has hardened overnight, tissues are harvested and fixed for scanning. Figure 4A shows a normal rat hind limb injected with Microfil[®]. The loss of active blood vessels is quite apparent immediately after the ligation has occurred (Fig. 4B). After two weeks of treatment with a proangiogenic compound, many of the vessels are restored (Fig. 4C). In addition to examining collateral vascular structure, it can be

applied to a variety of organs where the 3-D vascular structure needs to be elucidated.

MEASURING COATING THICKNESS IN 3-D ON ENTERIC COATED TABLETS

Ulcerative colitis is characterized by an inflammation of the lining of the rectum and colon. Therefore, in order to treat this condition, it is important that the drug be delivered in proximity to the site of the ulceration. Enteric coating allows the tablet to pass through the stomach and into the colon where it will dissolve at a pH of seven or greater. Since the stomach has greater acidity, it will pass through to the colon intact. Equally important is that the enteric coating has a uniform thickness and little deviation between thicknesses of tablets within a lot.

In our study, we examined 400 mg Asacol[®] tablets. These tablets are prescribed for ulcerative colitis and contain an iron oxide-based enteric coating, making the coating sufficiently attenuating for 3-D micro-computed tomography. The goal of this study was to use μ CT imaging as a calibration standard for near infrared analysis and conventional scanning electron microscopy.^[40] This study examined tablets that were being coated with a newly designed system. Custom designed software was developed so that the distinct regions of the upper and lower dome as well the girdle could be independently measured. To get a broad range of sample thicknesses, the tablets were coated for 45, 70, and 90 minutes (finished form). Figure 5 shows the coating thickness for two different time points. This application has been used repeatedly, not only

Fig. 4 μ CT rendering of vessels in rat hind limb ischemic rat model; (A) baseline, (B) one day after ligation of femoral artery, and (C) two weeks of treatment after ligation.

calibrating other modalities, but also troubleshooting issues with coating distribution.

CONCLUSION

Micro CT technology is a continually evolving field that is providing new insight into many fields of re-

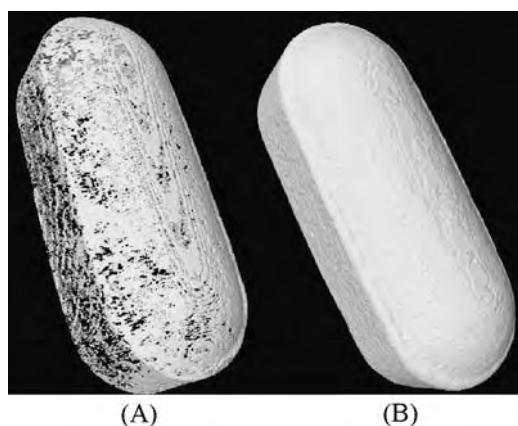

Fig. 5 μ CT analysis of enteric coated tablets; (A) 3-D rendering of coating after 45 minutes in coater, and (B) 3-D rendering of coating after 90 minutes in coater.

search. As detector performance continues to increase with improved resolution and better signal to noise, the image quality of the reconstructed images will continue to improve. Reconstruction times, which are largely a function of computer CPU speed, will continue to speed up, allowing for large reconstructed images to be created concurrent with data collection. In the area of bone research, many new in vivo scanners are being produced, which allow excellent delineation of trabecular bone in longitudinal studies of small animal models. This, in turn, is allowing sophisticated modeling of strength changes in bone using finite element analysis.

ACKNOWLEDGMENTS

I would like to thank Mses. Cindy Blanton and Elaine Eby-Wilkens for their work with using Microfil[®] for vessel identification, Dr. Mark Lundy and Ms. Katie Combs for their work in anabolic screening, Dr. Tom Cambron and Mr. Van Bullman for their efforts in near infrared and microscopy of the enteric coated tablets, and Dr. Sheng Liu for her assistance with the editing of this manuscript.

Microelectromechanical Systems (MEMS) Manufacturing

Marc Madou

University of California, Irvine, California, and Department of Mechanical and Aerospace Engineering and Biomedical Engineering Department, Integrated Nanosystems Research Facility (INRF), U.S.A.

INTRODUCTION

Humans are still best at building structures they can grasp with their hands and see with their eyes, and have only relatively recently started to craft objects at the micro- and nanoscale level. The manufacture of miniature devices is still principally based on top-down manufacturing methods; starting from bigger building blocks—say a whole Si wafer—and reducing them into smaller and smaller pieces by cutting, etching, and slicing to make, for example, an integrated circuit chip. Bottom-up manufacturing methods (also nanochemistry) are considered by many as the next natural step in human manufacture in which small particles such as atoms, molecules, and atom clusters are added or removed for the construction of bigger functional structures. Bottom-up methods are nature's way of growing things and in biomimetics one studies how, building bottom-up, that is, atom by atom, nature, through eons of time, developed manufacturing methods, materials, structures, and intelligence.

Given the fundamental differences between top-down and bottom-up manufacturing approaches, we have treated these manufacturing approaches in separate sections. As mentioned earlier, bottom-up manufacturing approaches are often nature-inspired, and we dedicate yet another section to biomimetics. Besides the aforementioned three sections, we start this short review on miniaturization methods with a historical perspective on human manufacturing techniques and we conclude it with our vision on manufacturing approaches for the next 10 to 15 years.

Miniaturization science (MEMS) in the year 2004 is still predominantly practiced by electrical and mechanical engineers, but as applications are becoming more and more biological in nature, biologists, materials scientists, chemists, and physicists must work together with electrical and mechanical engineers to develop new miniaturization solutions including bottom-up methods. We hope that this short article will further stimulate such collaborations and help bridge the gap between dry engineering, in air and with rigid materials, and wet engineering, with flexible materials in watery solutions.

HISTORICAL PERSPECTIVE

Toolmaking for manufacturing an object began perhaps when humans learned to walk erect and had their hands free to grasp objects of wood and stone and to shape them. Although tool-making hominids probably emerged millions of years earlier, we can only trace toolmaking history back two million years to the oldest surviving and recognizable flint hand axes.^[1]

The birth of mechanical, more precise machining dates back to the invention of the lathe, attributed to Anarcharis the Scythian (300 B.C.).^[1] Precision machining with a hand-operated lathe got a boost in the mid-1600s from demands for more precision in building better clocks.^[2] Ruling engines for the control of diffraction gratings have driven state-of-the-art precision machine tool design since the late 1700s. More than a century ago, Rowland at John Hopkins University built ruling engines with part-per-million (ppm) accuracy.^[3,4]

Tools driven by mechanical power brought on the machine age in the late 1700s.^[5] By 1920, the Lord's Prayer had been engraved with a diamond tool into an area measuring 100 μm by 40 μm . Cutting with very small diamond tools (e.g., 22 μm diameter) was developed in Japan in the 1980s (see Fig. 1 for a current example).

Today, the mechanical technology upon which photolithographic alignment systems are based is still grounded in the ruling engine design described earlier. Highly precise instruments such as servomotors, feedback devices, and computers had been implemented in manufacturing tools by 1977 and many types of machine tools are now equipped for computerized numerical control, commonly called CNC.

Processes more sophisticated than mechanical machining can be performed, often more effectively, by using nonmechanical forms of energy, such as chemical, electrochemical, and electrothermal. In electrothermal removing and forming processes, thermal energy, provided by a heat source, melts and/or vaporizes the volume of the material to be removed or deposited. Among electrothermal methods, electro discharge machining, or EDM, using electrical sparks for cutting, is one of the oldest. In the United States during the 1960s, EDM machining was used to create features in the 75- μm size

Fig. 1 Noh mask made by mechanical precision machining on Fanuc's ROBOnano UiA. (From Fanuc.)

range, and even more precise EDM, employing rotating spindles, was pioneered in Japan in the late 1980s (5- μm size range). Electron-beam machining (EBM) and laser-beam machining (LBM), two other examples of thermal techniques, were developed in the 1960s and 1980s, respectively. In EBM, high-velocity electrons are used instead of sparks, and in LBM, intense photon pulses are employed.

Chemical and photochemical etching underlies what we know today as integrated circuit (IC) manufacturing and microelectromechanical systems, or MEMS. In 1822, Niépce developed the photoprocess and five years later, Lemaître performed the subsequent chemical milling of a Niépce photoplate—marking the first deliberate use of photolithography in combination with chemical milling.^[6] The IC revolution in the 1950s

employed these same photolithography techniques and, on its coattails, brought along micromachining or MEMS in the late 1960s with the fabrication of the first Si strain gauges. The first Si micromachined devices were isotropically etched. The discovery of anisotropic etching of Si and etch-stop techniques catapulted MEMS firmly onto the commercial scene.

The use of X-ray lithography in combination with electroplating and molding, introduced by Ehrfeld and his colleagues in 1982, demonstrated to the world that lithography may be merged with more traditional manufacturing processes to make master molds of unprecedented aspect ratios and tolerances in order to replicate microstructures in ceramics, plastics, and metals^[7] (see Fig. 2A for an example of a LIGA product, and Fig. 2B for the LIGA process steps).

In soft lithography, a Si master mold is made based on “traditional” lithography and an elastomeric stamp (e.g., polydimethylsiloxane, or PDMS) is molded from this master (Fig. 3A). As illustrated in Fig. 3B, this method enables the manufacture of nonplanar 3D objects. This technique also combines top-down and bottom-up machining: Indeed, the PDMS stamp in Fig. 3A can be inked with a self-assembled monolayer (SAM) to print (stamp) substrates with micro- or nano-sized patterns. This method was introduced by Whitesides et al. in 1997.^[8]

In the coming decades, bottom-up manufacturing methods, in which small particles such as atoms, proteins, and atom clusters are added or removed for the construction of bigger functional structures, will become

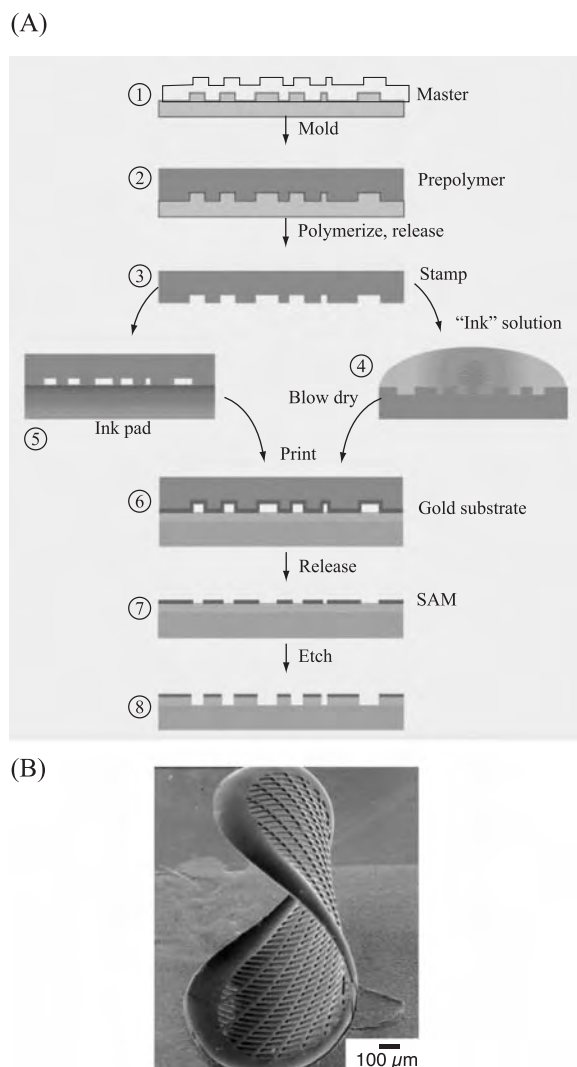

Fig. 3 Soft lithography: (A) Process flow: A prepolymer (2) covering the master (1) is cured by heat or light, and demolded to form an elastomeric stamp (3). The stamp is inked by immersion (4) or contacted with an inkpad (5), and printed onto a substrate (6), forming a self-assembled monolayer (SAM). The ink pattern (7) is then transferred into the substrate by a selective etch (8). (B) Curved glassy carbon structure made from photoresist patterned with an elastomeric stamp. (Courtesy of Dr. G. M. Whitesides, Harvard University.)

the most important research domain for the future of manufacturing. Bottom-up methods draw from work in supramolecular chemistry, protein engineering, molecular self-assembly, proximal probes such as scanning tunneling microscopes (STMs) and atomic force microscopes (AFMs), photon manipulation of individual atoms, carbon nanotubes, etc. An example of bottom-up manufacturing can be found in Eigler et al.'s work at IBM: Using an AFM, this team herds atoms together in any desired patterns (see Fig. 4).

Fig. 4 Kanji character for "atom," by Lutz and Eigler, IBM, Almaden. An example of manipulation/mechanosynthesis of iron atoms on a Cu surface with an STM. (Courtesy of D. Eigler.)

For the next two decades, we expect the size of objects that can be built with top-down and bottom-up approaches to overlap more and more as we learn new ways to combine ever smaller components manufactured through nanofabrication with the products of nature (e.g., rotor proteins). As a result, hybrid top-down and bottom-up constructs can be expected to provide guidance for future manufacturing strategies (see Fig. 5 for a recent example).

TOP-DOWN MANUFACTURING

Introduction

From the myriad of top-down manufacturing techniques (see the preceding discussion), we will only

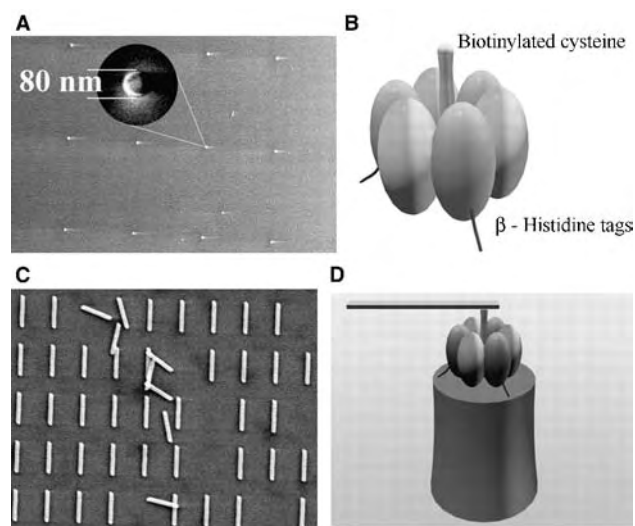

Fig. 5 A hybrid nanodevice with a Ni micromachined propeller attached to a biomolecular motor (a rotor protein). The propeller is powered by adenosine triphosphate (ATP). (Courtesy of Dr. C. Montemagno, UCLA.)

consider those that result in small devices ($<1\text{ cm}^3$) incorporating yet smaller features ($<1\text{ mm}$). More specifically, we will compare precision mechanical machining with Si micromachining or MEMS (micro-electromechanical systems).

Comparing Mechanical Precision Machining with MEMS

3D vs. 2D

Shaping device contours in top-down mechanical manufacturing results in truly 3D shapes (Fig. 6), whereas with MEMS lithography techniques, one can only obtain projected 2D shapes (Fig. 2).

Batch vs. Serial

MEMS and IC fabrication techniques lend themselves to economies of scale (large batches), which are unavailable with mechanical serial machining techniques. Although micromachining is often compared to IC microelectronics, it lacks the high degree of generality characteristic of microelectronics. ICs can be grouped in a limited number of classes, within which design and production follow well-defined and common steps. As a consequence, the price/performance ratio allows industry to make profits on complex ICs, and it makes ICs suited for mass production. MEMS sensors and actuators, on the other hand, are more specific and economy of scale does not apply as commonly as it does for ICs. Compared to mechanically machined devices, MEMS devices still do have a huge economy of scale advantage though.

Relative tolerance

For over 100 years, precise, rather large machines have been designed and built with mechanical removal techniques achieving part-per-million relative tolerances; recently, this type of machining has entered the realm of 0.1-ppm relative tolerances.^[4] In comparing Si

micromachines (MEMS) with larger, mechanically machined structures, Slocum^[4] notes that, whereas MEMS micromachines are impressive for their small size, their relative accuracy is two orders of magnitude worse than is typically achieved in large machines, which, moreover, are much more complex. The surface roughness of micromachines looks high compared to the specular finishes of bearing surfaces. In reality, the absolute roughness is about the same, but in micromachines, surface forces such as friction are relatively more important. Thermal errors, on the other hand, in a micromachine are more relaxed; the small scale and fast thermal equilibrium of the smaller structures is their saving grace. Another key issue Slocum brings up is that of position measurement systems; verification of fabricated geometry and tolerances are much more difficult for micromachines since measurement of a displacement of one part in 10,000 will typically get one down to the nanometer level. It is thus important to realize that whereas MEMS can achieve excellent absolute tolerances, relative tolerances are rather poor compared to those achieved by more traditional techniques. The decrease in manufacturing accuracy with decreasing size is striking; in traditional machining, relative tolerances of 10^{-6} (ppm) are becoming standard, whereas in the integrated circuit (IC) industry, a 10^{-2} relative tolerance is considered good. The definition of precision machining, with relative tolerances of 10^{-4} , actually excludes micromachining! To describe micromachining with the same terminology, it must be expanded to cover all machining methods where the relative accuracies are at least 10^{-4} or where absolute size in one or more dimensions is in the micrometer range. Precision machining and Si micromachining are complementary; both strive to improve absolute and relative tolerances, with Si-based technology better at obtaining smaller features (absolute tolerance, see the following section) and traditional methods better at obtaining tighter relative tolerances.

Absolute tolerances

In mechanical machining, various factors such as deformation of the workpiece and tool, vibration, thermal

Fig. 6 Microcar and rice grains. The car is 7 mm long, 2.3 mm wide, and 3 mm high and is made with traditional mechanical machining methods. (This figure is from A. Teshigahara, M. Watanabe, N. Kawahara, Y. Ohtsuka, and T. Hattori, *J. Microelectromech. Syst.*, 76–80, 1995.)

deformation, inaccuracies of machine tools, etc., affect the machining accuracy. Ultrahigh precision machines with sharp single-crystal diamond tools have made sub-micrometer precision machining possible (see Fig. 1). The first computer numerical controlled (CNC) machines became available in 1977. The smallest movement the machines could reproducibly make was $0.05\ \mu\text{m}$ by 1993, and today there is equipment available featuring $0.01\ \mu\text{m}$ and even nanometer step resolution.^[9] This progress is sketched in Fig. 7, where the Taniguchi curves show a machining accuracy for ultraprecision machining of $1\ \text{nm}$ for the year 2000. Because of these types of precisions, ultraprecision manufacturing is still the commercially preferred technique for the production of computer hard discs, mirrors for X-ray applications, photocopier drums, heads and camcorder viewfinders, high-definition television (HDTV) projection lenses, and VCR scanning heads, etc.

When looking at the progress in absolute tolerances achieved in ICs and MEMS as presented by Moore's law (Fig. 7), lithography methods only reached critical dimensions (CDs) of $0.18\ \mu\text{m}$ in 2000, as contrasted with the $1\ \text{nm}$ already achieved with mechanical machining at that time. It must be pointed out however, that the accuracy axis for traditional machining

describes accuracy in the height or z direction, whereas for lithography-based methods, it is the accuracy of carving out a feature in the x,y plane. In the x,y plane, mechanical machining is considerably less accurate than lithography-based methods because the writing tool in mechanical machining is crude compared to writing with light or electrons—the smallest diamond styluses are still about $22\ \mu\text{m}$ in diameter! In mechanical machining, for example the polishing of a mirror, the size of the tool does not influence the resulting accuracy in the z -direction, the edge of the tool does.

An intertwined future

Progress in absolute tolerances in top-down mechanical machining and lithography is, in part, based on continued improvement in positioning stages and that progress has slowed down for both machining methods.^[3] In lithography, the reasons for the slowdown go beyond the positioning stage though. The frequent alignment steps in lithography may be checked by laser-interferometer-controlled stages to an absolute positioning accuracy of $<10\ \text{nm}$, thereby allowing the registration of successive layers of a semiconductor device to a similar

Fig. 7 Progress of accuracy in machining. The development of achievable machining accuracy over the last 70 years is shown in this figure under the generalized classification of normal machining, precision machining, and ultraprecision machining. Left side ordinate: increase of manufacturing over time (based on Taniguchi). Right side ordinate: increase in transistor density over time according to Moore's law. The figure also lists the machines, process equipment, and metrology means by which the indicated resolution can be achieved. By ultraprecision machining, Taniguchi means those processes/machines by which the highest possible dimensional accuracy is or has been archived at a given point in time.

precision. Since interferometric schemes enable alignment to less than 10 nm, it is feasible to develop aligners compatible with line widths of 0.1 μm or even 50 nm.^[10] It is obviously not the metrology equipment that hampers further accuracy improvement in lithography techniques. The reason for the slowdown in electronic device miniaturization hinges indeed on securing more mechanical stability in the positioning stages, but more so on manufacturing cost and the fact that transistors are becoming too leaky below 0.1 μm where quantum effects start playing a role. To further extend manufacturing accuracy in electronics, one has to look beyond current manufacturing methodologies and consider methods such as molecular engineering and novel nanofabrication techniques. Micromachining of special lithography tools will play a pivotal role in those new machining approaches. For example, the scanning tunneling microscope (STM), based on micromachining ultra sharp tips on Si cantilevers, creates machining opportunities with accuracies on the atomic level,^[11] well beyond the predictions of the Taniguchi and Moore curves (see Fig. 4).

For mechanical structures, operation in the micro- and nanodomain imposes barriers other than those described for electronic devices. New design philosophies that are more error-insensitive with simpler mechanisms, smaller numbers of parts, and, wherever possible, flexible members rather than rigid ones must be adopted.

BIOMIMETICS

Introduction

Biomimetics is the study of how nature, building atom by atom, through eons of time, developed manufacturing methods, materials, structures, and intelligence. These studies are inspiring engineering and design of manmade miniature objects. As nanochemistry is currently inspiring a new wave of biomimetic efforts, caution is in order since, as the legend of Icarus so pointedly reminds us, most previous attempts at biomimetics have resulted in failure. In macroengineering, as S. Vogel points out in *Cats' Paws and Catapults* (W. W. Norton, New York, 1998),^[12] human and natural technologies form a separate, well-integrated entity, operating in an internally coherent context. Nature, for example, does not use steel, nor does it favor the production of flat surfaces and sharp corners—all very useful in human manufacturing. Nature builds with proteins and produces mostly curved surfaces and rounded corners, resulting in such masterfully engineered objects as biological cells. In large-scale engineering projects, both natural and human manufacturing approaches have their merits within their own proper frame of reference. It is in the nanoworld that

nature is way ahead of human engineering as it has learned to work with much smaller, more versatile building blocks and master the self-assembly of those building blocks. Because it uses relatively large building blocks, human manufacturing is rapid and the expectation is that nature, because it uses much smaller building blocks, must be very slow. To offset the time it takes to work with small, basic building blocks, nature, in growing an organism, relies on an additive process featuring massive parallelism and self-assembly. We believe that, just as in the macroworld, blindly mimicking nature will be unproductive, but studying nature and taking hints as to how to build nanostructures from the bottom-up (nanochemistry) certainly will be productive.

Hints from Nature

A few of the guiding principles involved in the construction of living organisms are:^[13]

- The use of composites (rather than monolithic materials in human engineering): Nanocomposite materials, for example, are widespread in biological systems as in bone, cell walls, soft body tissue, etc. The nacre (mother-of-pearl) of abalone shell, an oriented coating composed of alternating layers of aragonite (CaCO_3) and a biopolymer, is an often studied example (nacre is twice as hard and 1000 times as tough as its constituent phases).
- Almost all natural manufacturing processes occur in a liquid phase.
- Carbon is the prevalent element in building living things, not silicon.
- Massive parallelism: Multitude of cells all work in parallel.
- Several successive levels of organization (hierarchy): Proteins, bone, and tissue fibers have a hierarchical organization much more complex than materials of the nonliving world (e.g., crystals). This organization bestows many benefits on living organisms such as a high strength-to-density ratio and the ability to serve several functions simultaneously.
- Self-repair. Biological materials might have a narrower operating window than inorganics, but they are constantly repaired when damaged.
- Soft flexible materials: Skin, flesh, muscle, etc.
- Self-assembly and self-replication, all through weak bonds: Self-assembly is the lock- and-key assembly of complex molecules such as in the case of neurotransmitters assembling with molecular recognition sites on proteins that elicit chemical responses, for example, acetylcholine recognition at nerve-muscle junctions resulting in muscle contractions.^[14] In self-replication, molecules such as DNA encode the genetic information for cells and the resulting

organisms, thus allowing the manufacturing information to be passed on from cell to cell and from generation to generation.^[15]

- The use of templates: For example, the reading of genes by messenger RNA (m-RNA) to build proteins in the cells' ribosomes.
- Compartmentalization: Tissue is compartmentalized into cells and within cells there are many organelles.

These principles provide inspiration for the implementation of human nanochemistry. Nanochemistry holds the promise of the versatility of design offered by nature itself, and molecular self-assembly and replication add to the tremendous appeal of this type of nanotechnology.

BOTTOM-UP MANUFACTURING APPROACHES

Introduction

At the beginning of the twenty-first century, the performance criteria for top-down manufacturing techniques, that is, Moore's law, which projects the progress in achievable transistor density on a chip, and Taniguchi's curves, which predict improvements in accuracy for mechanical machining, have started to exhibit signs of a slowdown (see Fig. 7). Further miniaturization progress will most likely be based on methods originating in

nanochemistry, that is, bottom-up methodologies as well as combinations of top-down nanofabrication using traditional IC methods and nanochemistry. Over the next 10 years, the size overlap of objects fabricated with either approach will become more significant. Consequently, molecular engineers and supramolecular chemists who are manipulating, with rapidly improving dexterity, nature's building blocks such as atoms, molecules, proteins, and DNA, will, jointly with MEMS specialists who are now reaching the 0.1- μm lithography limits, find new ways to combine top-down nanofabricated components with bottom-up natural products (see Fig. 5).

Multiparallelism Micro- and Nanoassembly

Today, IC and MEMS hybrid assembly is performed mostly by humans with tweezers and microscopes or with pick-and-place robots.^[16] As long as we cannot master self-assembly, the challenge to assemble smaller and smaller components from different technologies is staggering. The existing microassembly approaches, divided into serial and parallel processes, are summarized in Table 1. In serial microassembly, parts are picked up and placed together on a substrate or workpiece one by one. Table 1 covers many methods enabling serial manipulation of very small particles, including individual atoms for nanoassembly, but unless one can

Table 1 Microassembly approaches

Serial microassembly		Parallel microassembly	
Manual assembly with tweezers and microscopes		<i>Deterministic</i>	<i>Stochastic driving forces</i>
Visually-based and teleoperated microassembly	[17,18]	Flip-chip wafer-to-wafer	[19,20] Fluidic agitation and mating part shapes [21–23]
High-precision macroscopic robots with submicron resolution	[24,25]	Microgripper arrays for massively parallel pick-and-place	[26] Vibratory agitation and electrostatic force fields [27–31]
Microgrippers (with gripper sizes 100 μm or less)	[26,32–34]		Vibratory agitation and mating part shapes [35]
Optical trapping	[36]		Mating patterns of self-assembling monolayers [37]
Microcapillary/pipette-based positioning	[37]		Magnetic field-mediated separation [38]
AFM/STM atom manipulation	[11]		Dielectrophoretic trapping [39]
			Ultrasonic levitation and transportation in standing acoustic waves [40]
			Hydrodynamic/electro-osmotic object manipulation in microchannels [41,42]

(From Ref. [16].)

manipulate many, many particles all in parallel, most of these techniques will remain research tools rather than manufacturing options. In parallel microassembly, where parts are assembled simultaneously, we distinguish between deterministic and stochastic microassembly.^[16] In the former, the relationship between the part and its destination on a substrate is known in advance. In the latter, this relationship is unknown or random; parts self-assemble during a stochastic process driven by some motive force.

Stochastic self-assembly is an attractive option to integrate dissimilar process technologies. To achieve self-assembly, there must be bonding forces present, the bonding must occur selectively, and the assembling parts must be able to move so that they can come together. Stochastic microassembly often encompasses vibration of the parts in combination with electrostatic, fluidic, and other forces that operate on singulated parts in various media (fluids, air, or vacuum). After reviewing scaling issues of the assembly process, examples of micro- and nanoassembly will be presented. The smaller the building blocks, the higher the need for stochastic self-assembly as handling the individual components becomes more and more of a mechanical challenge and the process would be too slow. Nature, building on the nanoscale, does rely heavily on self-assembly, and DNA-assisted self-assembly (see subsequent discussion) is an early attempt at coopting nature for human manufacturing endeavors.

Scaling of the Assembly Process

The newest robots with submicrometer resolution must be used to assemble nanoparticles as conventional robots that pick, transport, and place small parts having a control error of 100 μm at best, which would translate in relative errors of over 100%. Moreover, small parts (<1 mm and masses less than 10^{-6}g) are difficult to release as adhesion forces between gripper and object are significant compared to gravitational forces at that scale.^[16] In the microdomain, surface forces such as adhesion dominate over volume forces such as gravity or inertia. Adhesive forces involved in pick and place include surface tension due to moisture on the part and gripper, van der Waals forces (significant for gaps below 100 nm), and electrostatic attractions (e.g., induced by triboelectrification). To avoid some of these problems, the smallest components are often manipulated in a liquid medium, for example, with laser trapping or dielectrophoresis; the fluid eliminates electrostatic and surface tension effects. On a larger scale, vibration is used extensively in industrial part feeders which singulate, position, and orient parts before they are transferred to an assembly station.

Microassembly Examples

Serial microassembly

Many of the serial manipulation methods listed in Table 1 are used for manipulation of components such as biological cells, subcellular organelles, and even atoms.^[43] So the same tools may be used for micro- and bottom-up nanoassembly.

A small enough object that is relatively transparent to laser light of a particular frequency refracts an incident laser beam, bending the light. As a result of this refraction, momentum is transferred from the light to the particle. When the geometry of light beams and particle is correct, the momentum imparted pulls the particle in the direction of the incident beam. The beam (or multiple beams) can then hold the particle in place, or by moving the beam(s), the laser operator can move the particle from place to place. In other words, light has momentum and can be used to catch and manipulate objects in a size range from nm to μm in so-called optical tweezers. The laser wavelengths in optical tweezers are typically between 0.7 and 1.06 μm , and 25 to 500 milliwatts of power is generated in a focal spot between 0.5 and 1.0 mm in diameter. The first work with optical tweezers was done by Ashkin et al. at AT&T Bell Laboratories in pioneering works in 1985 and 1986, successfully demonstrating that small particles could be trapped by focused low-power laser light (under one watt).^[44,45] The first work on trapping of living biological objects was also done by Ashkin et al. in 1987.^[36] The authors not only trapped and manipulated single cells, they demonstrated that the trap was harmless to living biological species. Steven Chu, a 1997 Nobel laureate in physics, at Stanford University showed that laser tweezers can be used to stretch molecules such as DNA: with colloidal spheres attached to the DNA strands, the spheres were trapped and the DNA was stretched by moving in fluid flows.^[46] The most common form of optical tweezers in biology is the single-beam gradient trap, immobilizing transparent dielectric particles near the focal point of a tightly focused continuous-wave laser with a force proportional to the electric field gradient.^[43,47,48] Such a beam generates forces in the piconewton range, more than sufficient for trapping cells and moving organelles inside and outside the cells.

Two different serial manipulation approaches can be used together; for example, cages for biological cells have been made by combining optical trapping and dielectrophoresis.^[49] Such a combination enables manipulation of two bioparticles in close proximity, which would be impossible using two laser beams or two electrode fields, as those fields interfere. Dielectrophoresis is an AC electrokinetic force and it is a powerful tool for separating particles of the size of biological cells, but is less applicable for particles below 1 μm .

In mechanosynthesis, an STM is used to manipulate individual atoms, as demonstrated in Fig. 4 with the Kanji character for the word atom. Such serial manufacturing processes that use too small building blocks are not viable manufacturing candidates unless an army of them can work together on the same construction project.

Parallel microassembly

Many stochastic approaches for microassembly are under investigation. Yeh et al.^[22,23] trapped semiconductor LEDs, originally suspended in a liquid, in micro-machined wells on a wafer by solvent-surface forces. Carrier fluid containing the GaAs parts is dispensed over the host Si wafer with etched holes to assemble the GaAs blocks. Because of the trapezoidal design, the blocks fit preferentially into the holes in the design orientation. Random mechanical vibration of the microstructures enables large numbers of microstructures to be positioned into precise registration with the sites.

Cohn et al.^[28] demonstrated an interesting variation on the work of Yeh et al. by using alignment capabilities over electrostatic traps. A critical problem in attempting to vibrate microstructures into specific sites from a liquid is that when structures stick to the substrate or to each other, their progress toward optimal, precise registration is halted. Cohn et al. addressed this problem by levitating the microstructures a short distance above the target electrostatic trap site before letting them settle. As a result, random sticking is prevented and critical positioning and orientation of the microstructure with respect to the trap become possible with a relatively low applied field ($10\text{ V}/\mu\text{m}$). The levitation over the trap site is accomplished by creating a short-range repulsive force between the microstructure and the target site. This prevents contact between the site and the suspended microstructure. Critical positioning and orientation become possible, in the manner of a compass needle resting on a low-friction bearing.^[28] Böhringer et al. have subsequently also demonstrated the ability to break surface stiction forces using ultra low-amplitude vibration in vacuum, which holds promise as an extremely sensitive technique for positioning parts, as well as discriminating part orientation, shape, and other physical properties.^[29]

Several MEMS research groups have built actuator arrays for micromanipulation; these arrays typically consist of a regular grid of motion pixels (mechanical members such as cilia).^[50–57]

At Nanogen, electric fields are used to transport and control the placement of proteins, RNA, and DNA as well as semiconductor components on a substrate equipped with an array of electrodes in a low-conductivity

solution.^[31,58] In Fig. 8, we illustrate the use of electric fields for precision placement of microLEDs ($20\text{-}\mu\text{m}$ diameter) onto a Si substrate using electroosmosis. The InGaAs microLEDs used all have contacts on one side of the device, as shown in the cross-section schematic in Fig. 8A. The corresponding substrate has two sets of electrodes designed for the mounting process. As seen in Fig. 8B, a first pair of larger horseshoe electrodes brackets an inner set of electrodes. The inner set of

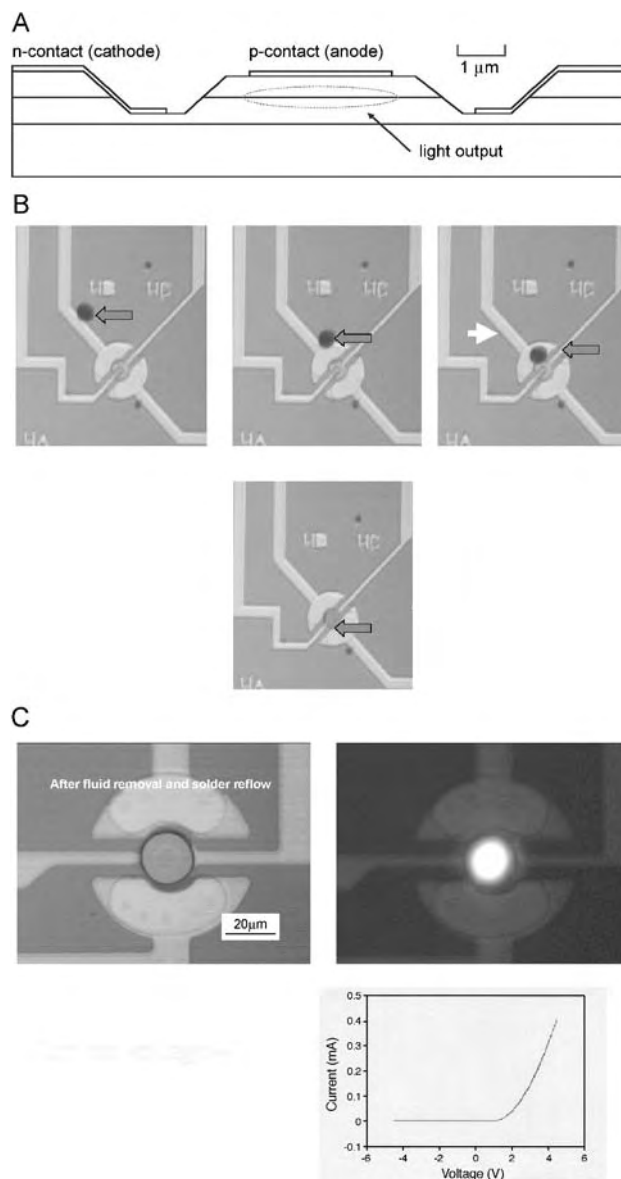

Fig. 8 (A) Schematic InGaAs microLEDs have contacts on one side of the device, as shown in the cross section. (Courtesy of Dr. M. Heller, Nanogen.) (B) Electric field directed placement of LED. electrodes is designed to mate and bond to the LED and is standard tin/lead electroplated to a height 50 nm above the surrounding surface. The linear structures connect traces, which are insulated to avoid contact with the overlaying aqueous solution. Activation of the outer electrodes with respect to a counterelectrode (not shown in the figure) causes an electroosmotic flow along the surface of the chip, and the LED placed in the solution moves with the bulk fluid flow. Once the LED is on the electrode, the electroosmotic flow is briefly reversed and the reversal of the fluid flow drives the LED onto the awaiting bonding points with microscale precision. After the fluid is removed, the solder is reflowed under forming gas at 250°C. Circuit integrity and LED activation is demonstrated by forward biasing the LED using the silicon circuit's contacts, as demonstrated in Fig. 8C.

The authors point out that the same process could be used to assemble a large variety of components simultaneously and selectively on a circuit by the parallel activation of sets of electrodes while maintaining a number of components present in the low-conductivity solution. They speculate that the process might be aided by the use of a self-sorting mechanism by attaching short sections of complementary DNA on components and target sites on the circuit (see next section).^[58]

DNA-mediated assembly

Many researchers have recognized that the exquisite molecular recognition of various complementary

biological molecules may be used to assist in the assembly of micro- or nanocomponents into complex networks. In this approach, DNA nanostructures and DNA-mediated assembly of nano- and microstructures have received the most attention in the literature. In the DNA nanostructures approach, pioneered by N. C. Seeman, the 2-nm-wide DNA molecules themselves are used to form 2D and 3D structures.^[59–63] As shown in Fig. 9A, DNA four-armed branched junctions are made by properly choosing the sequence of complementary strands. These DNA scaffolds can be linked together to make periodic crystals, as shown in Fig. 9B.

To use DNA for assembling nano- or microparts, one first needs to attach DNA molecules to these parts. The most widely used method is the covalent bond between sulfur and gold, that is, a metal thiolate (~44 kcal/mol). DNA molecules can be functionalized with a thiol (S–H) or disulfide (S–S) group and, upon immersion of microparts with clean gold surfaces in solutions of thiol-derivatized oligonucleotides, the sulfur adsorbs on the gold surfaces, forming a single layer of molecules. Using this methodology, Mirkin et al. described a method of assembling colloidal gold nanoparticles into macroscopic aggregates using DNA as the linking element.^[64] Noncomplementary DNA oligonucleotides were attached to the surfaces of two batches of 13-nm gold particles. An oligonucleotide duplex with ends complementary to the grafted sequences was then introduced into the particle mixture and the nanoparticles self-assembled into aggregates. The process is illustrated in Fig. 10. It can be reversed by increasing the temperature, thereby melting the double-stranded DNA linkers. Closely-packed assemblies of aggregates with uniform particle spacings of about 60 Å were demonstrated this way.

The concept of DNA-mediated self-assembly has been extended to metallic nanowires/rods.^[65] The idea behind this is to fabricate gold and/or platinum wires, functionalize them with single stranded DNA (ssDNA), and assemble a wiring network on a substrate, which has the complementary ssDNA molecules attached at specific sites. Thus, self-assembly of interconnects and wires is rendered possible. DNA has also been used as a template for the fabrication of nanowires. Braun et al. formed a DNA bridge between two gold electrodes, again using thiol attachment. Once a DNA bridge is formed between the 12–16 μm spacing of the electrodes, a chemical deposition process is used to deposit silver ions along the DNA through Ag⁺/Na⁺ ion exchange and reduction of the Ag complexes with hydroquinone. The result is a silver nanowire that is formed using DNA as a template or skeleton. The most ambitious goal is the DNA-assisted assembly (molecular velcro) of semiconductor active devices such as transistors, laser diodes, etc., proposed by Edman et al. at Nanogen.^[58]

Fig. 10 Fabrication process for the aggregated assembly of DNA-conjugated gold nanoparticles. (From Ref. [64].)

A vision for the future of manufacturing

IC techniques for batch manufacturing are applied today to a wide variety of non-IC products and are also combined with traditional precision manufacturing methods. Undoubtedly, the merging of traditional precision engineering and IC manufacturing methodology will lead to many more interesting new manufacturing processes. In the next 15 years, Moore's law will continue to run its course, but in parallel, we will start adapting nanochemistry principles and combine them with more traditional IC fabrication techniques.

There is little doubt that biotechnology analysis tools will keep on improving at an increasingly faster rate. Desktop DNA sequencers and three-dimensional protein readers will be a reality in the not-so-distant future. Genetic engineering will have the most profound impact though on how mankind looks at manufacturing. Since it is already possible to synthesize a virus bottom-up, given the sequence of the bases in its genes, it seems quite likely that we will be able to manufacture synthetic viruses designed to enter a cell and carry out diagnostic and therapeutic tasks. Along this line, Venter has proposed building bottom-up a minimal gene setup required to sustain life in a test tube. Many other applications will become evident; photovoltaic solar cells today have a high conversion efficiency of about 10 to

15%, but are expensive to deploy and maintain. Crops grown for energy are also expensive, involve harvesting, and are only 1% efficient. It is conceivable that genetic engineering will enable the production of energy crops that convert sunlight into fuel at a 10% efficiency. Through nanochemistry, the current digital information technology (IT) revolution might well be followed by a new analogue manufacturing revolution. Today, computers let us shape our digital environment, but by giving computers the means to manipulate the analogue world of atoms as easily as they manipulate bits, the same kind of personalization may be brought to our physical three-dimensional environment. In this context, Gershenfeld from the MIT Media Laboratory envisions a personal fabricator (PF) akin to the PC.

A human society based on nanomachining will be a much more balanced one with a manufacturing approach based on how the species itself is made. Products will be based on a fundamental understanding of the assembly of their ultimate components, atoms, molecules, and proteins, and on how to induce self-assembly into useful objects. Materials will be degradable, flexible, and fully reusable. The smaller building blocks used in manufacture will enable products of more variety and intelligence. There will be less emphasis on the traditional engineering materials such as steel, wood, stone, composites, and carbon, and proteins will become much more important.

The transition toward a nanosociety will require a major shift in workforce skill level as manipulation of data and applying knowledge of bioengineering will be part of a manufacturing worker's daily duties. In academia, less hyperspecialization and better grounding in all the sciences and engineering will be a must as the traditional dry engineering and sciences, such as electrical engineering, and mechanical engineering, will merge with the wet sciences and engineering, such as biology and bioengineering.

Micro-Particle Image Velocimetry in Biomedical Applications

Jinhua Cao

Steve T. Wereley

Department of Mechanical Engineering, Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

In recent years, the biological and biomedical applications of micro- and nanotechnology [commonly referred to as biomedical or biological micro-electro-mechanical system (BioMEMS)] have become increasingly prevalent and have found widespread use in a variety of applications such as diagnostics, therapeutics, and tissue engineering.

Fluid flow at the microscale exhibits unique non-intuitive behavior that can be leveraged to fabricate devices and components capable of performing functions useful for biological studies. Microfluidic systems for drug discovery in the pharmaceutical industry,^[1] molecular recognition in clinical diagnostics,^[2] and cell culture and manipulation for cellular and tissue engineering^[3] are changing the way in which biological information is processed. BioMEMS are devices that, much like microfluidic MEMS, are designed to interact specifically with biological entities. Some benefits of microscale fluidic technology for medical applications include reduced fluid consumption, reduced waste products, decreased reaction times, and improved parallel chemical processing capability.

The i-STAT device (i-STAT, Inc.) is one of the first microfabricated fluid devices that have seen routine use in the medical community for blood analysis. Other examples of microfluidic devices for biomedical research include microscale flow cytometers for cancer cell detection,^[4] micromachined electrophoretic channels for DNA fractionation, and polymerase chain reaction (PCR) chambers for DNA amplification.^[5]

BACKGROUND

As the field of BioMEMS and the development of microfluidic devices continue to expand, so too does the physical and geometric complexity of these devices. The details of the fluid motion through small channels, coupled with nonlinear interactions between macromolecules, cells, and the surface-dominated physics of the channels create very complicated phenomena, which can be difficult to simulate numerically.

Developing cutting-edge technologies requires cutting-edge tools. Various experimental techniques have

been developed for microfluidic research, such as laser Doppler velocimetry, the dual-slit method, optical Doppler tomography, scalar image velocimetry, molecular tagging velocimetry, and so on.^[6] Measurements with spatial resolutions smaller than 10 μm are necessary for making measurements in many MEMS applications. Only microparticle image velocimetry (μPIV) has demonstrated this high spatial resolution. The μPIV is a nonintrusive method that can be used to obtain high-resolution two-dimensional (2-D) full velocity fields instantaneously. By using a combination of advanced imaging and processing techniques, spatial resolutions on the order of single microns (and even smaller) can be achieved. μPIV also forms the basis for several applications in BioMEMS devices besides just velocity measurement. This article focuses on the applications of μPIV in biomedical research. We will give an overview of μPIV techniques first and then review its biomedical applications.

MICROPARTICLE IMAGE VELOCIMETRY

The experimental setup of a PIV system typically consists of several subsystems. Tracer particles are added to the flow in most applications, and these particles must be illuminated at least twice within a short time interval. The light scattered by the particles must be recorded either on a single camera frame or on a sequence of frames. The displacement of the particle images between the light pulses is determined through evaluation of the PIV recordings.

For evaluation, the particle images are divided into small interrogation windows. The local displacement vector for each window is determined by correlation-based statistical methods.^[7] Correlation-based PIV determines the average motion of small groups of particles contained within small interrogation windows, instead of the displacement of individual particles. The determination of the average particle displacement is accomplished by computing the spatial autocorrelation of a doubly exposed single image, or preferably the spatial cross-correlation of a pair of singly exposed images of the particle images over many interrogation windows. One displacement vector is calculated per interrogation window. For a multiple-exposure image,

the average displacement of the recorded particle image pairs is determined by computing the autocorrelation of the interrogation window. If the double frame/single exposure recording technique is employed, the cross-correlation function is used. An important advantage of the cross-correlation method is that this method removes the so-called directional ambiguity, which is inherent in the autocorrelation method.

Generally, after having acquired two sequential images of the flow, cross-correlation is employed to extract the velocity vectors from the images via an $N \times N$ pixel interrogation window, which is shown schematically in Fig. 1. The area of interest in the first frame is A and outside of this window is labeled A_0 . Their counterparts in the second frame are B and B_0 , respectively. An interrogation window $f(i, j)$ centered at a particular position (x, y) is sampled within A . Its counterpart is $g(i, j)$ within B . $f(i, j)$ and $g(i, j)$ are the gray value distributions of the two interrogation windows. The cross-correlation coefficient $R_{fg}(k, l)$ between the patterns $f(i, j)$ and $g(i, j)$ can be estimated by the convolution integral^[8]

$$R_{fg}(k, l) = \sum_{i=-\infty}^{\infty} \sum_{j=-\infty}^{\infty} f(i, j)g(i+k, j+l) \quad (1)$$

A high cross-correlation value is observed when many particle images in the first image match their corresponding spatially shifted partners in the second image. Small cross-correlation peaks may be observed when individual particle images match with other particle images. The highest correlation peak is considered to represent the best match of particle images between the windows $f(i, j)$ and $g(i, j)$. The offset $(\Delta x, \Delta y)$ of the peak, which are measured from the origin of the cross-correlation coefficient map, represent the average spatial shift of particles from image A to image B at position (x, y) . Typical 2-D correlation function is shown in Fig. 8.

Micro Particle Image Velocimetry refers to the application of PIV to measure velocity fields of fluid motion

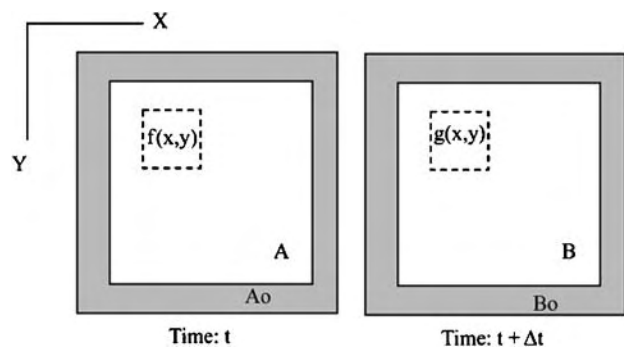

Fig. 1 Schematic interrogation windows of particle image velocimetry.

with length scales of order $100 \mu\text{m}$, and with spatial resolution of individual velocity measurements of order $1\text{--}10 \mu\text{m}$. In one of the predecessors to μPIV , flow-tracing particles were used estimate flow velocities in microscale geometries.^[9] A mercury arc lamp continuously illuminated $0.9 \mu\text{m}$ diameter fluorescent particles in an epi-fluorescent microscope. The length of the particle streaks in long-exposure images was used to estimate the local velocity. The resolution of the measurements was on the order of $10 \mu\text{m}$. The technique was extended by Santiago et al.^[10] using a mercury arc lamp to continuously illuminate 300 nm fluorescent particles. Discrete particle images were recorded by an intensified charge-coupled device (CCD) camera, using the intensifier as the shuttering mechanism. Correlation analysis was then applied to the particle-image field. This produced regularly spaced velocity data in contrast to Brody's work,^[9] where the measurements are spaced irregularly. To record particle images with continuous light sources, tens of milliseconds are required for exposure. This limits the magnitude of velocity that can be practically measured by μPIV using submicron flow tracing particles of the order $100 \mu\text{m}/\text{sec}$. Meinhart, Wereley, and Santiago^[11] used a pulsed Nd:YAG laser to illuminate 200 nm polystyrene beads. The pulsed illumination source creates effective exposure times equal to the pulse duration of the laser, $\sim 5 \text{ nsec}$. The pulsed illumination allows for much higher velocities to be measured ($\sim 10 \text{ m}/\text{sec}$) and smaller particles to be recorded. Meinhart, Wereley, and Santiago^[11] achieved a spatial resolution of $0.9 \mu\text{m}$. The first μPIV measurement in circular tubes was obtained by Koutsiaris, Mathioslakis, and Tsangaris.^[12] They used a 20 W Halogen lamp to illuminate a glycerol suspension of $10 \mu\text{m}$ diameter glass spheres flowing through $\sim 200 \mu\text{m}$ diameter glass capillaries. The $10 \mu\text{m}$ particle size allowed for relatively short exposure times with continuous illumination. The spatial resolution of these measurements was approximately $26 \mu\text{m}$. The μPIV technique has been applied to a variety of flow regimes ranging from fundamental studies of fluid motion to practical applications such as commercial inkjet print-heads, and BioMEMS devices. Fig. 2 is a schematic of a typical μPIV system, such as that originally described by Meinhart, Wereley, and Santiago.^[11] It is common to use a pulsed monochromatic light source, such as a pulsed Nd:YAG laser system. The laser system is specifically designed for PIV applications, and consists of two Nd:YAG laser cavities, beam combining optics, and a frequency doubling crystal. The laser emits two pulses of light at $\lambda = 532 \text{ nm}$. The time delay between light pulses can vary from hundreds of nanoseconds to a few seconds. The illumination is delivered to the microscope through beam-forming optics, which can consist of a variety of optical elements that will sufficiently modify the light so that it will fill the back of the

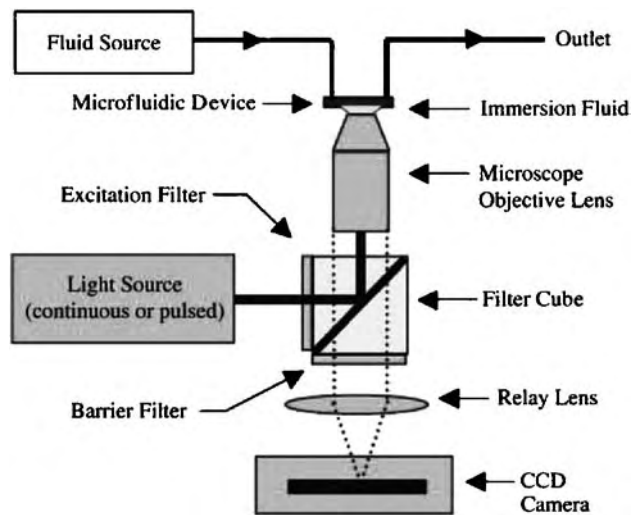

Fig. 2 Schematic of a μ PIV system using either a continuous or pulsed illumination light source. (From Ref. [13].)

objective lens, and thereby broadly illuminate the microfluidic device. The beam-forming optics can consist of a liquid-filled optical fiber to direct the light into the microscope or a simple beam expander. The illumination is reflected upward toward the objective lens by a dichroic mirror (designed to reflect 532 nm and transmit 612 nm).

Three fundamental differences of μ PIV from conventional macroscopic PIV are that the particles are small compared to the wavelength of the illuminating light; the particles are small enough that the effects of Brownian motion must be addressed; and the illumination source is typically not a light sheet, but an illuminated volume of the flow.^[11]

Because the diameter of the flow-tracing particles must be small enough that the particles not disturb the flow being measured, they can frequently be on the order of 50–100 nm. The diameter (d_p) is then 1/10 to 1/5 the wavelength (λ) of green light, and therefore approaching the Rayleigh scattering criteria where the amount of light scattered by a particle varies as d^6 . This makes it extremely difficult to record particle images. One solution to the imaging problem is to use epi-fluorescence imaging to record light emitted from fluorescently labeled particles, using an optical filter to remove the background light.

When the seed particle size becomes small, the collective effect of collisions between the particles and a moderate number of fluid molecules is unbalanced, resulting in a random particle motion known as Brownian motion, which prevents the particle from following the flow to some degree, causing a measurement error. It is an unbiased error that can be reduced by averaging over groups of particles.

The third significant difference between μ PIV and conventional PIV is the illumination mode. Conventional PIV uses light sheet illumination while μ PIV uses volume illumination because forming a light sheet inside a microscale device and aligning the light sheet with the focal plane would almost be impossible. Because the entire depth of the fluid is illuminated, the tracer particles within the volume are illuminated regardless of whether these particles are within the depth of field of the optical imaging system. Particle image size, intensity, and shape vary with distance from the focal plane. In conventional PIV, all illuminated particles are in focus because the depth of field is larger than the thickness of the light sheet. However, in μ PIV, the depth of field is determined by the optical system and camera characteristics.^[13]

The spatial resolution can be determined in terms of the depth of correlation. The depth of correlation is defined as the axial distance, Z_{corr} , from the object plane in which a particle becomes sufficiently out of focus so that it no longer contributes significantly to the signal peak in the particle-image correlation function. The expression of Z_{corr} , given by Wereley and Meinhart,^[13] is strongly dependent on numerical aperture, NA, and particle size, d_p , and is weakly dependent on magnification.

The resolution of μ PIV measurements can be increased further by applying a number of advanced evaluation techniques, which also work well for standard PIV systems. Measurement uncertainty of PIV data includes both bias and precision error. One of the most effective methods for reducing the bias error of PIV in complex flows is the central difference interrogation (CDI) method.^[14] Adaptive window offsetting is widely used with the fast fourier transform (FFT)-based correlation algorithm for reducing the evaluation error and with the image pattern tracking algorithms for increasing the spatial resolution. When using CDI, the first and second interrogation windows are shifted backwards and forwards, respectively, each by half of the expected particle image displacement. By applying CDI, the accuracy is improved to order Δt^2 (Δt is the time interval between the two images) instead of order Δt for conventional forward difference interrogation, by which only the first interrogation window is shifted forward.

To further reduce the measurement uncertainty, the random error must also be reduced. In a complex flow with both translation and rotation velocity, even when the flow is ideally seeded and the PIV recordings are made without any noise, evaluation errors may result from the deformation of the measured flow. To account for the deformation of the PIV image pattern, image correction techniques have been developed. Central difference image correction (CDIC), an efficient image correction algorithm, combines ideas of central

difference interrogation, adaptive continuous window shifting, and image correction, and enables a very reliable and accurate evaluation of digital PIV recordings.^[15] In the CDIC procedure, the particle image displacements at the four corners of each interrogation window are calculated based on previous iterations and used to deform the image patterns in the interrogation area for both exposures of the PIV recording pair using one of several interpolation schemes, so that the image patterns have an optimal match despite spatial velocity gradients at the particle image displacement.

The volume illumination used in μ PIV limits the number density of particles that can be used to trace the flow. If the particle density is too high, then background noise from out-of-focus particles will dominate the image and reduce the visibility of in-focus particles. The correlation function for a single-exposed PIV image pair has a peak at the position of the mean particle image displacement in the interrogation window, which should be the highest among all the peaks of $R_{fg}(k, l)$. Smaller subpeaks, which result from noise or mismatch of particle images, are usually obviously lower than the main peak, i.e., the peak of the particle displacement. However, when the interrogation window does not contain enough particle images or the noise level is too high, the main peak will become weak and may be lower than some of the “sub” peaks, causing an erroneous velocity vector. Because many of the low Reynolds number flows in microfluidic devices are either steady or periodic, it is sufficient to measure the time-averaged or phase-averaged velocity field. In steady or periodic flows, the main peak of $R_{fg}(k, l)$ is always at the same position for PIV recording pairs taken at different times while the subpeaks appear with random intensities and positions in different recording pairs. Therefore, when averaging R_{fg} for a sufficiently large number (N) of PIV recording pairs, the main peak will occur at the position of the particle image displacement with the same intensity level, but the subpeaks, occurring randomly, will disappear as N becomes large. By averaging the correlation function, the effective particle concentration is increased, so that the errors resulting from the low image density can be avoided.^[16]

FLOW FIELD MEASUREMENT

One straightforward application of μ PIV is to measure the velocity field inside a BioMEMS microfluidic device. In the present example, particle dynamics in response to both flow and electrical forces is studied using μ PIV.

DEP Particle Trap Device

It is important to determine the flow field at the micro-scale. Many biological processes involve chemical

reactions and the transport of macromolecules or cells through complicated channel networks. The details of the fluid motion in these small channels, coupled with interactions between macromolecules, cells, and the surface-dominated physics of the channels create complex phenomena, which can be difficult to simulate numerically. Understanding the flow patterns inside the micro channels by high resolution velocity measurement helps to understand the physics detail of the micro scale flow, characterize and quantify the performance of the BioMEMS device, and optimize the operating parameters.

Dielectrophoresis (DEP) is becoming a popular method for manipulating cells and other biological entities, such as virus, proteins, and DNA molecules. Dielectrophoresis has been used to separate blood cells and to capture DNA molecules.^[17] Despite the attention it is receiving, there is presently an incomplete understanding of the phenomenon, especially as it interacts with the hydrodynamic force on cells. The μ PIV technique was applied in a DEP device to characterize the flow field by Whitacre and Wereley.^[18]

The device was designed and manufactured at Purdue University.^[19] It has been designed to trap, separate, and concentrate biological components carried in solution. It consists of a microchannel with a depth of 11.6 μm , width of 350 μm , and length of 3.3 mm. The channel was anisotropically etched in silicon to produce a trapezoidal cross section and covered by a piece of anodically bonded glass. A schematic view and photo of the device are shown in Fig. 3. Bright regions represent platinum electrodes and the dark regions represent the electrode gaps. The electrodes are arranged in interdigitated pairs so that the first and third electrodes from Fig. 3 are always at the same potential. The second and fourth electrodes are also at the same potential, but can be at a different potential than the first and third electrodes. An alternating electric potential is applied to the interdigitated electrodes to create an electromagnetic field with steep spatial gradients. Particle motion through the resulting electric field gradients causes polarization of the suspended components, resulting in a body force that repels particle motion into increasing field gradients.

In the experiments, sample solutions were injected into the chamber using a syringe pump. The flow rate could be adjusted. An HP 33120A arbitrary waveform generator was used as the AC signal source to produce sinusoidal signal with frequency specified at 1 MHz. Images of particles were acquired using a standard μ PIV system, as shown in Fig. 2. A mercury lamp is used to illuminate the 0.7 μm polystyrene latex (PSL) microspheres (Duke Scientific) that are suspended in deionized water in concentrations of about 0.1% by volume. The particles are coated with a red fluorescing dye ($\lambda_{\text{abs}} = 542 \text{ nm}$, $\lambda_{\text{emit}} = 612 \text{ nm}$). The images were

Fig. 3 (A) Schematic view of experimental apparatus and (B) photo of apparatus. (From Ref. [18].)

acquired using a Photometric CoolSNAP HQ interline transfer monochrome camera (Roper Scientific).

The experiments used six sets of 800 images each to analyze the effect of DEP on particle motion in the test device. These images are high quality with low readout noise, as can be seen in the example fluorescent image of Fig. 4. Fig. 4A demonstrates the many different particle intensity distributions, which are typically present in a μ PIV image in which the particles are distributed randomly within the focal plane. Fig. 4B shows how, as the result of the DEP force, the particles migrate to the top of the channel and all have nearly identical images. Fig. 4B also shows that when a significant DEP force exists, the particles are trapped at the electrode locations by the increase in DEP force there.

The PIV results for experimental cases ranging from 0.5 to 4.0 V are summarized in Fig. 5, which is a plot of the average axial velocities for the six electrode voltage cases. An interrogation region of 32 by 32 pixels and a grid spacing of 8 by 8 pixels were used. While this grid

spacing over samples the data, it provides a good means of interpolating between statistically independent measurements. The advanced interrogation options included CDI, continuous window shifting, ensemble correlation averaging, and a multiple iteration scheme set to two passes. The velocity curves show that particles move fastest over the centers of the electrodes and slowest on the leading edge of the electrodes (electrodes are located at 20–40, 60–80, 100–120 μ m, etc., from the inlet of the channel), which testifies to the feasibility of DEP particle trapping. The three lowest voltages show a trend of decreasing particle velocity in the downstream direction, which may be explained by the impediment by each electrode a particle encounters. Another interesting result observed from Fig. 5 is that the average particle velocity increases as the voltage increases from 0.5 to 2.0 V, but decreases as the voltage increases from 2.0 to 4.0 V. This phenomenon is explained by particles being displaced from the channel bottom into faster area of the fluid flow, which biases the velocity

Fig. 4 Photo of PSL particles with 0.0 V (A) and 4.0 V (B). (From Ref. [18].)

distribution toward higher velocities, altering the shape of the cross-correlation peak to favor higher velocities even though the flow is constant. For higher voltages, the effect of particles being hindered by axial electric field gradients is compounded by particles being forced beyond the high-speed center of the flow profile by the DEP force.

Microviscometry

Based on the velocity measurement, many other related flow properties can be derived, such as shear stress, viscosity, pressure gradient, and even the wall location

Fig. 5 Average axial velocity from PIV results for all electrode voltage cases (From Ref. [18].)

in microvessels. Applications of μ PIV to microvascular hemodynamics help to get many dynamic, kinematic, and rheological properties of the blood flow, which have been difficult or impossible to assess in microvessels in vivo.

A microviscometry method based on μ PIV is presented by Long et al.^[20] The central tenet of this approach is that distributions in the local viscosity, $\mu(r)$, as a function of the radial position, r , over the cross section of microvessels, can be determined analytically from the cross-sectional axial velocity distribution, $v_z(r)$, where $v_z(r)$ can be extracted from particle tracers in the flow by using μ PIV. In addition to the viscosity distribution, various flow parameters in microvessels in vivo can also be predicted by this method, including axial pressure gradient, dp/dz ; volume flow rate, Q ; and the relative apparent blood viscosity, η_{rel} , defined as the ratio of steady volume-flow rates per unit pressure drop of blood plasma relative to whole blood. Quantitative validation of microviscometric methods is given and a decrease in local and apparent blood viscosity in individual microvessels as a direct result of reducing systemic hematocrit is shown. They also detect the presence of the endothelial-cell surface layer and estimate its hydrodynamically relevant thickness by least square fitting to the μ PIV data. This idea is first proposed by Stone et al.,^[20a] named “microfluidic nanoscope” for measuring the shape of internal cavities and flow channels with a spatial resolution of tens of nanometers. This technique uses μ PIV to measure the motion of fluid near a cavity wall. This information, combined with a model for the fluid’s boundary condition, typically the no-slip boundary condition, can be used to determine the wall’s location and topology.

Typically, rheological data are extracted from force measurements, which do not provide the detailed spatial distributions that this approach offers. The idea of using a velocity field to extract rheological data has applications beyond microvascular hemodynamics to a variety of generalized linearly viscous fluids and particle-suspension flows, including polymer melts, emulsions, extrusion, and polymeric drag reduction.

The small fluorescent particles ($<0.1 \mu\text{m}$) used in this method increase the spatial resolution in rheology studies and increase the size of particle fluctuations ($<1/r$), and therefore the random error. Fluorescent particles allow viscoelasticity to be probed in complex optical objects, e.g., allowing them to be easily located within living cells. However, fluorescence studies can encounter challenges with respect to the chemistry of the fluorescent tags. Photobleaching gives a finite time limit for the experiments. It is important to quantify the degree of noise inherent in PIV experiments, because this defines the largest moduli (smallest amplitude of particle fluctuations) that can be measured. Superior calibration of the PIV experiments can be achieved with

respect to the viscosity of a range of standard Newtonian fluids, e.g., glycerol/water mixtures at a range of concentrations. The dependence of the microrheological measurements on the fluorescent particle size and on its chemistry need to be carefully considered. Thus, a microrheologist must study the interactions of their probe particle with the complex fluids under examination. Ideally, the particle chemistry should have a negligible influence on the result of a rheological measurement.

Similar to that above, μ PIV can also be applied to measure the red blood velocity field,^[21] to elucidate the effects of disturbed flow on monocyte adhesion to endothelial cells by characterizing the disturbed flow in a vertical-step flow chamber,^[22] to study the deformation of DNA molecules under homogeneous extensional flow,^[23] and so on. A similar particle-tracking technique^[24] is also used in microrheology. It has been used to probe the dynamics of membrane systems^[25] and to measure the local mechanical properties of cells and cytoplasm.^[26] A novel method for measuring the microrheology of soft viscoelastic media, based on cross-correlating the thermal motion of pairs of tracking particles is demonstrated by Crocker et al.^[27] This method does not depend on the exact nature of the coupling between the tracers and the medium, and yields accurate rheological data for highly inhomogeneous materials.

PARTICLE DETECTION

Using the μ PIV technique, we can obtain not only velocimetry data by conventional (correlation-based) PIV analysis, but also other useful information by different analysis methods. For example, the peak location of particles in the PIV images can be found by Gaussian peak fitting. The point response function of the microscope objective lens can be approximated well by the Gaussian function.^[28] The particle image-intensity distribution can be derived by convolving the point-spread function with the particle geometric-image distribution. Assuming the intensity distribution of the particle geometric image is also a Gaussian function, which is the most common approximation used in PIV analysis, a Gaussian function would be a good approximation to the intensity distribution of a particle image. By using the Gaussian function to fit the particle image intensity function, several parameters of a single particle can be extracted: the peak intensity of the particle image, peak location, and particle diameter.^[29]

Concentration Measurement

This technique is used to study the Brownian particle migration in a microchannel tube flow.^[29] A rigid

spherical particle translating at a small tube Reynolds number in a shearing flow experiences lateral migration owing to small inertia and wall effect. In a suspension flow of sufficiently small particles, Brownian motion is another factor. The Peclet number is a dimensionless parameter to describe the relative importance of Brownian motion with respect to shear-induced migration, which is conceptually defined as

$$Pe = \frac{6\pi\mu\gamma a^3}{KT} \quad (2)$$

where μ is the absolute viscosity of the fluid; γ is the shear rate; a is the particle radius; K is the Boltzmann's constant; and T is the temperature. Large Peclet numbers imply that the shear forces dominate Brownian diffusion while the case is opposite for small Peclet numbers.

In this work, a dilute suspension flow (particle volume fractions $\ll 0.01$) of Brownian particles is studied using a μ PIV system to directly image particle concentrations and velocity. The suspensions consist of fluorescent PSL particles and water. The mean particle diameter d_p are 0.69, 1.0, and 3.0 μm . Seventy-five micrometer diameter capillary tubing made of fluorinated ethylene propylene (FEP) Teflon is used as the flow channel. As the refractive index of FEP is very close to that of water, the tubing is immersed into water to match the refractive index. The flow inside the tubing is driven by a pressure head. The flow velocity is varied, which results in the bulk Peclet number ranging over four orders of magnitude.

To study the spatial particle distribution, the locations of all the particles in each image are extracted by fitting the Gaussian function to the particle image intensity function. When a local maximum in an image is detected, the intensity matrix $I(X, Y)$ around that maximum is extracted, then a least squares curve fit is applied to get the parameters that describe the particle characteristics: the peak intensity of the particle image, peak location, and particle image diameter. After each particle image is detected, it is removed from the original image and the next particle is found. From the locations of the detected particles, the concentration distribution can be calculated and expressed as a probability density function.

The velocity is calculated using the software package EDPIV, developed by Dr. Lichuan Gui.^[15] Two hundred image pairs of images are used to ensemble-average velocity fields in correlation space to reduce random errors owing to image noise and tracer particle Brownian motion.

The relative concentration profiles of the 3.0 μm particles are shown in Fig. 6. The maximum tube velocity is in the range of 0.009–0.21 m/sec, corresponding to Peclet numbers between 3820 and 89700 and particle

Fig. 6 PDF (relative concentration) of $3.0\ \mu\text{m}$ particles. (From Ref. [29].)

Reynolds numbers between 0.013 and 0.32. It has been found that when Pe is small, particles migrate away from the channel wall, and that the particle concentration in regions remote from the wall is nearly uniform. The dominant mechanism is Brownian motion; when Pe increases, particles move away both from the wall and the center, toward a preferred position (r^*) with the migration effect becoming progressively stronger as Pe increases. The dominant mechanism is the shear-induced migration. We can also see that there is a particle-free zone near the channel wall and this zone expands as the velocity increases. A quantitative analysis based on the behavior of three different sizes of particles shows that the transition between these behaviors happens between Pe 1000 and 100,000.^[29] The radial velocity data agrees with this migration behavior by showing that particles move toward the equilibrium position r^* .

Many BioMEMS devices work with “particles” (cells, bacteria, DNA, etc.) suspended in fluids. The performance of some of those devices strongly depends on particle distribution as they pass through the sensor channels, such as the multifrequency particle impedance characterization system developed by Fuller et al.^[30] The work described above gives a good understanding of the migration of particles small enough to be susceptible to Brownian motion. It is very helpful to characterize and improve the performance of those BioMEMS devices.

It is also found that the equilibrium position r^* has a dependence on the particle size, it decreases as the particle-to-channel size ratio increases as is shown in Fig. 7. Based on this knowledge, a shear-activated cell sorter can be proposed. The advantage of this sorter is

Fig. 7 r^* vs. d_p/D (r^* decreases as the particle-channel size ratio increases). (From Ref. [29].)

the simple working mechanism—only hydrodynamic forces are needed.

Diffusion Measurement

This particle-detection method can also be used to measure the diffusion coefficients. Particle image diffusiometry is proposed by Gorti et al. Virus identification with particle image diffusiometry (submitted for publication) to directly measure the diffusion coefficients of submicron particles as a means of pathogen detection.

The mean square displacement traveled by a particle with diffusivity D owing to diffusion over a time period Δt is given by

$$\langle s^2 \rangle = 2nD\Delta t \quad (3)$$

where n is the number of translational degrees of freedom. They obtained 700 images with 300 msec between frames for each set. The particles in the images are detected by Gaussian fitting discussed earlier in this paper, and the center location of each particle is extracted. Because the volume fraction of the solution used here is extremely low (the particles images are separated by at least 10 particle diameters), the particle images in one image can be easily matched with those in the next image so that individual particles can be tracked over long times. From the trajectory of each particle, a large amount data of distance traveled by the particle over Δt (300 msec) can be obtained. This displacement data formed a Gaussian function and can be used to estimate $\langle s^2 \rangle$ by statistical means. In the 2-D flow field, the diffusion coefficient is one-fourth the slope of $\langle s^2 \rangle$ vs. t curve [Eq. (3)].

At a constant temperature, the diffusion coefficient is a function of the drag on the particle. If the particles

are functionalized with antibodies against a specific analyte and introduced into a sample containing that analyte, binding of the analyte with the particles will increase its hydrodynamic force, which results in a decrease in diffusion. The reduction in diffusion is correlated with the amount of analyte present, so that the amount of analyte can be sensed by measuring the diffusion coefficient by this particle image diffusometry technique. It is shown (Fig. 5, Ref. Gorti et al. Virus identification with particle image diffusometry, submitted for publication.) that analytes as small as 1 nm can cause measurable changes in the diffusion coefficients of appropriate particles, and therefore can be detected.

Typically, affinity biosensors use “sandwich” assays for detection and measurement. One drawback of sandwich assays is the difficulty in producing two antibodies that each bind to different sites of an antigen, and the probability of two binding events on a single antigen is significantly less than that of a single binding event. This method avoids the sandwich assay, as only one binding event is needed, and offers several advantages: high resolution, multianalyte detection capability, avoidance of sandwich assays, less preparation time, and quicker results. It is a more direct approach to biosensing compared to many other methods, such as immunoassays,^[31] enzyme-catalyzed reactions,^[32] nucleic acid-based reactions, use of biomimetic materials, and membrane protein-based detection.

CHARACTERISTICS OF CORRELATION FUNCTION

Correlation-based PIV analysis detects the peak location of the correlation function to obtain the displacement of the interrogation window. However, the correlation function carries more information than just the peak location, for example, the peak width.

It is noted earlier in this paper that for small tracer particles and low speed flows, Brownian particle motion is measurable and could be significant enough to introduce considerable error into the velocity measurements. Because it was viewed as an undesirable effect on velocity data, the effect of Brownian motion on the PIV correlation function—namely a width-wise spreading of the correlation peak, which added to the uncertainty of locating the peak center—was often intentionally and substantially reduced through ensemble averaging over multiple images. However, Olsen and Adrian^[33] developed the theoretical relationships with which such spreading of the correlation peak could be used to deduce fluid temperature. Furthermore, because peak location (which yields velocity information) and peak width are independent parameters, it is conceivable that

PIV may be used to simultaneously measure both temperature and velocity.

The diffusivity D of particles of diameter d_p immersed in a liquid of temperature, T , and dynamic viscosity, μ , is given by expression

$$D = KT/3\pi\mu d_p \quad (4)$$

Combining Eqs. (3) and (4), it is observed that an increase in fluid temperature, with all other factors held constant, will result in a greater expected particle displacement, $\sqrt{\langle s^2 \rangle}$. However, absolute viscosity, μ , is a strong function of temperature and $\langle s^2 \rangle \propto T/\mu$. The effect of this relationship depends on the phase of the fluid. For a liquid, increasing temperature decreases absolute viscosity—so the overall effect on the ratio T/μ follows the change in T . For a gas, however, increasing temperature increases absolute viscosity, meaning that the effect on T/μ , and hence $\langle s^2 \rangle$, would need to be determined from fluid-specific properties.

Brownian motion necessitates that, in a given elapsed time window, all particles immersed in a fluid undergo slight random variations in displacement, resulting in a correlation function with a predictable and measurable peak-width increase over the case of no Brownian motion. The relationship between a particle’s actual cross-sectional area and that of its image is governed by the characteristics of the imaging optics. Olsen and Adrian^[33] developed an expression for the correlation peak width based on particle diameter, imaging optics characteristics, and Brownian motion. Hohreiter et al.^[34] extended this expression to allow the temperature to be extracted from the correlation peak width (Fig. 8) shows the possible variations in peak width owing to Brownian motion for a pair of experimental PIV images.

This microparticle image thermometry idea is elucidated and applied experimentally in a zero-velocity particle-seeded water cell to measure temperature over the range 20–50°C.^[34] When compared with thermocouple-measured temperatures, results agreed within a range of $\pm 3^\circ\text{C}$.

Because volume illumination is employed in μPIV , the out-of-focus particles negatively contribute to the image by effectively varying the particle image size and luminous intensity, reducing the signal-to-noise ratio, and ultimately decreasing the strength of the correlation.^[35,36] However, these effects are present in both the auto-correlation and cross-correlation peak shapes, and hence can be removed from consideration by using the difference of the cross-correlation and autocorrelation peak widths to infer temperature. The time delay, Δt , must satisfy two criteria. It needs to be: 1) sufficiently long to allow measurable particle motion to take place, yet and 2) short enough that a significant fraction of the particles in the first image also be present in the second. The former criterion is imposed by Brownian particle

Fig. 8 A pair of correlation functions demonstrates possible variations in peak width. (From Ref. [34].)

motion and the latter by bulk fluid motion. Because the time interval between images cannot be too short, the sensitivity to dynamic change in temperature is not high. Experimental error for PIV thermometry is tied closely to the optical resolution of the PIV system being used—the higher the optical resolution, the more accurately fluid temperatures can be measured using this technique.

Thermal management is an important function required of emerging lab-on-chip systems as well as heat-producing integrated circuits. A variety of functions, such as DNA amplification and sensing, often require precise temperature control to guarantee successful and repeatable performance. For instance, PCR devices require operation at two or three different temperatures with a precision of $\pm 1^\circ\text{C}$.^[37,38] To monitor the temperature inside microfluidic channels, many methods were applied. A technique using the temperature dependence of the fluorescein dye intensity was first successfully employed by Ross, Gaitan, and Locascio to measure longitudinal temperature distributions in microchannels;^[39] another technique was developed using the temperature dependency of the conformational state of *N*-alkyl-substituted acrylamides polymer resulting in solubility below and precipitation above distinct (critical) temperatures.^[40] Including the microparticle image thermometry stated above, all three techniques allow visualizing thermal patterns in microfluidic systems under operating conditions. They can all be recommended for temperature measurements in optically accessible systems. The polymer method is ideal for detecting isotherms in steep temperature gradients close to heat sources. The fluorescein-based thermometry and the microparticle image thermometry have a comparable precision of about $\pm 3^\circ\text{C}$. The microparticle image thermometry has higher sensitivity over larger temperature ranges while the fluorescein-based thermometry has

higher sensitivity at a lower temperature range. The microparticle image thermometry technique can be introduced to monitor and control the temperature inside the flow systems. The advantages are that it is a nonintrusive method and it can measure both the temperature and the velocity simultaneously.

Because the cross-correlation peak area change is directly related to the expected particle displacement $\sqrt{\langle s^2 \rangle}$ and the temperature, T , through the diffusivity, D , it is conceivable that the diffusivity can be measured by this method too. It is another promising diffusometry method.

CONCLUSIONS

μPIV is a powerful, high-resolution measurement tool in the microfluidics field. The applications of μPIV are reviewed in this article. They can be categorized into three categories by the different analysis method that is used.

1. μPIV can be used to measure the flow field inside BioMEMS devices, microcirculation, and other biological environments. Both velocimetry data and other flow-related properties can be obtained, such as viscosity, shear stress, and pressure gradient. The velocimetry data can also be used to locate the wall position inside the microvessel.
2. Single particle images in a μPIV image can be detected by a Gaussian fitting. Particle location and particle size can be extracted. The motion and concentration of particles can be obtained. Microparticle image diffusometry, based on the Gaussian particle fitting, can be used to measure the diffusion coefficient and then detect the pathogen.

- Variation of diffusivity can result in variation of the PIV correlation function. By measuring the peak area change of the correlation function, we can measure diffusion-related parameters such as temperature and diffusion coefficient.

Microporous Materials

Julian R. Jones
Larry L. Hench

Department of Materials, Imperial College London, London, United Kingdom

INTRODUCTION

When a significant loss of tissue occurs as a result of trauma or by the excision of diseased or cancerous tissue, total healing occurs only with the aid of graft implants. Therapies employing graft material retrieved from a different site in a patient (autograft), from another human donor (homograft), or from other living or nonliving species (heterografts or xenografts) have been restricted by limited material availability, complicated multistage surgery at the detriment of the harvest site, and the risk of disease transmission. These factors create a great demand for synthetic substitutes specially designed and manufactured to act as a scaffold for tissue engineering and regeneration. One of the main criteria for a scaffold is that it is composed of an interconnected network of pores with diameters in excess of 100 μm (microporous materials) to allow tissue ingrowth, vascularization, and nutrient delivery. This entry begins by describing all the properties of an ideal scaffold and reviews processes that have been used in an attempt to create microporous ceramics and glasses for various applications, from fuel filters to biomedical scaffolds, and compares them to the criteria of an ideal scaffold. The entry continues by describing the latest advances in microporous materials that have the potential to be used to regenerate damaged tissues to their natural state and function and ends with an assessment of the attainability of the ideal scaffold.

TISSUE ENGINEERING AND REGENERATION

At present, the gold standard for surgeons repairing damaged bone is to restore it to its natural form and function by harvesting the patient's tissue from a donor site and transplanting it to a host site, at times even maintaining blood supply. The future goal is to be able to eliminate the need for transplants, but still repair tissue to its natural form.^[1,2] Tissue regeneration techniques involve the use of a scaffold that can be implanted into a defect to guide and stimulate tissue regrowth in situ. The scaffold should resorb (dissolve) as the tissue grows, leaving no trace of damage. In tissue engineering applications, the scaffolds are seeded

with cells in vitro to produce the basis of a tissue before implantation;^[2,3] cells could be extracted from a patient, seeded on a scaffold of the desired architecture, and the replacement tissue grown in the laboratory, ready for implantation.^[4]

AN IDEAL SCAFFOLD

An ideal scaffold is one that mimics the extracellular matrix of the tissue that is to be replaced so that it can act as a template in three dimensions onto which cells attach, multiply, migrate, and function. The criteria for an ideal scaffold for bone regeneration are that it:

1. Is made from a material that is biocompatible, i.e., not cytotoxic.
2. Acts as template for tissue growth in three dimensions.
3. Has an interconnected microporous network containing pores with diameters in excess of 100 μm for cell penetration, tissue ingrowth and vascularization, and nutrient delivery to the center of the regenerating tissue on implantation.^[5,6]
4. Bonds to the host tissue without the formation of scar tissue, i.e., is made from a bioactive and osteoconductive material.
5. Exhibits a surface texture that promotes cell adhesion, adsorption of biological metabolites.^[7]
6. Influences the genes in the bone-generating cells to enable efficient cell differentiation and proliferation
7. Resorbs at the same rate as the tissue is repaired, with degradation products that are nontoxic and that can be easily excreted by the body, for example, via the respiratory or urinary systems.
8. Is made from a processing technique that can produce irregular shapes to match that of the defect in the bone of the patient.
9. Exhibits mechanical properties sufficient to be able to regenerate tissue in the particular application such as bone in load-bearing sites.
10. Has the potential to be commercially producible to the required ISO (International Standards Organization) or FDA (Food and Drug Administration) standards.

11. Can be sterilized and maintained as a sterile product to the patient.
12. Can be produced economically to be covered by national and/or private healthcare insurances.

For bone regeneration, where the scaffold is implanted directly into a bone defect, mechanical properties of the scaffold are critical and the modulus and elastic strength of the microporous material should match that of the natural bone. If a scaffold with a modulus much lower than the host bone is implanted into a load-bearing site, the scaffold will fracture. If the modulus of the scaffold is much higher than bone, the load will be transmitted through the scaffold instead of the bone (stress shielding), causing bone resorption rather than bone regeneration. Stress shielding causes bone resorption because the body is continually remodeling bone according to the stress to which the bone is subjected. Osteogenic cells lay down new bone matrix to strengthen bone under high loads. When bone is not loaded, other cells called osteoclasts resorb it. This is one of the most common reasons for total hip replacements to fail.^[3]

For tissue engineering applications, only the mechanical properties of the final tissue engineered construct is critical.

BIOACTIVE MATERIALS

When bioinert materials are placed in the body, scar (fibrous) tissue surrounds the implant. Scar tissue will hinder repair and affect functionality of the tissue. Bioactive materials bond to tissue on implantation. The most commonly used bioactive materials are ceramics and glasses. Class A bioactive materials bond to both hard and soft tissue, whereas class B bioactive materials bond only to bone.^[3,7] Bioactive glasses are class A bioactive materials that are biocompatible, bioactive, resorbable, osteoconductive (allows bone to grow along its surface), and even osteoinductive (encourages bone growth away from the original bone surface).^[7]

Fig. 1 shows a scanning electron (SEM) micrograph of rabbit trabecular bone. Trabecular bone is a natural composite of collagen fibers and microporous bone mineral (55–70% interconnected porosity), which is similar to synthetic hydroxyapatite (HA) ceramic, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$.^[1,8] Therefore, it is desirable to produce a scaffold that mimics the morphology of the bone mineral and then can regenerate it. Synthetic HA and tri-calcium phosphate (TCP) have gained great attention as fillers, spacers, and bone graft substitutes in orthopedic and maxillofacial applications.^[7] They are class B bioactive materials that are osteoconductive. Synthetic stoichiometric HA dissolves very slowly

Fig. 1 SEM micrograph of the microporous structure of rabbit trabecular bone.

in the body, so slowly that it is usually considered as not resorbable. In contrast, TCP resorbs at a very high rate, sometimes too fast for bone regeneration applications.

HA, TCP, and bioactive glasses have been used successfully in the clinic as bone filler materials in powder form,^[7,8] however, the challenge is to develop them into 3-D microporous scaffolds with the properties listed earlier. The following sections will focus on that challenge.

HA AND TCP CERAMICS

Sintering

The simplest way to generate porous scaffolds from ceramics such as HA or TCP is to sinter particles. Particles are usually mixed with a wetting solution, such as poly(vinyl alcohol), to aid compaction. The powders are compacted by cold isostatic pressing the particles into cylinders at approximately 200 MPa^[9] to form a green body. The gaps between the particles are the pores and the green body will have low mechanical properties. Mechanical properties of the materials are improved by sintering at high temperatures, i.e., the material is raised to high temperature (e.g., 1200°C) in a furnace. As sintering temperature increases, pore diameter decreases and mechanical properties increase as the packing of the spheres increases. Porosity can be increased by adding fillers such as sucrose to the powder and the wetting solution, which burnout on sintering.^[10] Komlev et al.^[11] produced porous HA scaffolds with interconnected interparticle pore diameters of approximately 100 μm, and a tensile strength of approximately 0.9 MPa, using 500 μm spheres. Mechanical properties can be increased further by hot isostatic pressing (HIPing), which will also decrease the pore diameter.^[12]

Combustibles

A foreign combustible organic material, such as an amino acid derivative, is added to a ceramic powder and burned away during sintering, leaving voids in the matrix.^[13,14] Total porosities of 60–90% can be attained with pores in the range of 100–250 μm ,^[14] but there tend to be large distances between the pores and, therefore, the interconnectivity of the pores is generally low.

SHS and Combustion Synthesis (Volatile Agents)

Porous ceramics can be made by self-propagating high-temperature synthesis (SHS), otherwise known as combustion synthesis. Cylindrical compacts of stoichiometric powder mixture and volatile agents are mixed and pressed at 30 MPa. The SHS reaction is ignited in a nitrogen atmosphere. Without the inclusion of volatile agents, such a process creates high-purity products, but porosity is low ($\sim 1 \mu\text{m}$ in diameter) and generally closed. However, volatile agents can be added to increase the total porosity and interconnectivity to produce ceramics with an open porosity of up to 83% and pores in excess of 100 μm .^[15] Disadvantages of this procedure are that the pore distribution is difficult to control and the technique is complicated with the risk of toxic residues being left in the scaffolds.

Freeze-Dry Process

In this environmentally friendly technique, a ceramic slurry is frozen while the growth direction of ice is controlled.^[16] The frozen slurry is then dried under reduced pressure to cause sublimation of the ice, creating pores macroscopically aligned in the direction of freezing. The green bodies were then sintered to provide strength. Although porosity is open and the pore structure can be controlled by the concentration of the slurry, freezing temperature, and the sintering parameters, the maximum pore size obtained was not much greater than 10 μm and mechanical strength was low. Such a process is therefore more applicable in the field of catalyst supports and filters than the field of biomaterials.

Polymer Foam Replication

Open-celled polyurethane foams can be immersed in slurries of HA or β -TCP under vacuum to allow the slurry to penetrate into the pores of the foam. The foams are then heated at 250°C to burn out the organic

components (pyrolysis) and sintered at 1350°C for three hours, producing a scaffold with 300 μm interconnected pore diameters.^[17] Glass frit can be incorporated into the slurry to reinforce the material.^[18]

In a similar process, porous ceramics can be produced in certain compositions, such as silicon oxycarbide, by the foaming and pyrolysis of preceramic polymers. Preceramic polymers, generally containing silicon, are polymers that undergo polymer-ceramic transition when heated to temperatures above 800°C (pyrolysis).^[19,20] However, there are no preceramic polymers for calcium phosphate ceramics.

Rapid Prototyping

Rapid prototyping is a generic term for a processing technique that produces materials in a shape determined by CAD (computer aided design) software on a computer. Such materials are usually built up layer-by-layer using a liquid phase or slurry of the material that cures or sets on contact with a substrate.

Rapid prototyping of HA scaffolds has been developed as a way of controlling the pore architecture of the scaffold.^[21] Stereo lithography (SL) apparatus is used to create an epoxy resin negative image of the virtual scaffold that is developed using the CAD software. A thermal-curable HA/acrylate suspension is poured into the resin mold and cured at 85°C. The scaffolds are then removed from the mold and pyrolyzed in a furnace and then sintered at 1350°C. The scaffolds produced are cylinders with diameter of 8 mm and height of 6 mm containing channels with diameters of 340 μm , a porosity of 35%, and a compressive strength of the scaffolds is approximately 30 MPa.

Direct Foaming

Highly porous ceramics can be produced by foaming particulate suspensions or colloidal sols^[22] to obtain scaffolds with pore diameters from 20 μm to 1–2 mm. Foaming techniques have proven very successful in producing microporous ceramics and glasses with potential for tissue engineering applications. The different methods of direct foaming will be discussed later.

SOL-GEL-DERIVED BIOACTIVE GLASSES

There are two methods to produce bioactive glasses 1) the traditional method of melting oxides at high temperatures in a furnace and casting into solid shapes or quenching into a liquid to form powders called frits; and 2) via the sol-gel process.

The sol-gel process involves the production of a colloidal solution (sol) of Si–O groups by the

hydrolysis of alcoxide precursors, such as tetraethyl orthosilicate (TEOS) in excess water under acidic catalysis. Simultaneous polycondensation of Si–O groups will continue after hydrolysis is complete, beginning the formation of the silicate network. As the network connectivity increases, viscosity increases and eventually a gel will form. The gel is then subjected to carefully controlled thermal processes of ageing (60°C) to strengthen the gel, drying (130°C) to remove the liquid by-product of the polycondensation reaction and thermal stabilization/sintering to remove organics from the surface of the gel (500–800°C). A chemically stable glass is then produced. An advantage of gel-derived bioactive glasses over the melt-derived is that they exhibit a mesoporous (pores with diameters in the range 2–50 nm) texture. This texture enhances bioactivity and resorbability of the glasses and creates anchorage sites for cells such as osteoblasts.^[23,24] Microporous sol-gel-derived bioactive glasses have been developed in several ways, each exhibiting a hierarchical pore structure; micropores for tissue ingrowth and textural porosity in the nanometer range for enhanced bioactivity, cell seeding, and controlled resorbability.

Sintering

Vallet-Regi and coworkers^[25] produced five gel-derived glasses, each with different silica content, by milling the gels after the drying stage, pressing them under isostatic conditions, and sintering at 700°C. The glasses exhibited micropores and mesopores that decreased in pore volume and pore diameter as silica content increased. The modal pore diameter, from mercury intrusion porosimetry, for a 58S (58 wt% SiO₂, 36 wt% CaO, 6 wt% P₂O₅) glass was 2.01 μm decreasing to 0.52 μm for an 80S (80 wt% SiO₂, 16 wt% CaO, 4 wt% P₂O₅) glass. Such small pore diameters are unsuitable for tissue ingrowth and vascularization.

Phase Separation

Phase separation associated with the hydrolysis and polycondensation of alkoxysilanes (e.g., TEOS), in the presence of water-soluble polymers such as poly(ethylene oxide), can be used to fabricate films or fibers with controlled microporosity and mesoporosity.^[26] The solution separates into gel (silicate-rich) and liquid (solvent-rich) areas before the sol-gel transition. After the transition, the solvent evaporates, leaving micropores, but the modal interconnected pore diameter of a very narrow pore size distribution (mercury porosimetry) was 1 μm, which again is too small for tissue repair applications, but ideal for high pressure liquid chromatography.

Freeze-Gelation

In a similar process to freeze drying, freeze-gelation has been used to control the textural porosity of sol-gel-derived materials and prevent shrinkage during thermal processing. Freezing of many silica sols initiates gelation, due to high concentrations of colloidal silica particles between ice interstices. Once gelation is complete, the ice crystals are melted, leaving pores.^[27] It is very difficult to generate large micropores with this method.

Templating

Many authors have cast silica-based sol-gel glasses around removable templates such as surfactants and latex or polystyrene spheres in processes similar to those described for HA and TCP ceramics.^[28–30] Once the sol has gelled and templates are removed, voids are left in the gel. Yan and coworkers^[30] used close-packed arrays of monodisperse spheres, such as polystyrene (PS) and poly(methyl methacrylate) (PMMA), as templates to produce ordered microporous (3DOM) gel-derived bioactive glasses. The close-packed beads were added to the sol after hydrolysis was completed. After soaking, the impregnated arrays were removed for gelation, ageing, and drying. The organics were burned out when thermal stabilization was carried out at 600–800°C. The pore network was very homogeneous and interconnected, due to the close packing of the spheres. However, the mean pore diameter was only 410 nm and mean interconnected pore diameter was approximately 100 nm. The pore size is limited by the difficulty in producing organic spheres with diameters of the order of 500 μm required to produce an ideal scaffold for tissue engineering applications.

FOAMING OF CERAMICS AND GLASSES

In this entry, foaming is defined as the incorporation of a gas (often air) into a ceramic to produce a porous material, with pores either interconnected or closed. The incorporation of bubbles is achieved either by injection of gases into the fluid medium, mechanical agitation, blowing agents, evaporation of compounds, or by evolution of gas by in-situ chemical reaction.^[31] A surfactant is generally used to stabilize any bubbles formed in the liquid phase by reducing the surface tension of the gas-liquid interfaces.^[32] Surfactants are macromolecules composed of two parts, one hydrophobic and one hydrophilic. Owing to this configuration, surfactants tend to adsorb onto gas-liquid interfaces with the hydrophobic part being expelled

from the solvent and a hydrophilic part remaining in contact with the liquid. This behavior lowers the surface tension of the gas–liquid interfaces, making the foam films thermodynamically stable, which would otherwise collapse in the absence of surfactant.

A permanent method of stabilization is required to solidify the foam and maintain the foam structure during solidification, providing strength. There are therefore three main stages in the process for foaming ceramics:

1. Foam generation from the ceramic suspension, with the aid of a surfactant to stabilize the bubbles in the liquid phase.
2. Foam solidification to provide permanent stabilization.
3. Sintering to provide strength.

In the time period between foam generation and solidification, several transformations occur in the bubble structure, such as bubble coalescence and bubble coarsening. During coarsening, large bubbles expand at the expense of smaller bubbles, which is caused by the diffusion of gas that is driven by a pressure gradient from smaller to larger bubbles.^[33]

Bubble coalescence is a consequence of the displacement of liquid around neighboring bubbles to the point that the films become so thin that they rupture. The thinning of the cell walls is caused by mechanisms such as:

1. Drainage due to gravity.
2. Drainage due to capillary action.
3. Local depression of surface tension due to hot spots.
4. Van der Waals attraction between surfaces of thin films.^[33]

Other processes also oppose cell wall thinning, such as:

1. The ability of films to repair differential concentrations of surfactant, which may result from disruptions (elasticity).
2. The relatively high viscosity of liquid in the bulk.
3. The electrostatic repulsion between the two sides of a very thin film.
4. Cohesion between the adsorbed surfactant chains around the film.

These mechanisms affect the final foam structure and properties such as permeability and strength. For foams to exhibit high pore interconnectivity, the films between cells must rupture to form an open cell structure.

The methods for the setting of fluid suspensions that have been commonly used are:

1. Drying or freeze drying the solvent.
2. Compositions that can form a gel intrinsically (sol-gel process).
3. Incorporation of gelling substances, such as cellulose derivatives or alginates.
4. The in situ polymerization of monomers (gel casting).

Different types of foaming methods, using combinations of the aforementioned processes will now be discussed.

Gel-Casting

Sepulveda et al.^[31,34] used the gel-casting method to produce microporous bioactive hydroxyapatite (HA) ceramics. Gel-casting employs the foaming of suspensions, which contain HA particles, water, and dispersing agents, and organic monomers (6 wt% acrylate/diene). The organic monomers must be water-soluble and retain a high reactivity. Once the slurry has foamed, in-situ polymerization of the monomers is initiated and cross-linking occurs, forming a 3-D polymeric network (gel), which produces strong green bodies. Foaming was achieved by agitation at 900 rpm with the addition of Tergitol TMN10 surfactant (poly(ethylene glycol trimethylnonyl ether)) under a nitrogen atmosphere. The polymerization process was initiated using ammonium persulphate and a catalyst (TEMED, N,N,N',N'-Tetramethyl ethylene diamine) before casting. Porous samples were then sintered to provide mechanical strength and to burn out the organic solvents. Foam volume (and hence, porosity) could be controlled by the surfactant concentration in the slurry, but only low foam volumes could be generated, even at high surfactant concentrations. This was thought to be due to the high viscosity of the HA slurry, but it could also have been due to the choice of surfactant used. The materials produced exhibited pores of maximum diameter of 100–200 μm , which is ideal for tissue engineering applications. Unfortunately, data on the interconnected pore size distribution were unavailable.

Interconnected pore size distribution data were available for gel-cast alumina foams.^[31] Foams with a final bulk density of 0.33 gcm^{-3} exhibited a wide interconnected pore size distribution with a mode at approximately 130 μm and showing pores present up to 1500 μm . The flexural strength of these foams, which were 12% of the theoretical density of alumina, was found to be approximately 3MPa. Higher density foams (30% theoretical density) exhibited flexural

strengths up to 24 MPa. Although alumina is bioinert, it is not bioactive or resorbable. Therefore, applications of alumina foams would be filters or weight-saving structures.

Theoretically, the gel-casting process could be applied to melt-derived bioactive glass powders. However, such glasses undergo surface reactions on contact with solutions to produce an HCA surface layer, and it is desirable to have control over the reaction before a scaffold is ready for clinical use.

Foaming Agents

Herein, foaming agents are defined as reagents that create gas bubbles on reaction in solution. Gun et al.^[35] added 6–10 vol% hydrogen peroxide to the base-catalyzed sol-gel process. Decomposition of the hydrogen peroxide forms bubbles, which remain throughout polymerization. Crack-free large monoliths (rods 20 cm × 0.5 cm) were prepared that did not shrink during aging, but there were few pores greater than 10 μm in diameter.

Wu et al.^[36] applied polymer foaming techniques to a sol-gel system and utilized viscosity control to stabilize bubbles created by freon (CCl₃F) droplets dispersed in a sol to create cellular silica with porosities of 55–90% and corresponding mean cell diameters of 30–1000 μm. Porous silica can be resorbable if the specific surface area is high enough. The viscosity control was obtained by adjustment of pH with H₂SO₄. The foam structure was stabilized by:

1. A rapid polymerization reaction, which caused a rapid viscosity increase in the sol during the sol-to-gel transition and stabilized the foam structure.
2. The addition of an anionic surfactant (sodium dodecyl sulphate, SDS) that lowered the bubble-sol interfacial tension.
3. The addition of a cosurfactant (1-Dodecanol) that stabilized the bubbles.
4. The addition of a cosolvent (methanol) that dispersed the freon in the aqueous sol.

Bubbles formed because freon has a boiling point of 23.8°C, and incubation was carried out at temperatures above this boiling temperature. This step was controlled to occur simultaneously with gelation. An increase in freon concentration and incubation temperature caused porosity and cell size interconnectivity to increase. The bending strength (three point bend) of the silica foams ranged from 2 MPa at a porosity of 86% to approximately 8 MPa at a porosity of 66%. Although pore diameters were high and pores were spherical, the pore size distribution appeared broad and interconnectivity appeared to be low from SEM observations.

Sol-Gel-Derived Bioactive Glass Foams—An Ideal Scaffold?

Sol-gel derived bioactive glasses have been directly foamed by vigorous agitation, with the aid of surfactants, to produce scaffolds that fulfill many of the criteria of the ideal scaffold.^[22] Fig. 2 shows a SEM micrograph of a typical foam of the 70S30C composition (70 mol% SiO₂, 30 mol% CaO). The scaffolds can be produced with interconnected micropores, with porosities in the range of 60–90% and a modal interconnected pore diameter of up to 150 μm^[37] with many interconnections in excess of 300 μm in diameter. Comparing Fig. 2 to Fig. 1 shows that the pore structure closely mimics that of trabecular bone.

The sol-gel-derived bioactive glass contributes high bioactivity, controlled resorbability, and the potential for the ionic dissolution products (Si and Ca) to stimulate the genes in bone cells to enhance bone regeneration.^[38]

Due to the nature of the sol-gel process, the scaffolds can be produced in many shapes, which are determined simply by the shape of the casting mold. The scaffolds can be produced from various compositions of gel-derived glasses. All foam compositions can be easily cut to a required shape. Fig. 3 shows foams produced in various shapes.

The only criterion not addressed is the matching of mechanical properties of the scaffolds to bone for in-situ bone regeneration applications. The compressive strength (~1 MPa)^[37] of the foams is much less than that of trabecular bone (~10 MPa). However, the mechanical properties of these foams should be sufficient for tissue engineering applications, where bone would be grown on a scaffold in the laboratory before implantation. Work on improving the mechanical properties is ongoing.

The surface of the gel-derived foams has also been modified with organic groups and proteins to create scaffolds that have the potential for lung tissue engineering.^[39,40]

Fig. 2 SEM micrograph of a sol-gel-derived microporous foam of the 70S30C composition (70 mol% SiO₂, 30 mol% CaO).

Fig. 3 Typical sol-gel-derived microporous scaffolds made in various shapes. (Picture courtesy of Dr. Pilar Sepulveda.)

Fig. 4 shows a flow diagram depicting the foaming process. The scaffolds are produced by using a catalyst (hydrofluoric acid) to cause rapid gelation of the sol. As viscosity increases, the sol is foamed by vigorous agitation. Air is entrained into the sol, forming bubbles that are stabilized using a surfactant. As gelation occurs, the bubbles are permanently stabilized and become pores in the scaffold. The porous gel is then subjected to the standard thermal processes used in the sol-gel process.^[22] The properties of the pore network can be controlled at each stage of the process depicted in Fig. 4, e.g., by the type and concentration of catalyst and surfactant, the glass composition, and the process temperature.^[41]

POROUS MELT-DERIVED BIOACTIVE GLASSES

Melt-derived bioactive glasses of the 45S5 composition (Bioglass[®], 46.1 mol% SiO₂, 24.4 mol% Na₂O, 26.9 mol% CaO, and 2.6 mol% P₂O₅) have been used

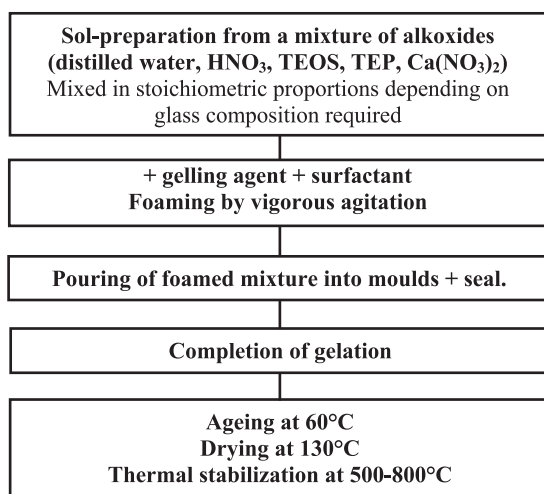

Fig. 4 Flow diagram of the sol-gel foaming process.

in the clinic in a powder form for over a decade.^[7] Therefore, producing porous Bioglass[®] scaffolds would provide a quicker route to clinical use than the sol-gel derived bioactive glass foams. However, porous melt-derived glasses have only recently been produced and it has proven difficult to produce materials with high porosity.

Livingston et al.^[42] produced a simple sintered scaffold by mixing 45S5 melt-derived bioactive glass (Bioglass[®]) powders, with particle size range of 38–75 μm, with 20.2 wt% camphor (C₁₀H₁₆O) particles, with particle size range of 210–350 μm. The mixture was dry-pressed at 350 MPa and heat treated at 640°C for 30 minutes. The camphor decomposed to leave porous Bioglass[®] blocks. Micropores were in the region of 200–300 μm in diameter, however, total porosity was just 21%, as there were large distances between pores, therefore interconnectivity was low.

Yuan et al.^[43] produced similar scaffolds by foaming Bioglass[®] 45S5 powder with a dilute H₂O₂ solution and sintered at 1000°C for two hours to produce a porous glass-ceramic. The pores were irregular in shape and relatively few in number, implying that interconnectivity was poor, but pore diameters were in the range 100–600 μm, ideal for tissue ingrowth. The pores appeared to be more like orientated channels running through the glass, rather than a pore network. The samples were implanted into the muscle tissue of dogs and were found to be osteoinductive, containing osteoblasts and osteocytes, in soft tissue. Pathological calcification (not containing osteocytes) was also observed in pores near the surface of the material. Crystal layers rich in Ca and O formed in pores away from the outer surface implant and were thought to be unrelated to the Ca-P rich layer that forms on the surface of bioactive glasses in vivo. Bone was formed directly on the solid surface and on the surface of crystal layers that formed in the inner pores and in pores containing pathological calcification. Osteogenic cells were observed to aggregate near the material surface and secrete bone matrix, which then calcified to form bone. However, although the implants had a porosity of about 30%, only 3% bone was formed. The authors suggested that any osteoconductive calcium phosphate-based biomaterial can be osteoinductive if it is made to the right geometry.

COMPOSITES

The obvious way to try to improve the mechanical properties of bioactive ceramics and glasses is to increase toughness by combining them with polymers, forming a composite. This is an extensive field of research.^[44,45] Microporous composites containing a

bioactive phase and a resorbable polymeric phase show promise for tissue engineering applications including soft tissue regeneration,^[46] however, a drawback to resorbable composites for in-situ applications is that the polymers do not resorb at the same rate as the ceramic or glass. The mechanical properties of the scaffolds therefore decrease rapidly with time and glass particles may migrate from the implantation site. Research to control the resorption rates of both phases is very active.

SUMMARY

Many techniques have been employed to produce microporous bioactive ceramics. Techniques such as the incorporation of organic phases that are eliminated during firing and the partial sintering of ceramics produce pore sizes up to 100 nm in diameter, which are not suitable for tissue engineering applications. The replication of polymer foams by impregnation of slurries produces pores in excess of 300 μm , however, mechanical properties were generally low. The most promising techniques for producing microporous ceramics and glasses with pore sizes suitable for tissue engineering seem to be direct foaming and gel-casting.

The possibility of an ideal microporous scaffold rests in the further development of present scaffolds by improving mechanical properties or by producing a microporous bioactive composite, where the resorbability of the polymer can be closely controlled.

Modeling, Biomedical

Andrew J. Pullan

Nicolas P. Smith

Department of Engineering Science, University of Auckland, Auckland, New Zealand

INTRODUCTION

Mathematical modeling is the process of combining quantitative data with a qualitative understanding to produce an explanatory and predictive tool. The level of advancement from qualitative to quantitative prediction via mathematical modeling is one measure that marks the maturity of a scientific discipline.

In contrast to the areas of physics and chemistry, where many major modeling-related advances were made in the 18th and 19th centuries, respectively, the medical and life sciences are only now undergoing this transition, albeit very rapidly. The advancement of modeling in the biomedical field has been delayed because of the inherent complexity in characterizing biological systems. This complexity manifests itself in two forms. The first is in the number of variables required to define the state of a system; the second is in the interactions between these variables that determine function.

Experimental techniques from the fields of molecular biology, structural biochemistry, physiology, and medical imaging are now able to provide enormous amounts of data relevant to the huge range of spatial-temporal scales needed to define the state of many biological systems. This large quantity of data means the link between measurement and function outside a specific scale is beyond rationalization using the human mind alone. However, recent increases in computational power are now providing the ability to rapidly process and database these large data sets.

Thus to take full advantage of these data sets and to apply basic science in a clinical or biological context, the development of formal mathematical frameworks is being accelerated. In the simplest sense the purpose is one of biological bookkeeping although through iteration with experiment it has the power to elucidate mechanisms, predict function, and provide information not accessible via measurement.

In this article we expand further on the place of mathematical modeling in the biomedical field, and where this field is heading. A brief history is given first, together with our view on the philosophy of modeling. We present some of the major difficulties associated with biomedical modeling, not the least of which is the very large range of time and space scales that must be

addressed in an integrated biophysically based model of an organ. Despite these difficulties, increasingly sophisticated whole-organ models are currently being developed. By way of illustration, we examine one such model. Finally, we provide a glimpse into the future of biomedical modeling when we describe the Physiome project and its grand ambitions to integrate all information from genomic level to clinical medicine using mathematical frameworks.

A BRIEF HISTORY

Only a brief glimpse of the history of biomedical modeling is given here to illustrate the rich and varied past. One of the first uses of mathematics in the biomedical field was made by William Harvey (1578–1657), a doctor of King Charles I of England. In 1628, Harvey published his famous *Anatomical Treatise on the Motion of the Heart and Blood in Animals*,^[1] in which he explained how blood was pumped from the heart around the body and then returned to the heart for recirculation. This was a very controversial idea that cost Harvey several patients—the common view at that time was that blood did not circulate, but sloshed back and forth, an idea that, by using simple arithmetic, was shown by Harvey to be absurd.

Galileo Galilei (1564–1642) was also publishing controversial ideas around the same time, although in a different field. He was ultimately imprisoned for his writings on astronomy, which were at odds with the Catholic Church at that time, and forbidden to publish anything more. However, his book *Discourses on Two New Sciences*^[2] was smuggled out of Italy and published in Leiden (in the Netherlands) in 1638. In this work Galileo presented a study of the relations between length, volume, weight, and strength and gave applications of this work to the shape and strength of animals. Giovanni Borelli (1608–1679) was also interested in this subject, and in 1680 presented a study of bones and muscles and the forces between them in his book *De Motu Animalium*.^[3]

Edmund Halley (1656–1742), most famously known for the comet that bears his name, published a set of mortality tables for the city of Breslau that were designed to aid in calculating annuities and pensions.^[4]

This was probably the first time data of this kind had been published and it was highly influential in the future production of actuarial tables for life insurance. Daniel Bernoulli (1700–1782) also spent some time studying the mortality of man. He is known to have analyzed the effectiveness of inoculation against smallpox, reaching the conclusion that the number of people who died as a result of the treatment was in fact smaller than the number who would otherwise have died. Bernoulli's greatest achievements, however, were in the field of hydrodynamics, and one of the most famous results in this field bears his name (Bernoulli's law). Together with Leonard Euler (1707–1783) (who is regarded as the greatest Swiss mathematician of all time), Bernoulli focussed significant attention on the relationship between the speed at which the blood flows and the pressure. His work ultimately led to a device to record blood pressure, albeit rather painfully, and soon physicians all over Europe were sticking point-ended glass tubes directly into patient's arteries.

Thomas Young (1773–1829) was an English physician and physicist who, through his studies on the behavior of light, was the initiator (with Herman Helmholtz (1821–1894) of the three-color theory of perception. The basis of this theory is that there are three different groups of cones in the retina, and each group is particularly sensitive to only one of the colors red, green, and blue. Only in recent years has conclusive evidence been obtained that shows that this theory is indeed accurate. Young also did work in elasticity, and a measure of the rigidity of materials, Young's modulus, is named after him. As well as the three-color theory of perception, Helmholtz made many other famous contributions in the biomedical field. He studied, among other things, the conservation of energy, the velocity of nerve impulses, and the heat output of muscles and through his work unified the fields of medicine, physiology, anatomy, and physics. Helmholtz was a superb exponent of combining mathematical modeling with experimentation and through his studies he brought about major advances in experimental measurement techniques and equipment.

Developments grew apace in the 20th century and we cannot hope to touch on them all here. However, there are at least three major works that must be commented on, even in this briefest of reviews. The first involves the work of Willem Einthoven (1860–1927). Einthoven measured the electrical activity of the human heart using external recording devices and produced a simple dipole model of the electrical activation of the human heart.^[5] This work, and his simple model, gave birth to the most widely used diagnostic technique in clinical cardiology, namely the electrocardiogram. Einthoven was duly recognized for such an important contribution with the Nobel Prize in Physiology/Medicine in 1924.

The second famous 20th-century use of biomedical modeling is the work of Alan Hodgkin (1914–1998) and Andrew Huxley (1917–) (for which they also won the Nobel Prize in Physiology/Medicine in 1963). Hodgkin and Huxley performed a series of studies and developed a mathematical model of a nerve cell based on the results of these experiments. This model was then used elegantly to test a number of fundamental hypotheses not directly measurable by experiment.^[6,7] This work still forms the basis of our current understanding of electrophysiology and ion regulation of cells in a multitude of tissue types today. Remarkably, Andrew Huxley was also a key figure in the parallel field of muscle mechanics, developing the sliding filament hypothesis. Huxley used mathematical modeling to predict the tissue response from a molecular model of how contractile proteins bind and unbind to generate tension.^[8] Only recently have sophisticated imaging techniques provided sufficient resolution to verify this model successfully and fully.^[9]

While the application of mathematics to study aspects of biomedical processes dates back more than three centuries, the complexity in the models has increased significantly in the latter half of the 20th century. This increase is largely due to parallel advances in the related fields of experimental biology and computer science.

In biology techniques such as DNA sequencing, protein structure measurement, and cell patch clamping, magnetic and nuclear magnetic resonance imaging have rapidly been developed and refined. These procedures provide rich data sets that, in combination, can provide the full gambit of information relevant to effective biological modeling. For instance, individual model parameters can be directly measured and related to whole system behavior, a process that is essential for model verification.

The second significant advance has been the increase in computational power. There is an oft-quoted mantra in the computer industry, encapsulated in Moore's law,^[10] which states that the computational power available for a given price will double every 18 months. This rate of advance shows no sign of abating in the near future and we now have readily available powerful computer systems that can be used to solve the increasingly sophisticated models. Before the computer revolution, models had to be solved by hand, which by necessity limited the amount and type of detail that could be included. Contemporary biomedical modeling is characterized by a constant interplay between the level of detail needed to characterize a system effectively (which is provided by experimental techniques) and the ability to process this information (which is provided by computational technologies). The increased information generated by the advances in experimental and clinical technologies

has demanded increased model sophistication as limitations of existing models have been revealed. However, without the power to solve such advanced models, the increased detail would have been little more than academic.

MODELING PHILOSOPHY

The goal or intended use of a mathematical model is an important influence not only on its level of detail but also its form. At the most basic level, a model for interpolating experimental data can be a phenomenologically fitted function whose form has no reference to the physical system. However, to predict function outside of a set of experimental conditions, it becomes important to include an anatomical and/or biophysical structure in the model. When such a model has been extensively verified, it then becomes possible to predict function powerfully, including, for instance, the effect of interventions such as medical treatments.

Central to the philosophy and process behind mathematical modeling in all fields is the distinction of key elements and parameters from those which can be simplified. To model everything that is known about a system is often both prohibitively complex and ultimately adds nothing to the understanding of the system. At the beginning of model development, insight is needed to decide what is important and what can be simplified. These decisions often depend not only on the system being studied but also the questions being asked of the model e.g., fast process variables that change on a slow time-scale can be assumed to be constant.

Biomedical modeling, particularly that involving whole-organ function, can be extremely complicated. It typically involves many subsystems that can span several orders of magnitude in the relevant spatial and temporal scales. Spatial scales can range from the 1-nm pore diameter of a membrane protein to the 1-m scale of the human body, a range of 9 orders of magnitude. Temporal scales range from 1 microsecond for Brownian motion to 70 years for a human life span, a range of 15 orders of magnitude. There are also typically multiple types of physical problem at the same spatial scale. In the heart, for example, myocardial contraction governed by the laws of mechanics is initiated by an electrical wave whose propagation is governed by conservation of electrical current, and supplied with energy via a blood stream also obeying the equations of mechanics but with entirely different constitutive laws. It is challenging in itself to understand these subsystems. To understand how these systems interact to produce the observed large-scale behavior is significantly more difficult. Due to the increasing sophistication in experimental techniques

we are continuously increasing our knowledge about the structure and function of the different subsystems. An obvious example of this is the genome project. From a sequenced gene the structure of the corresponding protein can be found, a prerequisite for understanding how it functions. This type of research has led to an explosion in the amount of information that is available on systems at the smallest scales.

Modeling provides a framework within which the building blocks coming from such research and experiments can be placed. This is a common approach in the traditional areas of engineering and physics where many researchers routinely design and analyze complex structures through computer models. The fact that this is a common approach in these areas is partly due to the solid base of information on material properties and interactions that is available for many traditional building materials. Biological materials and systems are far more complex than human-engineered systems and the complex interactions of these systems are correspondingly harder to predict. For this reason it is important to verify model results with all possible experimental data. Such verification determines the correctness of the model and its scope of use. Furthermore, a biophysically based model that does not fit experimental data points to a flaw in the underlying assumptions, which is often an interesting and relevant result in itself.

The complexity in biology often means systems are grouped in submodels that contain extra detail at a finer spatial or temporal scale than that of the main model, but interface to the main model using a few variables. An example of this technique is the spatial embedding of cell models in a tissue model. At the cellular level, a large number of chemical concentrations are tracked through time but output only one parameter, such as transmembrane potential or muscle tension, to the tissue model.

THE USE AND NEED OF MODELS

In all forms of modeling it is important to challenge the use or scope of a model and the need it satisfies or its ability to elucidate a given hypothesis. With the additional complexity that accompanies many biomedical models and the associated need for extensive development and computational resource, these questions have even more relevance and thus require consideration.

One argument that is raised against the mathematical models in the biological field is that they cannot be predictive, meaning that they are only capable of reproducing the experimental results that were used to create them. The sliding filament theory of Huxley mentioned previously shows just how wrong that

generalization can be. There are many other such counter-examples that show how computer-based models can allow insights into underlying mechanisms in a complex, integrated setting. For instance, in a recent paper,^[11] mutations of the cardiac sodium channel were investigated. A Markovian model of the channel with both normal (wild-type) and mutated channels was placed within a cardiac cellular model. This allowed the mechanism of early after depolarizations (a clinically important, but not well understood phenomenon) to be elucidated through the inactivation and subsequent reactivation of the L-type calcium channel. This would not have been possible using experiments on isolated sodium channels and illustrates the importance of modeling to gain an understanding of the overall picture.

The above example on the cardiac channels also reinforces the fact that behavior of the whole cannot be understood by simply understanding the behavior of each component. The process is highly nonlinear with very complicated interactions between each of the components that cannot be understood without modeling. Only by performing computer simulations is it possible to aggregate the pieces into a whole and see what consequences an altered component has on the overall system. An example of this is to investigate the effect of a drug designed to block the passage of chemically charged ions through a channel in the cellular membrane. The immediate effect is a reduction of the ion flow through that particular channel, but the resulting voltage action potential is not found by simply removing this current. The reason for this is that other currents are affected by the altered current and thus the overall result can be counter-intuitive.

These examples, and many others like it, provide strong evidence that models are already being used in a predictive manner and not just to reproduce experimental data. Bassingthwaight comments on the fact that even though our knowledge of these complex biological systems is very limited, computer-based models seem to be the only conceivable alternative to follow up on animal experimentation.^[12]

However, the issue still remains that the range of spatial and temporal scales is too large to provide an exact model of the physical situation. It is not practical to adopt a traditional top-down or bottom-up approach to these problems. Instead, the modeling may be undertaken using a middle-out approach, where the desired spatial and temporal scales are specified and information is gleaned from the scales that lie immediately below those of interest. While this approach may lead to some simplifications, groups of researchers at all levels may then benefit from the advances made at the next level down. Another approach could be to optimize the model for a particular medical problem based on knowledge of the important biological

determinants. The fact that under certain circumstances all models can be proved wrong can put modeling of this nature into a negative light. However, that does not mean one should not model, but that one should recognize that all models are to some degree approximations of reality, and one should be aware of the assumptions and approximations underlying any interpretation of the outcome of a model.

THE HEART AS AN EXAMPLE

To demonstrate many of the modeling techniques and philosophies outlined above, it is instructive to review an example. The methods demonstrated in the following example have also been successfully applied to model the gastrointestinal, pulmonary, and musculoskeletal systems. However, because of its relevance to mortality and mobility, modeling of the heart is arguably the most advanced example of integrative biomedical modeling that currently exists.

The heart is a variable-speed biochemical pump. Electrical impulses originating in specialized cells and caused by the flow of ions across the membrane of the cell give rise to a self-perpetuating wave of activation that spreads through the entire myocardium. This activating wave initiates and, via the nature of its spreading, coordinates the contraction of the cardiac cells, pumping blood to the body and to the heart itself. This simple description belies the complexity and many subprocesses that exist at a large number of scales within the beating of a heart. The modeling approaches associated with each spatial scale are described below along with an outline of how each scale is integrated into a whole-heart modeling framework that can be used to determine function in health and disease.

Molecular-Level Modeling

At the molecular level, protein chains interact to enable a cell to contract or regulate its internal or external ion concentrations. Actin and myosin are long protein chains that progressively bind and unbind in a ratcheting motion to contract a cell along their length. Their function, as discussed previously, was first elucidated by Andrew Huxley using a mathematical model of two coupled partial differential equations that account for the spatial strain and the rates of attachment and detachment.^[8] This approach has since been extended in a number of models to include a larger number of binding states between the two proteins and a related increase in the number of coupled equations.

The interaction of proteins also controls the flux of ions into or out of a cell by lining pores in the cellular

membrane. There are a large number of models that use a single or system of ordinary differential equations to quantify how the overall conductance of channel changes over time or is affected by the concentration of ions that may bind to sites on the channel. The structure and function of the pore proteins is determined by their encoded gene sequence. A mutated gene can affect ion motility across the cell membrane, affecting the activation and recovery of the cell, which, in the worst-case scenario, can lead to cardiac arrhythmia and death. Detailed imaging data is now becoming available that shows individual channel structure. In the near future we expect the emerging link between DNA sequencing data and channel protein structure to rapidly produce continuum-based mathematical models that link genomics to channel structure and channel function.

Cell-Level Modeling

Cellular models that describe the chemical reactions within the cell are used to determine functions such as excitability, tension generation, and metabolic energy production. Figure 1 shows a schematic diagram of the biochemical reactions encapsulated in a recently developed cell model.^[13] Each of these reactions is expressed as a series of coupled rate equations whose parameters include such properties as temperature, ion concentrations, and dimensions of the cell.

Well-known examples of such models include N98^[14] and LRH^[15,16] for the electrical activity, HMT^[17] for mechanics, and the Salem model^[18] for cardiac metabolism. Each of these models contains

three different components: 1) model parameters such as physical constants and fixed reaction rates or channel conductances, 2) state variables that define the state of the cellular system at any given point in time, for instance, ion concentrations or channel-gating states, and 3) derived variables such as an ion current through the membrane. Typically, functions of the derived variables and model parameters are used to construct expressions that determine the rate of change of each state variable with time. The system of equations composing the cellular model is then integrated through time to determine transient cellular function. One difficulty of coupling distinct cellular functions together are the very different time scales of each system. For example, at the cellular level excitation occurs on the scale of milliseconds, whereas metabolic processes can take many minutes to develop fully. This problem is often overcome using mathematical techniques that solve a model of a fast system using a fine time-scale and a model of a slow system using a much courser time-scale while still storing the values of state variable at all times. Recent coupled cellular models encompassing excitation, contraction, and metabolism contain up to 50 state variables, 100 parameters, and 80 derived variables.^[13]

Tissue-Level Modeling

Cardiac structure plays a pivotal role in the contraction of the heart—cells individually contract along their length, but this cell shortening in itself is not sufficient to generate the volume changes seen in a whole heart beat. Significant sliding of groups of cells

Fig. 1 Schematic illustration of some of the major processes involved with the electrical, contractile, and metabolic activity of the cell. (Based on the model from Ref. [13].)

over other groups also occurs, the directions of which are determined by the arrangement of the cells within the heart, and the distribution of collagen. Conduction speeds through tissue are also critically dependent on tissue structure, being typically tenfold faster in the fiber direction.

To model both health and disease, these effects of tissue structure are clearly beyond the scope of single-cell models. Thus, to determine tissue and ultimately whole-organ function, a modeling framework to which structural information can be added to cellular function is required.

The cell models outlined above are used to provide sources of current, mechanical tension, and oxygen tension to tissue-level models. Using a finite element mesh to spatially represent the tissue sample, a cell model can be embedded at a number of points whose locations within the mesh can be defined at whatever spatial resolution is required. Each point is treated as a black box, whose source/sink characteristics are determined by the complex ion kinetics of the underlying cellular model. The spread of current is then modeled by numerically solving the well-known bidomain equations underlying myocardial activation and extracellular current flow, which are formulated with a diffusion tensor based on the structural model. These equations are typically solved on a spatial scale much finer than that used to represent tissue geometry, meaning many cell model embedding points are defined within each finite element. Within the tissue model, conductivity and

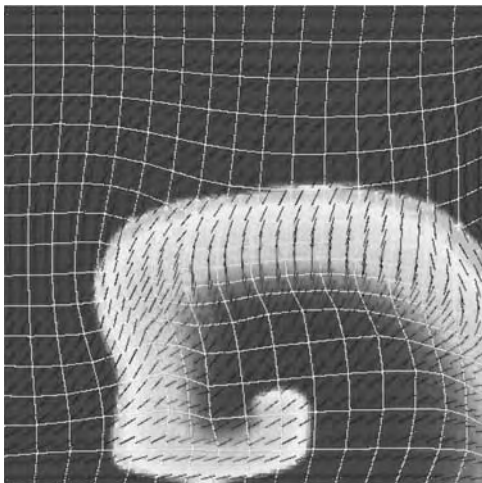

Fig. 2 A simulation on a two-dimensional block of cardiac tissue demonstrating the propagation of a spiral wave and the contraction of the tissue. The white lines represent the elements of the finite element mesh. In the resting state each element is square—distortions from this are the consequence of the contraction that is caused by the electrical wave moving through the tissue. The direction of the cardiac fibers is shown with the black lines.

capacitance determine the electrical coupling between approximation points and ultimately the spread of activation throughout the tissue. The anisotropic nature of cardiac tissue means this conductive coupling is represented by a tensor with values that are determined from the tissue microstructure.

In addition to the active tension generated by the embedded cellular models, the mechanical behavior of tissue models is dependent on the passive stress strain relationships. This passive relationship is quantified using a nonlinear constitutive law that determines the tissue stiffness locally about the axes defined by the tissue organization. The parameters of this constitutive law are estimated from biaxial tension, compression, and shear tests on small samples of ventricular tissue. Using these material properties, tissue deformation is determined using the finite element method to solve the governing equations of finite deformation elasticity. An illustration of the results of such a model is given in Fig. 2.

Organ-Level Modeling

The step up in scale from tissue to whole-organ modeling is initially one of adding geometry and characterizing the regional variation in structure. Careful dissections of hearts^[19] together with detailed imaging^[20] have gathered significant information on the unique organization of cardiac myocytes within the heart. These detailed measurements have been encapsulated within whole-organ continuum models using nonlinear optimization fitting techniques and piecewise parametric modeling. Figure 3 shows a finite

Fig. 3 A finite element mesh of the ventricles of a heart that has been constructed using detailed information from a pig heart (left). The regional variation in principle stresses and their direction at end-diastole at midwall points of the finite element mesh (right). Outward pointing cones represent tension while compression is represented by inwardly pointing cones. element mesh of the ventricles of a heart that has been constructed by using detailed information from a pig heart.

Applying the tissue modeling techniques described previously to this anatomical model, the dynamics of heart excitation and contraction can be determined at the whole-organ level. Figure 3 (right) shows the directions and magnitudes of the principal stresses in the heart at the end of contraction, illustrating the ability of a model to calculate and display data that is extremely difficult to measure experimentally.

To understand heart function in health and disease more fully, a model of coronary blood flow needs to be added that can predict the regional distribution of blood flow through the heart wall. Figure 4 shows an anatomically based finite element model of the coronary blood vessels embedded in the ventricular geometry. The anatomy of the epicardial coronary vasculature is obtained from direct measurements. To represent smaller vessels that branch into the heart wall a nonlinear network-growth algorithm is used to add spatial information to detailed topological measurements made from silicon casts of the coronary vessel tree.^[22] A prediction of the regional and temporal variation in coronary blood flow is achieved by applying computational fluid dynamic methods to the domain of the anatomically generated model of the large coronary vessels.

Body-Level Modeling

Physically the cardiac electrical activity is connected to current flow in the torso via the extracellular potential

Fig. 5 The body surface potentials calculated at 45 ms after the onset of activation using an anatomically based torso model. Voltage is scaled between -1 and 1 mV and each band represents a 0.25 mV increment. (Original figure generated using the techniques described in Ref. [23].)

field. Cutaneous electrodes are routinely used in electrocardiology clinics all around the world to record such activity. Mathematical models of human torsos have been developed that can incorporate the information from the cell- and organ-level models described previously, and thus simulate electrocardiographic (ECG) signals. While the individual details of a single cell's electrical activity cannot be uniquely distinguished at the body surface, to simulate an ECG accurately still requires much of the detail of the cellular-level models described previously. An example of the torso potentials generated from one such model is illustrated in Fig. 5.

WHERE MODELING IS HEADING—THE PHYSIOME PROJECT

We are on the verge of a model-based revolution in the biomedical field. Much publicity has been afforded to the completion of the first draft of the human genome sequence.^[24] However, rather than signal the end of an event, this achievement, remarkable as it is, really signifies the beginning of something much bigger. The authors themselves allude to this when they state “In principle, the string of genetic bits holds long-sought secrets of human development, physiology, and medicine. In practice, our ability to transform such information into understanding remains woefully inadequate.” The challenge, therefore, is clear—to integrate this incredible wealth of information to allow

the determination of structure and function at all levels of biological organization.

This challenge has been recognized by the International Union of Physiological Sciences (IUPS), and confronted face-on by the establishment of what has been termed the “Physiome project.” This concept was presented in a report from the Commission on Bioengineering in Physiology to the IUPS at the 32nd World Congress in Glasgow in 1993. The name comes from “physio-” (life) and “-ome” (as a whole), and is intended to provide a quantitative description of physiological dynamics and functional behaviour of the intact organism. A satellite workshop “On designing the Physiome Project,” organized and chaired by the Chair of the IUPS Commission on Bioengineering in Physiology (Prof. James Bassingthwaite), was held in Petrodvoretz, Russia, following the 33rd World Congress in St. Petersburg in 1997. A satellite meeting on the Physiome project was held at the 34th World Congress of IUPS in Christchurch, New Zealand, in August 2001, and the Physiome Project was designated by the IUPS executive committee as a major focus for IUPS during the next decade.

The long-range goal of the Physiome project is to understand and describe the human organism, its physiology and pathophysiology, and to use this understanding to improve human health. A major aim is to develop mathematical and computer models to integrate the observations from many laboratories into quantitative, self-consistent and comprehensive descriptions. Integrated, biophysically based modeling is thus set for a revolution. Glimpses of this can already be seen. The pharmaceutical industry is beginning to appreciate the importance of mathematical modeling in reducing the massive cost of bringing a new drug to market: “Computer modelling will even provide the tools with which to perform in silico clinical trials, based on whole organ body models that test for everything.”^[25] Several companies have recently been formed to exploit biological modeling for drug discovery (Entelos, Pharsight, Physiome Sciences, Simulations Plus). The U.S. Food and Drug Administration (FDA) has indicated clearly that it would like submissions to include computer simulation and this in fact has been used by Roche to gain approval from the FDA for its cardiac calcium-channel blocker Posicor.^[26]

CONCLUSION

The use of modeling in the biomedical field lags behind that of many other fields. This is perhaps not surprising given the complexity of biological systems compared with many constructed by humanity.

However, the stage is set for a revolution in the biological sciences driven by the rapid development and application of biomedical modeling. This is being driven in part by the significant increases in computational power, enabling ever more complicated models to be constructed and solved.

Accelerated model development is also being driven by the massive amounts of data now being generated, courtesy of such technologies as gene sequencing and advances in medical imaging. One has very little choice but to use models to help cope with this explosion in complexity. This has been recognized by a number of companies and organizations, and has led to the development of the so-called Physiome project (<http://www.physiome.org/>). A major aim of this project is to develop mathematical and computer models to integrate the observations from many laboratories into quantitative, self-consistent, and comprehensive descriptions and to use this understanding to improve human health. Although very new, momentum is gathering, and one should not be surprised to find in the not too distant future the use of modeling in the biomedical field to be as pervasive as all other forms of experimentation.

INTRODUCTION

The fields of nanoscience and nanotechnology are creating new possibilities for investigating and dealing with difficult neurosurgical problems such as brain tumors, neurodegenerative disorders, and spinal cord injury. Glioblastoma multiforme (GBM), a common highly malignant primary tumor of the central nervous system (CNS), is characterized by a tumor mass surrounded by normal brain containing invading tumor cells. In this disease, many of the tumor cells invade the healthy regions of brain, but systemically delivered therapeutic agents are largely ineffective against them because of the screening effects of the blood-brain barrier (BBB). However, standard tools of nanotechnology, such as atomic force microscopy, are now being used to study the structures of individual GBM cells in ways that are beginning to shed light on how the invasion process works.

Moreover, the technique of positive pressure infusion is presently being deployed as a means of driving the flow of therapeutic agents directly through the nanoscale interstitial space between the cells within the CNS, thus providing a means of circumventing the screening effects of the BBB. The knowledge gained from laboratory studies of GBM cells and clinical studies of infusion therapies will carry over to other neurosurgical applications, too. For example, nanostructured materials that might be used as postresection surgical implants to deliver targeted therapies might be modified to serve as in situ scaffolds for guiding axonal growth cones in restorative neurosurgical procedures aimed at bridging regions of glial scar tissue in the treatment of spinal cord injury. In what follows, the scientific basis, clinical status, and potential applications for nanoscale neurosurgical modalities are described and discussed.

THE STRUCTURE OF THE BRAIN AT THE SUBMICRON SCALE

With roughly 1 trillion cells, 100 trillion synapses, and 1 million kilometers of neural pathways,^[1] the human

brain is often considered the most structurally complex object in the known universe. The brain's cellular and subcellular organizations have been studied for over a century and, far from being completely characterized, continue to amply furnish fresh subjects of inquiry and debate. Almost all knowledge of brain microstructure has been drawn from two-dimensional planar measurements; yet novel techniques, such as diffusion tensor imaging of the brain and computerized neuronal forest reconstruction, promise to greatly advance the micro- and nanostructural understanding of it. The brain is composed of many different cell types, among which are the most morphologically variable in the body.

Neurons are the CNS cells specialized for sending and receiving signals, and therefore they have highly extended cytoarchitectures to allow multiple intercellular contacts locally and at great distances. The nucleus is located in the cell body, also called the soma or perikaryon. Axons conduct signals away from neurons; most neurons have only a single axon, which can vary greatly in length in different neuron types. Dendrites are branching processes that receive impulses. Most CNS neurons are multipolar, meaning that they have at least several dendrites. Axons and dendrites are collectively termed neurites. Neurons are structurally diverse. Neuronal cell bodies measure anywhere from 5 to 135 μm across. Pyramidal cells in the parietal cortex in humans generally range from 8 to 36 μm (Ref. [2], as cited in Ref. [3]), but the giant pyramidal cells of Betz can reach 92 μm in length and 71 μm in width. The volume of human pyramidal cells ranges from 297 μm^3 to 3200 μm^3 depending on the area and layer of cortex (Ref. [4], as cited in Ref. [3]). The average volume of cortical neurons in man is 1600 μm^3 (the range is from 300 to 20,000). Neuron cell body densities have been thoroughly characterized in the different layers and areas of the adult human cortex. These densities range from 30 to 106 neuron cell bodies per 0.001 mm^3 (Ref. [4], as cited in Ref. [3]). In another study, cortex cell body densities were measured to be between 15 and 165 per 0.001 mm^3 .^[5] The human mean has been stated to be 48 neuronal cell bodies per 0.001 mm^3 . The neuronal

cell body cytoplasm is rich in structural elements such as microtubules, which are 25 nm in diameter; and neurofilaments, which are similar to intermediate filaments of other cell types and are 7.5 to 10 nm in thickness. In the neuronal perikaryon, microfilaments and neurotubules seem to occupy most of the space not preempted by the larger and more prominent organelles. In the neuronal cell body, these elements are of relatively short length and run parallel to one another in loose bundles. Microfilaments, which are 4 nm in diameter and composed of the contractile protein actin, are particularly abundant in the subplasmalemmal region of the cell.^[6]

Axons are specialized for conduction and transmission of neuronal output. The majority of CNS neurons have a single axon that can deliver signals to numerous other neurons. Axons are cylindrical, with a uniform diameter and a round or oval cross section. Within most cell types, axon diameter is proportional to axon length. Human axon diameters range from 100 nm to

20 μm .^[7] Collateral branches may be given off at right angles, and tend to be distal to the cell body. Axon branches form at approximately right angles and tend to have diameters similar to the parent stem. Terminal branches called telodendria end in synaptic terminals also known as boutons terminaux. Axons of the CNS may be quite long. For example, axons of certain pyramidal neurons course several centimeters in the subcortical white matter to furnish cortical-thalamic and cortical-cortical connections, often giving off recurrent collaterals or radial collateral branches that travel up to 8 mm. Because the lengths of these axons are many orders of magnitude greater than the micro- and nano-mechanical scales of length, it is more meaningful to consider the idea of axon length-density. Axon length-density indicates the total length of axons that are packed into a small volume of brain tissue. Using three different approaches, it has been estimated^[8] that the axonal length-density in the mammalian cortex is between 1.5 and 4.1 m per 0.001 mm^3 . Table 1 contains a

Table 1 Volume percentage, length-density, and Young's modulus measurements^a

Cortical tissue component	Percentage of total cortex volume (%)	Length-density (0.001 mm^{-3})	Effective Young's modulus (N m^{-2})
<i>Gray matter</i>			
Neuronal cell bodies	7.8	—	—
Axons	25.2	≈ 2.0 m	$0.7\text{--}4.0 \times 10^3$
Dendrites	25.9	~ 1.0 m	$0.7\text{--}4.0 \times 10^3$
Dendritic spines	10.4	—	—
Protoplasmic astrocytes	5.1	≈ 26 mm	$1.0\text{--}20 \times 10^3$
Oligodendrocytes	3.0	—	—
Extracellular space	17.0	—	—
Small arterioles	0.6	0.004 mm	1.0×10^5
Capillaries	3.2	1.00 mm	1.1×10^5
Small venules	1.8	0.012 mm	1.1×10^5
<i>White matter</i>			
Neuronal cell bodies	≈ 0	—	—
Axons (total)	31.9	338 mm	(see below)
Myelinated nerve fibers (5 μm)	76.8	39.2 mm	5.5×10^4
Small axons (0.3 μm)	2.1	299 mm	$0.7\text{--}4.0 \times 10^3$
Oligodendrocytes	46.4	39.2 mm	(see above)
Dendrites	≈ 0	≈ 0 mm	—
Fibrous astrocytes	1.8	43.8 mm	$1.0\text{--}20 \times 10^3$
Extracellular space	18.0	—	—
Small arterioles	0.2	0.002 mm	1.0×10^5
Capillaries	1.1	0.300 mm	1.1×10^5
Small venules	0.6	0.004 mm	1.1×10^5

^aDetails of the citations the many sources for the values reported in this table are contained in the document "Brain Tissue Structure and Micromechanics," available at the website <http://www.vcu.edu/mdphd/CurrentStudents/StudentPages/Haar/haar.html>.

list of a number of length-density characteristics for various cellular components of the CNS that have been compiled from the literature.

The cytoplasm of an axon, called the axoplasm, contains many structural support elements, including neurofilaments, microtubules, and actin microfilaments, among other sparsely scattered organelles, such as mitochondria and fragments of smooth endoplasmic reticulum. Microtubules are involved in rapid internal transport of protein and small molecules. Neurofilaments usually have side arms that limit their packing density. It has been shown that axon caliber is a function of neurofilament and microtubule numbers with neurofilaments predominating in large axons. Actin microfilaments are particularly abundant in presynaptic terminals and in the tips of growing axons, termed growth cones. It is believed that microfilaments play a key role in responding to external changes and in positioning the various receptors and ion channels at specific locations on the neuronal surface, by virtue of direct and/or indirect interactions with the intracellular portions of transmembrane components associated with the receptors and ion channels. Axons in the human CNS greater than $2\ \mu\text{m}$ are usually myelinated. Most cortical pyramidal cell axons are encased in a myelin sheath, which begins near the origin of the axon and ends short of its terminal branching. The myelin is laid down by oligodendocytes. The length of each myelin sheath, known as the internodal distance, is proportional to fiber diameter for each cell type and typically ranges from 150 to $1500\ \mu\text{m}$. The thickness of the myelin sheath and the internodal distance are directly proportional to the axon's diameter and length. The bare portions of axon between the internodes are termed nodes of Ranvier. The axon and its myelin sheath are collectively termed a nerve fiber. Dendrite architecture is organized to integrate synaptic responses from many other neurons. A typical CNS neuron receives about 1000 to 10,000 synaptic inputs, but some may receive an estimated 1 million inputs. Dendrites are continuous with the perikaryal cytoplasm and a transition point cannot be distinguished. Dendrites taper from the cell body and may branch immediately. Dendrites narrow along their length and therefore have irregular cross sections. Like axons, dendrites also have abundant structural support. The dendritic cytoskeleton appears less organized than that of axons. Microtubules dominate in large dendrites, and actin microfilaments are particularly abundant in dendritic gemmules. Microtubules are not well aligned with each other, and are less regular in their spacing than they are in axons.

Neuroglia—literally nerve glue cells—include all of the cells of the brain that are not neurons or cells of the vascular stroma. Neuroglia are not primarily involved with excitation, inhibition, and propagation of the nerve impulse. Neuroglia and neurons are in close contact

with each other and are highly interdependent metabolically. Although neuroglia function to support and maintain neuronal physiology, their overall functions are not completely understood in most cases. In the entire brain, the number of neuroglial cells has been estimated to be roughly 10 times greater than the total number of neurons; however, in the cortex, neuroglia outnumber neurons by only five times. On average, a $0.001\ \text{mm}^3$ volume of human brain contains 80 to 100 neuroglial cells (Ref. [9], as cited in Ref. [3]). In humans, the ratio between oligodendrocytes, astrocytes, and microgliaocytes in motor cortex was found to be 54:38:8.^[10] Astrocytes are the largest of the neuroglial cells and in the adult brain they perform many functions, both demonstrated and hypothesized. These functions include structural support, reaction to injury, neuronal insulation, and extracellular environment regulation. Astrocyte cell bodies have an average diameter of $40\text{--}50\ \mu\text{m}$, and astrocytes are believed to account for roughly 20–50% of the volume of most brain areas. Within the CNS, astrocytes are divided into two general categories. Protoplasmic astrocytes, also called velate astrocytes, are found in gray matter. They have numerous, thick, short, flattened, and highly branched processes which form delicate lamellae around terminal branches of axons, dendrites, and synapses. Fibrous astrocytes occur in the white matter. They have long processes with coarse bundles of gliofilaments. Each fibrous astrocyte has approximately 10–30 processes that are long, thin, smooth, and poorly branched. When grown in vitro with neurons, fibrous astrocytes exhibit fine complex processes hundreds of microns long. Both protoplasmic and fibrous astrocytes exhibit a high degree of morphological plasticity and can undergo marked structural changes.

Astrocytes project processes to neuron somas, ensheath synapses and dendrites, and form cuffs around nodes of Ranvier. Astrocytes are connected to each other by gap junctions, forming a syncytium that allows transfer of ions and small molecules. Astrocytes are also joined by desmosomes that create mechanical coupling. Astrocytes do not form the blood-brain barrier, but induce and maintain the tight junctions in endothelial cells that form the barrier. Astrocytic cytoplasm contains abundant gliofilaments, which are slightly finer than neurofilaments and are gathered into bundles. These intermediate filaments lack side arms, which allows for tighter packing. Gliofilaments are made of glial fibrillary acidic protein. Several observations seem to indicate that gliofilament bundles play a role in brain structural support, much like the connective tissue in other organs. Astrocytes often contain a large number of filaments arranged in parallel bundles, which are attached to the relatively rigid vascular tree and are held together by intercellular junctions. Protoplasmic astrocytes are more readily damaged than fibrous ones

because they contain a smaller number of fibrils. Following intense and prolonged mechanical stresses, astrocytes undergo an increase in size and show a marked increase in the amount of their fibrils. However, evidence indicates that the blood vessels, not the neuroglia, are the primary support structure of the brain.

Astrocytes have very close functional and structural relationships with neurons and the extracellular space (ECS). It has been demonstrated that neurotransmitters such as norepinephrine and glutamate can alternately stimulate and reverse glial stellation, respectively. Changes in astrocytic morphology would in turn affect the volume of the ECS and consequently neuronal activity. If accurate, this model suggests that the morphology of astrocytes and the volume of the ECS may be constantly changing under the influence of the activity of different sets of neurons. A quantitative analysis of the elasticity of astrocytes was performed using atomic force microscopy.^[11,12] The Young's modulus of the surface layer of cultured astrocytes ranged from 1 to $20 \times 10^3 \text{ N m}^{-2}$. Over the nucleus, the cell was softest, having a Young's modulus of only $2\text{--}3 \times 10^3 \text{ N m}^{-2}$; where the cell membrane was dense with F-actin, the cell was stiffest, having a Young's modulus of $10\text{--}20 \times 10^3 \text{ N m}^{-2}$. It is important to note that these studies measured elastic moduli of the astrocyte cell body, not the astrocyte processes. Given the fibrous structure of astrocyte processes, they are hypothesized to behave viscoelastically like the neuron processes.

Oligodendrocytes form the myelin sheaths that surround axons. Microglia mediate immune responses in nervous tissue by acting as macrophages. Resting microglial cells compose about 5% of the total neuroglial population. Ependyma is the simple cuboidal or columnar epithelium that lines the ventricular system. Ependymocytes comprise the majority of ependymal cells. Tanycytes are primarily found in the floor of the third ventricle. These cells have long basal processes that end on the pia mater and on the blood vessels in the median eminence of the hypothalamus. Tanycytes may respond to hormone levels in the CSF and help control the endocrine system. Choroidal epithelial cells cover the surfaces of the choroid plexus and have microvilli at their apical surfaces. They are characterized as having tight junctions. The vasculature allows a continuous blood perfusion to brain tissue, but a difference between brain endothelial cells and those of the systemic circulation is the presence of interendothelial tight junctions, also known as the zonula occludens. These tight junctions are responsible for the BBB that limits communication between the intravascular space and the brain ECS.

The complex geometries of blood vessels, neurons, and neuroglial cells are in close apposition to each other, and the ECS between them is thin, highly convoluted, and characterized geometrically by a parameter

referred to as the tortuosity. Spaces of only 10 to 20 nm are observed by electron microscopy between the cells and their processes.^[13] The ECS widens only at specific sites—for example, the nodes of Ranvier. As a result, estimations for the volume of this system of spaces have varied greatly. Early researchers reported that the ECS occupied 35% of the total volume in gray matter. Other researchers arrived at ECS percentages in gray matter of only 5–7%, and only 15% in white matter (Ref. [14], as cited in Ref. [3]). More recent determinations of the volume percentage of the ECS, using several different experimental methods, indicate that it occupies 17–20% of the brain.^[15,16] It is believed that standard fixation procedures greatly reduce measurements of this space. The ECS has a matrix of proteoglycans and glycosaminoglycans. The matrix composition varies with the cytoarchitectonics, but little is known about its density. Astrocytes are a major source of ECM proteins and adhesion molecules in the CNS; these proteins include nerve cell-nerve cell adhesion molecules, laminin, fibronectin, cytactin, and the J-1 family members janusin and tenascin.

DELIVERY OF THERAPEUTIC AGENTS THROUGH THE NANOSCALE STRUCTURE OF THE ECS

The complex process of glioma cell invasion takes place within the submicron scale milieu of cells, cellular processes, and vasculature described earlier. The fluid-filled ECS provides a natural conduit for the delivery of therapeutic agents to glioma cells via positive pressure infusion, also referred to as high flow-rate microinfusion and intraparenchymal or intracerebral clysis. In this technique, one or more catheters are surgically placed in the brain using appropriate methods of image-guidance, and the selected agent is then pumped through them; it subsequently infuses into the ECS. Pioneering studies of this technique and related transport mechanisms have been conducted by a number of workers—for example, Rech and Domino,^[17] Nicholson and Phillips,^[18] and Bobo et al.,^[19] who over the past several years have investigated the mechanisms by which macromolecules and other species are transported within the ECS. Various analyses of such data and parallel efforts to provide useful mathematical models of the fluid transport process have led to the elucidation of parameters such as the tortuosity factor, the volume fraction, and the porosity parameter that help to provide insight into the complex path for interstitial fluid movement. Experimental validation of the theoretical transport models has provided the foundation for the design and implementation of treatment planning systems for infusion therapy protocols.

To develop an understanding of the clinical basis for image-guided intraparenchymal drug delivery, one must first identify the biophysical mechanisms underlying the transport process. For simplicity of the current discussion, we consider the brain tissues to be isothermal and we ignore the slow physiological perfusion of the interstitial fluid that occurs continuously within the brain. Under these assumptions, there are then two principal mechanisms by which transport of externally introduced fluids can take place within the parenchymal tissues of the CNS; the first is flow along a concentration gradient (diffusive flow) and the second is flow along a pressure gradient (infusive or bulk flow). Drug delivery via the second mechanism is synonymously referred to as convection-enhanced delivery. The starting point for the modeling of the diffusion process is most typically Fick's laws of diffusion, modified to take into account the effects of the tortuosity and volume fraction of the tissues. Expressions can be developed that relate the flux to the concentration gradient. This then permits one to estimate the diffusion time constants and location-dependent concentration profiles, all as a function of the molecular weight of the diffusate.^[20] In contrast, the infusion process is most often analyzed in terms of Darcy's law for the flow through a poroelastic medium,^[21] which takes into account the swelling of the tissues due to the presence and spread of the initial bolus of infusate through the ECS, and the subsequent change in the permeability or hydraulic conductivity of the tissues due to the swelling. Such modeling of fluid behavior enables predictions of the volumes of distribution of the infusate as a function of the fluid's time-dependent pressure and velocity profiles. The pressure profiles can be measured by inline monitoring during the treatment protocol, and the time-dependent volume of distribution (and thus the direction-dependent velocity of the fluid through the ECS) can be mapped by magnetic resonance (MR) imaging techniques.

Because the flow of therapeutic or diagnostic agents through the ECS consists of both diffusive and infusive components, the determination of the transport ratio for these flow components requires an understanding of the dynamics of both processes. An important point to note is that during an infusion therapy session that lasts for a few hours, the transport distance traversed by a macromolecule through the nanoscale ECS due to diffusion will be significantly less than that due to the advective flow. Therefore, the volume of distribution that would be due only to diffusion is negligible over that period and we can assume that the advective component of the flow is what will be driving the spread of the infusate.^[22] This works to simplify the development of any associated treatment-planning algorithm that the clinician might wish to use, as there is only one physical process to model for the early stage part of the

protocol. The final concentration of the agent in the tissues will result from a balance between the source and sink terms in the model, which represent the influx of the agent into the region of tissue being treated, the vascular clearance, the rate and directionality of interstitial fluid flow, and the metabolic uptake or degradation of the agent. Techniques for MR-based confirmation of the volumes of distribution and of the concentrations are being developed by several workers—for example, Kucharczyk and Moseley.^[23] Such techniques will be critical to the ultimate clinical success of the method.

A useful consequence of the infusion of therapeutic agents directly into the nanoscale ECS arises because this delivery occurs to the brain side of the BBB; agents selected for their ability to penetrate the BBB would also tend to diffuse into the brain microvasculature after infusion and would thus be more readily cleared. Therefore, drug candidates that have been selected for delivery to the CNS by way of parenteral routes may actually be those that will be more rapidly cleared after direct intraparenchymal infusion. As a result, listing of possible therapeutic compounds in order of their lipid solubility would have to be inverted in this case to determine which candidates would be more likely to persist within the CNS parenchyma postinfusion. Broaddus et al.^[24,25] have discussed the status of clinical applications for positive pressure infusion.

Last, we note that a useful tool for optimizing the performance characteristics of neurocatheters designed for infusion therapies is positive pressure infusion into agarose gel surrogates of CNS tissues. In particular, 0.6% agarose gel has a nanoscale porosity that mimics that of the *in vivo* human ECS. This makes it a very attractive test bed for evaluating the volumes of distribution and the pressure profiles produced by catheters that are candidates for clinical applications. Figure 1 shows an infusion of a low-molecular-weight dye (bromphenol blue, MW = 693) into a Petri dish of 0.6% agarose gel. The gel was poured into a dish that contained glass fibers 8 μm in diameter in order to introduce a controlled anisotropy into this otherwise homogeneous and isotropic medium. The principal advantages offered by such an experimental arrangement are the simplicity, low cost, and robustness of the model, which make it possible to do critical preclinical testing on many types of neurocatheter designs before any level of *in vivo* testing becomes necessary. Gillies and colleagues^[26,27] have reported the results of various experimental studies of nanoscale flows in brain tissue surrogates of these kinds. In addition to the valuable model for brain anisotropy just described, the availability of inert size-delimited nanoparticles is expected to provide great utility in probing the behavior of the interstitial space of animal brain and *in vitro* model systems.^[25]

Fig. 1 A sequence of photographs showing the spread of a low-molecular-weight blue dye through the ≈ 200 nm interstitial pores of a 1-cm thick layer of 0.6% agarose gel into which 8- μ m diameter glass fibers have been added. The fibers introduce a simple type of controlled anisotropy that is meant to mimic the gross features of nerve fiber bundles and axons in the CNS.

NANOTECHNOLOGICAL TOOLS FOR INVESTIGATING TUMOR CELL INVASION AND AXONAL EXTENSION

Cell motility and movement is a well-developed area of study, and the invasion of tumor cells through the brain tissues is a subspecialty of that field that receives a considerable amount of attention. Standard methods of monitoring cell invasion mechanics involve the use of videomicroscopy, e.g., in experimental studies of tumor cell motility-based measures of malignancy. In

terms of monitoring invasion via cellular markers, a variety of different invasion assays are under development, several based on measurements of expression of matrix metalloproteinase (MMP). However, a new line of work now being undertaken in various laboratories centers on using atomic force microscopy (AFM) to join these other lines of effort. Scanning probe systems of this kind can be used to obtain images of glioma cell structure that are based on morphological maps of the cell surface obtained while the cells are plated on nanostructured substrates. A touch-point between this type of work and the invasion assays is that AFM can be used in principle to image directly whether or not different types and levels of MMPs do indeed influence the cell's motility; studies to explore this possibility are now being planned.

Recent AFM studies of glioma cells include those of Fillmore et al.,^[28,29] which focused on obtaining scanning probe images of the invadopodia extended by glioma cells into their surroundings. These slender cellular processes can have length-to-diameter ratios in excess of 100:1 and are involved in the sensing of and movement through the environment local to the cell; they play an important role in glioma invasion. For instance, AFM observations of T98 human glioma cells have revealed that some invadopodia produced by cells plated on collagen substrates can be approximately 100 microns long, with diameters of 600 to 700 nm. In one case,^[28] the invadopodia maintained a linearity in their path of extension of better than 1%, with interesting implications for the nanodynamics of the invadopodia growth process and cell-to-cell signaling mechanisms. In a related study^[29] observations were made on glioma cells that produced multiple invadopodia.

In terms of the axonal mechanics, many different methods are under study for the repair of paralysis-producing spinal cord injuries; Gillies et al.^[27] have published a succinct review of these methods. Central to these efforts is the need to regrow or otherwise bridge axonal bundles through or across the zone of damage that consists of traumatized and disrupted axonal processes, reactive glial and inflammatory cells, and developing glial scar tissue. Several strategies have been proposed for initiating such a process. These include the surgical placement of nerve grafts and/or scaffolding implants and a variety of other approaches in which axons from either existing or stem cell-grown neurons can then bridge the glial scar via chemotactic and cytomechanical action. Mechanical tension in particular has long been known to be an effective means of achieving axonal extension. Smith et al.^[30] have recently shown that axons under continuous mechanical tension can grow successfully when drawn at elongation rates of $\approx 12 \text{ nm s}^{-1}$ but will not work at a rate twice this fast. The question of how one would carry out such a procedure in situ in the patient is a key one, and several

strategies have been discussed. One interesting possibility proposed is the magnetic stretching of the axons, and various groups are exploring this approach. In principle, particles of magnetic material would be either attached to or taken up by neurons in vitro, and their axons would then be stretched by application of an external magnetic field. To gauge the magnitude of the magnetic force that would be needed, another standard tool of nanotechnology—the optical tweezer—is being proposed for use. In such an approach the cell body would be fixed to a substrate and a dielectric particle would be attached to the growth cone. The radiation pressure field of an appropriately shaped beam of laser light can then be used to capture the dielectric particle and place the axon under tension. Pre- and post-experiment calibrations allow one to determine the size of the force to be applied.

CONCLUSION

The development of scientific tools for use in measuring subnanonewton forces and for observing and controlling motions in the nanometer range of distances is making it possible to envision new clinical techniques for attacking difficult neurosurgical problems such as glioblastoma multiforme and spinal cord injury. These approaches constitute a movement toward nanoscale neurosurgery, in which new modalities for treating CNS disorders are expected to arise from an improved understanding of the nanomechanics of glioma cell invasion, extracellular matrix, CNS interstitial space, and neurite process extension. In this article we have presented a survey of the relevant neuroanatomy at the submicron scale of distances, described how positive pressure infusion makes use of the nanoscale interstices of the CNS to deliver therapeutic agents to the CNS parenchyma and invading tumor cells, and discussed how tools of modern nanotechnology are being put into use to develop improved understanding of the dispersal of primitive neural cell types and the processes extended by them. For further background information on these topics, please see the references to the cited literature.

INTRODUCTION

The human nervous system has the potential to regenerate, although a number of biological restrictions are evident. Healing of lesions must occur via true regeneration, because simple scar formation (i.e., filling of tissue gaps by nonneuronal tissue) will reestablish electrical connectivity neither within the neuronal network nor with target cells, including muscle fibers. Neuronal regeneration is confined to regrowth of severed nerve fibers and proliferation of such accessory cells as myelinating glial cells. With the exception of quantitatively negligible stem cell proliferation, no new neurons can be generated in the adult nervous system. In the broadest sense, the aims of neural tissue engineering are: 1) to restore aspects of the three-dimensional architecture using biological or synthetic scaffolds (e.g., nerve guides in lesion sites); 2) to supplement biological functions, as by the implantation of neurotransmitter-producing cells (e.g., dopamine-producing cells in Parkinson's disease); or 3) to counteract defective metabolism, inflammation, or cell death using genetic engineering with viral vectors (e.g., apoptosis in amyotrophic lateral sclerosis).

This review provides a survey of nerve guides used as implants to bridge gaps of lesioned nerves. Through observations of biological phenomena during de- and regeneration, the applications for and potential uses and limitations of nerve-guide concepts have been elucidated. Different nerve guides have been developed—involving biological, synthetic, inert, resorbable, purely material-based, and biohybrid approaches—and have proven to be promising methods to enhance regeneration after implantation. Nevertheless, further tissue-engineering improvements are needed to fully exploit the complete regenerative capacity of the nervous system. In the future, neural tissue engineering will greatly profit from more detailed understanding of cellular mechanisms, allowing for more rational designs of implants.

PERIPHERAL NERVOUS SYSTEM (PNS)

If lesions have compromised the integrity of neural tissue, the damage may be repaired using nerve guide implants. Understanding the functional architecture of

nerves will clearly facilitate prosthesis development. In most peripheral nerves, several hundreds or thousands of individual nerve fibers (nonmyelinated axons and axons myelinated by Schwann cells) are grouped into units called fascicles (Fig. 1). An individual nerve contains a limited number of fascicles, with each fascicle surrounded by a perineurium composed of flattened cells and basement membranes, which together form a mechanically stabilizing envelope. All fascicles of a nerve are embedded in loose connective tissue termed epineurium. The intrafascicular connective tissue is called endoneurium. Nutrients are supplied by a microvascular system organized in a segmental fashion. Extrinsic vessels often approach the nerve trunk in a loosely coiled manner, then typically divide into branches running longitudinally in the epineurium (Fig. 2). Collaterals are formed in the perineurial sheet, continuing mainly as capillaries in the endoneurium. Endothelial cells of these endoneurial capillaries display specific barrier and carrier functions, collectively summarized as a blood-nerve barrier that is not evident in perineurial vessels. Vascular plexuses are found at all nerve layers. Because no lymph vessels are present in the endoneurial space,^[4] following nerve trauma, edema may form in the epineurium, but will not penetrate into the fascicle due to the protective ensheathment of the perineurium.

The key components of peripheral nerves are axons, which are long cell processes of neurons situated outside the nerve in functional relay stations, as in the spinal cord or in peripheral ganglia. The axons propagate neuronal information from relay stations to peripheral targets, including muscle fibers and endocrine glands, or convey information in the opposite direction (e.g., from the skin to more central relay stations). To ensure proper function of the electrically conductive axons of the PNS, axons must be ensheathed by Schwann cells, be embedded in a connective tissue scaffold, and receive nutrients via a vascular network as outlined in the foregoing. Schwann cells provide some of the most vital structural and biochemical support for PNS axons. The great importance of these support cells and nonneuronal tissue elements must be appreciated, especially in light of the fact that axons

Fig. 1 Microanatomy of the peripheral nerve trunk. a, Bundles of nerve fibers are surrounded by the perineurium (p), thereby creating fascicles that are embedded in loose connective tissue—the epineurium (epi). The intrafascicular connective tissue is called the endoneurium (end). The appearance of nonmyelinated and myelinated nerve fibers is illustrated in b and c, respectively. Schw—Schwann cell; my—myelin sheat; ax—axon; nR—node of Ranvier. (From Lundborg, G.: *Nerve Injury and Repair*; used with permission of Churchill and Livingstone, Edinburgh, 1988.)

represent cell extensions of enormous length. These lengths of one meter or more mean that the distance between the distal axon tip and its nurturing neuronal cell body can be 10,000 times the diameter of the neuron itself.

During movements, nerve trunks are protected by a conjunctive adventitia on their exterior surface, which enables gliding of the nerve trunk. The mobility of fascicles in deeper nerve layers is ensured because the fascicles can slide against each other. The plexus brachialis shows a total excursion of about 50 mm during abduction-adduction of the shoulder. During elbow flexion-extension, median and ulnar nerves glide some 8 mm proximal to the elbow and some 14 mm near the carpal tunnel. If these gliding mechanisms are hampered by extra- or intraneuronal fibrosis after nerve lesions, chronic nerve irritation or loss of function may occur. Partial or complete compression and transient or permanent disruption of one or more of these neuronal or nonneuronal structures may severely affect the function of nerve conduction.

BIOLOGICAL ASPECTS OF DEGENERATION AND REGENERATION

According to the nomenclature of Seddon, nerve lesions are classified into three categories: 1) neurapraxia;

2) axonotmesis; and 3) neurotmesis.^[5] Neurapraxia describes traumata originating from severe compression without significant structural damage to the nerve. Transient motor paralysis is a typical consequence, whereas less vulnerable sensory and sympathetic functions of unmyelinated axons remain largely unaffected. Spontaneous recovery without neurosurgical intervention is observed within 3 months. Axonotmesis describes a severe crush or traction injury. Axons within otherwise preserved endoneurial tubes are ruptured. Due to the fact that truncated axons can regenerate within endoneurial tubes, no surgery is performed. Neurotmesis describes lesions with loss of continuity of some or all connective tissue components (endo-, peri-, or epineurium). If the internal organization of the nerve is disrupted or the nerve is completely transected, surgical repair becomes obligatory. Of the three types of nerve lesions, only neurotmesis injuries are therapeutically addressed using nerve guide implants.

Because the adult nervous system is essentially unable to generate new neurons, neuronal regeneration is restricted to the regrowth of new cell processes (axons and dendrites). If nerve lesions do not occur too close to the neuronal cell bodies, the neurons survive, pass through a series of degenerative states, and initiate regeneration in concert with support cells of the severed nerve. After injury, neurons swell, decrease metabolism associated with neurotransmission, and increase the production of cytoskeleton and membrane components necessary for axonal regrowth. During an initial response, the tip of the proximal nerve stump still in continuity with the neural cell body retracts for several millimeters. After several days, axons within the proximal nerve stump form growth cones that

Fig. 2 Microvascular system of the nerve trunk. Extrinsic vessels (exv) support the regional feeding vessels (rv). The vascular plexuses are located in the epineurium (epi), perineurium (p), and endoneurium (end). The vessels pierce through the perineurium obliquely (open arrowhead). Note the intrafascicular double-loop formation (*). (From Lundborg, G.: *Nerve Injury and Repair*; used with permission of Churchill and Livingstone, Edinburgh, 1988.)

represent the leading tip of regrowing axons. The highly motile growth cone is the sensimotoric unit that directs axonal regrowth by exploring the microenvironment. The growth cone must adhere to permissive substrata such as laminin-containing basal lamina via integrin receptors, or will retract after encountering repulsive extracellular matrix (ECM) components or membrane constituents, including proteoglycans or myelin-associated proteins.^[6] Growth cones extend numerous exploratory filopodia until the first of these contacts a permissive terrain. Subsequently, the other filopodia die back in a pruning process. The leading filopodium becomes stabilized and continuously elongates via insertion of membrane components at the growth cone base, after which new filopodia again begin to explore the microenvironment. Any neuroprosthetic concept must take into account these fundamental growth characteristics, which are based on selective and transient cell and ECM adhesion.

Wallerian degeneration begins in the distal nerve stump within hours, characterized by complete deterioration of the distal axon segments that have been separated from their cell bodies. Within the next few days, the myelin sheets formed by Schwann cells around axons become degraded. Macrophages invade affected nerve segments and remove cell debris via phagocytosis. Resident and migrating cells release growth- and differentiation factors in addition to many types of interleukins, which act in concert to regulate the degeneration and subsequent regeneration processes. During this period the basal lamina components remain surprisingly resistant to degradation, which is important because its ECM components provide a directional scaffold for proliferating Schwann cells and axonal regrowth. Additionally, in the absence of Schwann cells, the ECM alone can function as a directional cue for axonal extension, even weeks after the nerve lesions were induced. Proliferating Schwann cells organize themselves in longitudinally oriented bands of Büngner. If axons can successfully navigate across the lesion site between the proximal and distal nerve stump, they are likely to encounter these Schwann cell columns, which then provide a perfect environment for axonal elongation. Several nerve-guide concepts attempt to imitate the positive influence of permissive matrix molecules and Schwann cells (discussed subsequently). In humans, the axonal elongation rate is on average 1 mm per day until the axons have traversed the length of the distal nerve and contacted synaptic target cells. Misrouting during muscular and sensory reinnervation is a rather frequently observed phenomenon, occurring mainly at the site of injury. Attempts to reduce mismatched connections have focussed on reconnecting individual fascicles rather than nerves as a whole. However, due in part to the

nonlinear architecture along the longitudinal axis of nerves, it is notoriously difficult to correctly rejoin proximal and distal fascicle stumps. Axonal subtypes (motor, sensory, sympathetic) display synaptic specificity, which may result in the elimination of incorrectly rewired axons. Despite this tissue specificity, the specificity for distinct nerve fascicles has remained controversial.^[7] Due to the functional plasticity of the adult nervous system, relearning based on rewiring of central neural networks is possible. This rewiring allows for some adaptation to changes in the microanatomy after aberrant synaptogenesis within distinct populations (e.g., motoneurons). Note that loss of innervation leads to progressive atrophy of such synaptic targets as muscles. Therefore, a primary clinical goal is the acceleration of regeneration to prevent muscle wasting and loss of sensory units. In addition, complete failure to reestablish any connectivity may lead to the formation of a neuroma at the lesion site. A neuroma is a pathological aggregate with dense, irregular tangles of axons devoid of peripheral synaptic targets. Because neuromas often cause painful sensations, nerve-guide implants may be used to direct axons to (even inappropriate) synaptic targets, as to neighboring muscles. A major cause of unsuccessful regeneration is fibrosis, a connective tissue scar formed by infiltrating fibroblasts. These secrete collagen type IV, which, although a permissive substrate, may function additionally as a molecular scaffold for inhibitory extracellular matrix components (including chondroitin sulfate proteoglycan).^[8] In addition to neuroma therapy, nerve guides are indicated where nerve gaps cannot be bridged by natural means.

NERVE SUTURES AND TRANSPLANTATIONS

In humans, essentially no regeneration is observed across severed nerves with a gap or extensive scars between both nerve ends. Therefore, therapeutic approaches always aim to reestablish some sort of continuous growth line. If the ends of severed nerves can be joined without tension, an end-to-end repair is possible. Fine monofilament nylon sutures are employed, passing through either the epineural connective tissue (perineural repair) or the perineural tissue (fascicular repair) to realign nerve ends or fascicles, respectively. Fibrin glue—based on the polymerization of fibrinogen after enzymatic activation by thrombin—is another means by which truncated nerve ends can be stably interconnected.

In instances where true nerve gaps are present, some sort of bridging becomes essential. Currently, autologous nerve graft transplants continue to represent the gold standard. Sensory nerves are employed in most cases, the removal of which result in only minor

functional deficits. Most frequently, sural nerves from the right and left lower leg are transplanted. Obvious drawbacks occur at the secondary surgical site, with concomitant risks of infection and inflammation, morbidity at the donor site, and potential formation of painful neuromas. To circumvent these problems, heterologous transplants have been employed in animal models. Additionally, decalcified bone channels or inside-out veins and arteries have been used, which expose the collagen-rich adventitia to regrowing axons. In the case of heterologous grafts, transplantation has been followed by immunosuppression to prevent graft rejection. To remove the most highly immunogenic components, alternating freezing-and-thawing and detergent extraction have been employed.^[9-11] Common to all these approaches is preservation of the fairly durable basal lamina, which provides a template for axonal regrowth. Evaluation of these acellular grafts indicates that regeneration is delayed compared to regeneration resulting from use of fresh grafts *in vivo*. This indicates the importance of such functioning cells as Schwann cells. As outlined subsequently, integration of Schwann cells into nerve-guide conduits improves regeneration substantially. To date, none of the heterologous approaches has fulfilled its promise. These approaches consequently are not in clinical use.

NERVE-GUIDE PRINCIPLES

Nerve guides are compact or porous scaffolds or tubular conduits of natural or synthetic polymers destined to replace biological transplants in order to bridge the gaps between injured nerve stumps. Besides rerouting regenerating axons to synaptic targets, nerve guides may serve to enhance angiogenesis, prevent infiltration of fibrous tissue, and limit dilution of growth factors secreted by accessory cells, while still allowing for diffusion of vital nutrients and gases. The material used for nerve-guide production should neither provoke inflammation nor enhance scar formation, and ought to be generally biocompatible without release of toxic degradation products, such as an excessively rapid shift in pH due to acidic hydrolysis. In addition to these biological aspects, nerve guides should be pliable but able to resist collapse during body movement, should maintain their shape during regeneration, and should undergo resorption after regeneration is complete. Polymer hydrolysis or degradation times of resorbable nerve guides should be temporally adapted to the regeneration period required to bridge nerve gaps. This aspect is of vital importance, because myelination of axons follows regrowth, increasing the diameter of individual fibers and leading in turn to compression if inert conduit walls are used.

Fig. 3 Nerve-guide concepts. Aspects of nerve-guide designs that promise to aid medical performance are: (A) Biodegradability and porosity to control nutrient exchange and exclude scar-forming cells; (B) intraluminal channels to mimic the fascicular structure of nerves; (C) electrical microdevices, piezoelectric elements, and electrets to stimulate growth or externally control axonal activity; (D) controlled release of regenerative factors; (E) longitudinally-oriented matrix to guide regenerating axons; and (F) incorporation of support cells. (Adapted from Hudson, T.W., Evans, G.R., and Schmidt, C.E., *Engineering strategies for peripheral nerve repair*, 1999, *Tissue Engineering*, **26**, 617-628.)

In addition, nerve guides may be fashioned to actively stimulate regeneration and play a structural role during axonal outgrowth. Surface texture, longitudinally-oriented microchannels or polymer fibers, porosity, and electrical stimulation devices are adjuncts that may improve the regenerative performance of guidance channels. The impregnation, inclusion, or covalent linkage of biomolecules to conduit polymers (smart materials) represent means to regulate neuronal survival via retrograde transport, axonal elongation, proliferation of Schwann cells, chemotaxis of blood vessel-forming endothelial cells, or repulsion of scar-forming fibroblasts. In addition, Schwann cells or genetically-engineered fibroblasts that act as self-sustained biofactories for growth factors and ECM proteins may be introduced into nerve guides. Several conduit concepts are summarized in Fig. 3. A broad range of synthetic polymers for nerve-guide production has been reviewed.^[12]

THE SILICONE TUBE MODEL/ NONRESORBABLE NERVE GUIDES

The chronological sequence of regeneration in nerve guides was evaluated in simple inert silicone tubes used

to bridge 10-mm gaps of rat sciatic nerve.^[13] Although this model has been shown to be relevant only for very short regeneration distances, it elucidates four principle steps: 1) matrix formation; 2) cell migration; 3) axon migration; and 4) myelination. 1) After the proximal and distal nerve stumps have been coadapted to an empty silicone tube, the conduit fills with wound fluid within hours. Because the fluid contains the clotting factor fibrinogen, a fibrin network forms within the first week. If the tube distance does not exceed 10 mm, this network may be oriented in a longitudinal fashion. 2) Within the second week (or earlier), fibroblasts, Schwann cells, endothelial cells, and macrophages migrate from both nerve stumps into the tube. 3) Axons appear to be the last cellular constituents, despite the fact that axonal migration is in principle nearly one order of magnitude faster than the migration of Schwann cells.^[14] The likely explanation for this temporally reversed regeneration sequence in conduits is the fact that Schwann cells must biologically pave the way for axons. Based on histological sections, the forefront of regenerating axons does not exceed the front of migrating Schwann cells. Axons sprouting from the proximal nerve end traverse the silicone tube within about 4 weeks. 4) During this period, myelination will have begun, leading to nerve-fiber conduction velocities determined to be 60% of control values.^[15] This paradigm clearly highlights the basic regeneration potential of peripheral nerves, including removal of debris after degeneration, axonal regrowth, myelination, angiogenesis, and successful synaptogenesis. Nevertheless, it has been acknowledged that inert, nonpermeable conduits do not provide a therapeutic solution for nerve gaps longer than 5–10 mm.^[16]

Because of their inert and elastic properties, silicone-based nerve guides were among the first and most frequently used implants, including applications in humans (discussed subsequently). Entubulation of regenerating nerves, however, suffered drawbacks due to fibrosis and chronic nerve compression. In a number of cases, pronounced initial axonal regrowth and functional recovery were observed using nerve-guide tubes. Unfortunately, a decline in sensory and motor performance became evident after longer recovery periods. Histological analysis revealed that progressive myelination led to deleterious compression of axons within the limited volume of the conduit. These observations led to the conclusions that: 1) nerve guides should be resorbable; and 2) disintegration of nerve guides should begin soon after axons have traversed the conduit. We suggest that conduits are ideally resorbed in a graded fashion, with fast degradation near the proximal nerve end and slower resorption at the distal end. This concept may be especially important in the case of nerve-guide implants traversing long distances.

Electrical stimulation via leads integrated into silicone tubes and used as cuffs surrounding lesioned nerves was shown to increase regeneration in the rat model.^[17] Biocompatible electrets such as polytetrafluorethylene (PTFE) are dielectric polymers that provide electrically stable, monopolar charges without the need for an external power supply. Polyvinylidene fluoride (PVDF) is a piezoelectric material that displays transient charges depending on the degree of physical deformation (i.e., dipole displacement). Although the cellular and molecular mechanisms remain unclear, nerve guides made of positively-poled PVDF and PTFE appear to facilitate in-vivo regeneration to a higher degree than negatively-poled tubes.^[18,19] To our knowledge, the feasibility of clinical applications for this scientifically interesting approach implementing nonresorbable PTFE and PVDF implants has not yet been examined.

RESORBABLE ARTIFICIAL NERVE GUIDES

Numerous biological and resorbable synthetic materials have been investigated for neural-tissue engineering applications (Table 1). Tubes of poly- β -hydroxybutyrate (PHB), purified from energy storage granules of microorganisms, have been employed in the rabbit common peroneal-nerve injury model. Nerve regeneration across 2–4 cm gaps was observed 1–2 months postoperative, similar to the recovery seen using autologous nerve transplants.^[20] Nerve guides have also been synthesized from chemically modified collagen type I. Instead of tubes, 2000 collagen filaments 20 μ m in diameter were stabilized with a cross-linking epoxy reagent. Experimental defects in rat sciatic nerves were bridged using these 20-mm implants. Eight weeks postoperative the implants displayed the same amount of regeneration as autologous nerve transplants (about 5000 myelinated axons, 2–3 μ m thick).^[21] One of the earliest grafts was made from a Vicryl mesh (polyglactin or PLGA 10:90, noted subsequently). This graft resulted in some nerve regeneration, but provoked minor inflammatory responses and yielded nerve fibers with a morphology slightly different from that of normal nerves.^[22,23] Another family of degradable polymers includes polyglycolic acid (PGA),^[24,25] poly(L-lactide-co-caprolactone),^[26] and PLGA, which contains copolymers of lactic acid and glycolic acid in various ratios. These polymers were especially attractive because of their early availability, ease of processing, and approval by the U.S. Food and Drug Administration (FDA). For a series of studies, 75:25 PLGA was formed into tubes with 1.6 mm inner diameter and 3.2 mm outer diameter. These tubular conduits were interposed in rat sciatic

nerve defects. Walking track analysis revealed restoration of muscle innervation and sciatic functional indexes approaching control values at 12 weeks.^[27] However, histological data demonstrated an

inappropriately early partial collapse of the conduits. As an alternative, poly(L-lactic acid) (PLLA) was used in subsequent trials to generate more stable geometries. In-vivo evaluation suggested the PLLA conduits to be superior to PLGA conduits of the same design, because there was no evidence of conduit collapse or breakage upon ambulation.^[28] However, unsatisfactory results were obtained with poly(L-lactic acid) blended with 10% poly(L-lactic acid) oligomer conduits in the rat spinal-cord lesion model. Despite obvious axonal regrowth and myelination over the first 2 months, the rate of regeneration declined thereafter, possibly due to compression and hazardous fragmentation of the polymer walls.^[29] In another approach, random copolymers of trimethylene carbonate and ϵ -caprolactone (50:50) showed good biocompatibility in vitro (Schwann-cell survival, adhesion, metabolism, and proliferation) and only a mild soft tissue reaction with no adverse chronic inflammatory reaction in vivo.^[30] Poly(L-lactide-co-caprolactone) (PLA) employed in vivo as 12-mm long semipermeable tubes with walls 1.3-mm thick yielded good regeneration over a period of 3–10 weeks.^[31] As later discussed in greater detail, these examples elucidate the delicate task of balancing the needs for stability, flexibility, and such structural features as porosity for metabolic diffusion with the requirement that implants degrade spontaneously (representing a loss of the aforementioned attributes).

In addition to polyesters, resorbable polyurethanes^[32] and poly(organo)phosphazine^[33] were employed as guide-channel materials. Although the number of available conduit materials has continuously increased over the years, the need for further development is evident. To our knowledge to date, no composition has been found that provides all required mechanical properties and excellent biological performance without causing complications like inflammation or toxicity.

BIOHYBRID NERVE GUIDES

This review considers biohybrid nerve guides composed of both synthetic and biological components (proteins, cells).

ECM-Derived Guides

Because growth cones (the leading tip of regrowing axons) require adhesion to appropriate substrata for proper growth, various ECM components including laminin, collagen, and fibronectin or mixtures of components (Matrigel[®]) have been introduced into polymer conduits. Alternatively, short oligopeptides of 3–10

amino acids (GRGDS, YIGSR, SIKVAV, etc.) that are recognized by axonal integrin receptors have successfully been employed as substitutes for large ECM molecules. These short-recognition sequences are less likely to elicit immune responses and more durable than large molecules. Three-dimensional hydrogels chemically modified with laminin-derived oligopeptides promoted axonal outgrowth *in vitro* and *in vivo*.^[34] Another innovative approach was incorporation of peptides derived from laminin and the cell-adhesion molecule N-cadherin into a fibrin matrix. With the enzymatic aid of factor XIIIa, lysine residues of neuroactive peptides were cross-linked to glutamine residues of fibrin. The resulting matrix resulted in enhanced regeneration when used as a nerve guide in lesioned rats.^[35]

Hydrogels, Alginate

Other bioresorbable conduit materials used in a biohybrid composition are hydrogels such as poly(2-hydroxyethyl methacrylate)^[36] or alginate, a polysaccharide composed of 1,4-linked β -D-mannuronate and 1,4-linked α -L-glucuronate blocks. Alginate has been used to form nerve-guide implants as both a sponge alone and as spongy filling for a polyglycolic acid mesh (PGA).^[37] Gaps in cat sciatic nerves 50 mm in length were successfully bridged using these implants, with locomotor function recovered within 8 months in both approaches. By this time, the myelinated nerve displayed a fascicular organization and alginate had been completely resorbed. Even longer nerve gaps were investigated in dogs. Polyglycolic acid-collagen tubes 80 mm in length and filled with either laminin-soaked sponges or collagen fibers were implanted into severed peroneal nerves. Motor and sensory nerves had partially regenerated within 12 months, with reestablishment of functional synapses (as deduced from essentially normal dorsiflexion of ankle joints and based on histological data).^[38]

Alginate has also been used to coat PHB fibers together with fibronectin. The coated PHB fibers were implanted into lesioned rat spinal cord. Eight weeks postoperative, 50% of rubrospinal neurons could be rescued, although they are most affected in this paradigm.^[39] Although no enhanced axonal regrowth onto these fibers was evident, the neuroprotective effect observed may have been the result of coated PHB fibers serving as a molecular scaffold for diffusible growth factors, consequently increasing the local concentration or half-life of growth factors.

Growth Factors

Factors that support neuronal survival (neurotrophic) or attract axons (neuritotropic) include nerve growth

factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 and -4/5 (NT-3, NT-4/5), platelet-derived growth factor (PDGF), glial cell line-derived neurotrophic factor (GDNF), acidic and basic fibroblast growth factor (aFGF, bFGF), ciliary neurotrophic factor (CNTF), and insulin-like growth factors (IGF), to name just the most prominent ones. Various factors address neurons, whereas, e.g., NGF also promotes Schwann-cell proliferation and migration in an autocrine fashion.^[40] Nerve injury leads to a biphasic synthesis of NGF, with a first peak 6 hours and a second peak 3 days postinjury. Blood-borne macrophages are attracted during the first phase, whereas during the second phase, Schwann-cell responses are triggered.^[41] A number of studies have demonstrated that coapplication of these factors enhances regeneration.^[39,42-44] Critical aspects of applying macromolecules *in vivo* can be rapid inactivation (conformational changes, enzymatic modifications) or degradation *in vivo*. Therefore, it will be extremely helpful if drug-delivery and controlled-release techniques, and strategies for molecular stabilization of macromolecules for extended regenerative periods (i.e., weeks or months) can be improved.

Support Cells

The most promising alternative to the application of recombinant factors and synthetic peptides is the integration of self-sustained cells that produce many of these factors and may even respond to microenvironmental signals in self-regulatory feedback loops. Fibroblasts engineered to express the factors bFGF and NGF constitutively or in a drug-controlled fashion do not display all of these features but have been shown to enhance regeneration (e.g., after spinal cord lesions).^[45] Schwann cells appear to be more potent than transfected/transduced cells as additives in nerve guides.^[29] These cells are not only self-regulatory sources of growth factors NGF, BDNF, IGF-1, and CNTF, but also represent an excellent substratum for growing axons *in vitro* and *in vivo*.^[46] The cells produce a growth-permissive ECM and interact with blood vessel-forming endothelial cells (blood-nerve barrier) and connective tissue cells. Although Schwann cells are able to invade nerve conduits more than a limited distance from the distal and proximal nerve stumps, it appears to be advantageous to insert Schwann cells into conduits before implantation. *In vitro* axons migrate 8 times faster than Schwann cells^[14] (Fig. 4), while axons *in vivo* do not migrate beyond the forefront of Schwann cells, suggesting that the slow proliferation of Schwann cells is the limiting factor during regeneration through nerve conduits.^[47] Procedures have recently been established to purify

Fig. 4 Migration and growth velocities of Schwann cells and axons. Dorsal root ganglia were explanted in vitro and axonal outgrowth was monitored via time-lapse video recording, shown (A) at time point 0 and (D) after 60 min. Schwann cells were synchronized in a two-field migration assay at a start line (the line between black arrows in part B). (E) After 24 h, cultures were fixed and Coomassie-stained, and the migration distance was determined. (C) Quantitative comparison revealed that axons migrate about 8 times faster than Schwann cells. (F) Time-lapse video recording of low-density cultures was also used to analyze the directionality of Schwann-cell migration. The enlarged color-coded trajectories of four Schwann cells were plotted from a virtual starting point (black dot in F). Cell positions were determined every 30 minutes. (G) Cell migration was nondirected. Cells were evaluated for (F) at time point 0. All figures represent views from the top. Scale bars (D for A and D): 25 µm; (E for B and E): 50 µm; (G): 65 µm; (F): 60 µm. (From Ref. [14] with permission.)

human and rat adult Schwann cells and accelerate their growth via the combinatorial addition of glial growth factor, forskolin, and isobutylmethylxanthine, whereby the proliferation of fibroblasts becomes inhibited.^[48] A combination of methods may further improve the biological performance. Regeneration in a spinal-cord lesion model may be significantly enhanced by implantation of Schwann-cell seeded polyacrylonitrile-polyvinylchloride copolymer conduits and coapplication of BDNF and NT-3 into neighboring spinal-cord tissue with a miniosmotic pump.^[49]

PHYSICAL PROPERTIES OF NERVE GUIDES

Physical and physicochemical properties of nerve guides are of pivotal importance for successful regeneration. This survey focuses on nerve guides in the form of tubular conduits, although guides composed of meshes or a collection of filaments have been introduced.^[21,39] Features such as conduit dimension, resorption time, degradation by-products, wall porosity,

surface texture and hydrophilicity, flexibility, and torsional stability must be considered. Length, cross-sectional area, and wall thickness are important parameters, because nerve guides should be adapted to the native dimensions of the severed nerve, which in the clinical setting may range from 1–10 mm in diameter and from 0.5 to about 50 cm in length. In the rat model, consistently good regeneration has been achieved for lengths up to 1 cm, whereas longer distances could often be bridged only upon coapplication of growth factors or growth factor-producing cells. A comparative study suggested that for a distinct nerve-lesion model, a conduit diameter of 1.8 mm was superior to smaller (1.2 mm) and larger (3.1 mm) diameters. These restrictions may reflect counteracting phenomena—excessively small diameters are likely to cause damage upon insertion of nerve stumps into conduits, or may later result in compression during myelination of axons. Conversely, an overly large opening may permit infiltration of scar-forming fibroblasts and outward diffusion of vital neurotrophic factors produced by migrating Schwann cells.

Furthermore, sufficient diffusion of gases and metabolites across the conduit diameter and through the conduit wall is a prerequisite for cell survival and differentiation—especially during the initial phase of regeneration, when blood vessels have not yet been formed. Semipermeable conduit walls are clearly preferable to nonpermeable walls, because these allow in- and outward diffusion of nutrients and intoxicating cellular waste products but hamper the infiltration of scarring fibroblasts. Again, counteracting aspects must be balanced, because longer diffusion distances and lower wall porosity will lead to oxygen concentrations lower than 2 µg/ml, which is considered the minimal requirement for axonal elongation.^[1] Calculations have suggested that the diffusion distance should not exceed 1 mm. In addition, it is noteworthy that an early increase in oxygen levels in permselective tubes may minimize connective tissue formation, due to hindered fibroblast migration. On the other hand, limited anoxia represents a natural stimulus for endothelial cell invasion and subsequent angiogenesis, which are indispensable.

Pore size may be a means to not only regulate the in- and outward movement of cells versus molecules, but also to differentiate between molecules of different sizes.^[50] Some growth-inhibiting, high-molecular-weight ECM components (e.g., chondroitin sulfate proteoglycan) produced by the tissue that fills the nerve guide may possibly be excluded. For resorbable conduits, the ability to act as a molecular sieve typically depends exclusively on inner and outer surface layers just microns thick. The temporal stability of these thin layers must be considered, because the pores will enlarge with progressive degradation. All of these requirements must be met while still providing compression resistance and flexibility, as discussed earlier. As a basis for nerve-guide generation, it is noteworthy that in animal experiments, compression of 25 mm Hg results in reduced blood flow in epineural venules. Long-term pressure on endoneurial capillaries increases permeability, because oxygen depletion leads to edema in the endoneurium. Extraneural pressure of 80 mm Hg results in total intraneural ischemia.^[51] Notably, nonmyelinated axons (and possibly early axons) are less vulnerable to the effects of compression than are myelinated axons.

The selection of distinct synthetic nerve-guide materials will determine the polymer's crystallinity, and consequently affects not only the rigidity and flexibility of the polymer, but also its rates of hydrolyzation and degradation. Polymers such as PGA and PLA are resorbed after acidic hydrolysis, which acidifies the microenvironment. (This process accelerates with decreasing pH.) The total amount of polymer used will determine whether cells are capable of buffering the increasing hydrogen ion concentration in order to survive. This leads back to the question of how best to

design nerve guides—conduit walls, in particular—that are only transiently mechanically stable. (This is because the less polymer used, the lower the degree of acidification upon degradation.)

Hydrophilicity and surface texture are additional features to consider. PLA, PGA, alginate, and others are essentially nonpermissive for outgrowing axons, although Schwann-cell attachment is partially evident. Increasing the hydrophilicity via oxygen-plasma treatment improves cell attachment but simultaneously decreases the stability of nerve-guide walls.^[14] Surface functionalization via coating with polycationic polymers such as degradation-stabilized poly-D-lysine improves cell attachment.^[46] Additionally, accelerated regeneration is likely to occur if meandering of axons in the nerve guide can be prevented. As mentioned earlier, some approaches use collagen fibers as a scaffold,^[21,38,52] although microstructured compact polymer filaments with microgrooves are favored. These microgrooves induce longitudinal alignment of Schwann cells. Cocultures with nervous tissue *in vitro* have shown that axons orient themselves along the Schwann-cell chains very much as they align along the bands of Büngner during regeneration *in vivo* (Lietz, Tschöcke, Doser, and Schlosshauer, unpublished). In this manner, the direct passage of regrowing axons through nerve guides will likely result in faster synaptogenesis and thus stop the ongoing atrophy of previously denervated muscle fibers. Surface texture in the form of an oriented microstructure plays the central role in this regeneration concept. Surface texture also appears to be fundamental for the stability of the ECM–nerve conduit linkage, based on comparison of regeneration through smooth- and rough-walled conduits.^[53]

Microelectrodes represent an additional means to improve nerve implants, by allowing for communication with regenerating axons and external modulation of muscle function. Outgrowing axons may be demonstrated to penetrate polyimide-embedded sieve electrodes.^[54] These electrode arrays were integrated into short nerve guides and implanted into lesioned rat sciatic nerves. Stimulation of the regenerated axons evoked nerve and muscle responses.^[55]

HUMAN APPLICATIONS

The clinical application of nerve guides has been limited in the past, but usage is expected to increase with the recent advent of commercially available implants. Polytetrafluorethylene (ePTFE, Gore-Tex) conduits were implanted in the upper extremities for clinical repair of 15–60-cm long median and ulnar nerve defects in 43 patients. The recovery of motor and sensory function was nearly 80% for repairs up to 40 mm in length, although the rate of recovery declined to about

10% if the implants were longer.^[56] Also using non-resorbable Gore-Tex tubing implants, only minor regeneration was observed in 7 patients (16–56 years of age, 2–15 mm defects) who suffered from lesions of the inferior alveolar and lingual nerves. In another early study, median nerves were successfully reconstructed via silicone entubulation in 2 male patients with nerve gaps of 3–5 mm. At 36 months, motor recovery was about 80%.^[57] When the same authors compared microsurgical and tubular repair (silicone conduits) in a subsequent randomized clinical prospective study, follow-up examinations after 4–5 years revealed comparable recovery of sensory and motor function in both groups.^[58] In some cases where median and ulnar nerves had been severed, gaps of up to 30 mm were bridged with silicone-based conduits.^[59]

Clinical nerve reconstruction with poly(glycolic acid) tubes was first performed in 15 patients with 5- to 30-mm gaps in digital nerves.^[24] Sensibility was evaluated within a postoperative interval of 11 to 32 months, with excellent to good recovery observed in 86% of all cases. Absence of pain at the site of reconstruction was noted by 73% of patients. Additionally, a randomized multiclinical prospective study of nerve guides made from poly(glycolic acid) was performed.^[60] This study enrolled 98 subjects with a total of 136 nerve transections in the hand. Treatment involved implantation of autologous nerve grafts, poly(glycolic acid) conduits, or end-to-end repair. Two-point discrimination was quantified at 3, 6, 9, and 12 months postsurgery. After receiving short implants, about 75% of all patients in all groups exhibited good to excellent recovery. In patients with implants of both types longer than 8 mm, PGA conduits provided better regeneration. Seven of 17 PGA patients showed excellent recovery, but none in the group with autologous nerve transplants displayed this level of improvement.

Besides bridging lesion gaps, nerve-guide implantation promises to be a helpful approach to prevent aberrant axonal sprouting and formation of painful neuromas. A case report described secondary digital reconstruction in the foot after a posttraumatic neuroma of the medial plantar nerve had formed. Introduction of the nerve trunk into a bioresorbable PGA nerve conduit after complete neuroma resection eliminated neuroma pain in a male child.^[61] Silicone tubes 20 mm long were also used to treat neuromas after accidental transection of radial nerves at wrist levels, with patients describing different degrees of pain relief.^[62]

THE ECONOMIC IMPACT

More than 8 million surgical interventions are performed in the United States each year to treat organ and tissue deficiencies. The annual costs associated with these

medical treatments exceed \$400 billion.^[63,64] Because tissue engineering has considerable potential for improving quality of life and reducing health care costs, operating expenses allocated for tissue engineering exceeded \$450 million in 1997. The amount of tissue research increases 20–25% per annum, making spin-off benefits for neural-tissue engineering more than likely. Future savings for the health care field due to these activities has been estimated to be in the range of \$80 billion, in addition to the value of their positive impact on quality-of-life. By 1998, the capital value of start-up companies with a focus on tissue engineering was \$1.7 billion.^[65]

The biotechnological progress made in various fields of tissue engineering will also foster therapeutic developments in neuropathology. Some 400,000 patients suffer neurotraumas of the peripheral nervous system annually, subjecting them to neurosurgery (www.polygarnics.com). Additionally, the many patients suffering from idiopathic damage, compression syndromes, traumata, iatrogenic injuries, and systemic diseases must be considered. In Germany, about 1% of the population of 80 million suffers a sports-related injury annually, with about 5% of all peripheral-nerve lesions arising from these injuries.^[66] With regard to the central nervous system, spinal-cord injuries have an annual incidence of 30,000 cases worldwide.^[67] These lesions could be treated to some extent using nerve-guide implants. The market for nerve-guide products in the peripheral nervous system has been calculated to be in the range of \$50 million, plus applications in the central nervous system. To our knowledge, by the summer of 2003, three SME-biotech-companies had received approval for their nerve-guide implants from the U.S. FDA. There is clearly a medical need for nerve-guide implants. The benefits gained by the health care field will likely compensate for expenses arising from research spending, especially when advances arising from neurological tissue engineering research^[1–3] are combined with advances from nonneural research.

CONCLUSION

It is obvious that future developments will benefit from more detailed insights into the intercellular and molecular regulatory mechanisms of regeneration, yielding intelligent nerve-guide designs. Axonal regeneration recapitulates embryonic development to a considerable extent, as deduced from gene expression studies.^[68] Integration of knowledge about growth-promoting factors and, perhaps more important, inhibitory and repulsive factors in the CNS and PNS will foster implant development. Major classes of these factors are ephrins, semaphorins, netrins, slits, NOGOS, and proteoglycans. As for the latter factors, it has been shown that their enforced degradation greatly enhances regeneration

after spinal-cord lesions.^[8] Integration of counteractive therapeutic means such as pharmacologically active antagonists of inflammatory factors, regeneration-suppressing molecules, or their second-messenger cascades will lend new qualities to nerve guides.^[69] Such approaches will also allow more stringent treatment of CNS lesions, where current conduit implantations merely serve to bridge fluid-filled cysts after spinal-cord lesions. The suggested biohybrid concepts are likely to successfully manipulate the inhibitory microenvironment in order to induce reentry and synaptogenesis of regrowing axons into the spinal cord. Besides the focus on repulsive or inhibitory growth mechanisms (fibrosis, myelin-mediated inhibition, etc.), emphasis should be also put on aspects of angiogenesis. Recent efforts concentrate principally on axonal regrowth, to the extent that support cells and nonneural tissue domains have been essentially neglected. For treatment of neuropathic pain (nerve compression without transection), which spares nerve continuity and blood vessels, regeneration performs at its best. This situation should probably be duplicated in neurotmesis (complete transection) by establishing a capillary network before regeneration of long axons is attempted. In this way an optimal nutrient supply may be established, helping to overcome the current restriction; namely, that nerve guides often fail to facilitate regeneration over distances longer than about 4 cm. The medical need for neural-tissue engineering products and the existing market for medical products of this type demand quick remedies for the present shortcomings of nerve-regeneration treatments. Thanks to advances in materials sciences as well as in life sciences, nerve-guide development is predicted to accelerate in the near future, providing promising solutions.

Neuroprostheses

Milos R. Popovic

Inst. Biomaterials and Biomedical Eng., University of Toronto, Toronto, Ontario, Canada

T. Adam Thrasher

Lyndhurst Centre—Research, Toronto Rehabilitation Institute, Toronto, Ontario, Canada

INTRODUCTION

A neuroprosthesis, sometimes called a neural prosthesis, is a device that provides short bursts of electrical impulses to the central or peripheral nervous system to produce sensory and/or motor functions. Over the past four decades, neuroprostheses have been developed for a wide variety of applications. Some have achieved great success, such as the cochlear implants and bladder management stimulators that are produced in large volume worldwide. Other neuroprostheses, such as those for walking and grasping, have not yet matured to a level that creates a significant consumer demand. There are far too many neuroprostheses on the market and in development to list comprehensively, so this review involves the general features, principles, and functions of some of the most notable devices past and present.

PHYSIOLOGICAL OVERVIEW

In nerve cells, information is coded and transmitted as a series of electrical impulses called action potentials, which represent a brief change in cell electric potential of approximately 80 mV. Nerve signals are frequency modulated; that is, the number of action potentials that occur in a unit of time is proportional to the intensity of the transmitted signal. Typical action potential frequency is between 4 and 12 Hz. An action potential can be elicited artificially by changing the electric potential of a nerve cell or a nerve axon by inducing electrical charge into the cell (Fig. 1). This process, when used to produce action potentials in motor neurons to generate body function, is termed functional electrical stimulation (FES).

Where sufficient electrical charge is provided to a nerve cell, a localized depolarization of the cell wall occurs, resulting in an action potential that propagates toward the end of the axon (orthodromic propagation). Concurrently, an action potential will propagate backward towards the cell body (antidromic propagation). Typically, FES is concerned with orthodromic impulses, using them to generate muscle contractions by stimulating motor nerve axons that

can produce desirable body functions. Until recently, antidromic impulses were considered a useless side effect of FES, but there is new interest in the potential role of antidromic impulses in neural rehabilitation.^[1]

Since generation of action potentials and their propagation occur in the axons, the motor nerves of the stimulated muscles must be intact. If peripheral axons are missing (if they have been cut or have degenerated, for example), the muscle becomes denervated and therefore highly resistant to electrical stimulation. However, contractions can be elicited from denervated muscles by applying extremely intense electrical fields across the muscle fibers, as demonstrated by researchers at the University of Vienna.^[2]

Nerves can be stimulated using monophasic or biphasic current or voltage pulses. The monophasic pulses are seldom used because they lead to unbalanced charge delivery to the tissues, potentially causing damage due to galvanic processes. Most modern FES systems implement biphasic current or voltage pulses, or so-called monophasic compensated pulse shapes.

Another way to activate muscles is to stimulate ascending axons of sensory neurons that trigger reflex arcs. The case where electrical stimulation is used to stimulate sensory neurons and thus alter reflexes or central nervous system functions is commonly described by the term neuromodulation.

TECHNOLOGY

Neuroprostheses come in many different shapes and sizes and serve many different purposes. The common components in all neuroprostheses are: 1) a power source; 2) a stimulus generator; 3) a user-control interface; and 4) electrodes. Most modern neuroprostheses use batteries, disposable or rechargeable, as a power source. Some still use external AC power. Stimulus generators have been miniaturized dramatically over the years. Nowadays, commercial and laboratory-class stimulators tend to be lightweight (less than 1 kg) and handheld. User-control interfaces usually consist of a simple control panel with standard manual controls such as switches, buttons, dials, and

Fig. 1 Illustration of direct stimulation of a motor neuron. The cell body (a) is responsible for synthesizing input from dendrites and deciding whether or not to generate signals, which are transmitted to the corresponding muscle fibers (b). Following a stroke or spinal cord injury, muscles are impaired because motor neurons no longer receive sufficient input from the central nervous system. A neuroprosthesis (c) injects electrical current into the cell axon (d). A train of negative pulses (e) produces a series of action potentials. Depolarization occurs where negative current enters the axon at the active electrode indicated.

sliders, plus some kind of visual output such as light emitting diodes or, on more sophisticated models, a liquid crystal display. In addition, input devices are often mounted on the user's assistive devices, such as a pushbutton attached to a cane or walker. In some cases, input devices are attached to the user's clothing or body, such as an inclinometer on the shank of the leg or pressure sensors in the insole of a shoe. The most sophisticated neuroprostheses use real-time feedback control, which requires sensors such as goniometers, accelerometers, or gyroscopes to provide continuous-state feedback.

Nerves can be stimulated using either surface (transcutaneous), percutaneous, or implanted electrodes. Surface electrodes contact the skin (Fig. 2). They are noninvasive, easy to apply, and generally inexpensive. However, due to the impedance of the skin and the dispersion of current, much higher-intensity signals are required than with subcutaneous electrodes. Current amplitude typically ranges from 10–150 mA in surface stimulation. A major limitation is that some nerves, for example, those innervating the hip flexors, are too profound to be stimulated by surface electrodes. Percutaneous electrodes consist of thin wires that are inserted through the skin and into muscular tissue, remaining in place for a temporary period of time. In percutaneous stimulation, current amplitude is rarely higher than 25 mA. The third class of electrodes is implanted electrodes, which are

permanently implanted. Compared to surface electrodes, implanted and percutaneous electrodes potentially have higher stimulation selectivity with much less electrical charge applied, both of which are desired characteristics of FES systems. The drawbacks are that implants require a lengthy, invasive surgical process to install and that percutaneous electrodes can be used only temporarily and may cause infection at the penetration site.

There is a brand of miniature electrode, the BION™, that can be implanted via hypodermic needle.^[3] They are cylindrical in shape, with a diameter of 2 mm and a length of 15 mm. Once implanted, they are powered

Fig. 2 Reusable, self-adhesive electrodes for surface stimulation come in a variety of shapes and sizes.

and controlled via radio waves from an external controller that can be worn by the patient.

HISTORICAL NOTES

In 46 A.D., Scribonius Largus described what may be considered the first neuroprosthesis: the torpedo ray, which is capable of generating an electric potential of 25 to 30 V.^[4] For centuries, torpedoes were prescribed for all sorts of ailments, including headaches, hemorrhoids, and even mental illness.

Following the invention of the electrostatic generator in the late 17th century, electrical discharges were found to excite animal muscles. Stronger discharges, and hence stronger biological responses, were made possible when the first capacitor was invented in 1745. Physicians began treating a wide range of diseases by applying electrical discharges to their patients. Benjamin Franklin pioneered some of these techniques.

In 1791, Luigi Galvani published his discovery that dissected frog legs could be stimulated by touching a bimetallic rod to nerve and muscle. Michael Faraday built the first electric generator in 1831. It introduced the possibility of applying a series of high-frequency electrical pulses to nerves, which is the basis for all modern electrical stimulation. G. B. Duchenne utilized Faradism extensively in the latter part of the nineteenth century to treat various neurological disorders. Duchenne developed electrodes for localizing currents, and he produced a set of maps of the body indicating locations called motor points, where electrodes can be positioned to excite specific muscles.

NEUROPROSTHESES FOR WALKING

There are many neuroprostheses that address lower-extremity movement. As early as 1960, Kantrowitz demonstrated paraplegic standing by applying continuous surface FES to the quadriceps and gluteus maximus muscles of a patient with complete spinal cord injury.^[5] Around the same time, Liberson and colleagues developed a simple neuroprosthesis to correct drop foot. This common symptom in hemiplegia is characterized by a lack of dorsiflexion during the swing phase of gait, resulting in short, shuffling strides.^[6] Liberson's device, which has the distinction of being the first neuroprosthesis to receive a patent, consisted of a power supply worn on a belt, two surface electrodes positioned for stimulation of the common peroneal nerve, and a heel switch. The stimulation was activated whenever the heel lost contact with the ground, and was deactivated when the heel regained contact with the ground.

Stimulation of the common peroneal nerve causes contraction of the muscles responsible for dorsiflexion (i.e., tibialis anterior and extensor hallucis longus, among others). It can also trigger the flexor withdrawal reflex, which may not be desirable. The flexor withdrawal reflex occurs naturally when a sudden, painful sensation is applied to the sole of the foot. It results in flexion of the hip, knee, and ankle of the affected leg and extension of the contralateral leg in order to get the foot away from the painful stimulus as quickly as possible. To prevent this from happening during FES-assisted ambulation, Vodovnik proposed using a low-pass filter to slow the onset of stimulation current.^[7]

Following Liberson's invention and Vodovnik's revisions, a number of drop foot stimulators were developed. Some were commercialized, for example the MikroFES (Josef Stefan Institute, Ljubljana, Slovenia) and the Odstock Dropped Foot Stimulator.^[8] The latter was shown to significantly increase walking speed and efficiency, and a carryover effect was observed in stroke patients; that is, their walking speed and efficiency without the stimulator were improved.^[9] Similar studies have reported no carryover effect.^[10] Users of the Odstock device were generally satisfied with it, but almost all of them identified the surface electrodes as problematic, and two thirds would consider an implanted system instead.^[11]

The first commercially available implanted drop foot stimulator was developed by Rancho Los Amigos Medical Centre and Medtronic Inc.^[12] The surgically implanted compounds were a radio-frequency (RF) receiver, a pulse train generator, and one bipolar electrode implanted adjacent to the peroneal nerve. An external unit worn on the belt delivered power via the RF coil and received input commands from a wireless foot switch. Despite some problems with electrode migration and infection, the device was considered successful. Since then, more reliable and easier to implant systems such as the IPPO^[13] and the Aalborg University implanted stimulator^[14] have been devised, but they are not commercially available. The latter uses input from an implanted cuff electrode around the sural nerve, which is the nerve innervating the skin sensors on the sole of the foot. This system is unique in that it requires no external sensors.

Most modern drop foot stimulators continue to use a heel switch for active input. Burrige et al. tried using the foot switch on the nonaffected leg, but found it was not preferable unless the patient was unable to reliably achieve heel contact on the affected leg.^[15] Vodovnik was one of the first to experiment with manual push-buttons and EMG sensors.^[7] Other alternatives to the heel switch include a heel/toe switch,^[16] an array of four single-axis accelerometers positioned on the shank,^[17] a tilt sensor positioned on the shank,^[18]

electroneurography,^[14] a knee goniometer,^[19] and the Gait Phase Detection System.^[20]

The earliest neuroprostheses for paraplegic gait provided continuous stimulation to the quadriceps to produce a mode of gait similar to long leg-brace walking. Later systems used alternating bilateral quad/glut stimulation (during stance phase) out of phase with peroneal nerve stimulation (during swing phase). One such system was a six-channel stimulator developed at the University of Ljubljana in Slovenia.^[16] Later at the same institution, Kralj and colleagues described a technique for paraplegic gait using surface stimulation, which remains the most popular method today.^[21] According to Kralj's technique, four channels of stimulation are used. Electrodes are placed over the quadriceps muscles and peroneal nerves bilaterally. The user controls the neuroprosthesis with two pushbuttons attached to the left and right handles of a walking frame, or on canes or crutches (Fig. 3). When the neuroprosthesis is turned on, both quadriceps are stimulated. The left button initiates swing phase in the left leg by briefly stopping stimulation of the left quadriceps and stimulating the peroneal nerve. This stimulation is applied suddenly so as to trigger the flexor withdrawal reflex, resulting in simultaneous hip and knee flexion as well as dorsiflexion. After a fixed period of time, peroneal nerve stimulation is stopped and quadriceps stimulation is resumed. Similarly, the right button initiates swing phase in the right leg. Kralj and colleagues successfully applied this system to more than 50 subjects with spinal cord injury.

Many neuroprostheses for walking have employed the basic technique described in this section. As

microprocessor technology developed, neuroprostheses became more portable and flexible. The Parastep system uses Kralj's technique.^[22,23] It is the only neuroprosthesis for walking to receive approval from the United States Food and Drug Administration (FDA) and the first neuroprosthesis of any kind to receive FDA approval. It includes an ankle-foot orthosis to bolster ankle stiffness. The Parastep is commercially available, and more than 600 people have used it successfully.

A major limitation of neuroprostheses for walking that are based on surface stimulation is that the gait is slow, awkward, and unnatural looking. Perhaps a major reason for this is that the hip flexors cannot be stimulated directly. Therefore, hip flexion during walking must come from voluntary effort, which is often absent in paraplegia, or from the flexor withdrawal reflex (initiated by peroneal nerve stimulation). Implanted systems have the advantage of being able to stimulate the hip flexors. They also provide better muscle selectivity and more natural gait patterns. Two such systems are the Praxis24 and the system proposed by Kobetic, which use 24 and 32 electrodes respectively.^[24,25] The Praxis24 system also enables bladder voiding.

NEUROPROSTHESES FOR REACHING AND GRASPING

A number of neuroprostheses have been developed and used to assist stroke and spinal cord-injured subjects to improve their grasping function. The best-known grasping neuroprostheses are the Freehand system,^[26]

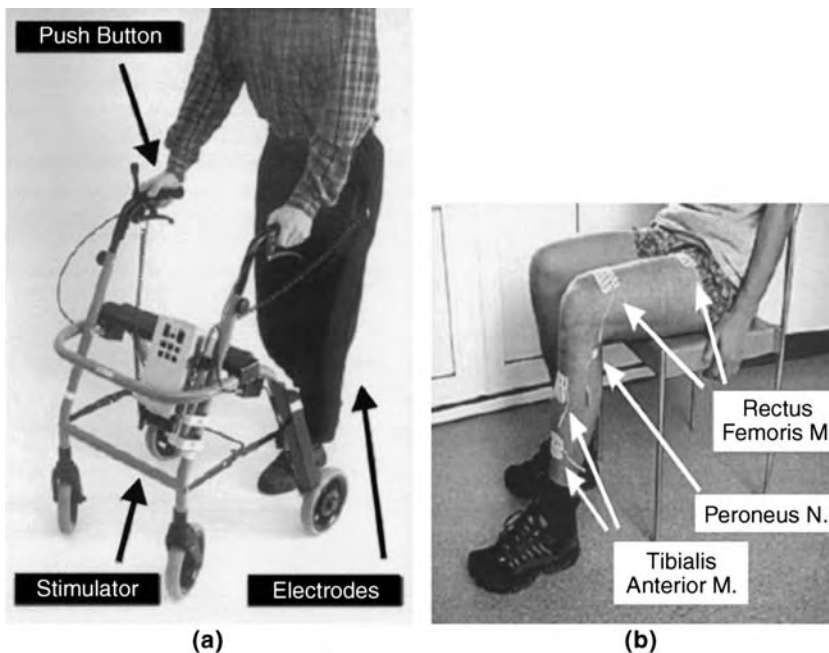

Fig. 3 The ETHZ-ParaCare walking neuroprosthesis for hemiplegic subjects and subjects with unilateral paraplegia, developed in Zurich, Switzerland. (From Ref. [38].) (a) Stimulator and push button attached to walker; (b) surface electrodes attached to legs underneath clothing.

the Handmaster NMS-1,^[27] the Bionic Glove,^[28] the NEC FESMate system,^[29] the Compex Motion neuroprosthesis for grasping,^[30,31] and the systems developed by Rebersek and Vodovnik^[32] and Popovic et al.^[33] With the exception of the Freehand and NEC FESMate systems, all use surface stimulation.

The key element for achieving the synergistic activity of muscles that results in reaching and grasping is the appropriate sequencing of electrical pulses. The available neuroprostheses for grasping can restore the two most frequently used grasping styles: the palmar and the lateral grasp. The palmar grasp is used to hold bigger and heavier objects such as cans and bottles, and the lateral grasp is used to hold smaller and thinner objects such as keys, paper, and compact discs. The lateral grasp is generated by first flexing the fingers to provide opposition, which is followed by the thumb flexion. The palmar grasp is generated by first forming opposition between the thumb and the palm, which is followed by simultaneous flexion of both the thumb and the fingers.

The Freehand system, manufactured and distributed by NeuroControl Co., U.S.A.,^[34] consists of eight implanted epimysial stimulation electrodes that stimulate flexion and extension of the fingers and the thumb in order to provide lateral and palmar grasp. Commands are given by an external position sensor that is placed on the shoulder of the subject's opposite arm. An additional external switch allows the user to choose between palmar and lateral grasp. This sequence is then sent via a radio frequency coil to the implanted unit, which generates the stimulation sequences for each channel.

The electrode leads are tunneled subcutaneously to the implanted stimulator located in the pectoral region. Surgical procedures to enhance both voluntary and stimulated hand functions are often performed in conjunction with the stimulator implantation. More than 200 quadriplegic subjects have received the Freehand neuroprosthesis at more than a dozen sites around the world. The subjects have demonstrated the ability to grasp and release objects and to perform activities of daily living more independently when using the neuroprosthesis. The Freehand system is the first neuroprosthesis for grasping approved by the FDA. The main advantage of the Freehand system is that it is implanted, and the time needed to don and doff the system is shorter compared to most of the surface FES systems.

In the 1980s, the group led by Handa at Sendai University, Japan, developed a microcomputer-controlled neuroprosthesis for grasping. Soon after that, Handa's team proposed a system with 16 percutaneous intramuscular stimulation electrodes that is both portable and programmable.^[29] This system consists of a NEC PC-98LT personal computer and an

external microcontroller-based stimulator. The stimulator applies trapezoidal stimulation patterns to generate muscle contractions. The stimulation patterns were "cloned" from the muscle activity recorded during voluntary grasping movements of able-bodied subjects. Stimulation sequences were triggered with a pushbutton or a pneumatic pressure sensor. This system demonstrated that spinal cord injured subjects with complete C4 to C6 spinal cord lesions could reach and grasp. In collaboration with NEC Inc., the Sendai team developed a fully implantable 16-channel electric stimulator called the NEC FESMate. Although 200 of these stimulators have been manufactured,^[35] the NEC FESMate is not available outside of Japan.

The neuroprosthesis developed by Rebersek and Vodovnik was one of the first FES systems for grasping.^[32] This neuroprosthesis has three stimulation channels, which are used to generate grasping by stimulating the finger flexors and extensors and the thumb flexors. Although this device was developed almost three decades ago, it is one of the rare systems that allows a subject to control the stimulator via different sensory interfaces such as an EMG sensor, a sliding resistor, or a pressure sensor. This option is important because it allows the neuroprosthesis to be tailored to the subject. The main disadvantages of this neuroprosthesis are that donning and doffing times are long and that selectivity of stimulation is quite limited. Merelitti et al. modified this system and used it for stroke subjects.^[36] They applied two channels to augment the elbow and fingers/wrist extension. They concluded that FES contributed greatly to recovery of hand and elbow movements in five stroke subjects, but in the remaining three the improvement was significant only at the elbow joint.

The Handmaster (Fig. 4) is a neuroprosthesis for grasping that is manufactured and distributed by NESS Ltd., located in Israel.^[27] It consists of an orthosis that has built-in flexibility to enhance and control freedom of movement within the forearm and hand, while supporting the wrist joint at a functional angle of extension. The Handmaster multiplexes a single channel of stimulation through a selected combination of surface electrodes on the inner surface of the orthosis, which effectively transforms the device into a six-channel neuroprosthesis. One stimulation channel is used to stimulate the extensor digitorum communis at the dorsal side of the forearm. The second channel stimulates the flexor digitorum superficialis. Electrodes are positioned over the muscles of the forearm and hand intrinsics during an initial setup session with a clinician. The setup position of the electrodes depends on the device user's specific needs. The Handmaster is controlled with an array of push buttons allowing the subject to select the operating mode and to trigger programmed movement

Fig. 4 The Handmaster system manufactured and distributed by NESS Ltd., Israel. (From Ref. [27].) The flexible, adjustable unit is worn over the forearm, wrist, and palm.

sequences. Using the buttons, the subject can also control stimulation intensity and thumb posture, thereby adjusting the grasp to the size and the shape of the target object. Originally, the Handmaster was envisioned as a permanent orthotic system, but it is also used as an exercise and rehabilitation tool. One of the major advantages of the Handmaster is that it is easy to don and doff. It is exceptionally well designed and is one of the best neuroprostheses for grasping on the market. There are currently more than 2000 in use.

The Bionic Glove is a neuroprosthesis designed to enhance the tenodesis grasp in subjects who have good voluntary control over wrist flexion and extension.^[28] By extending their wrist, users can cause passive finger flexion due to the limited length of the finger flexors. The Bionic Glove stimulates finger flexors and extensors during tenodesis grasp, significantly enhancing the strength of the grasp. Four self-adhesive surface stimulation electrodes provide stimulation, and the stimulator and a wrist position sensor are located on the forearm of the glove. An easy-to-use interface with three push buttons on the stimulator is used to set the stimulation parameters, and the optional audio feedback facilitates faster learning. Clinical evaluation of the Bionic Glove has indicated that it is generally beneficial to quadriplegic subjects, but only about 30% of potential users accepted it for long-term use.^[37] It is available only for clinical evaluation from the University of Alberta, Canada, and it is presently being modified into a new system called the Tetron that will provide several grasping patterns and strategies.

The Belgrade Grasping-Reaching System proposed by Popovic et al. is a neuroprosthesis for grasping that also provides reaching function.^[33] It consists of four stimulation channels, three of which are used to generate grasping function. The fourth channel is used

to stimulate the triceps brachii muscle augmenting elbow extension. Reaching is achieved by measuring the subject's shoulder velocity with a goniometer and by generating a synergistic elbow motion by stimulating the triceps brachii muscle. This neuroprosthesis, similar to the system proposed by Rebersek and Vodovnik, requires more time to don than the Handmaster and is not yet commercially available.

The Complex Motion neuroprosthesis is a very flexible device designed to improve grasping and walking functions in both spinal cord injury and stroke patients.^[38] This multichannel surface stimulation system is programmable and can be interfaced with any sensor system. As a four-channel neuroprosthesis for grasping, it provides both palmar and lateral grasps. It can be controlled with proportional EMG, discrete EMG, pushbuttons, or sliding resistor control strategies. Thus far, more than 50 stroke and spinal cord-injured patients have used the neuroprosthesis in a clinical setting or at home in activities of daily living. One of the main disadvantages of this system is that it requires about eight-minutes to put on or take off.

NEUROPROSTHESES FOR BLADDER MANAGEMENT

Neuroprostheses have been very successful in treating lower urinary tract dysfunctions commonly associated with spinal cord injury, such as urge incontinence and urinary retention. The first attempts to electrically stimulate the bladder were made in the 1950s, when researchers sought ways to induce bladder emptying. At that time, a bladder wall stimulator was developed and implanted in three humans,^[39] and animal studies of pelvic nerve stimulation were carried out.^[40] Later, it was found that electrical stimulation of the sacral anterior roots produces excellent results, and this led to the development of the Finetech-Brindley stimulator, which is the most widely used neuroprosthesis for bladder management today.^[41]

Attempts to manage incontinence using electrical stimulation began in the 1960s.^[42] It was found that urethral resistance could be increased by stimulating the muscles of the pelvic floor, vagina, and rectum using external electrodes.^[43] Eventually, fully implanted systems were developed to suppress the detrusor muscle, thus preventing reflex incontinence and increasing bladder volume.^[44] Most spinal cord injuries result in reflex incontinence. Typically, detrusor-sphincter dyssynergia develops, in which the detrusor and urethral sphincter contract simultaneously rather than reciprocally. The detrusor also becomes hyper-reflexic, and the bladder becomes overactive. The standard treatments are anticholinergic

medication, which blocks the neuromuscular junctions, and sensory rhizotomy (surgical transection of the posterior sacral roots). Neuroprostheses for bladder management serve as a practical alternative to these treatments. They can also augment sensory rhizotomy.

The Finetech-Brindley stimulator has been implanted in more than 2000 patients, usually those who have had a rhizotomy.^[45] The electrodes are positioned on the second, third, and fourth sacral roots, bilaterally and extradurally. If a rhizotomy has not been performed, the electrodes must be implanted inside the dura to prevent crossover stimulation of the sensor neurons, which will trigger the detrusor reflex. A portable external controller transmits power to the implant via radio frequency coil, and the user initiates bladder voiding by pushing buttons on the external unit. Micturition is usually achieved with residual volumes of less than 50 mL, contributing to a dramatic reduction in urinary tract infections.^[46] The Finetech-Brindley stimulator has proven to be extremely robust, with only one failure expected every 80 implant-years.^[47]

The Medtronic Interstim stimulator is a sacral root implant for incontinence, using neuromodulation to correct the inappropriate reflex behaviour.^[48] It consists of fine wire electrodes inserted into the sacral foramina. When active, these electrodes inhibit the detrusor, but the mechanism of this inhibition is not yet properly understood. Thorough testing must be done using a temporary implant before permanent implantation is recommended. The stimulation parameters commonly used are a pulsewidth of 60–270 μ s and a frequency of 10–15 Hz, with the stimulation on for 10 s, then off for 2 s. Current amplitude is twice the sensory threshold. The clinical success rate of this device is about 50%. Bladder emptying has to be achieved either voluntarily or by means of intermittent catheterization.

COCHLEAR IMPLANTS

Cochlear implants are neuroprostheses for the hearing impaired who have severe (70 to 90 dB) or profound (>90 dB) hearing loss. A long wire electrode is implanted directly into the cochlear duct, and electrical stimulation is applied to the residual spiral ganglion cells of the cochlear nerve. These devices were first developed in France in 1957. Since then, cochlear implants have been refined and miniaturized, and now they have received widespread acceptance, more so than any other class of neuroprostheses. More than 75,000 patients have received cochlear implants worldwide. Originally, few hearing-impaired people were eligible for cochlear implantation, but as the technology has improved, the selection criteria have

expanded greatly to include a wide range of hearing impairments.^[49]

Due to the success and popularity of cochlear implants, there are many different brands on the market. Most brands, however, are essentially similar. Differences between the currently available cochlear implants mainly involve the number of electrode channels (12 to 22), speech coding strategies, and the mode of electrode stimulation.^[50] A recent study carried out at the University of Toronto, for example, concluded that the Clarion CI (Advanced Bionics, Symlar, CA) and the Nucleus 22 (Cochlear Corp., Sydney, Australia) cochlear implants were totally comparable in function and performance.^[51] Both devices succeeded in reducing tinnitus, thereby increasing word and sentence recognition, but there was no significant reduction in vestibular function. Among the implantees, 76% reported that they were satisfied with their implants, and 96% reported an overall positive impact on quality of life. Some other brands of cochlear implant are the COMBO 40+ system (MED-EL, Durham, NC), Digisonic (MXM, France), and the SOUNDTEC direct system (SOUNDTEC, Palo Alto, CA), most of which are FDA approved.

Cochlear implants generally consists of the following: 1) an external earpiece; 2) a speech processor; and 3) an internally implanted unit (Fig. 5). The earpiece, usually very small and lightweight, is worn comfortably behind the ear, much like a hearing aid. It

Fig. 5 The Clarion CII Bionic Ear system by Advanced Bionics (Symlar, California). (a) Sound processing unit; (b) internal, implantable unit; (c) external earpiece.

contains an ear-level or in-ear microphone and a radio frequency coil to transmit signals to the implanted components. The speech processor, can be in the form of a small box worn somewhere on the body or, in some models, it is contained in the external unit worn behind the ear. The internally implanted unit consists of a receiver coil located underneath soft tissue in a cavity drilled in the temporal squama, and a 20–24 mm insulated wire ending in a multichannel electrode array, which is inserted into the cochlear duct. Sound waves are received by the external microphone and converted into electrical signals that are input to the external speech processor. There, the signals are digitally encoded and transmitted to the internal unit via radio frequency coil. The internal unit decodes the radio signals back into elementary electrical signals to stimulate each channel of the electrode array. Therefore, the multichannel device provides a complex sound analysis similar to the physiological analysis of sound in normal patients.

CONCLUSIONS

The first modern FES devices were developed over 40 years ago, and since then there has been a great deal of innovation resulting in scores of new neuroprostheses. The most successful of these technologies, in terms of consumer acceptance, are cochlear implants—more than 75,000 units have been implanted worldwide. Bladder management stimulators have also achieved wide acceptance, but not quite to the same degree.

Despite many advances and positive reports over the decades, neuroprostheses for walking and grasping have not achieved widespread approval. Most are used only for research purposes, and few have been used regularly by patients for activities of daily living. Some have been put to clinical use, and those are usually abandoned after a short period of time. The general perception among clinicians is that the neuroprostheses for grasping and walking are not fully matured and their application is often labor-intensive, whereas a favorable outcome cannot be guaranteed. Nevertheless, recent studies indicate that these tools have great potential in the rehabilitation of stroke and spinal cord-injured subjects.^[30,3152,53] In particular, these studies indicate that a significant number of patients who were trained with these systems recover voluntary reaching, grasping, and walking functions due to intensive and repetitive training with these systems. Current efforts are focused on understanding the mechanism of short- and long-term improvements and recoveries observed in these patients.

Neuroprostheses are a new and emerging technology that has significant potential. However, implementation

of this technology to its full potential presents numerous challenges that have yet to be addressed. We believe that the 21st century will be the century when most of these technical and implementation issues are resolved and neuroprostheses are established as one of the important classes of rehabilitation systems available to patients with disabilities ranging from spinal cord injury to blindness.

Neutrophil-Biomaterial Interactions

Vibeke Videm

Department of Laboratory Medicine, Children's and Women's Health, The Norwegian University of Science and Technology, and Department of Immunology and Transfusion Medicine, Trondheim University Hospital, Trondheim, Norway

INTRODUCTION

This chapter first gives a brief overview of normal neutrophil functions that parallel many of the reactions to biomaterials. Differences that influence neutrophil reactions in various settings employing biomaterials are mentioned, and mechanisms for neutrophil adhesion to biomaterials are discussed. The various consequences of neutrophil adhesion to biomaterials are described, including the oxidative burst, degranulation, neutrophil functional changes, and changes in neutrophil lifespan. The last part of the chapter provides a brief overview of some methods commonly employed to study neutrophil–biomaterial interactions.

Neutrophil Granulocytes—Part of the First-Line Defense

Neutrophil granulocytes (polymorphonuclear cells) constitute approximately 40–75% of the leukocytes in blood. These short-lived, highly mobile cells are important in the body's first-line defense, and their reactions to biomaterials are parallel in many respects to their reactions against other foreign substances such as microorganisms. A brief description of these normal reactions is therefore given.^[1]

In the resting state, neutrophils patrol the microcirculation. If they encounter activating stimuli that are liberated as a result of tissue damage, microorganisms, etc., they first become primed and develop a lower threshold for activation and subsequently may become more and more strongly activated. Activated neutrophils express adhesion molecules that bind to complementary receptors on activated endothelium in the threatened area. If the activating stimuli are strong enough to cause firm adhesion, the neutrophils traverse the endothelium and migrate into the tissues, guided by chemoattractants that lead them to the damaged or infected area. Here, neutrophils phagocytose (ingest) microbes and kill them by a combination of mediators such as proteinases from their abundant cytoplasmic granules and highly reactive oxygen species generated in reactions initiated by the enzyme complex NADPH

oxidase. This increased production of reactive oxygen metabolites is denoted the respiratory burst. During activation and degranulation (liberation of mediators from the cytoplasmic granules), there is always some external release of substances that may harm the surrounding tissue. Faced with foreign material that is too big to be phagocytosed, such external degranulation is augmented, a process sometimes called frustrated phagocytosis. Adhesion of slightly activated neutrophils to endothelium may be reversible, permitting primed cells with a reduced activation threshold to reenter the circulation. Resting neutrophils undergo apoptosis after a few days, whereas activated neutrophils live somewhat longer in the tissues until they either undergo apoptotic or non-apoptotic cell death.

Neutrophil–Biomaterial Interactions Depend on the Setting

Neutrophils readily identify biomaterials as foreign and react by becoming primed or activated. The interactions depend on the specific biomaterial, but also on the specific application. Important modifying factors are whether the biomaterial contact is time limited (e.g., during cardiopulmonary bypass) or permanent (e.g., in a vascular graft) and whether the exposure is repeated (e.g., hemodialysis). For biomaterials with direct blood contact, blood flow rates and the level of shear stress will also influence the interactions. Neutrophils normally react more strongly if there are other activating stimuli present as well, such as complement activation products or proinflammatory cytokines. The presence or absence of other cells such as monocytes or platelets influences the reactions, as well as plasma proteins including complement. Finally, there are large individual variations in the intensity of the reactions among different persons. Metabolic derangements, e.g., as in uremic patients, may also modify the responses. Thus, even though some general principles may form the basis for anticipation of the responses, specific testing of a biomaterial in the intended application is mandatory to fully characterize its interactions with neutrophils.

A number of studies on neutrophil–biomaterial interactions involve the use of isolated neutrophils. Isolation procedures should be carried out at 4°C to avoid in vitro priming or activation by biomaterials in pipette tips, tubes, etc., and polypropylene tubes should be used instead of polystyrene.

NEUTROPHIL INTERACTIONS ARE MAINLY WITH ADHERENT PROTEINS

In vivo, neutrophils react directly with the biomaterial surface only to a small extent, even if they do so during in vitro tests employing protein-free buffers. This is because biomaterials in contact with blood immediately become coated with plasma proteins and later platelets as well. Although less well characterized, protein adsorption will also take place on implants in tissues. They may become coated with plasma proteins as a result of bleeding during implantation and also absorb proteins from the extracellular fluid. The nature of the adsorbed protein coat is assumed to be decisive for the subsequent interactions with neutrophils. The composition of the protein layer, in turn, is highly dependent on the biomaterial, e.g., the chemical structure, charge and whether it is hydrophobic or hydrophilic, whether active molecules such as heparin or anti-inflammatory agents have been incorporated, etc. The adsorbed proteins may become more or less denatured, and their orientation subsequently exposing or hiding reactive groups is of importance. Some biomaterials activate the complement system and contribute to formation of complement activation products that may react with neutrophils, either in the circulation or locally if the biomaterial also binds the activation products.

MECHANISMS FOR NEUTROPHIL ADHESION TO BIOMATERIALS

A number of proteins and chemical groups on biomaterials may react with neutrophil granulocytes. For some molecules, the receptor or receptors on neutrophils are identified, but receptors yet unidentified are clearly involved as well^[2] and unknown groups on the biomaterials also engage in the interactions. Table 1 summarizes neutrophil receptors for various proteins that are commonly adsorbed onto biomaterials in vivo. In settings where platelets adhere to the adsorbed proteins, adhesion of neutrophils to these platelets may also take place. Table 2 summarizes neutrophil receptors to the most important ligands on biomaterial-adherent platelets. It is probable that neutrophil adhesion to platelets may also involve bridging molecules such as fibrinogen or von Willebrand factor.

Table 1 Neutrophil receptors for proteins on biomaterials

Surface-adsorbed protein	Neutrophil receptor
Albumin	CD43 (leukosialin)
Coagulation factor X	CD11b/CD18 (CR3, Mo1, Mac-1)
Complement	
C1q	Various C1q-receptors
C3 breakdown products	CD35 (CR1), CD11b/CD18 (CR3, Mo1, Mac-1)
C5a	CD88 (C5a receptor)
Fibrinogen/fibrin	CD11b/CD18 (CR3, Mo1, Mac-1), CD11c/CD18 (p150,95)
Fibronectin	CD49e/CD29 (VLA-5), CD51/CD29, integrin α V β 5
IgG	CD16 (Fc γ RIII), CD32 (Fc γ RII)
Kininogens	CD11b/CD18 (CR3, Mo1, Mac-1), CD49e/CD29 (VLA-5)
von Willebrand factor	CD162 (PSGL-1), CD11b/CD18 (CR3, Mo1, Mac-1), CD11c/CD18 (p150,95)
Hydroxyl groups (–OH)	Carbohydrates?
Unknown	Proteoglycans?

Abbreviations: CR3, complement receptor-3; VLA-5, very late antigen-5; PSGL-1, P-selectin glycoprotein ligand-1.

Because the detailed composition of the adsorbed proteins on different biomaterials in use in vivo is mostly unknown, we can only point at possible interactions with neutrophils. In addition, the most important mechanisms may not necessarily involve the most abundant proteins.

Table 2 Neutrophil receptors for platelets on biomaterials

Platelet receptor	Neutrophil receptor
CD62P (P-selectin)	CD162 (PSGL-1)
CD42b–V-IX complex	CD11b/CD18 (CR3, Mo1, Mac-1)
JAM-C	CD11b/CD18 (CR3, Mo1, Mac-1)?
CD41/CD61 (GPIIb/IIIa)	CD11c/CD18 (p150,95), fibrinogen

Abbreviations: CR3, complement receptor-3; JAM-C, junctional adhesion molecule-C; PSGL-1, P-selectin glycoprotein ligand-1.

The dominating mechanisms for neutrophil adhesion to hydrophilic and hydrophobic surfaces are probably different, but generalization is difficult because the specific chemical groups and charged molecules of the biomaterial also influence the reactions. The protein layer adsorbed to hydrophobic surfaces contains substantial amounts of fibrinogen, and the complement system is also strongly activated by many hydrophobic surfaces. Neutrophil adhesion may take place directly to fibrin/fibrinogen, to complement activation products, and to platelets. Similar mechanisms are involved on hydrophilic surfaces, but the adsorbed fibrinogen is subsequently partly exchanged with coagulation factor XII (Hageman factor) and kininogens. Factor XII induces coagulation and adsorption of thrombin. Complement activation is less intense with many hydrophilic surfaces, and neutrophil adhesion to adsorbed IgG may therefore become more dominating. Surfaces with negatively charged groups bind kininogens, but the site that reacts with neutrophil receptors is thereby hidden. Adsorbed kininogens therefore tend to reduce the material's reactions with neutrophils. A similar "pacifying" effect is seen with adsorbed albumin. Some data indicate that increased hydroxylation and expression of other negative groups on the surface result in more neutrophil adhesion,^[3,4] but positive charges may also increase the reactions.^[5]

FACTORS THAT MODIFY NEUTROPHIL-BIOMATERIAL ADHESION

A number of other factors than biomaterial composition influence neutrophil adhesion. Smooth surfaces generally lead to less adhesion than rough ones,^[6,7] but the mechanisms for this effect are not well understood. The number of adherent neutrophils increases gradually with shear stress up to approximately 3–4 dyn/cm² and then decreases.^[8,9] The use of different anticoagulants during extracorporeal circulation may also be of importance: Citrate reduces the available Ca²⁺, which may inhibit neutrophil functions, whereas heparin in clinical doses primes neutrophils and reduces their activation threshold.^[10]

CONSEQUENCES OF NEUTROPHIL BIOMATERIAL ADHESION

Neutrophil adhesion is coupled to other aspects of activation. The β 2-integrin CD11b/CD18 (CR3, Mo1, Mac-1) is involved in adhesion to many substrates (Table 1), and both this and other adhesive receptors interact with the cell's cytoskeleton. As they adhere, the neutrophils change shape, becoming flat and

outstretched and acquiring pseudopods and the ability for amoeboid movement (diapedesis). Most often, these shape changes parallel the degree of activation and are related to how firmly the cells have adhered, but sticking and spreading should be regarded as partly separate phenomena. The presence of pillars, holes, ridges, etc., greatly influences neutrophil motility on implanted biomaterials.^[11]

Two other important downstream events are assembly of the NADPH oxidase, responsible for production of reactive oxygen metabolites, and degranulation, which are further described in the following paragraphs. Neutrophil adhesion to biomaterials may therefore lead to liberation of the blood or tissues of substances that contribute to local damage and sometimes even systemic activation of inflammation. The more intense activation the biomaterial elicits, the higher the concentrations and wider the selections of mediators are released, and the more harm may be caused.

Oxidative Burst

The NADPH oxidase consists of several protein components from the cytosol as well as the membrane-bound cytochrome *b*₅₅₈ and other membrane-bound proteins. Probably as a safeguard against erroneous production of highly reactive oxygen metabolites, these components are not physically assembled before an activating stimulus such as adhesion to a biomaterial is received. Activation of the oxidase results in the so-called oxidative burst, i.e., the production of large quantities of superoxide anions and liberation of hydrogen peroxide (H₂O₂) that is used for the production of long-lived reactive species, including hypochlorous acid (HOCl), catalyzed by the enzyme myeloperoxidase. These reactive oxygen species may damage a variety of molecules, including lipids in cell membranes, but they also lead to activation of proenzymes to form tissue-destructing proteinases such as collagenase and gelatinase, as well as impairment of the antioxidant defenses by inactivation of α 1-antitrypsin. Ideally, these highly reactive substances should mainly be released into phagosomes containing internalized microorganisms to be killed, but in the setting of biomaterial adhesion, they are often released extracellularly in substantial amounts and may cause damage.

Degranulation

Neutrophils contain three types of granules in addition to secretory vesicles, forming reservoirs of molecules necessary to rapidly change phenotype and perform new functions upon activation. Table 3 indicates a few

Table 3 Some constituents of neutrophil granules and vesicles^[12]

Granule/vesicle type ^a	
Secretory vesicles	Membrane-bound Adhesion molecules (CD11b/CD18) Activation receptors (complement receptor 1, C1q-receptor, FMLP receptor, CD14, CD16)
Gelatinase granules	Membrane-bound Adhesion molecules (CD11b/CD18) Activation receptors (FMLP receptor) Cytochrome <i>b</i> ₅₅₈ Matrix Enzymes (gelatinase) Antimicrobial substances (lysozyme)
Specific (secondary) granules	Membrane-bound Adhesion molecules (CD11b/CD18, CD66, laminin receptor, vitronectin receptor) Cytochrome <i>b</i> ₅₅₈ Matrix Enzymes (collagenase, gelatinase, sialidase) Antimicrobial substances (lactoferrin, lysozyme)
Azurophilic (primary) granules	Matrix Enzymes (myeloperoxidase, proteinase-3, sialidase, elastase) Antimicrobial substances (lysozyme, cathepsins, defensins, BPI)

Abbreviations: BPI, bactericidal permeability increasing protein; FMLP, formyl-methionyl-leucyl-phenylalanine.

^aThe distinction into different granules is less absolute in vivo than indicated here, with partly overlapping species.

important constituents of these granules and vesicles, but is far from complete.^[12] Upon activation, the secretory vesicles are mobilized first and their membranes are fused to the cell membrane, immediately providing the cell with more adhesion molecules and receptors to receive further activating stimuli. Next, gelatinase granules are mobilized and then the specific granules, and upon even stronger stimulation the azurophilic granules. The gelatinase and specific granules contain enzymes that can degrade basement membranes and adhesion molecules, facilitating migration into the tissues. The further down in the degranulation hierarchy, the more molecules involved in microbial killing—including cytochrome *b*₅₅₈ and myeloperoxidase—become available.

Functional Changes

Neutrophil–biomaterial contact may also result in functional changes. In this context, it is important to note that adhesion may not necessarily be permanent, especially in settings with biomaterial–blood contact such as hemodialysis or cardiopulmonary bypass.

Shear stress and changes in receptor binding strength over time may permit cells to reenter the bloodstream. Such neutrophils may be either primed or functionally less responsive (exhausted). The changes may be complex, as indicated in an in vitro model study of cardiopulmonary bypass, where neutrophil adhesion to endothelial cells was unchanged after recirculation but reduced upon subsequent stimulation,^[13] but where adhesion to gelatin representative of collagen in the extracellular matrix was increased. Both primed and exhausted neutrophils may pose risks to the patient, especially because there also is extensive fluid-phase liberation of proinflammatory mediators during extracorporeal circulation. Primed neutrophils released after biomaterial contact may be “overactive” in this proinflammatory milieu, adhering to activated endothelium or exposed subendothelial tissues in different organs and contributing to the “post-pump syndrome” following cardiopulmonary bypass or respiratory symptoms in hemodialysis. At the same time, extracorporeal circulation may increase the risk of infections because neutrophils that are exhausted after biomaterial contact are incapable of performing their normal antimicrobial functions.

In the setting of implants, functional changes in adhered neutrophils may pose similar risks. Depending on the nature of the adsorbed proteins on a biomaterial surface, bacterial phagocytosis and killing may be impaired, perhaps as the result of an excess of cytoskeletal organization induced upon adhesion.^[14] The nature of the biomaterial and topographic details also influences mobility of adherent neutrophils,^[11,15] which may be of importance for their ability to move toward microbes in order to phagocytose and kill them. Finally, products released from adherent neutrophils may induce hyporesponsiveness in fresh neutrophils,^[16] a phenomenon that may contribute to explaining implant-associated infections.

Biomaterial-Associated Changes in Neutrophil Lifespan

Biomaterial contact may change neutrophil lifespan, resulting in either increased or decreased apoptosis or non-apoptotic cell death. Various inflammatory mediators including reactive oxygen species, complement activation products, and proinflammatory cytokines such as IL-6 and IL-8 downregulate neutrophil apoptosis. This may be seen as a useful adaptation when combating infections. In the context of cardiopulmonary bypass, however, delayed apoptosis^[17] may contribute to prolonged inflammatory response. Dialysis patients demonstrate greater neutrophil apoptosis than control subjects, both as a consequence of biomaterial contact and through the interaction with monocytes.^[18] This may contribute to the increased propensity to infection in patients on hemodialysis. Adhesion to certain biomaterials may also induce non-apoptotic cell death, and this effect is dependent on surface roughness. Neutrophils adherent to a roughened surface produce more reactive oxygen species than cells adherent to a smooth surface of the same biomaterial, and, in parallel, activation of a src kinase family-mediated signaling pathway triggers non-apoptotic cell death.^[7] This may represent an alternative form to apoptosis of activation-induced cell death, perhaps as a regulatory mechanism to avoid too-strong inflammatory responses. However, in non-apoptotic cell death released cellular contents such as enzymes may damage the surrounding tissue.

Factors That Modify Systemic Neutrophil Activation upon Biomaterial Contact

In extracorporeal circulation, the foreign surface area relative to the blood volume is important for the degree of systemic neutrophil activation. With a relatively larger area, activation of non-adherent neutrophils is greater.^[19] Conceivably, this effect is of

importance both in hemodialysis and in cardiopulmonary bypass. However, because substantial differences in activation are seen among the various membrane biomaterials employed in hemodialysis, the choice of membrane may be much more important for neutrophil activation than the surface area in this setting.

Biomaterial-induced neutrophil activation increases with lower hematocrit levels, although hemodilution alone does not induce neutrophil activation.^[20] This is of importance in cardiopulmonary bypass, especially in children. The relationship between surface area and degree of hemodilution with the magnitude of the inflammatory responses is an important reason for the trend toward smaller cardiopulmonary bypass circuit surface areas.

METHODS FOR EVALUATION OF NEUTROPHIL-BIOMATERIAL INTERACTIONS

As outlined above, neutrophil-biomaterial interactions are diverse, including adhesion, functional changes of adherent and non-adherent cells, and changes in lifespan, and may be influenced by several other factors than the chemical composition of the biomaterial. This complexity renders evaluation of such interactions difficult, and there is no general consensus regarding which methods should be preferred. Two paramount requirements should be considered. First, more than one parameter should be evaluated, because biomaterial contact induces a number of changes that are not necessarily correlated. Second, evaluation should be performed during the intended application or in a model setting that mimics this application. Some standard methods to evaluate various parameters are given in Table 4 and are further discussed in the following paragraphs.

Biomaterial-Related Adhesion

Many of these methods are based on different forms of microscopy, with the advantage that not only the number of adherent neutrophils can be quantified, but also cellular morphology. The degree of spreading often provides an indication of the level of activation. Methods based on microscopy are labor intensive and, with the exception of light microscopy that may even be performed on unstained cells, often costly. Cell enzyme immunoassay is a versatile, inexpensive method that is useful for large series of experiments. The cell number on a surface is quantified by employing an enzymatic reaction dependent on binding of a primary antibody to the adherent cells. Primary antibodies against myeloperoxidase are often used

Table 4 Commonly used methods to evaluate neutrophil-biomaterial interactions^a

Test parameter	Method
Adhesion to biomaterial	Scanning electron microscopy
	Fluorescence or confocal microscopy
	Light microscopy
	Cell enzyme immunoassay (cell ELISA)
	Quantification of constituent after solubilization
Adhesion molecule expression	Counts in incubation medium or blood sample
	Cell enzyme immunoassay on adherent cells
	Flow cytometry on adherent cells after detachment
Degranulation	Flow cytometry on circulating cells
	Enzyme immunoassay of supernatant
Phagocytosis	Enzymatic assay in supernatant
	Flow cytometry
Oxidative burst	Methods based on radiolabeled bacteria
	Flow cytometry
Bacterial killing	Chemiluminescence
Motility	Bacterial colony counts
	Chemotaxis assay under agarose, in Boyden chamber, or in tissue culture wells
Viability	Chemotaxis assay on biomaterial surface
	Dye uptake or exclusion tests

Abbreviation: ELISA, enzyme-linked immunosorbent assay.

^aSee text for details.

because neutrophils contain abundant quantities, but antibodies against any granule constituent that is relatively specific for neutrophils may be employed. No information on morphology is available, and results are given on a relative scale if not calibrated against a method based on some form of counting. Adherent neutrophils may also be solubilized to allow granule constituents to be released to the medium, in which quantification, for example of myeloperoxidase, is performed. The advantages and disadvantages are as for cell enzyme immunoassay, but results often demonstrate somewhat larger variation as a result of the extra steps involved. A very simple method is to quantify the number of neutrophils in the incubation medium, assuming that any differences from the

starting counts are a result of removal by adhesion to the biomaterial. This works reasonably well in vitro even if cell death may be a source of error, either because cells disintegrate or because they become apoptotic and divide into a number of apoptotic particles. In vivo, changes in margination and liberation of neutrophils from the bone marrow as part of the inflammatory response render such counts fairly unreliable.

In some experiments, circulating neutrophils after biomaterial contact are tested for their subsequent ability to adhere to specific substrates, such as gelatin, vitronectin, or laminin, or to cultured endothelial cells in order to evaluate priming or exhaustion. The mentioned methods may also be employed in such studies.

Adhesion Molecule Expression

Cell enzyme immunoassay on adherent cells may also be used to quantify changes in adhesion molecule expression. With this method, it is important that the cells are not permeabilized, because this will allow the primary antibody to bind to intracellular stores of adhesion molecules, as well as those expressed on the cell surface. An alternative method is to stain the cells with antibodies against the relevant adhesion molecules after detachment from the biomaterial and analyze them using flow cytometry. For neutrophils, this method has some caveats, rendering thorough evaluation of the detachment conditions necessary. If detachment is performed using trypsin, the adhesion molecules one wishes to quantify may be partly or completely removed, even with low trypsin concentrations. Detachment using ethylenediaminetetraacetic acid is not always sufficiently effective for the most activated cells, thereby creating a selection bias. Removal using a cell scraper may be useful. Flow cytometry is labor intensive, but has a higher sensitivity than cell enzyme immunoassay and permits simultaneous assessment of many adhesion molecules. Flow cytometry is an excellent method for measurement of adhesion molecule expression on circulating neutrophils after in vivo or in vitro extracorporeal circulation, providing information specific to each sampling time point. However, the most activated neutrophils may be adherent to the biomaterials or activated endothelium and thus are unavailable for assessment. The β 2-integrins (CD11/CD18, especially CD11b) are often used as activation markers. It is important to note that conformational changes in integrins may activate them to increased binding without changes in receptor numbers. L-selectin, which is shed during activation, may also be a useful marker.

Degranulation

Even if degranulation is required for changes in adhesion molecule expression, the two parameters are not always correlated. One explanation may be that adhesion molecule expression gives a single-moment picture, whereas degranulation products become accumulated over time and may stem from both adherent and non-adherent neutrophils. Enzyme immunoassay of supernatants or plasma after neutrophil–biomaterial contact is an easy, inexpensive method with high sensitivity that is well suited for large series. By combining analysis for constituents from different granules, a more detailed picture of events may be obtained. Lactoferrin is often used as a marker for specific granules and myeloperoxidase or elastase may be used as markers for azurophilic granules. Because the granules contain a number of enzymes, quantification of enzymatic activity in supernatants or plasma may also serve as an indicator of degranulation. Sensitivity is often lower than for enzyme immunoassay, but these methods are often rapid, inexpensive, and well suited for large series. Enzyme immunoassay or tests for enzymatic activity may also be performed in neutrophil lysates after biomaterial contact in order to quantify the remaining amount of some granule constituent, often in comparison with lysate from precontact samples. Measurement of degranulation products released from neutrophils after biomaterial contact and subsequent stimulation, e.g., with phorbol ester or formyl-methionyl-leucyl-phenylalanine (FMLP), gives an indication of the “remaining function,” i.e., if the cells have become primed or exhausted.

Phagocytosis

The capacity of neutrophils for phagocytosis after biomaterial contact is often measured by flow cytometry after an incubation period with opsonized fluorochrome-labeled bacteria. This method is simple and sensitive and imposes no risk of infection. Other methods are based on phagocytosis of radiolabeled bacteria with subsequent counting of neutrophil-related radioactivity. This is also a sensitive method, but requires adequate protection of the researchers and routines for disposal of the radioactive waste.

Oxidative Burst

The simplest and most sensitive methods are based on flow cytometry. The neutrophils are incubated with a non-fluorescent substance such as dihydrorhodamine, which is oxidized to a fluorescent compound by hydrogen peroxide or superoxide anions. Both spontaneous

production of reactive oxygen metabolites and production after stimulation may be quantified, and the method is easily combined with measurements of adhesion molecule expression. Other methods are based on chemiluminescence, which is usually dependent on stimulation of the neutrophils and thus indicates only the “remaining function,” not the spontaneous level of reactive oxygen metabolite production. Using luminol or lucigenin as probes, intracellular or secreted oxidants, respectively, may be measured with high sensitivity. The cytochrome *c* reduction assay is an alternative method to measure the oxidative burst. It is specific for measurement of secreted superoxide anions, but will not detect intracellular oxidant production. Both the cytochrome *c* reduction assay and chemiluminescence-based methods are less used after the introduction of the much simpler flow cytometric assays. All methods for measurement of oxidative burst are relatively labor intensive.

Bacterial Killing

The most standard methods are based on incubation of bacteria with neutrophils that have been in contact with biomaterials, followed by plating of the bacteria and subsequent counting of bacterial colonies.

Motility

Many motility assays are dependent on transferring the neutrophils that have been in contact with biomaterials to the test setup, e.g., a petri dish with wells cut out in agarose, a Boyden chamber, or a tissue culture well with a porous filter insert. The cells are then induced to move in one direction by a chemoattractant such as FMLP, and the results are evaluated by staining and counting. In the tissue culture well setup, the laborious counting step may be substituted if the neutrophils are preincubated with a fluorescent or radioactive label. The cells that have passed through the pores are solubilized and quantified using a fluorometer or gamma/beta counter. All these methods are unsuitable for evaluating the mobility of cells adherent to the biomaterial. In order to overcome this disadvantage, assays have been developed in which the biomaterial is fixed on the bottom of a tissue culture well under a layer of agarose. Neutrophils are added to a well in the agarose so that they move on the biomaterial surface in the direction of a chemoattractant. The counting step may also be substituted with image analysis techniques, permitting a much more detailed analysis of movement, including repeated observation of single neutrophils.

Viability

The simplest tests are based on differences in dye exclusion or uptake between live and dead neutrophils. For example, trypan blue, ethidium bromide, and propidium iodide are excluded as long as the cells are alive, whereas acridine orange permeates the membranes of live cells. Stained and unstained cells are evaluated either by light microscopy (trypan blue) or by fluorescence microscopy/flow cytometry (e.g., ethidium bromide, propidium iodide, acridine orange). Detection of apoptosis may be performed using a number of methods that are beyond the scope of this text. One alternative is to employ flow cytometry with fluorochrome-conjugated annexin V, which binds to phosphatidylserine that is exposed on the plasma membrane in apoptotic cells.

CONCLUSION

Upon biomaterial contact, neutrophil granulocyte priming, adhesion, or activation may lead to clinical consequences such as increased inflammation with subsequent organ dysfunction, as well as an increased risk of infections. Therefore, biomaterials intended for clinical applications should be thoroughly screened for potential neutrophil-related adverse effects by examining various aspects of neutrophil activation and functions in a relevant setting.

Nickel and Nickel Alloys

Rachel L. Williams

Department of Clinical Engineering, University of Liverpool, Liverpool, United Kingdom

INTRODUCTION

Nickel alloys play an important role in dentistry, orthopedics, and cardiovascular applications. In these applications, Ni is alloyed with another metal that forms a stable oxide layer—for example, chromium or titanium. These control the dissolution of Ni into the biological environment, which is important because of potential adverse biological responses to the nickel ions.

NICKEL CHEMISTRY

Nickel is a transition element with atomic number 28.^[1] It has a melting point of 1455°C and a boiling point of 2730°C. The prevalent oxidation states of nickel are 0 (as in nickel metal and its alloys) and 2+ (as in most of its inorganic compounds). The main nickel compounds are its oxides, sulfides, and salts. As a pure metal it is silvery-white in color, has ferromagnetic properties, and is malleable and ductile. Ni²⁺ forms complexes in aqueous solutions with negative groups or neutral polar molecules. Nickel is widely distributed in nature, making up about 0.008% of the earth's crust. Its main ores are pentlandite (a nickel/iron sulfide) and garnierite (a nickel/magnesium silicate). Of the many hundred thousand tons of nickel produced annually, 70% is used in the production of alloys. These alloys are used in a wide range of industrial processes. Alloys of particular interest to biomedical applications are the Ni–Cr dental casting alloys, austenitic stainless steels, and Ni–Ti shape-memory alloys.

NICKEL ALLOYS

Ni–Cr Alloys

Cast Ni–Cr alloys have been extensively used in dentistry since the 1960s for partial denture frameworks, crowns and bridges, and porcelain-fused-to-metal restorations.^[2–6] More recently, Co–Cr alloys have been predominantly used for framework structures, but Ni–Cr alloys continue to be used for crowns, bridgework, and endodontic posts^[3] (Figs. 1 and 2).

The important properties for these applications are castability, sufficient mechanical properties, and corrosion resistance. The fulfilment of these requirements derives from the relationship between composition, structure, processing, and material properties.

A typical composition for a cast Ni–Cr dental alloy is shown in Table 1. The major alloying element Cr is added to provide the alloy's corrosion resistance by forming a passivating oxide layer. The minor alloying elements, in fact, have a greater influence on the physical and mechanical properties of the alloy. Mo and Al both contribute to increasing the strength of the alloy. Aluminium forms a Ni₃Al compound that significantly increases the yield and ultimate tensile strength of the alloy. Carbon plays a significant role in increasing the hardness of the alloy due to the formation of metal carbides with other alloying elements—for example, Cr, Si, Mo, and Ni. The actual percentage of C must be carefully controlled: If too much C is added (i.e., more than 0.2%), the alloy becomes too hard and brittle for use in dentistry; if too little is added, the yield and ultimate tensile strengths become too low for the alloy to be effective. Beryllium (Be) is added as a solid-solution strengthener. It plays an important role in increasing the castability of the alloy by lowering the melting temperature by about 100°C, and has been demonstrated to improve the surface oxide and enhance adhesion of porcelains to the metal alloy. The Al content can help in this regard as well as Fe, which also reduces shrinkage following casting. Si and Mn are added to increase the fluidity and castability of the alloys.

Typical ranges for mechanical properties are given in Table 2. The percentage elongation is critically dependent on the microporosity of the casting. This can be controlled by the melting and casting variables (e.g., the alloy should not be overheated during melting). Control of the C and Mo content can also increase ductility without reducing strength. A higher elastic modulus can be an advantage because the greater rigidity of the structure allows the design of restorations with reduced dimensions. It is also argued that a well-designed rigid appliance provides a better distribution of forces to the supporting tissues during use.^[2]

The corrosion resistance of Ni–Cr dental alloys has dominated research on these materials. The oral

environment is aggressive to metal surfaces, and degradation of the material surface occurs due to corrosion in the saliva, wear and erosion caused by food and chewing, and bacterial activity.^[7] These all result in the release of metal ions into the environment, leading to the formation of various compounds (e.g., chlorides, sulfides, and oxides). The mechanism to minimize ion release is by control of the formation of a strong passive layer, usually an oxide, on the surface of the alloy. In Ni–Cr alloys this is achieved with Cr, but it must be remembered that all metal will release ions through the passivating oxide layer, although the rate may be very low. The biological significance of the metal ion release is discussed later.

Stainless Steel

Stainless steels are Fe–C alloys with the addition of Cr to provide a passivating oxide layer of Cr_2O_3 . There are many stainless steels with different properties depending on their composition and microstructure that, as a consequence, have a role in many different biomedical applications. The 300 series (American Iron and Steel Institute, AISI) of stainless steels^[8] also contains Ni and has applications in medical devices, including orthodontic wires in dentistry, wires, pins, plates and screws in orthopedics (Fig. 3), and stents in cardiovascular applications. The following discussion concentrates on this group of alloys.

Fig. 2 Ni–Cr endodontic post. (a) A radiograph showing positioning of the post; (b) SEM of etched surface of the post. (Reproduced with kind permission of Dr. Nicolas Jedynakiewicz.)

Typical compositions of the 300 series of stainless steels are shown in Table 3. The main constituents are Cr, Ni, and Mo with low levels of other elements. (C content in particular is carefully controlled.) Chromium is added to provide a stable oxide, which

maintains the corrosion resistance of the alloy. There must be at least 12% chromium to impart sufficient corrosion resistance for implantation into the body; Mo is also added to increase corrosion resistance. The amounts of Cr and Mo are controlled so that $\%Cr + 3.3 \times \%Mo \geq 26$. This is known as the pitting resistance equivalent (PRE).^[9] Nickel is added to the composition to maintain a completely austenitic microstructure at room temperature. It is important to have a completely austenitic microstructure to maintain the corrosion resistance and nonmagnetic properties, even though this restricts the maximum strength of the alloy that can be obtained. The carbon content is very carefully controlled. In implantable 316L stainless steel, the carbon content is maintained below 0.03%. It has been observed that in higher-carbon content 316 stainless steel ($C=0.08\%$) after prolonged heating above 400°C, chromium carbides can form at the grain boundaries. This has a significant influence on the alloy's corrosion resistance owing to the depletion of Cr in the vicinity of the carbides, and therefore reduction in the stability of the passive oxide layer in these areas. The sulfur content is kept low to restrict the formation of sulfides (e.g., MnS) that can impair surface quality. The Si content is also kept low to decrease silicate-type inclusions, thus providing greater stability of the austenitic structure. A low phosphorus content maintains improved ductility of the alloy, especially in implant devices that require cold-working to provide sufficient strength.

The microstructure of implant-quality stainless steel has single-phase austenitic structure and fine grain size. This allows the production of an alloy with a good combination of tensile strength and fatigue resistance. The alloy cannot be heat-treated to increase mechanical properties, but can be cold-worked. Typical values of the mechanical properties are presented in Table 4. The annealed alloy is particularly used for wires and fracture fixation plates where the strength is sufficient and the higher ductility an advantage to allow the surgeon to conform the plate to the shape of the bone during surgery. The cold-worked alloy is used in the manufacture of bone screws, bone plates, and intramedullary nails where increased strength is required. It is also reported^[9] that the torsional properties of 316L stainless steel allow the surgeon to feel when a bone screw has reached its yield torque, thus reducing the potential to overtighten screws, causing failure. Cold-drawn material is used for pins and wires where high resistance to bending is required (e.g., in Kirschner wires and Schanz screws). The cold-worked alloy also has increased fatigue resistance compared to annealed material, but at the expense of corrosion resistance (due to increased dislocation density).

In orthodontics, 316 stainless steel is used in the manufacture of archwires that apply force to straighten teeth. The wires are produced in wrought form by rolling and drawing. After being formed into appliance-specific correct shape, they are usually heat-treated to relieve stresses induced by fabrication. This produces wires with good corrosion resistance and the excellent mechanical properties of yield strength, elastic modulus, and spring rate.

Coronary artery stents are used to maintain patency of blood vessels following interventional cardiology and have rapidly developed into the principal method of percutaneous coronary revascularization.^[10] Ideal stent characteristics include flexibility, low unconstrained profile, high radial strength, high corrosion resistance, good biocompatibility, and low thrombogenicity. Most commercially available stents are manufactured from 316L stainless steel. The actual properties of each design depend on the configuration

of the stent. Concerns over the potential release of Ni from 316L stainless steel and its influence on restenosis^[11] have led to the development of coating technologies with other metals, metal oxides, or polymers containing antithrombotic or antiproliferative drugs.

The corrosion resistance of stainless steel is afforded by the chromium oxide that forms on the surface, protecting the underlying alloy from corrosive attack. The stability of the passive layer is critical to the corrosion resistance of the alloy. Many conditions can influence the stability of the oxide. In anodic polarization studies of medical-grade stainless steel, it has been shown that the difference between the corrosion potential and the protection potential is less than in other metallic biomaterials (e.g., Ti alloys and Co–Cr alloys),^[12] and it is therefore relatively easy to breach the passive layer and allow active corrosion to proceed. This can be influenced by geometrical factors (e.g., the existence of crevices) or relative motion between components (e.g., fretting). Areas of local high stress—perhaps resulting from dislocations or impurities—may lead to weakening of oxide stability and result in pitting corrosion.

Ni–Ti

Ni–Ti is an alloy with exceptional properties owing to its crystal structure. These properties include shape-memory behavior and pseudoelasticity (sometimes known as superelasticity). Ni–Ti alloys possess shape memory and pseudoelastic properties owing to the temperature- and stress-dependent transformation of their crystal structure from a parent phase, B2 (often called austenite), to a martensitic phase, B19'. (Find details of these transformation processes elsewhere in this encyclopedia.) Ni–Ti shape-memory alloys are based on an equiatomic composition of nickel and titanium. They can be manufactured by conventional

vacuum-induction melting^[13] or powder metallurgy^[14] techniques. The microstructure consists primarily of a single phase with small amounts of other phases dispersed in the matrix. If the composition changes from the equiatomic, the amount of the second phase can increase, affecting the properties of the alloy. The temperatures associated with the phase transformation (M_s , the martensite start temperature; M_f , the martensite finish temperature; A_s , the austenite start temperature; and A_f , the austenite finish temperature) are critically dependent on the composition. It is reported that, particularly on the Ni-rich side of the equiatomic, control of the composition must be on the order of 0.01%.^[13] A 0.1% difference in compositions can cause a 10°C change in M_s .^[14] The transformation characteristics may also be influenced by the inclusion of impurities such as C, O, H, and N during the manufacturing process due to Ti's high affinity for these elements.^[15]

The thermomechanical treatment of Ni–Ti alloys is critical to their performance and must therefore be carefully controlled. Fully annealed equiatomic Ni–Ti alloys have very good pseudoelastic and shape-memory properties. Thermomechanical treatment, however, is often required to increase the strength of the alloys. Cold-working alone will increase the yield strength of the alloy but destroy the pseudoelastic and shape-memory properties. Annealing postcold-working will

Table 4 Typical mechanical properties of implant quality 316L stainless steel

Condition	UTS (MPa)	Yield strength (MPa)	Elongation (%)
Annealed	490–690	> 190	> 40
Cold-worked	860–1100	> 690	> 12
Cold-drawn	1350–1600	–	–

(Adapted from Ref. [8].)

restore the memory effect but decrease the yield strength. By controlling the annealing conditions and degree of cold-working, it is possible to optimize the mechanical properties of the alloy. It is believed^[13] that cold-working alone introduces a high density of random dislocations and that annealing rearranges the dislocations into cells of relatively dislocation-free zones within which the martensite twins can be mobile but are surrounded by dislocation networks that restrict further mobility.

The introduction of dislocations also has a significant influence on transformation temperatures. A sample with a high dislocation density will have a lower M_s and a higher A_f than the fully annealed sample. The dislocations stabilize the B2 (austenite) phase such that on cooling, the transformation from B2 to B19' is hindered by the dislocations.^[13,16-18] There will also be a similar change in the critical stress required to initiate stress-induced martensite. Samples with low dislocation density and coarse grain structure (i.e., high annealing temperature) will have a lower critical stress than samples with high dislocation density and fine grain structure (i.e., low annealing temperature). The dislocations present in the matrix act as obstacles to the martensite growth during stress-induced martensite formation.

The shape-memory effect relies on the transformation of the phase structure from a B2 structure at high temperatures to a B19' structure at lower temperatures. In fully annealed alloys, the transformation occurs directly from B2 to B19' on cooling. For a cold-worked sample, the transformation occurs via the R-phase (i.e., B2 to R to B19').^[15,16] The mechanical properties of a Ni-Ti alloy are critically dependent on the amounts of the three phases present.^[17] The R-phase is a rhombohedral distortion of the B2 parent lattice structure. It can nucleate on a single dislocation, whereas the martensitic lattice structure can not, due to the large transformation shape change compared to the strain around a single dislocation.^[15] The R-phase appears on cooling prior to martensite under certain conditions and can be associated with a temperature hysteresis as small as 1.5°C.^[19] It shows pseudoelastic and shape-memory characteristics, and can occur more easily than the transformation to the B19' phase, as it requires smaller temperature changes or smaller loads. Thermomechanical treatments can be used to optimize the properties of Ni-Ti alloys for use in medical devices. The treatments can enhance the mechanical properties and be used to tailor the phase transformation temperatures to values suitable for in-vivo applications.

As with most implant alloys, the corrosion-resistance behavior in Ni-Ti alloys relies on a passive oxide layer. Many studies have examined the corrosion behavior of Ni-Ti alloys. Ni-Ti alloys process a stable,

passive oxide layer that will maintain its passivity when exposed to potentiodynamic polarization over a potential range similar to other Ti-based alloys. However, if for any reason the passive layer is breached, then repassivation may be slow and difficult. Any configuration or prior treatments that influence the stability of the passive oxide can therefore have a very significant effect on the corrosion resistance of the alloys. This includes scratching and wear,^[20,21] crevice geometry,^[22] roughened surfaces,^[23,24] stress concentrations,^[25] intermetallic inclusions,^[26] acid environments,^[22] protein adsorption,^[27] and pretreatments that modify the chemistry of the oxide.^[28,29]

The passivity of the oxide layer will depend on its composition. Some studies have suggested that the oxide is entirely Ti-oxide-based without any detection of Ni in the surface.^[27] Other studies have demonstrated the presence of metallic Ni and Ni oxides throughout the Ti-oxide layer.^[28-30] Depth profiling through the oxide has shown that its composition is critically dependent on prior treatment.^[31-33] However, it would appear that in many situations the outermost layer of the oxide is composed of TiO₂. It may be that this is how the wide passive region is conferred to the alloys that has been measured in some studies. However, if the outermost oxide is removed by wear or a scratch, then the underlying mixed oxide of Ti oxide and Ni oxide may be less stable in the aggressive chloride environment, leading to a slow and less stable repassivation.

A crevice geometry or roughened surface may exploit weaknesses in the surface protection and, as discussed in the foregoing, this may be due to the inclusion of Ni and Ni oxides in the predominantly Ti-oxide surface layer. Many practical Ni-Ti alloys have been pretreated with thermomechanical processes to optimize their mechanical performance. The presence of the dislocations formed could be considered to produce preferential sites for passive film breakdown owing to internal stress concentrations.^[25] Intermetallic phases (NiTi₂) have also been shown to act as preferential sites for pit initiation in Ni-Ti alloys.^[26] The intermetallic phase has been shown to form with only a very slight excess of Ti.^[13]

It has been reported^[34] that corrosion in an aggressive chloride environment has the ability to modify the microstructure of the alloy, even though the chemical composition remains unchanged. For heavily corroded sections of the sample, the phase transformation with change in temperature had almost been eliminated. Further into the corroded sample, the ability of the phase transformation to take place had been greatly reduced and the temperatures of the transformation had been lowered. It is also reported^[26] that the microstructure of the alloy can influence its corrosion resistance, and that a greater corrosion

resistance was observed on an alloy with an austenitic phase structure than a martensitic phase structure. Therefore, if corrosion causes a shift in the phase transformation temperature, the phase composition of the alloy at body temperature may change, thereby influencing its corrosion resistance as well as its mechanical properties.

Most of the studies on the corrosion behavior of Ni–Ti alloys have been performed using inorganic electrolytes to represent the *in vivo* or artificial saliva environments. It is well known, however, that proteins in the *in vivo* environment can have a significant influence on the corrosion behavior of implant metals and alloys. It has been suggested that the protein molecules in serum have a strong influence on the passivity of Ni–Ti alloy.^[27] Protein was shown to adsorb onto the oxide surface and cause a decrease in the breakdown potential and an increase in the passive corrosion current density.

Pretreating the surface of NiTi in some oxidizing environments (e.g., dilute HNO₃) can increase the passivity of the surface, resulting in a wider passive region and reducing the likelihood of localized corrosion due to pitting.^[22,24,28] Shabalovskaya^[29] reports on a study of the effect on surface properties of a Ni–Ti alloy of several procedures used for sterilization. This study reports that the pretreatments have a highly significant influence on the composition of the surface oxide, and that the composition of the oxide correlates with the elemental release into cell culture media from these surfaces. In particular, it was found that surfaces exposed to hydrogen peroxide possess a high Ni:Ti ratio in the surface oxide, and consequently a large release of Ni from the surface into the cell culture medium was measured. The oxide film on specimens that had been autoclaved was ten times more effective at preventing Ni release, compared with specimens exposed to hydrogen peroxide. Autoclaving or boiling the specimens in water resulted in very low Ni content in the surface, but high Ni concentration was measured in the water following treatment, indicating that the Ni diffused to the surface and was released under these conditions. When the specimens were initially autoclaved in steam, the Ni concentration in the surface was higher than for those specimens autoclaved in water. (This was assumed to be due to diffusion of Ni to the surface without a medium for it to be released into.) If the samples were steam autoclaved for longer periods, however, the Ni concentration in the surface was reduced. It was suggested that this is due to the tendency of the treatment to increase the thickness of the Ti-oxide layer in preference to Ni-containing oxides.

The corrosion resistance of Ni–Ti alloys can be deliberately influenced by modifying the surface oxide. The effect of electropolishing, heat treatment, and

nitric acid passivation on the surface oxide of a Ni–Ti alloy was examined by Trepanier.^[28] It was demonstrated that the uniformity of the oxide layer was the predominant factor in protecting the NiTi stent from corrosion. Nonuniform oxide layers grown on the plastically deformed surface of mechanically polished specimens were found to be less corrosion-resistant than more homogeneous and uniform surface oxides grown on electropolished specimens. The thickness of the oxide layer was shown to have less influence on the corrosion resistance than the uniformity. In fact, heat-treated specimens tended to have a higher Ni:Ti ratio in the surface oxide (attributed to diffusion of the Ni into the oxide through a defective Ti-oxide layer).

Medical devices have been manufactured from Ni–Ti alloys with considerable success. Two examples are shown in Fig. 4—vascular stents and bone staples. Vascular stents and bone staples take advantage of the shape-memory properties of the alloy. Vascular stents can be cooled and deformed to reduce their diameter, thus allowing them to be introduced into the vascular system via a small-diameter catheter. Once in position, the stent will be released from the inside of a catheter and will warm to body temperature and transform into its austenitic shape. Bone staples are used to increase compressive forces across a fracture, again taking advantage of the shape-memory effect. In its low-temperature condition, the staple is U-shaped. When it is heated, the legs of the staple bend toward each other, pulling the fracture together.

Other devices successfully manufactured from Ni–Ti alloys include orthodontic archwires and springs, which take advantage of the alloy's

Fig. 4 Ni–Ti medical devices. (a) Vascular stent and (b) bone staple.

pseudoelastic behavior to move teeth more effectively. When a stainless steel wire or spring is used to move teeth, high force is initially applied, but as the teeth move in response to the force, the force applied will be reduced. When using a Ni–Ti wire on the other hand, the force applied to the teeth will be maintained over a greater range of stain, allowing lower force to be initially applied and maintained for a longer period, resulting in improved clinical response.

BIOLOGICAL CONSEQUENCES

From the preceding discussion, it is clear that Ni ions can be released into the biological environment from any of the Ni alloys used in medical applications. Although the amount of Ni ions released may be quite low, it is important to consider the biological consequences of Ni²⁺ accumulation in the body. Many studies have been conducted on the biological response to nickel-containing materials.

It is well known that Ni²⁺ can induce a hypersensitivity reaction. It is reported^[35] that Ni²⁺ is the most common contact allergen, with up to 10% of the Caucasian population having a positive skin test to Ni²⁺. The resulting Ni²⁺-induced allergic contact dermatitis is caused by a delayed-type hypersensitivity. When Ni ions are released into the biological environment they are incomplete antigens owing to their small size. However, they bind readily to the peptides and form complexes to become full antigens. The Ni²⁺ associates in a trimolecular complex of MHC II molecules, peptide, and T-cell receptor to induce a specific T-cell response. Ni²⁺-specific T cells express CD4 and CD8 surface molecules and produce T-helper cytokines (Th1:IL-2 and INF- γ or Th2: IL-4 and IL-5). The presence of Ni²⁺-reactive T cells in peripheral blood or the skin of individuals demonstrating a Ni allergy suggests that these cells are effector cells in Ni²⁺-induced contact sensitivity. The route of administration of the Ni ion is important to the body load of the ion. It has been shown that skin administration leads to a greater uptake of the metal ion and a slower excretion rate through the urine than intramuscular administration. The longer retention of Ni²⁺ in the skin therefore leads to a prolonged period for antigen processing and recognition in dermal tissue.

A link has been investigated between the hypersensitivity reaction induced by Ni²⁺ and the restenosis rate following implantation of Ni-alloy stents. Restenosis following stent implantation results from an excessive fibroproliferative and inflammatory response. It is reported^[11] that immunocompetent cells have been detected (particularly around stent struts), suggestive of a local immune and inflammatory response. It was found that all patients with delayed-type

hypersensitivity to Ni required clinical intervention for in-stent restenosis. Corrosion products from 316L stainless steel wires^[36] have been shown to be toxic to primary smooth muscle cells, and the inhibition of cell growth was correlated with the concentration of nickel ions above 11.7 ppm.

It is known that Ni ions are released into the oral cavity when Ni alloys are used in dental applications. They can be absorbed in the gastrointestinal tract, the oral mucosa and skin, or in the respiratory tract.^[7] The resultant hypersensitivity reaction can manifest as an oral contact allergy demonstrated by redness and swelling of the oral tissues, mucosal erosion, and lichenoid reactions. A series of studies on the release of metal ions from dental materials and their effect on various components of the biological response have been reported.^[37–40] They show that metal ions continue to be released for periods up to 10 months, that a longer-term low-level exposure to monocytes of Ni²⁺ alters cells' metabolism and proliferation, that the Ni ion is taken up rapidly by macrophages, and that it accumulates in the nucleus, possibly influencing its function. A further study investigated whether the mechanism of the recruitment of macrophages and lymphocytes following implantation of Ni-based alloys occurs via a change in the expression of CAMs on endothelial cells. It was found that the influence of Ni ions on the expression of ICAM-1 depends on its concentration; at high concentrations ICAM-1 expression may be promoted, and at low concentrations the expression of ICAM-1 on stimulated cells may be suppressed.

Many studies reported in the literature have investigated the potential toxicity of Ni–Ti alloy in either in vitro cell culture or in vivo^[41–46] environments. Attempts have been made to correlate the biological response to the amount of Ni or Ti released from the specimen over a certain period of time. Some studies relate the cytotoxicity of the NiTi to the surface oxide composition.^[28,29] These demonstrate that pretreatment of the surfaces can have a very significant influence on their cytotoxicity. In particular, surface oxides that contain significant amounts of Ni^[29] appear to release it into the biological environment and cause significant cytotoxicity. Careful pretreatment of Ni–Ti alloys using techniques that increase their passivation can increase their biocompatibility.^[47] Trepanier et al.^[47] evaluated the in vitro fibroblast response in terms of proliferation and the in vivo inflammatory response to heat-treated, electropolished, air-aged, and acid-passivated Ni–Ti stents. It was concluded that in general the in vitro response is very similar to the control group and that after longer implantation, the fibrous capsules surrounding the different implants reduce in thickness to a similar low value.

CONCLUSION

Nickel alloys play a significant role in the production of medical devices, although there is concern over the potential release of Ni ions into the body and the consequent adverse biological response to these ions. Optimization of the material properties in terms of their corrosion resistance allows these alloys to be used with minimal release of nickel. Some experimentation in the design of nickel-free austenitic stainless steels^[9] may overcome this problem for fracture fixation devices; careful pretreatment of Ni–Ti devices can stabilize the Ti-oxide surface and minimize Ni release from these alloys.^[33]

Nitric Oxide

Matthew J. Bizzarro
Vineet Bhandari

New Haven, Connecticut, U.S.A.*

INTRODUCTION

The first synthesis of nitric oxide (NO) in the laboratory has been credited to Jan Baptista van Belmont in 1610. In 1772, Joseph Priestly studied some of the molecule's actions and called it "nitrous air." In 1987, NO was discovered to be identical to endothelial-derived relaxing factor (EDRF). The role of NO as a unique signalling molecule in the vascular system is well known. It was also soon appreciated that NO had a diverse range of physiological and pathological actions. From then on, research on NO has been exponential in nature and has expanded our knowledge of this molecule as exemplified by over 50,500 citations in the literature.

SYNTHESIS AND CHEMISTRY OF NITRIC OXIDE

The realization that NO was identical to EDRF^[1-3] has spurred the understanding of the production, release, and effects of NO. L-arginine is the substrate for the three known NO synthases (NOS), which result in the production of L-citrulline and the generation of NO. NOS1 was the first enzyme to be purified and, as a result of its extraction from neural tissue, was dubbed neuronal NOS (nNOS). NOS2, also called inducible NOS (iNOS), is a calcium-independent isoform present in leukocytes. NOS3 is the isoform first derived from endothelial cells—hence endothelial NOS (eNOS). NOS1 and NOS3 are termed constitutive since they are expressed continuously in neurons and endothelial cells, respectively.^[4] Unlike NOS2, NOS1 and NOS3 are dependent on a rise in tissue calcium concentration for activity.^[4] However all the enzymes require nicotinamide adenine dinucleotide phosphate (NADPH), flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), and tetrahydrobiopterin (H₄B) as cofactors.^[5]

Induction of NOS2 results in continuous production of NO because of tight calmodulin binding, which allows electrons to pass from the heme group to the flavin (FMN, FAD) and nicotinamide (NADPH) electron-accepting cofactors.^[4] In contrast, induction of NOS1 and NOS3 results in production of lower, transient concentrations of NO.^[4]

The arrangement of one atom of nitrogen and one of oxygen leaves an unpaired electron, which makes NO a highly reactive free radical.^[4] NO readily reacts with superoxide, oxygen, and thiol groups to produce a number of other products, such as nitrosothiols, peroxynitrite, and nitrites.^[4] The interaction between NO and superoxide ion leads to the generation of peroxynitrite, which is a powerful oxidant. Peroxynitrite is very toxic through nitrosation and/or nitration of amino acids such as tyrosine and cysteine on various proteins.^[6-8] Such modifications alter protein function and disrupt cellular activity.^[6-8] Peroxynitrite is particularly toxic to DNA and enzymes involved in DNA repair.^[9] Comprehensive reviews of NO chemistry, biogenesis, and regulation have been published.^[9,10]

MECHANISM OF ACTION OF NITRIC OXIDE

NO diffuses freely from its site of production to mediate biologic actions in adjacent target tissues and has a half-life in the order of seconds. For example (Fig. 1), NO produced by endothelial cells diffuses into surrounding smooth muscle where it induces relaxation of vascular smooth muscle and vasodilation.^[11] NO also diffuses into the flowing blood and is inactivated by its reaction with the iron-containing heme groups of oxyhemoglobin, which produces methemoglobin and nitrate ions.^[11] Despite this deactivation of NO, enough bioactivity remains to exert control over vascular tone.^[11] The rapid destruction of NO by hemoglobin raises the issue of the molecule having only local effects (paracrine) or the possibility that NO can disseminate throughout the body. If NO acts like the latter, as a hormone, then it could have potential for significant pharmacologic use.^[11]

It has been suggested by some investigators that S-nitrosohemoglobin is a source of bioactive NO.^[12] S-nitrosohemoglobin is formed when NO reacts with the cysteine at position 93 of the beta chain of hemoglobin.^[11] It has been proposed that S-nitrosohemoglobin forms in tissues at high oxygen concentrations, whereas at low oxygen concentrations, it decomposes and releases NO.^[11] However, other investigators have questioned this mode of action.^[13,14]

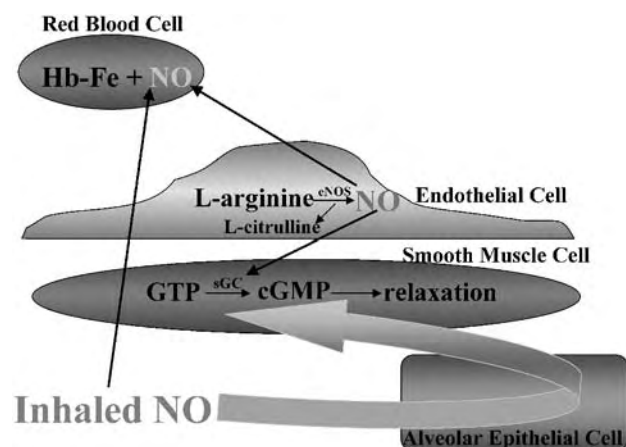

Fig. 1 Synthesis of endogenous NO and its interaction with iNO and pulmonary vascular smooth muscle. This figure depicts the synthesis of endogenous nitric oxide within the vascular endothelial cell. L-arginine and oxygen are converted to nitric oxide (NO) and L-citrulline by the enzyme endothelial nitric oxide synthase (eNOS). NO then diffuses out of the endothelial cell and into the vascular smooth muscle. Here, NO binds with the enzyme soluble guanylate cyclase (sGC) to convert guanosine triphosphate (GTP) to cyclic guanosine 3',5'-monophosphate (cGMP). cGMP is then responsible for mediating relaxation of the smooth muscle. NO can also diffuse out of endothelial cell and into the blood stream, where it can combine with the iron in hemoglobin (Hb-Fe) to form methemoglobin and eventually nitrite and nitrate. The figure also depicts the interaction of iNO with vascular smooth muscle. iNO diffuses through the alveolar epithelial cell and into the smooth muscle cell, where it exerts the same action as endogenous NO. The molecule then diffuses into the blood stream, where it interacts with the red blood cells and is deactivated via the same pathway described previously. The net effect of both exogenous and endogenous NO is vascular smooth muscle relaxation and pulmonary vasodilation.

Other models include the possibility that NO remains active in the plasma longer than previously assumed or it can react with plasma proteins in ways that stabilize and protect it.^[15] Moreover, iron-nitrosyl hemoglobin, nitrite ions, and the erythrocyte membrane are also potential sources of NO under certain conditions.^[11]

The physiologic actions of NO can be divided into two main groups. The first occurs as a result of the molecule's interaction with the heme group in the enzyme guanylate cyclase, which results in the activation and generation of the second messenger cyclic guanosine monophosphate (cGMP). The physiologic effects of this pathway include regulation of vascular tone and neuromodulation of the central nervous system. The second grouping of actions are cGMP-independent.^[4] These play a pivotal role in angiogenesis especially through interactions with vascular endothelial growth factor (VEGF).^[4,16] (Table 1).

Table 1 Effects of endogenous and exogenous nitric oxide

Endogenous NO produced via neurons; neuronal, Type 1 NOS:

Acts as a neurotransmitter through regulation of:

Nonadrenergic, noncholinergic function resulting in reduction of smooth muscle tone in:

- Respiratory tract
- Gastrointestinal tract
- Genitourinary tract

Information storage and memory

Pain perception

Cortical and retinal development

Catecholamine release in the cardiovascular system

Endogenous NO produced via leukocytes; inducible, Type 2 NOS:

Inhibition of neutrophil adhesion and release of inflammatory mediators

Activation of cytokines

Promotion of leukocyte demargination

Promotion of neovascularization

Endogenous NO produced via endothelial cells; endothelial, Type 3 NOS:

Reduction of pulmonary and systemic vascular tone

Inhibition of cellular proliferation

Inhibition of platelet adhesion and activation

As research has uncovered more and more physiologic effects of endogenous NO, clinicians and investigators have sought the discovery and production of an exogenous form to be implemented in the treatment of various disease states. This eventually came in the form of inhaled NO (iNO). This review will highlight the major physiological effects of iNO and focus on its use and potential for use in different disease conditions as well as in the field of biomedical engineering.

PHYSIOLOGIC EFFECTS OF INHALED NITRIC OXIDE

The use of iNO has been implemented in many diverse clinical scenarios. To fully comprehend the therapeutic rationale behind the use of iNO in medicine, its most beneficial physiologic effects must first be reviewed (Table 2).

PULMONARY VASODILATION

Like endogenous NO, exogenous iNO is a potent, but selective, pulmonary vasodilator. Within the endothelial

Table 2 Substantiated and proposed^a effects of exogenous, inhaled NO

Selective pulmonary vasodilation
Bronchodilation ^a
Inhibition of neutrophil aggregation ^a
Inactivation of inflammatory mediators ^a
Increased oxygen affinity of hemoglobin S ^a

cells of the pulmonary vascular bed, NO is synthesized, diffuses into, and reacts with the cells of the vascular smooth muscle, which results in a reduction in muscular tone and a subsequent vasodilation.^[17] Once iNO diffuses out of the pulmonary vascular smooth muscle, it is inactivated and thus cannot exert its effects on the systemic vascular resistance.^[17]

PROTECTION AGAINST CELLULAR TOXICITY

NO may also play a role in preventing cellular damage from oxygen-free radicals and cellular-toxic oxidants.^[18] Although, in high concentrations iNO has been shown to cause cellular damage, some animal models have demonstrated that low-dose iNO may instead protect the lung from injury.^[19] This is mediated through NO's reaction with—and inactivation of—H₂O₂, O₂⁻ and alkyl peroxides, all of which are directly injurious to pulmonary tissue.^[20,21] Local injury can trigger a systemic inflammatory response, which results in further damage to the lung. iNO may diminish the damage by inhibiting neutrophil migration, adhesion, and release of damaging oxidants into the alveoli.^[22,23]

THE USE OF INHALED NITRIC OXIDE IN THE NEONATE

Although iNO has several clinical uses in the treatment of newborn infants, its most significant impact has been made in the treatment of persistent pulmonary hypertension of the newborn (PPHN). PPHN is a life-threatening condition that occurs in about 1 in 1000 live births^[24] and is caused by a sustained increase in pulmonary vascular resistance due to any of a number of diverse etiologic possibilities. Conventional therapies in the treatment of PPHN are aimed at promoting systemic to pulmonary blood flow. Despite these maneuvers, a significant number of infants fail conventional treatment and require the use of extracorporeal membrane oxygenation (ECMO), a procedure with its own associated morbidities.

The discovery of iNO's action as a selective pulmonary vasodilator seemed the perfect therapeutic

intervention for PPHN and fueled several large, randomized controlled trials.^[25–28] The results of these trials revealed that, whereas use of iNO in term neonates with PPHN did not improve their overall rate of survival, it did result in a significant improvement in arterial oxygenation. Its use also effectively reduced the need for ECMO. As a result, the implementation of iNO in newborns with PPHN has become part of standard therapeutic intervention and remains the only FDA-approved application of the inhaled medication to date.

Another area in which iNO therapy plays a significant role is in the treatment of neonatal congenital heart disease (CHD). It is estimated that approximately 0.8 to 1% of all newborns have some form of CHD.^[29] Several forms of CHD may result in cyanosis and hypoxemia in the neonate, which result in a secondary pulmonary hypertension. It would seem logical that iNO would therefore be an effective therapeutic intervention. However, decreasing pulmonary vascular resistance in the setting of CHD associated with poor left ventricular function, i.e., hypoplastic left heart, can have drastic consequences and expedite cardiac failure.^[30] Alternatively, iNO can have beneficial therapeutic effects for patients with right ventricular outflow tract obstruction and severe right to left shunting through the improvement of pulmonary blood flow.^[17,30] Therefore, it is essential that proper anatomic definition of the underlying structural defect be made before implementation of iNO is considered.

When used in the correct setting, iNO can have significant therapeutic benefit to the CHD patient. Cardiac surgery often necessitates the use of cardiopulmonary bypass (CPB). CPB can result in a secondary pulmonary hypertension in the newborn as a result of microemboli, excess thromboxane and endothelin production, platelet aggregation, and hypoxic pulmonary vasoconstriction.^[30] This complication, combined with baseline elevated pulmonary vascular resistance as a result of the underlying cardiac anomaly can result in life-threatening pulmonary hypertensive crises in the postoperative period. iNO may therefore be beneficial in treating this process as described in several randomized controlled trials.^[31–33] In all, the use of postoperative iNO has been shown to facilitate postoperative management and reduce the need for postoperative ECMO such that more patients may be eligible for corrective surgical repair.^[34,35]

In addition to PPHN and CHD, much research has focused recently on the use of iNO in premature infants. In particular, there is some discussion involving the possible role of iNO in the treatment of respiratory distress syndrome (RDS). iNO may enhance pulmonary blood flow and improve the ventilation-perfusion mismatching that is the hallmark of this disease process. Studies on both animal models and premature

neonates have yielded similar results showing significant increases in arterial oxygenation without added morbidity and yet also without significant reduction in mortality.^[36-38] Despite these findings, no current recommendations regarding the use of iNO in premature infants have been made.

THE USE OF INHALED NITRIC OXIDE IN CHILDREN

ARDS, or acute respiratory distress syndrome, is an inflammatory-mediated process triggered by some localized pulmonary or systemic insult. Despite optimal conventional management, the overall mortality rate for ARDS still remains about 30–50%.^[39,40] iNO, as the result of its documented action as a pulmonary vasodilator, its potential as an inhibitor of neutrophil activation and cellular injury, and its possible role in reducing pulmonary edema through decreasing pulmonary capillary pressure and the transvascular movement of albumin,^[41,42] would seem a likely therapeutic agent for use in ARDS. Clinical trials in the pediatric population revealed that, although iNO was somewhat effective in reducing pulmonary arterial pressure and improving oxygenation, there was no significant improvement in overall mortality.^[17,40,43]

The use of iNO in the pediatric population is also seen in the presence of CHD. Its use as a pulmonary vasodilator is utilized in the postoperative period for reasons similar to that described in the neonate.^[31-33] However, in the pediatric population, iNO also plays a significant diagnostic role in evaluating patients as potential surgical candidates.

In children with pulmonary overcirculation, progressive increased pulmonary vascular resistance may result in irreversible pulmonary hypertension.^[17] As a result, these infants may not be candidates for certain corrective surgical procedures.^[30] iNO can be used in the preoperative period to assess pulmonary vasoreactivity and thus separate patients who may benefit from surgery from those in whom surgery would be contraindicated.

There are other proposed clinical uses of iNO in the pediatric population that are still being investigated. One is in association with sickle cell disease (SCD). SCD results in production of defective hemoglobin, termed hemoglobin S (HbS), which has a low affinity for oxygen. It is the resulting deoxygenation of HbS that causes the erythrocyte to take on an abnormal shape, which results in hemolysis and vasoocclusion. iNO has been investigated as a potential therapy in SCD based on data that has shown that iNO may increase the oxygen affinity of HbS and thus decrease the potential for SCD crises.^[44]

Another area of particular interest in the neonatal and pediatric populations is the use of iNO in patients with septic shock. Animal studies have yielded data that supports the use of iNO in this scenario through its actions in limiting the effects of leukocyte sequestration and subsequent inflammation in addition to inhibiting platelet-activating factor induced septic shock.^[45-47] Alternatively, results of a prospective study in 15 neonates and infants being treated with iNO showed that the use of iNO decreased neutrophil production of superoxide anion, a substance necessary for host defense against microorganisms.^[48] Therefore, iNO may put the pediatric patient with an already compromised immune system at an increased risk for developing infection. As a result of this conflicting data, no recommendations have been made for or against the use of iNO in patients with or at risk for sepsis.

THE USE OF INHALED NITRIC OXIDE IN ADULTS

ARDS is a disease process that also affects adults. One large multicenter trial enrolled and randomized 177 patients to receive either placebo or iNO. Patients in the iNO group, as a whole, achieved significant improvement in arterial oxygen saturations and achieved lower mean pulmonary arterial pressures as compared with the placebo group. However, no significant difference in mortality was seen.^[39]

iNO also plays a role in adults in management of patients undergoing cardiac surgery. Like in children, adults often experience a transient increase in pulmonary arterial pressure believed secondary to damage induced by CPB.^[18] iNO has been shown to significantly reduce pulmonary vascular tone in this setting and decrease the need for ECMO.^[49] iNO may also play a role in reducing pulmonary arterial pressure in patients with long-standing left atrial pressure from valvular disease.^[18]

iNO has been implemented in the adult population in an attempt to treat asthma and COPD. It is believed that endogenous NO also plays a role as a neurotransmitter in controlling smooth muscle tone in the bronchial airways.^[50] Some animal models revealed that iNO may act as an effective bronchodilator, comparable to β_2 -agonists, in bronchospastic disease.^[51] However, when used in humans, the results were less encouraging. In fact, iNO (80 ppm) appeared to have no bronchodilatory effect on patients with COPD and only a minimal effect on relaxation of airway smooth muscle in patients with asthma.^[52] However, it is believed that higher doses of iNO may play some role in bronchodilation, but the data is currently unavailable.^[53]

THE USE OF NO IN BIOMEDICAL ENGINEERING

In addition to its use in clinical medicine, the use of NO has been extensively investigated and implemented in the field of biomedical engineering. NO-generated biomaterials and NO-modified tissue production have utilized the action of the molecule as an inhibitor of platelet-activating factor and inflammation to prevent operative and postoperative complications.

USE OF NO GAS INFUSION

ECMO procedures have been shown to induce complement and leukocyte activation and release of endotoxin, inflammatory mediators, and platelet-activating factors. Heparin-coated bypass circuits have been implemented in an attempt to improve the biocompatibility of ECMO.^[54,55] In an in-vitro system to study the effect of NO on platelet deposition on biomaterials, gaseous NO was delivered via a semi-permeable membrane to a radio-labeled platelet suspension.^[56] Platelet inhibition was essentially complete at 0.1 ppm gaseous NO exposure.^[56] NO gas infusion to the oxygenator circuit enhanced the biocompatibility of heparin-coated ECMO circuits.^[55] In a study comparing the effects of heparin-coated bypass circuit and NO gas infusion, NO (100 ppm) was equivalent to the heparin-coated circuit for attenuating bypass-induced blood activation, and a combination of the two significantly surpassed the results of either modification alone.^[57]

USE OF NO-GENERATING BIOMATERIALS

The success of many intravascular medical devices has depended on favorable biocompatibility of the blood-contacting surfaces of such implants.^[58] A great deal of research has been devoted to developing polymeric materials with improved thromboresistance.^[58] As mentioned above, NO is useful in prevention of platelet adhesion and activation. Thus, one attractive option would be the use of slow NO-releasing hydrophobic polymer materials.^[58] Different approaches to preparing polyurethane and polyvinyl chloride polymer films containing NO-releasing diazeniumdiolate have been described.^[58] These films release NO for variable periods (10–72 hours) and differ in the mechanism, location, and amount of NO released.^[58] In one study, use of the NO-releasing diazeniumdiolate, spermine/NO, produced a marked localized inhibition of neointimal proliferation in balloon-injured arteries in a rat model.^[59] In contrast, tantalum wire coil coronary stents coated with polycaprolactone impregnated with the diethylenetriamine adduct of

nitric oxide, (Z)-1-[N-(2-aminoethyl)-N-(2-aminoethyl)amino]diazene-1-ium-1,2-diolate did not prevent restenosis in a pig balloon injury model.^[60] The investigators speculated that these findings could have been due to a lack of efficacy of NO or a profuse and overwhelming stimulatory effect of the polymer in the coated stents.^[60] However, incorporation of the NO-releasing polymer [NO donor, (Z)-1-[N-Methyl-N-[6-(N-methylammoniohexyl)amino]]diazene-1-ium-1,2-diolate (MAHMA/N₂O₂)] coated onto the inner surface of ECMO circuits reduced platelet consumption and eliminated the need for systemic heparinization in a rabbit model.^[61]

Another approach utilized three NO donors with different half-lives by covalent incorporation into photopolymerized polyethylene glycol hydrogels.^[62] Under physiological conditions, NO was produced by these hydrogels over periods ranging from hours to months, depending upon the polymer formulation.^[62] NO production was inhibited at acidic pH, which may be useful for storage of these materials.^[62] The NO releasing materials successfully inhibited smooth muscle cell proliferation in culture and prevented platelet adhesion to collagen-coated surfaces.^[62]

NO-releasing silicone rubbers have been developed that have been shown to exhibit improved thromboresistance in vivo in an ECMO circuit in a rabbit model.^[63] Use of amperometric, oxygen-sensing catheters coated with such NO-releasing silicone rubber polymer (DACA/N₂O₂ SR) in vivo (in a swine model) have shown to have accurate measurements of pO₂ levels with the sensors exhibiting no significant platelet adhesion or thrombus formation.^[64] In comparison, non-NO-coated sensors had a high propensity for cell adhesion and bulk clot formation.^[64]

Other investigators have utilized L-arginine by immobilizing it into a supramolecular-structured polyrotaxane.^[65] L-arginine-immobilized polyrotaxane exhibited sustained NO-generation for a period of 250 hours.^[65] Consequently, after the generation of NO and the release of L-arginine from the L-arginine-immobilized polyrotaxane, the residual component would be a polyrotaxane with superior biocompatibility and mechanical properties.^[65]

USE OF NO-GENERATING TISSUE VIA BIOMEDICAL ENGINEERING

The seeding of the blood-contacting surfaces of cardiovascular prostheses with autologous endothelial cells to improve their biocompatibility had little success as the cells subsequently sloughed off under high-flow conditions. On the other hand, left ventricular assist devices (LVADs) have shown some efficacy. Use of genetically engineered smooth muscle

cells (GE-SMC) transduced with NOS3 gene have resulted in viable cells that produce NO at concentrations that reduce platelet deposition and SMC proliferation when tested in vitro.^[66,67] An in-vitro circulatory loop was designed to expose cell-lined LVADs to in-vivo operating conditions.^[67] Cumulative cell loss was less than 10% after 24 hours of flow, and, based on these results, the first implantation of an LVAD containing GE-SMC lining was successfully implemented in a bovine model.^[67]

Using adenoviral vectors, gene transfer of NOS3 has been achieved.^[68-70] Using a different (nonviral) approach, local intramural delivery of NOS2 lipoplexes have been shown to exert therapeutic effects in inhibiting stent-induced neointimal lesion formation.^[71] Other potential uses include that of a hybrid artificial lung with interleukin-10 and NOS3 gene-transfected endothelial cells inhibiting interleukin-8 release and increased NO production,^[72] NOS3 gene transfection of saphenous vein grafts with naked DNA or liposomal vector,^[73] and cell-based NOS3 gene transfer to pulmonary artery SMCs to combat pulmonary hypertension.^[74] NOS gene transfer has also shown promise as a potential treatment of erectile dysfunction.^[75-77]

CONCLUSION

Endogenous NO has many physiologic effects on various organ systems in the human body. As a result, investigators have sought to develop and incorporate the medical implementation of exogenous NO in the newborn, pediatric, and adult populations. iNO has been sought as one such therapy due to its selective effect on reducing pulmonary arterial pressure. To date, however, FDA-approved use of inhaled nitric oxide remains limited to PPHN despite some data to support its potential use in other clinical scenarios. Further research is needed though in the form of large, randomized controlled trials to evaluate its efficacy in these and other, possibly yet undiscovered, areas of medicine.

In biomedical engineering, the usefulness of NO gas in inhibition of platelet activation and inflammation in ECMO circuits has sparked the development of NO-generating biomaterials to improve the biocompatibility of intravascular devices. Another active area of research is in the use of NOS gene transfer via different mechanisms to endothelial cells and/or SMCs to achieve the same purpose. The potential for using the NOS gene transfer approach in certain cardiovascular diseases and erectile dysfunction is actively being pursued.

It is evident that discovery of the physiologic actions of endogenous NO has initiated extensive research in

an attempt to apply this physiology to the treatment of disease processes. Modification and utilization of endogenous and exogenous NO has resulted in a great deal of progress both in clinical medicine and biomedical engineering. While more information to the potential uses of NO is being uncovered, we eagerly await the possibility of further therapeutic implementations.

Nuclear Magnetic Resonance Spectroscopy

Mari A. Smith
Peter B. Barker

Department of Radiology, Johns Hopkins University School of Medicine, Baltimore, Maryland, U.S.A.

INTRODUCTION

Nuclear magnetic resonance (NMR) spectroscopy is based upon the measurement of the absorption of electromagnetic radiation in the radiofrequency region by atomic nuclei. For absorption to occur, the degeneracy of the nuclei's energy states is removed by placement in an intense magnetic field.

HISTORICAL PERSPECTIVES

The concept of NMR spectroscopy was first postulated in 1924 by W. Pauli's suggestion that exposure to a magnetic field would cause the energy levels of atomic nuclei possessing spin and angular momentum properties to separate.^[1] However, experimental verification of the absorption of electromagnetic radiation in bulk matter by nuclei did not occur until 1946, when both F. Bloch and E. Purcell independently demonstrated that a strong magnetic field induced splitting of the energy levels, and thus they detected the resonance phenomena.^[2,3] The method was originally of interest only to physicists for the measurement of gyromagnetic ratios (γ) of different nuclei, a constant specific to a particular nucleus, but applications of NMR to chemistry became apparent after the discovery of chemical shift and spin-spin coupling effects in 1950 and 1951, respectively.^[4,5] The spectra of high-resolution liquid NMR contain fine structure information because the absorption frequency (nuclear resonance) is influenced by neighboring nuclei and the chemical environment; hence NMR spectroscopy has rapidly become an important and widely used technique for chemical analysis and structure elucidation of chemical and biological compounds.

Major technical advances in the 1960s included the introduction of superconducting magnets in 1965, which were very stable and allowed higher field strengths to be attained than was possible with conventional electromagnets; and the use of the Fourier transform (FT) in 1966 for signal processing. In nearly all contemporary spectrometers, the sample is subjected to periodic radiofrequency pulses directed perpendicularly to the external field; the signal is

Fourier transformed to give a spectrum in the frequency domain. FT NMR provides increased sensitivity compared to previous techniques, and has led to the development of a huge variety of pulsed NMR methods, including multidimensional NMR techniques.

Biological and medical applications of magnetic resonance were developed in the early 1970s with the introduction of magnetic resonance imaging (MRI) and magnetic resonance spectroscopy (MRS) of biological tissue. In vivo MRS of humans became possible in the early 1980s with the advent of whole body magnets with sufficiently high field strength and homogeneity.^[6] Magnetic resonance imaging studies in humans are based on the proton resonances of tissue water, in which the water content and the water relaxation times T_1 and T_2 are used to generate tissue contrast. T_1 and T_2 are the longitudinal and transverse lifetimes and describe the decay of the parallel and perpendicular components of magnetization, respectively, relative to the static magnetic Zeeman field. In addition to anatomical imaging, there has been a recent surge of interest in functional imaging in which dynamic properties such as water diffusion, brain-blood flow and blood volume, oxygenation, and macromolecule-water proton interactions can be used as image contrast.^[7,8] Although clinical applications of MRI were immediately apparent because of its anatomical imaging capabilities, MRS has until recently been predominantly a tool for biomedical research. For example, in vivo MRS and MR spectroscopic imaging (MRSI) of the brain is used to measure equilibrium levels of brain metabolites and to study active brain transport and metabolism. Early MRS studies predominantly used the phosphorus-31 (^{31}P) nucleus, but more recently the proton (^1H) nucleus, which is the most sensitive and fully abundant naturally occurring nucleus, has been used more extensively, particularly for studies of the brain.

BASIC THEORY

The NMR experiment involves the observation of transitions between nuclear spin states that are

perturbed by a Zeeman interaction with an external magnetic field. If the magnetic field is described by B_0 , then the energy of the nuclear spin state is given by

$$E = -\mu \cdot B_0 \quad (1)$$

where μ is the nuclear magnetic moment. The magnetic moment is related to the spin angular momentum P by the gyromagnetic ratio γ ,

$$\mu = \gamma P = \gamma(I\hbar/2\pi) \quad (2)$$

where γ is a characteristic constant for each nucleus, I is the spin quantum number, and \hbar is Planck's constant. By definition, the direction of B_0 is taken to specify the Z axis, so Eq. 1 reduces to

$$E = -\mu_z B_0 \quad (3)$$

where μ_z is the component of μ along the Z axis. For a nucleus with spin quantum number I , there are $(2I + 1)$ different possible orientations of μ in the field, each with a component m_I in the Z direction. For example, for a spin $1/2$ nucleus ($I = 1/2$), m_I can take the values $+1/2$ and $-1/2$ (Fig. 1).

Applying the magnetic dipole-allowed selection rule $\Delta m_I = \pm 1$, the resonance frequency is given by

$$\nu_0 = \Delta E/\hbar = \gamma h B_0 / (2\pi\hbar) = \gamma B_0 / 2\pi \quad (4)$$

which can be expressed in angular frequency units as

$$\omega_0 = \gamma B_0 \quad (5)$$

ω_0 is called the Larmor frequency. With typical magnetic field strengths currently available (≈ 0.2 to 20 Tesla), most magnetic nuclei resonate in the high-frequency to very-high-frequency regions of the electromagnetic spectrum (10 to 900 MHz for the proton). Systems for human spectroscopy studies typically

Fig. 1 Energy levels for a nucleus with spin quantum number $I = \pm 1/2$. In the absence of an externally applied field, B_0 , the two energy levels are degenerate. Nuclei with spin $1/2$ have two energy levels corresponding to the two discrete values of I . The spin with $I = +1/2$ is aligned with the external magnetic field and thus is lower in energy.

operate between 0.5 to 4.0 Tesla (1.5 T being the most common); smaller horizontal-bore systems for animal studies are available up to about 9 Tesla (384 MHz). Vertical small-bore superconducting magnet systems for high-resolution NMR spectroscopy are commercially available to over 20 Tesla (900 MHz).

Signal and Signal-to-Noise Ratio

In NMR, the difference between energy levels is very small; hence it is an intrinsically insensitive technique. The excess population of the lower level compared to the upper level can be calculated from the Boltzmann factor

$$\frac{n(\text{upper})}{n(\text{lower})} = \exp(-\Delta E/kT) \quad (6)$$

where k is the Boltzmann constant and T is the absolute temperature (for protons at room temperature at 100 MHz, $n(\text{upper})/n(\text{lower}) \approx 0.999984$). The excess population of the lower level creates the macroscopic nuclear magnetization that is observed in the NMR experiment. The net nuclear magnetization M_0 is given by

$$M_0 = NB_0\gamma^2\hbar^2I(I+1)/3kT \quad (7)$$

where N is the total number of spins in the sample and \hbar is Planck's constant divided by 2π . The signal (S) detected in the receiver coil is proportional to the magnetization times the resonant frequency

$$S \propto M_0\omega_0 \quad (8)$$

giving a final dependence of the signal on B_0^2 for a given nucleus (γ fixed) or alternatively a γ^3 dependence for different nuclei at a fixed B_0 . In a typical experiment, the NMR signal induced in the receiver coil is of the order of a few microvolts. For nonconducting samples, the noise in the system is predominantly from the random (thermal) motion of electrons in the receiver coil (Johnson noise). The noise power is independent of frequency; however, the noise voltage increases with approximately the square root of frequency, because the resistance of the coil increases with frequency (the skin depth effect). Therefore, for a given nucleus, the signal-to-noise ratio increases as $B_0^{3/2}$, whereas for a given field strength the S/N ratio increases as $\gamma^{5/2}$. For instance, the ratio of γ for proton and carbon-13 is about 4:1; therefore, the S/N ratio is 32 times greater on ^1H than on ^{13}C for equal numbers of nuclei. For biological samples, the noise is often dominated by the sample's resistance, which increases linearly with frequency. In this case, the S/N is only linearly proportional to B_0 for fixed γ , or to γ^2 for fixed B_0 .

Fig. 2 Typical ^1H chemical shift range (10 ppm) for various functional groups. The resonances of water and the standard reference compound TMS are shown at 4.7 and 0.0 ppm, respectively.

THE NMR SPECTRUM

The Chemical Shift

Early in the development of NMR, it was discovered that nuclei in different molecular environments resonate at slightly different frequencies.^[4] The origin of this effect lies in the response of the molecule's electrons to the applied magnetic field; in simple terms, a rotating current is induced that generates a small magnetic field that opposes the external field (a diamagnetic effect). Hence, the nucleus experiences a smaller net field than that which is actually applied. The effective field at the nucleus, B , can be expressed in terms of a shielding parameter, σ ,

$$B = B_0(1 - \sigma) \quad (9)$$

so that the nuclear resonance frequency becomes

$$\nu = \gamma B / 2\pi = \nu_0(1 - \sigma) \quad (10)$$

This effect is known as the chemical shift; it is of prime importance because nuclei in different chemical environments can be distinguished on the basis of their resonant frequencies. The shielding parameter is usually defined in parts per million (ppm) of the resonance frequency measured relative to a reference compound. Although the shielding parameter is a constant, the chemical shift (measured in Hz) increases linearly with field strength (Eq. 7). Thus the resolution of the NMR spectrum increases linearly with increasing field strength. To compare chemical shifts measured at different field strengths, it is standard to report chemical shift values (δ) in ppm relative to a standard reference compound; for ^1H and ^{13}C spectra (in vitro), tetramethylsilane (TMS) is often used as the reference,

$$\delta = (\nu - \nu_{\text{TMS}}) * 10^6 / \nu_{\text{TMS}} \quad (11)$$

where ν and ν_{TMS} are the frequencies of the signal of interest and the reference signal, respectively. Figure 2 illustrates the typical ^1H chemical shift range for various functional groups. Whereas the typical

chemical shift range for ^1H is quite small (≈ 10 ppm), much larger chemical shift ranges (e.g., up to several 100 ppm) exist for ^{19}F , ^{31}P , ^{13}C , and ^{15}N .

Spin-Spin Couplings

In addition to chemical shift effects, it was discovered that spectra from liquid samples exhibit further fine structure in the forms of splittings (or multiplets).^[5] These arise from the electron-coupled spin-spin interaction, also known as J- or scalar-coupling. Spin-spin coupling results from nuclei experiencing the magnetic fields of their neighboring nuclei through polarization of the electrons in the molecular bonds between them. The effective magnetic field experienced by one nucleus depends on the spin state of a neighboring coupled nucleus. The nomenclature to describe spin systems assigns letters to each individual spin, which are close together in the alphabet if the spins are strongly coupled or far from one another in the alphabet if the spins are weakly coupled ($|\delta_A - \delta_X| \gg J_{AX}$). The simplest multiplet pattern that can be observed is in a two-spin AX system (Fig. 3).

Spin-spin couplings have the following properties:

1. They act through the bonding electrons and are therefore intramolecular.

Fig. 3 Multiplet pattern of a weakly coupled two-spin (AX) system. The splitting is equal to J_{AX} . σ represents the shielding constant of the A or X spin. The arrows indicate alignment with (↓) or against (↑) the static magnetic field.

2. They are independent of the strength of the applied magnetic field.
3. Spin multiplet structure reflects the states of neighbor nuclei.
4. The interaction is reciprocal; if A splits X, then X splits A.
5. Splitting cannot be observed due to coupling between equivalent nuclei.
6. Coupling can be homonuclear or heteronuclear.

Typical coupling patterns

For spins that have widely different chemical shifts, the multiplet pattern is symmetrical around the chemical shift frequency, with relative intensities given by the binomial coefficients $(1+x)^N$ for $I=1/2$ nuclei.

Strong coupling

The simple treatment of multiplet patterns is valid only if $|\delta_A - \delta_X| \gg J_{AX}$, which is known as the weak coupling, or first-order approximation. When this is not true, the spectra are strongly-coupled or second-order, the symmetry of the multiplet is destroyed, and the splittings are no longer equal to the coupling constant. New lines may appear (combination lines), and lines are no longer assignable to a single nucleus. In general, the spectrum can be assigned only through the use of computer simulation, although some simple spin-coupling features may remain that can be assigned by factoring the spin system into subsystems and introducing an additional spin to calculate how it affects the subsystem (the X approximation).^[9,10] This is justified as long as the new spin is only weakly coupled to the spins under consideration.

Coupling with $I > 1/2$ nuclei

Nuclei with $I > 1/2$ produce more complicated multiplet patterns. The deuterium nucleus ($I=1$) produces a triplet in neighboring atoms with an intensity ratio 1:1:1, corresponding to $m_I = -1, 0,$ and $+1$, respectively. However, some quadrupolar nuclei relax too rapidly to generate observable splittings. It should also be noted that spin-spin splitting can be modified or eliminated by chemical exchange or double resonance experiments (decoupling).

PULSED FOURIER TRANSFORM (FT) SPECTROSCOPY

The production of transverse magnetization through perturbation by radiofrequency (RF) pulses is required

to record a spectrum. In an FT NMR experiment,^[11] an RF pulse is applied and the receiver is then turned on to record the time varying signal (free induction decay, or FID) from the resulting magnetization as it precesses in a static magnetic field B_0 . The signal from the entire spectrum is collected in a single scan (provided the RF pulse has sufficient bandwidth, i.e., it is a hard pulse). Therefore, FT NMR has an enormous sensitivity advantage over continuous wave (CW) NMR where each resonance is observed in turn. The signal-to-noise ratio can be improved through time-averaging, i.e., signals are digitized and summed in a computer memory; the signal S (which is coherent) accumulates linearly ($S \propto n$, where n is the number of scans), whereas the noise \sqrt{N} (which is incoherent) accumulates in memory as n ; therefore the signal-to-noise ratio S/N improves as a function of \sqrt{n} .

The Fourier Transform

The FID consists of the summation of all of the resonant frequencies in the spectrum:

$$f(t) = \sum_{j=1}^k \exp(i\Omega_j t) \exp(-\lambda_j t) \quad (12)$$

Ω_j and λ_j are the resonant frequencies and decay rates, respectively, of the j th out of k resonances in the spectrum. In a perfectly uniform (homogeneous) magnetic field, λ is the inverse of the T_2 relaxation time ($\lambda = 1/T_2$). In an inhomogeneous magnetic field, the rate of decay of the magnetization is faster because of destructive interference of the signals precessing at different frequencies, and the time constant is called T_2^* ("tee-two-star," $\lambda = 1/T_2^*$). The spectrum is calculated from the FID by Fourier transformation:

$$f(\omega) = \text{F.T.}[f(t)] = \int_{-\infty}^{+\infty} \exp(-i\omega t) f(t) dt \quad (13)$$

Substituting Eq. 12 into Eq. 13 and evaluating the integral gives (for the case of a single resonance, $k=1$)

$$\begin{aligned} f(\omega) &= \frac{\lambda}{\lambda^2 + (\Omega - \omega)^2} + \frac{i(\Omega - \omega)}{\lambda^2 + (\Omega - \omega)^2} \\ &= A(\omega) + iD(\omega) \end{aligned} \quad (14)$$

$A(\omega)$ and $D(\omega)$ are Lorentzian functions. The real part of this expression is called the "absorption" lineshape (A); the imaginary part is called the "dispersion" lineshape (D) (see Fig. 4). The absorption lineshape is the preferred lineshape for spectral display because it has no negative intensity and tails off more rapidly than the dispersion mode. In practice, the continuous

Fig. 4 Real (absorptive) and imaginary (dispersive) components of the complex frequency domain NMR spectrum obtained by Fourier transformation of the FID.

time domain signal $f(t)$ is sampled discretely on an equidistant set of time points, Δt , within the Nyquist frequency, the maximum frequency for a given t ,

$$f_n = \frac{1}{2\Delta t} \quad (15)$$

Therefore, the frequency spectrum is conventionally generated from a finite discrete Fourier transformation (DFT) of the time domain signal. The DFT closely approximates the continuous FT.

SIMPLE PULSED NMR EXPERIMENTS: THE ROTATING FRAME

The theoretical description of NMR experiments can be done at various different levels of complexity. Although spin angular momentum is inherently a quantum-mechanical effect, the classical (vector) description of the interaction between the net macroscopic nuclear magnetization and the applied magnetic fields is the simplest to understand and most widely used. For NMR experiments on weakly coupled spin systems, the product operator formalism is often used,^[12] but for strongly coupled spin systems a full quantum-mechanical density matrix approach is required.^[13]

For most experiments in MRI and localized spectroscopy, the classical vector approach is sufficient. Visualization of the motion of the magnetization vector during a pulse sequence is most easily appreciated in the rotating frame of reference, a coordinate system that rotates about the Z axis at the Larmor frequency. In this frame, the precessional frequency of the spins around B_0 and the oscillations of the B_1 field are both removed, so the only effective field during an RF pulse is the (now static) B_1 field, taken to define the X axis (Fig. 5A). If the initial magnetization is aligned along the Z axis, application of the B_1 field causes a rotation of the magnetization around the X axis with an angular frequency $\omega_1 = \gamma B_1$. Therefore, if the RF pulse is applied for a period τ , the flip angle α (in radians) is given by

$$\alpha = \gamma B_1 \tau \quad (16)$$

Because the NMR spectrometer detects signal in the transverse plane, maximum signal is excited (on a single scan, ignoring relaxation) when $\alpha = \pi/2$ (i.e., a 90° pulse) (Fig. 5A). In general, it is not possible for all spins to be exactly on-resonance at the same time in the rotating frame because of the inherent frequency distribution in the spectrum. Therefore, during an RF pulse, spins that are off-resonance precess around an effective field in the rotating frame that has both a Z component ($= (\omega - \omega_0)/\gamma$, where ω is the frequency of the spin and ω_0 is the frequency of the rotating frame) and an X component (γB_1) (Fig. 5B). As the spins become farther off-resonance, the effective field becomes progressively larger and tilted toward the Z axis; once the field is tilted more than 45° , it is impossible to rotate the magnetization fully into the transverse plane using simple radiofrequency pulses. Selective excitation and slice-selective processes are based on the use of this off-resonance effect.

Measurement of T_1 Relaxation Times

Progressive saturation—optimization of sensitivity

The simplest pulsed NMR experiment uses a single RF pulse followed by detection of the FID (Fig. 6A). When a pulse-and-collect NMR experiment is repeated several (n) times to improve S/N, the longitudinal magnetization reaches a steady state after a few repetitions. The steady-state magnetization depends on the flip angle used (α) and the spin-lattice (T_1) relaxation time, whose inverse describes the rate at which longitudinal magnetization recovers after it has been displaced from equilibrium by an RF pulse. For a 90° pulse ($\alpha = \pi/2$), the steady-state signal is given by

$$S(TR) = S_0(1 - \exp(-TR/T_1)) \quad (17)$$

Fig. 5 (A) Effect of an applied RF field, B_1 , on initial magnetization, M_0 , in the rotating reference frame. The application of a 90° pulse with phase x creates transverse magnetization, shown here to be aligned along the Y axis; (B) orientation of the effective field, B_{eff} , experienced by spins that are off-resonance.

Fig. 6 (A) The simplest pulsed experiment consists of a single RF pulse of flip angle, α , followed by detection of the FID, and can be repeated n times to improve the signal-to-noise ratio. For a 90° pulse ($\alpha=90$) with a repetition time (TR) of zero, the detected signal will also equal zero, indicating that the spins are saturated; (B) diagram of the inversion recovery experiment that can be used to determine the T_1 relaxation time by varying the delay, τ , provided the recovery delay, RD, is $\sim 5 > T_1$.

where TR is the repetition time of the experiment. In the limit $TR=0$, the signal will also be zero (the spins are saturated). In a progressive saturation experiment, T_1 can be calculated by recording the signal as a function of several different TR values. At any given TR, there will be an optimum flip angle for maximum signal known as the Ernst angle:

$$\cos \alpha = \exp(-TR/T_1) \quad (18)$$

Inversion recovery

One of the earliest pulsed FT NMR experiments was the inversion recovery experiment, which can also be used to measure T_1 relaxation times. Inversion recovery consists of a 180° pulse to invert the Z magnetization, a delay (τ) during which T_1 relaxation occurs, and a 90° read pulse to detect the NMR signal (Fig. 6B). The experiment is repeated with several different values of τ ; the T_1 relaxation time can be obtained from fitting the detected signal to the expression

$$S(\tau) = S_0(1 - 2 \exp(-\tau/T_1)) \quad (19)$$

The repetition delay RD between experiments must be sufficiently long to allow complete recovery of Z magnetization before the next pulse is applied (typically, $RD > 5T_1$).

Spin Echoes: Measurement of T_2 Relaxation Times

The rate of decay of transverse magnetization is described by the T_2 , or spin-spin, relaxation time constant. In addition to true T_2 relaxation, transverse magnetization is also dephased as a result of B_0 magnetic field inhomogeneities. The effects of field inhomogeneity can be reversed by applying a 180° refocusing pulse that generates a spin echo, a reappearance of the signal a finite time after disappearance of the initial FID^[14] (Fig. 7).

The amplitude of the spin-echo signal is given by

$$S(TE) = S_0 \exp(-TE/T_2) \quad (20)$$

T_2 can be calculated by recording the signal as a function of the echo time TE. If the 180° pulse is imperfect, or if spins diffuse into different regions of magnetic field strength before and after the 180° , echo rephasing will be imperfect, leading to a reduction in signal intensity and an underestimate of the T_2 relaxation time. These problems can be partially overcome by using multiple 180° pulses (the Carr-Purcell Method B^[15]) with appropriate phase-shifted 180° pulses (the Carr-Purcell-Meiboom-Gill (CPMG) method^[16]) (Fig. 8A).

Pulses of flip angle other than 180° can produce echoes (Hahn's original spin-echo paper was based on the 90° - 90° sequence^[14]), and if more than two pulses are

Fig. 7 Illustration of a spin echo. After application of a 90° pulse with x phase, the magnetization is aligned along the Y axis. Immediately prior to application of the 180° pulse the magnetization has experienced a delay ($TE/2$) that causes the magnetization to dephase. Application of the 180° pulse causes the magnetization to be flipped 180° , and after an equivalent delay ($TE/2$), the magnetization will refocus along the Y axis as a spin echo, represented by the shaded diamond icon.

Fig. 8 (A) Carr-Purcell-Meiboom-Gill (CPMG) method. Multiple 180° pulses are employed to counteract imperfect 180° pulses—those that cannot flip all spins within a desired bandwidth, and/or spin diffusion to produce an echo of the signal; (B) similarly, a (third) stimulated signal echo can be observed at a time $TE/2$ after the application of the third 90° pulse in a train of three 90° pulses.

applied, more than one echo can be observed. In particular, for a train of three 90° pulses, a third stimulated echo can be observed at a time $TE/2$ after the third pulse (Fig. 8B). Spin and stimulated echoes are used extensively both in MRI imaging and in localized NMR spectroscopy.

MAGNETIC NUCLEI OFTEN USED FOR BIOLOGICAL STUDIES

Many elements have isotopes with nonzero nuclear spin. However, to generate a strong high-resolution NMR signal, the following factors are required: 1) spin $1/2$ (or small quadrupole moment if $I > 1/2$); 2) large chemical shift range; 3) high γ ; and 4) high natural abundance (unless isotopic enrichment is used). ^1H and ^{31}P best fulfill these criteria for studies of biological tissue.

An example ^{31}P spectrum from the human brain is shown in Fig. 9. In vivo, the phosphocreatine resonance is often used as a chemical shift reference (set to zero ppm). The ATP resonances exhibit homonuclear ^{31}P spin-spin couplings ($J \approx 20$ Hz); the

β -ATP is a triplet because it is coupled to both the α and the γ spins, whereas the α and γ resonances are doublets because they are coupled only to the β nucleus.

Generally, magnetic resonance studies are associated with anatomical imaging generated from the tissue contrast due to water content and relaxation times T_1 and T_2 (see Fig. 10). Imaging, however, is a relatively recent application of nuclear magnetic resonance spectroscopy. NMR spectroscopy is routinely used in the analysis of liquid and solid state materials. For example, solid state nuclear magnetic resonance (SSNMR) and imaging have been used to study both natural and synthetic biomaterials such as bone mineral, calcification (atherosclerosis), and polymer, ceramic, and composite implants.^[17,18] SSNMR is useful for structural studies of molecules that cannot be easily crystallized or dissolved, including surface-adsorbed biopolymers and membrane-associated proteins, and for large and complex molecules such as proteins and ribonucleic acids (RNA).^[19,20] SSNMR defines molecular structure through the measurement of internuclear distances and torsion angles. Structural measurements

are accomplished through the application of magic angle sample spinning to remove anisotropic magnetic interactions, in conjunction with a pulse sequence that selectively recouples the dipolar interaction, from which direct structural information can be obtained.

FUNDAMENTALS OF HUMAN (BRAIN) SPECTROSCOPY

In vivo MR spectroscopy is possible in many human organ systems and with many nuclei: ³¹P spectroscopy of muscle metabolism, ¹³C spectroscopy of the brain and liver, and ¹H spectroscopy of the brain, breast,^[67] and prostate^[21] are a few examples. Early studies focused on the phosphorus nucleus, because this was the most technically feasible at that time. Methods were developed for spatially localized ³¹P MRS,^[22] and studies of major neuropathologies (such as stroke or brain tumors) were performed.^[23–25] A significant problem with ³¹P MRS, however, is its low sensitivity, mainly because of the relatively low γ of ³¹P and low concentrations of phosphorus-containing compounds. Because the spatial resolution in in vivo spectroscopy is largely limited by the signal-to-noise ratio, the typical voxel size for ³¹P spectroscopy of the human brain is usually at least 30 cm³ using conventional techniques and 1.5 Tesla magnets. ³¹P spectroscopy can therefore usually be applied only to either very large lesions or diffuse and/or global diseases.

In recent years, there has been more interest in ¹H spectroscopy, particularly after it was demonstrated that it was possible to obtain high-resolution spectra from small well-defined regions in reasonably

short scan times.^[26] The higher sensitivity of the ¹H is due to several factors, including higher γ , higher metabolite concentrations, and more favorable relaxation times compared to ³¹P or other nuclei. Also, because the same nucleus is measured as in MRI, no additional hardware is required. Although ¹H spectroscopy has been demonstrated in a number of organ systems, the overwhelming number of applications have been in the brain because of the absence of free lipid signals in normal cerebrum, ease of shimming, and lack of motion artifacts. Human brain pathology has now been extensively studied by ¹H spectroscopy.^[27]

Spatial Localization Techniques for In Vivo Spectroscopy

Generally, two different approaches are used for ¹H spectroscopy of the brain: 1) single voxel methods based on the STEAM (STimulated Echo Acquisition Mode: 90°-TE/2-90°-TM-90°-TE/2-Aquire, where TM is the mixing time)^[26] or PRESS (Point RESolved Spectroscopy: 90°-TE₁-180°-TE₁₊₂-180°-TE₂-Aquire)^[28] pulse sequences for localization; or 2) spectroscopic imaging (SI, also known as chemical shift imaging (CSI)) studies usually done in two dimensions using a variety of different pulse sequences (spin-echo, PRESS).^[29–31] Usually, but not exclusively, single voxel scans are recorded at short echo times (TE < 30 ms), whereas SI studies are done at long echo times (e.g., TE > 135 ms). Short echo-time spectra contain signals from more compounds and have better signal-to-noise ratios, but also have worse water and lipid suppression factors. Long echo-time spectra have lower signal-to-noise ratios, fewer detectable

Fig. 11 (A) Long (TE 272 ms) and (B) short (TE 30 ms) ^1H MR spectra from normal human brain recorded using the STEAM pulse sequence. H_2O = residual water, Cho = choline, Cr = creatine, NAA = N-acetyl aspartate, mI = *myo*-inositol, Glx = glutamine and glutamate.

compounds, and a variable amount of T_2 -weighting, but are usually better resolved spectra with flatter baselines. Lactate is usually best detected at long echo times (TE = 140 or 280 ms so that the J-modulation is rephased) to distinguish it from lipid signals. Examples of short and long TE SV spectra of the human brain are shown in Fig. 11. Whereas single-voxel methods allow the optimized detection of individual brain regions at short echo times, they also have a number of disadvantages; voxel sizes are rather large, and in many conditions choice of voxel location is difficult. For diagnostic purposes, one would in principle like to study the complete brain. The combination of MRS with imaging (MRSI) can alleviate these problems. An example of a spectroscopic imaging study is given in Fig. 12, along with a T_1 -weighted image for reference. The metabolite maps display elevated levels of choline, the presence of lactate, and the absence of N-acetyl aspartate (NAA) in the tumor region, as does the spectrum selected from a voxel within the tumor region. Figure 13 demonstrates a conventional proton MRSI in normal human breast. The figure shows a T_1 localizer image (middle of 3 slices); reconstructed

images of residual water, residual lipid (both after suppression), and choline; and selected spectra from individual regions of interest in adipose and glandular tissue. The data show that no choline signal was detectable above the noise floor of the spectroscopic image, and that residual water and lipid signals after suppression were reasonably small. Water signals are predominantly observed only in glandular tissue and chest wall, whereas lipid signals are predominantly seen in the adipose tissue, indicating sufficient resolution for proton MRSI measurements of choline in breast cancer patients.

The choice of method depends (in addition to availability) on the information required by the particular medical or research application. For instance, if spectroscopy were being used to search for the location of a stroke or a seizure focus, spectroscopic imaging would be preferable because this generates maps of metabolite levels that can be screened for abnormalities in different locations. Alternatively, if the issue is to observe changes in compounds such as glutamine/glutamate or myoinositol, which can only be detected in short echo-time spectra, in global or diffuse

Fig. 12 Example of an MRSI in a 4-yr-old boy with a choroid plexus carcinoma. Shown are metabolic maps of Cho, NAA, and Lac along with a T_1 -weighted MRI (left) and spectra from the tumor region (right) for comparison. Both the tumor spectra and spectroscopic images show elevation of choline and lactate with complete absence of N-acetyl aspartate and creatine (see spectra).

Fig. 13 Spectroscopic images of residual water, choline (integration range 3.3 to 3.1 ppm), and residual lipid from one slice in a normal human breast. Selected spectra are shown from individual 1.27-cm^3 voxels in (A) adipose tissue showing methyl and methylene lipid signals; and (B) chest wall showing predominantly residual water signal. Note that the broad water signal is the residual water signal in the chest wall where field homogeneity is worse than in the breast.

diseases such as hepatic encephalopathy, then short echo-time single-voxel spectroscopy is the method of choice.

Water and Lipid Suppression

Brain metabolite levels are on the order of 10 mM or less, whereas brain water is 80 M and lipids in pericranial fat are also present in very high concentrations. Therefore, water and lipid suppression techniques are essential in ^1H spectroscopy in order to reliably observe the much smaller metabolite signals. Numerous methods for solvent (water) suppression have been developed in high-resolution NMR spectroscopy, and some of these methods have been applied to in vivo spectroscopy. The most common approach is to presaturate the water signal using frequency-selective 90° pulses (CHESS pulses^[32]) prior to the localization pulse sequence. By using more than one pulse, and with correct choice of flip angles,^[33,34] very good suppression factors can be attained (>1000).

Lipid suppression can be performed in several different ways. One approach is to avoid exciting the lipid signal, using STEAM^[26] or PRESS^[28] localization, confined to brain regions, and avoiding the scalp. Alternatively, outer-volume suppression pulses can be used to presaturate the lipid signal.^[31] An inversion pulse can also be used for lipid suppression, making use of the different T_1 values of lipid (typically 300 ms) versus metabolites (typically 1000–2000 ms).^[35] Choice of a short inversion time of approximately 200 ms ($= T_1 \cdot \ln(2)$) (derived from Eq. 19 with $S(\tau)=0$) will selectively null the lipid signal, and most of the metabolite signal will remain inverted. Because both water and lipid resonances have shorter T_2 relaxation times

than many metabolites, suppression factors are also usually better in long TE compared to short TE spectra.

Information Content of Proton MR Spectra of the Brain

Figure 11 shows examples of proton spectra recorded at long ($TE = 272$ ms, Fig. 11A) and short ($TE = 30$ ms, Fig. 11B) echo times. The largest metabolite signal, resonating at 2.02 ppm, occurs from the N-acetyl group of N-acetyl aspartate (NAA), with perhaps a small contribution from N-acetyl aspartyl glutamate (NAAG).^[36] An important property of NAA is that hardly any is found outside the nervous system.^[37,38] The evidence for NAA as a neuronal marker is widespread,^[27,39] for instance, NAA reductions measured by ^1H MRS were in excellent agreement with neuronal enzyme activity assays in an animal model of neuronal damage induced by striatal injection of kainic acid.^[40] In a similar model of excitotoxic neuronal injury,^[41] NAA levels were also shown to decrease in regions with neuronal loss. In addition, immunocytochemical staining of rat brain sections using monoclonal antibodies specific for NAA showed immunoreactivity in neurons and axons only.^[42] Decreased levels of NAA have also been observed in numerous human pathologies associated with neuronal and axonal loss, such as brain tumors (of glial origin), multiple sclerosis, stroke, or epilepsy.^[43–49] Although there is some evidence that NAA is present in glial cells (isolated oligodendrocyte preparations),^[68] on balance it appears that most of the NAA signal in mature brain is of neuronal-axonal origin, and that reductions in NAA may be a reasonably good surrogate marker for neuronal-axonal injury in many neuropathologies.^[69]

The choline signal (Cho, 3.24 ppm) arises from the $N(\text{CH}_3)_3$ groups of glycerophosphocholine (GPC), phosphocholine (PC), and a small amount of free choline, compounds that are involved in membrane synthesis and degradation. Both increases and decreases in Cho have been reported in pathological conditions; processes leading to elevation of choline signal include active demyelination,^[45] resulting from the degradation of myelin phospholipids primarily to GPC, or increased numbers of glial cells.^[50,51] Low Cho has been observed in hepatic encephalopathy,^[52] and there is also some evidence to suggest that dietary intake of choline can modulate cerebral Cho levels.^[53]

The creatine signal (Cr, 3.02 ppm) is a composite peak consisting of creatine and phosphocreatine (PCr), compounds involved in energy metabolism via the creatine kinase reaction generating ATP. Because creatine is synthesized in the liver, chronic liver disease leads to lower cerebral creatine concentration.^[27,42] In vitro, glial cells contain a two- to fourfold higher concentration of creatine compared to neurons.^[54] In the past, it was suggested that the sum of these Cr plus PCr may be relatively constant, both in different brain regions and in pathological processes. For this reason, Cr is sometimes used as a reference peak. However, it should also be recognized that there are quite strong regional variations in Cr^[70] and many conditions in which Cr will change (e.g., reduced due to general cell loss (as might occur, for example, in cerebral infarction)), so it is unwise to assume that Cr is invariant in most cases.

In normal human brain, lactate (1.33 ppm) is below (or at the limit of) detection in most studies. Any detectable increase in lactate can therefore be considered abnormal. Increased lactate is usually the result of deranged energy metabolism, and has been observed in ischemia (both acute (highest) and chronic^[46,47]), brain tumors,^[43] mitochondrial diseases,^[55] and other conditions. Small elevations of lactate have also been reported in the visual cortex during photic stimulation,^[56] believed to be due to increased nonoxidative glycolysis, but this effect does not appear to be particularly reproducible.^[57]

At short echo times, additional compounds are detected that are not visible at long echo times, because of either short T_2 relaxation times or the dephasing effects of J-coupling (Fig. 11B). One of the largest signals occurs from *myo*-inositol (mI) at 3.56 ppm. The function of mI is largely unknown, but it appears to be altered in many pathological conditions. It has been suggested that mI is found only in glial cells, and could therefore be a glial marker.^[58] mI has also been found to be reduced in hepatic encephalopathy^[59] and increased in Alzheimer's dementia^[60] and demyelinating diseases.^[61]

Glutamate (Glu) and glutamine (Gln) are difficult to separate in proton spectra at 1.5T and are often labeled as a composite peak Glx. At higher fields (such as 3 or 4T), the C4 resonances of Glu and Gln start to become resolved. Increased cerebral glutamine has been found in patients with liver failure (hepatic encephalopathy,^[59] Reye's syndrome^[52]) as the result of increased blood ammonia levels, which increase glutamine synthesis.

Under certain conditions (e.g., the use of editing sequences, high field strengths, or very short echo times), other signals can also be detected in proton brain spectra, such as GABA,^[62] glucose,^[63] *scyllo*-inositol,^[64] purine nucleotides,^[65] lipids, and macromolecules.^[66] Finally, occasionally exogenous substances that cross the blood-brain barrier can be detected by MRS; these include propandiol, mannitol, ethanol, and methylsulphonylmethane.

CONCLUSIONS

Many methods are presently available to perform magnetic resonance spectroscopy in vivo, all of which have been applied successfully to study cells, both animal and human; metabolic images of equilibrium levels of metabolites can be obtained on standard clinical equipment. In vivo MR spectroscopy of humans is possible in many organ systems and with many nuclei. Although ^1H spectroscopy has been demonstrated in a number of organ systems, the overwhelming number of applications have been in the brain, and human brain pathology has now been extensively studied by ^1H spectroscopy.

INTRODUCTION

The human eye is a complex organ of vital importance for everyday life and a major target for a range of implants and accessory biomedical devices. Biomaterials are used to fabricate ocular devices to correct functional deficiencies caused by disease, age, and ocular trauma. This article examines the various types of ocular implants, with particular reference to the approaches adopted for improving ocular compatibility and ensuring the longevity of indwelling ocular devices.

ORBITAL IMPLANTS

In contrast to many indwelling devices, orbital implants are employed with mainly cosmetic intent.^[1] A wide range of problems can lead to the need to eviscerate or enucleate the eye including retinoblastoma, trauma, uveitis, and rubeotic glaucoma. Removal of the globe or its internal contents requires the insertion of a solid implant to maintain the orbital volume; device motility is also desirable to optimize cosmesis. A range of materials have been used to manufacture orbital implants including glass, cork, ivory, and aluminium.^[1] It is now recognized that cellular invasion and vascularization is a desirable characteristic of orbital implants because it discourages bacterial colonization of the surface and permits treatment of low-grade ocular infection with systemic antibiotics.^[2] For this reason, modern implants are frequently based upon hydroxyapatite or porous polyethylene.^[3,4] Evisceration involves the removal of the contents of the globe, introduction of the implant into the scleral shell, and conjunctival closure. Enucleations involve direct suturing of the extraocular muscles to the implant, or, more commonly, to the implant wrapped in donor or synthetic material, and the closure of Tenon's capsule followed by separate conjunctival closure. Porous implants have been shown to have an overall

failure rate of approximately 10% with higher failure rate when used in eviscerations than enucleations. Failed implants that have been histologically characterized reveal a failure of fibroblast ingrowth and a chronic inflammatory response. It has been suggested that such a response can be partially avoided by wrapping the implant in autologous donor tissue.^[5]

KERATOPROSTHESES AND INTRACORNEAL IMPLANTS

On occasions, direct intervention surgery is necessary to replace a diseased cornea or alter its refractive state; such surgery can involve the implantation of permanent indwelling devices such as keratoprotheses or intracorneal implants. The former devices involve full-thickness penetration of the cornea and result in the full substitution of corneal function, whereas the latter are implanted within the cornea to improve its refractive performance.

The intracorneal lens is implanted in the central corneal stroma to correct conditions such as myopia and hyperopia. Modern intracorneal lenses are most commonly fashioned from PMMA, which combines a range of good optical and mechanical properties with acceptable biocompatibility.^[6] An intrinsic problem with solid PMMA lenses is the disruption of nutrient transport across the cornea; mechanical irritation also renders such implants less than ideal. Epithelial thinning over the implant, reduced keratocyte density anterior to the lens, and stromal opacity have all been reported as side effects of such implants.^[7]

To address the problem of nutrient flow, hydrogel intracorneal lenses have been evaluated. Primate trials indicate that these implants are well tolerated for at least five years.^[16] Clinical studies indicated a reasonable initial correction of hyperopia although this had returned to preoperative values within one year. Lens migration and epithelial cell invasion were reported as significant side effects in approximately 10% of

patients. A more generic issue is the relatively low refractive index of currently available hydrogels relative to PMMA.^[6] These implants exert their refractive effect principally through the alteration of corneal curvature.

In contrast to hydrogels, polysulfone lenses have extremely high refractive indices and can thus be made extremely thin, simplifying the surgery needed to implant them. Polysulfones, however, are impermeable to aqueous solutions and thus disrupt nutrient flow in an analogous manner to PMMA; an acceptable compromise appears to be the fenestration of polysulfone lenses with a network of 10- μ m diameter holes to allow fluid movement.^[8] Such holes allow the retention of adequate optical quality and appear to be too small to permit cellular invasion of the implant.

An alternative method for the correction of myopia involves the implantation of an intrastromal ring designed to alter the anterior corneal curvature.^[9] Such rings are inserted into a surgically prepared enclosed tunnel within the cornea and flatten the central corneal curvature. Varying ring thickness alters the degree of flattening produced. Intrastromal rings are generally manufactured from PMMA and are tolerated in both rabbit and human eyes.

In addition to intrinsic functional deficits, a wide range of external hazards can permanently damage the healthy cornea. Penetrating injury, alkali burn (particularly exposure to lime in the building industry), viral infection, and ulceration can damage and opacify the cornea. The most common clinical response in this situation is to perform a penetrating keratoplasty (a corneal graft) using a donor cornea. Unfortunately, supplies of donor corneas are limited and graft failure is common, with the risk increasing over time. In particular, patients with severe chemical burns, chronic ocular surface inflammation, herpes simplex viral infection, and Stevens-Johnson syndrome have a poor prognosis for grafting. A variety of solutions have been offered including corneal repopulation using cell lines^[10] and tissue grafts based on hyaline cartilage. In the immediate term, however, polymer-based tissue replacements, keratoprotheses, appear to offer the greatest potential for success. A range of materials and designs of these implants are now available.

In contrast to intracorneal implants, keratoprotheses are penetrating replacements of the cornea. A general problem with keratoprotheses is thus the maintenance of a clear visual window while allowing sufficient cellular invasion to fix the implant firmly in place. Extrusion of the keratoprosthesis as a result of internal globe pressure is a common problem resulting from a failure to promote wound healing at the implant margins. The original keratoprotheses designed by Cardona and coworkers in the 1960s had a failure rate of over 30% as a result of tissue erosion followed

by extrusion of the implant.^[11] Other problems with such keratoprotheses result from a fixed implant size and a fixed surgical position. In the original Cardona-style keratoprosthesis a nut-and-bolt manufactured from high-quality PMMA^[12] was employed. Following surgical removal of the epithelial layer and extraction of the underlying corneal stroma and endothelium, the implant was secured into the extracted tissue by means of a trephined bolt hole and the tissue containing the keratoprosthesis was then sutured back into the eye. Overtightening of the implant had a regrettable tendency to trigger aseptic necrosis of the tissue.

Girard keratoprotheses are modifications of the Cardona type.^[13] Doane et al. have manufactured twin-plate keratoprotheses from PMMA but with design modifications that permit their use in very dry eyes.^[14] These have been used in the clinical situation. Attempts have also been made to improve the retention of such solid keratoprotheses by surface modification, but, in general, PMMA keratoprotheses have not achieved large-scale usage or great success. It has been suggested that an ideal keratoprosthesis should be 1) tightly retained in the cornea to prevent extrusion, 2) easily and completely colonized by corneal epithelial cells on the external face, and 3) should suppress downgrowth of such cells into the implant bed. Keratoprotheses have also been fashioned from a range of materials including melt-blown polyolefins and vitreous carbon. Studies using the commercial polytetrafluoroethylene (PTFE) Proplast demonstrated over 50% implant extrusion after four months.^[15] Comparative studies using Impra, Gore-tex, and Proplast PTFE demonstrated that a significant invasive response was promoted only by Impra.^[16]

As water impermeable materials generally appear to be poorly tolerated by the residual corneal tissue, considerable interest is being shown in the exclusive use of pHEMA-based hydrogels for the fabrication of new keratoprotheses.^[17] However, the results of clinical trials using such materials have shown considerable patient variability.^[18]

An alternative device, the osteo-odonto-keratoprosthesis (OOKP), was developed in Italy by Strampelli in 1963.^[19] This device uses a lamina prepared from a single-root tooth extracted from the patient. A PMMA optic is cemented into the center of the lamina and the device is implanted in a subcutaneous pocket below the eye in the patient's cheek. After three months the device is removed from the pocket, the optic is placed through a hole trephined in the cornea into the anterior chamber, and the device is sutured over the cornea below a covering of buccal mucosa. Although complex, this approach probably has had the greatest clinical success to date. Further details on these various technologies may be found in the article entitled *Corneal Implants*.

SCLERAL BUCKLES

Retinal detachment complicates a small percentage of natural age-related posterior vitreous detachment cases and is routinely repaired using a scleral implant known colloquially as a buckle. Buckles indent the sclera bringing the separated layers of the neural retina and the underlying pigment epithelium together. Since the introduction of this implant technique in the 1930s a range of materials have been used to manufacture the actual buckle.^[20] A broad distinction can be made between absorbable buckles, which appear to have limited advantages and many problems, and non-absorbable implants.

General problems associated with the use of scleral buckles include implant extrusion, chronic irritation, alterations in the intraocular pressure of the buckled globe, decreased extraocular motility, and infection. Absorbable materials address the problem of extrusion by being broken down and replaced by scar tissue in the normal course of tissue turnover. The simplest absorbable materials consist of autogenous tendon or fascia lata from the patient.^[20] Such grafts have the advantage that rejection is eliminated but the patient is subject to extra surgery. Cadavers are occasionally used as sources of donor material, in which case lyophilized or fixed samples of dura mater or sclera are implanted. Cadaver material that is generally stored in ethanol or lyophilized is generally more rigid than autologous graft material; this increases the risk of implant erosion. Host rejection and transmission of a novel pathogen are also associated problems with the use of such material. A generic problem with grafts is their lack of elasticity, which limits the ability to produce scleral buckles of exact dimensions.

A variety of other degradable materials have been used for buckles including stabilized fibrin, absorbable gut, and collagen. However, the most widely used protein in this respect remains pigskin gelatin. Gelatin has the advantage that the implant can be precisely shaped and impregnated with antibiotics to control potential infections. Reabsorption proceeds smoothly over a three- to six-month period, however it has a regrettable tendency to trigger low-grade inflammation of the eye that can escalate to include vitreous haze and macular edema. All absorbable buckles suffer from the problem that reabsorption of the implant reduces the buckling effect and the removal of a partially absorbed implant is a difficult surgical technique. Temporary buckles based on injection of plasma into the suprachoroidal space have also been attempted; this produces a buckling effect for approximately one week. Plasma injection, and related techniques such as the use of hyaluronan, can, however, cause choroidal perforation and substantial hemorrhaging. In addition, control of buckle shape and size by injection is also very poor.

Nonabsorbable devices have undergone extensive design work in recent years and now offer distinct advantages over the absorbable materials. A range of polymers have been used to produce nonabsorbable implants, particularly silicones and hydrogels. Polyethylene tubing has been used in the production of encircling scleral implants since the 1950s. The main advantage of this material was the facility to introduce a suture into the lumen of the tubing that could then be tensioned to regulate buckle height. An incidental advantage of the use of such tubing was the opportunity to fill the lumen with antibiotics to reduce the risk of infection. However, the buckles produced using polyethylene tubing tended to be narrow, infections still occurred, and the tubes themselves had a tendency to erode the underlying sclera and choroid over time. To address these problems, implants based on softer silicones and silicone sponges were introduced. These materials remain flexible when implanted and thus do not cause erosion. A further advantage of the use of silicones is the formation of a tough fibrous capsule around the implant that both strengthens the sclera and allows the easy removal of the implant should reintervention be required. Soft silicones tend to be superior to sponges in this respect due to their greater surface smoothness but sponges do produce a more even buckling effect and can also be impregnated with antibiotics to limit bacterial colonization of the implant. Unfortunately, silicone implants show a post-operative infection rate of 2–5%.^[21] An elastic material with a higher endogenous biocompatibility might offer advantages in this regard.

Poly(glyceryl methacrylate) (PGMA), poly(2-hydroxyethyl acrylate) (PHEA) and co-poly(methyl acrylate-2-hydroxyethyl acrylate) (MAI) have all been used as base materials for scleral buckles. The major advantages of the hydrogels are softness, defined swelling on hydration, and the potential to act as drug delivery devices for antibiotics. Of the three hydrogels commonly used, PGMA suffers from a lack of tensile strength when swollen and PHEA has a tendency to fragment after swelling. MAI has good bulk characteristics and promotes the formation of a strong surrounding capsule. As a result of these properties it is the most commonly used hydrogel and is sold under the commercial name Miragel. Although these various technologies have been developed, the clinical preference remains for the silicone tire or sponge.

GLAUCOMA FILTRATION IMPLANTS (GFIs)

Glaucoma is a common cause of severe visual handicap in which raised intraocular fluid pressure (IOP) causes progressive optic nerve damage and visual field loss. The principal surgical treatment, glaucoma

filtration surgery (GFS), involves the formation of a drainage passage through the sclera/cornea connecting the anterior chamber of the eye to the subconjunctival space, bypassing the normal drainage routes. Although GFS is generally highly successful, in a number of cases an artificial drainage implant is required. Early approaches included the use of various types of seton made from a range of materials including horse hair, silk, metals (such as gold, platinum, and magnesium), and polymers such as nylon. These early devices had high rates of filtration failure primarily as a consequence of the chronic foreign body inflammatory response caused by the devices, which led to subconjunctival fibrosis and fistula closure. In 1969, Molteno introduced a two-piece drainage implant that comprised a drainage tube attached to a plate device.^[22] The plate, which is sutured to the sclera under a quadrant limbal conjunctival flap, was designed to maintain the patency of the subconjunctival filtration reservoir during subconjunctival fibrosis. Since then a range of different tube and plate devices have been developed.^[23] The early Molteno and Baerveldt devices had no resistance elements and suffered from problems with early-stage hypotony. Molteno attempted to address this by developing a two-stage surgical technique in which the device was implanted and allowed to encapsulate before insertion of the tube element into the anterior chamber in a second operation. Other approaches that have been adopted to overcome this problem include various ligation procedures and temporary occlusion of the tube. Later embodiments of the Molteno and Baerveldt GFIs incorporated plate-based resistance elements that depend on tissue fibrosis over the plate to restrict the flow. Other workers have developed various alternative systems, including the use of microtubules and various types of valve, to restrict fluid flow and avoid postoperative hypotony. Recent in-vitro studies of these devices have indicated considerable variation in resistance values obtained from devices from the same manufacturer, indicating deficiencies in manufacturers' quality control and likely variability between implanted devices.^[24] The recommended technique for insertion of the device involves the formation of a paracentesis track using a 22- or 23-gauge hypodermic needle. As a consequence, uncontrolled extrinsic leakage caused by a poor tube to paracentesis fit is believed to contribute to the problems of hypotony following device implantation. Other common complications include chronic inflammation, internal occlusion of the tube lumen, infection, and corneal endothelial damage from tube contact. It has been suggested that these problems are related to both the micromovement of the device following implantation causing tissue irritation and inappropriate selection of device material for optimal ocular compatibility.

INTRAOCULAR LENSES

Cataract is the most common treatable form of blindness throughout the world. Cataract extraction and intraocular lens implantation is the most frequent form of ophthalmic surgical procedure, with an excess of 1.6 million operations being performed per annum in the United States alone.

The surgical method most frequently employed in the developed world for the treatment of this condition involves removal of the cataractous material while leaving most of the lens capsule in place and insertion of an intraocular lens (IOL) to compensate for the loss of the natural crystalline lens. Of increasing popularity is the technique of phacoemulsification, in which the hardened nucleus of the crystalline lens is emulsified and removed through a 3.5-mm incision into the eye, as opposed to a 14-mm incision for a standard extracapsular cataract extraction. The advantages of this technique lie in the smaller, generally sutureless wound, causing quicker, safer rehabilitation and less surgically induced astigmatism.

During cataract extraction the anterior lens capsule is opened and the contents of the capsular bag removed. Following this, it is necessary to correct the loss of refracting power of the lens by the use of either a spectacle correction, which results in magnification and distortion of the image seen by the patient, a contact lens with all the complications associated with maintenance, or an IOL. Three types of IOL have been used: an anterior chamber IOL that sits in front of the iris but behind the cornea, an iris clip lens that straddles the pupil, and finally a posterior chamber IOL that sits behind the iris within or on the capsular bag. This latter type of lens is now the lens of choice.

PMMA was the first IOL material developed for the purpose by Harold Ridley in 1949. These IOLs are generally lathe-cut from PMMA rods or buttons and comprise a central optic that is supported by haptics, projections from the main body of the lens. The haptics are usually constructed from PMMA or the base material of the optic, although other polymers may be used. Current lenses usually employ a 7-mm-diameter optic, a 6.5-mm oval-shaped optic, or a 5-mm round optic. These posterior chamber lenses may thus be inserted wholly within the capsular bag or with the optic supported within the capsular bag remnants and the haptics lodged in the ciliary sulcus, the anatomical groove between the iris and the ciliary body. The lenses require a large incision and are now less frequently used, being unsuitable for small incision phacoemulsification surgery.

IOLs reside within the eye as foreign bodies, but were until recently largely regarded as inert. Indeed, PMMA was selected as the material of choice because of its low weight and biocompatibility. Although this

material has been used for over 40 years, major problems still occur as a consequence of its relatively low surface energy, which may result in both corneal endothelial damage on insertion and postoperative adhesion of inflammatory cells to the IOL. Uveal contact with the IOL surface has also been shown to cause increased and prolonged postoperative intraocular inflammation, which may lead to iris adhesion to the IOL, uveitis, breakdown of the blood retinal barrier causing cystoid macular edema, or loss of vision.^[25]

Attempts to improve the biocompatibility of IOLs have included: process modifications to produce a highly polished surface, the generation of both soft, high-energy surfaces using NVP and HEMA and hard low-energy surfaces using perfluoropropane, and the binding of heparin and hyaluronic acid to the outer surface of the lens. More recently, the use of phosphorylcholine-based polymeric coatings has been reported.^[26] These latter coatings were shown to reduce protein adsorption, cellular adhesion, and neutrophil activation by the PMMA surface and were shown in vivo to reduce cellular deposition onto the lens. Such materials have the propensity to reduce material-associated postimplantation opacification, which appears to occur as a consequence of an ongoing inflammatory response to the implanted material.

Phacoemulsification, with its small incision, has encouraged the development of foldable IOLs for implantation. The need to insert these devices through a 3.5-mm incision has also encouraged companies to investigate other design modalities including the concept of plate design IOLs. These foldable lenses have been manufactured from silicone elastomers, collagen copolymers, PHEMA hydrogels, and acrylic polymers. In developing these materials, particular emphasis has been placed on the handling, foldability, and unfolding characteristics of the lenses since they must be easy to insert, unfold slowly, and leave no crease mark. In this respect, it has been reported that the acrylic lens unfolds more slowly and in a more controlled fashion than the silicone lenses; the higher refractive index of the acrylic material gives rise to a thinner IOL. Evidence suggests that the hydrophilic materials are less damaging to the corneal endothelium and produce lower levels of inflammatory response in terms of cellular adhesion and foreign body response when compared to PMMA IOLs. Studies have also suggested that phosphorylcholine-based acrylate polymers may have application in the development of novel biocompatible foldable IOLs.^[27]

Recent emphasis has focused on the development of materials that will reduce posterior capsule opacification (PCO). This phenomenon is attributed to the migration of lens epithelial cells across the posterior capsule bag. Although this secondary cataract can be

treated using a neodymium:YAG laser to rupture the capsular bag, poor focussing can result in dislocation, decentralization, fragmentation, and pitting of PMMA lenses. Acrylic, silicone, and PHEMA IOLs have been shown to be more tolerant to the YAG laser than PMMA. Furthermore, recent in-vivo studies have suggested that PCO occurs less often following implantation of acrylic IOLs than other materials. This may be attributed to the physical inhibition of lens cell migration by adhesion of the posterior capsule to the IOL following implantation. Other approaches that have been investigated to reduce PCO include the modification of the IOL surface with antimetabolites. Although these approaches appear to be effective in in-vitro models, there is some concern over the effects of these antimetabolites on other ocular tissues.

Unlike the natural crystalline lens, standard IOLs provide no means of accommodation for near and far vision. In most cases the visual adjustment is achieved through the wearing of spectacles. Various approaches have been investigated for the fabrication of lenses that utilize the natural muscular action exerted on the capsular bag as a means of accommodation.^[28] A two-piece lens system has been patented in which the distance between the two lenses is controlled by the pressure exerted by the ciliary muscle on a U-shaped flange connecting the periphery of the two lenses. Relaxation of the ciliary muscle causes the lens to flatten, thereby changing the focal distance of the lens. Other approaches rely on the postoperative healing following surgery, during which the anterior capsule remnant fuses to the posterior capsule causing fibrosis around the lens haptic on the implanted lens, which leads to a rearward deflection of the lens against the posterior capsule. Accommodation is achieved through contraction and relaxation of the ciliary muscle that relaxes and stretches the fused remnant causing the lens to move forward and backward relative to the retina, thereby adjusting the focal distance. These approaches have recently led to the clinical evaluation of a number of accommodating lens designs.^[29] Other approaches include the use of viscoelastic IOL implants that may be injected into the capsular bag following removal of the natural crystalline lens. The viscoelastic gel's dimensions and refractive properties are modified as the ciliary muscle contracts and relaxes causing the capsular bag to either stretch or bulge, respectively.^[30]

Recent concern over the potential damage to the posterior segment of the eye arising from UV radiation following removal of the natural crystalline lens has encouraged companies to include UV absorbing chromophores in IOL materials. These chromophores are generally derivatives of benzotriazole that absorb UV radiation below 400 nm and that are either physically blended or chemically incorporated into the IOL material.^[31]

SILICONE OIL

Various agents have been used in conjunction with scleral buckles in the treatment of retinal detachment. These agents are injected into the eye to provide an intravitreal tamponade. Silicone oil is the most commonly used material despite various problems including poor biocompatibility and emulsification within the eye.^[32] In addition to the use of silicone oil as a tamponade, various workers have investigated the potential for the use of silicone oil for the delivery of antiproliferative agents for the treatment of proliferative vitreoretinopathy.^[33] This is a field of ophthalmology that could potentially benefit significantly from the development of novel high-density liquid biocompatible materials.

VISCOELASTIC AGENTS

Viscoelastic agents play an important role in ophthalmic surgery for both protection of the corneal endothelium during cataract extraction and in the treatment of retinal detachment. Corneal endothelial cell damage, particularly following implantation of anterior chamber IOLs, was until recently a common occurrence. This problem was overcome to some extent with the increased use of posterior IOLs that are placed in the capsular bag rather than in front of the iris. However, the insertion and removal of IOLs and surgical instruments was still found to cause some corneal endothelial cell damage. To prevent this, viscoelastic agents have been introduced into the anterior chamber to protect the corneal endothelium while allowing the surgeon to insert and remove optical instruments and implants. These agents have been prepared from a variety of materials including hydroxypropylmethylcellulose (HPMC), hyaluronic acid, chondroitin sulphate, polyacrylamide, collagen, and various mixtures of these materials.^[34] 1% hyaluronic acid has also been successfully employed as an internal tamponade in the treatment of retinal detachment but is generally less effective in patients with proliferative vitreoretinopathy than other agents.^[35]

DRUG DELIVERY

Various biomaterials have been employed for drug delivery to the eye including in-situ forming gels, nanoparticulates, and microparticulates; these have been recently reviewed by Ding (1998).^[36] Various implantable devices are in commercial use including Ocusert and Vitrasert with several other systems under development including osmotic minipumps, biodegradable scleral plugs, and biodegradable

poly(caprolactone) matrices. The use of biomaterials in ocular drug delivery will inevitably increase in future years and there will be a need to improve biocompatibility and patient comfort in these implanted systems.

CONCLUSION

This article illustrates the extensive range of biomaterials that have found use in the development of indwelling ocular implants. In many cases, these materials have been selected primarily on the basis of their mechanical properties and biofunctionality without full consideration of their ocular compatibility. With an improved understanding of the factors that affect material-related ocular compatibility has come the realization of the importance of material surface characteristics. Companies will need to consider both surface characterization and the assessment of ocular compatibility in the development of new biomaterials for ocular applications.

INTRODUCTION

Advances in materials science, biomedical engineering, and surgical techniques have encouraged the development of a variety of intraocular therapeutic devices. One class of intraocular devices includes implants for drug delivery, designed to improve the ability to deliver therapeutic drug levels into the eye. Most sight-threatening diseases occur in the back of the eye and frequently involve the retinal tissue. Diabetic retinopathy and age-related macular degeneration (AMD) are the most common causes of blindness in the United States. Local drug delivery with implants can overcome the many barriers that inhibit effective treatment of retinal diseases with traditional mechanisms of drug delivery, such as with eye drops or medications given systemically (i.e., by oral or intravenous route). The modified mucosal surface that covers the cornea is a significant barrier to topically applied eye drop medications (Fig. 1). The tight junctions between the basal epithelial cells of the cornea and the tear fluid drainage causes less than 5% of topically applied drug to permeate the cornea and reach intraocular tissues.^[1,2] As a result, drugs delivered with eye drop formulations are generally limited to treating tissues in the front of the eye. Examples include topical antimicrobials used to treat bacterial conjunctivitis or ocular antihypertensive drops that function by reducing the aqueous humor production at the level of the ciliary body (located in the front of the eye) to treat glaucoma. An attempt to deliver drugs to the posterior structures of the eye with systemic medications is impeded by the blood-retinal-barrier, which consists of the tight junctional complexes of the retinal pigment epithelium and retinal capillaries.^[1] This barrier reduces the penetration of most drugs given systemically to the posterior segment of the eye and hinders the treatment of many retinal diseases. Although high doses of systemically administered

medications may be able to penetrate the blood-retinal-barrier and provide therapeutic drug levels to the back of the eye, serious systemic side effects may occur.^[3] Delivery of drugs directly into the eye by intravitreal injection through the pars plana is another approach to achieve therapeutic levels of drug to treat retinal diseases (Fig. 2).^[4-7] However, given the short half life of most drugs injected into the vitreous, frequent injections 1–3 times per week are required to maintain therapeutic drug levels. As a result, intravitreal drug injections are very useful in treating acute bacterial infections of the eye (i.e., endophthalmitis)^[8] that may require one or two injections, but are not well tolerated by patients that may require months or years of injections to treat chronic eye diseases such as AMD or cytomegalovirus (CMV) retinitis (Fig. 3). Furthermore, frequent injections increase the risk of retinal detachment, vitreous hemorrhage, endophthalmitis, and cataracts.^[9-11]

Intraocular implants for drug delivery are capable of bypassing the barriers to intraocular drug absorption and avoid frequent procedures required using intravitreal injection therapy. Drug release rates of implants can be controlled so that therapeutic drug levels are maintained in the eye, while avoiding toxic or subtherapeutic levels. Moreover, higher intraocular drug levels can be achieved using implants compared with systemic or topical administration, making the drug more effective for treating a variety of retinal diseases.^[12] Since the dose of drug released by intraocular implants is in the range of 0.5 to 10 micrograms per day, these small doses significantly reduce the risk of systemic drug toxicity. Finally, ocular implants are more convenient for patients and reduce patient compliance issues with taking frequent eye drops or systemic medications.^[13] This article reviews the development of intraocular drug delivery implants and the potential for treating eye diseases.

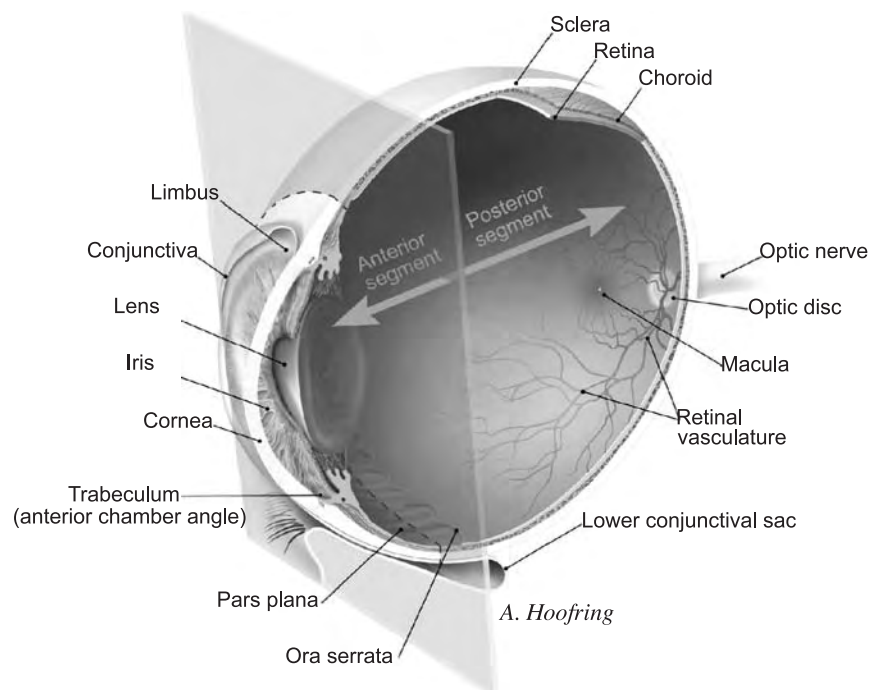

Fig. 1 Anatomy of the eye.

DRUG DELIVERY IMPLANTS: BASIC CONCEPTS

Ocular implants are engineered for optimal therapeutic efficacy. However, ocular implants should be biocompatible and properly sterilized to minimize the potential for an inflammatory reaction in the eye. In addition, implants should release drug at predictable and constant release rates to achieve therapeutic levels of drug to the target tissue with minimal toxicity to adjacent tissues. It is necessary for implants to be comfortable, preferably visible for inspection in the eye, while avoiding blockage of the visual axis. Implants should be easily inserted and removed, if not bioerodible^[14,15] and must be cost-effective when compared with systemic administration of the same drug. Drug stability in the implant is important and needs to be evaluated early during the implant development. From an ophthalmologist and patient's viewpoint, when considering drug delivery with an implant, the severity of the disease being treated should warrant the risks of implant surgery and should also have the potential for greater efficacy and less toxicity compared with the equivalent drug given by systemic administration.

Drug delivery implants can be designed to deliver drug to different parts of the eye (Fig. 2). The choice of implant design and location in the eye depends on the disease the ophthalmologist is treating. Since most of the current implants available clinically are diffusion-based, the closer the implant is located to the target tissue, the more drug will be delivered to that site. For example, an implant designed for the subconjunctival

space will deliver higher drug concentrations to best treat diseases that affect the conjunctiva or sclera (Fig. 2C). Implants designed to directly deliver drug into the vitreous cavity (Fig. 2B,D,E) are used to treat retinal diseases. The decision to use one implant design over another may also be influenced by the surgical risks of implanting a particular device. For example, implants that require an incision leading to the vitreous cavity significantly increase the risk of vitreous hemorrhage, infection, and retinal detachment. Implants inserted in the subconjunctival space are associated with few complications, especially if they are biodegradable and do not require removal. However, implants placed in the subconjunctival space may have some difficulty in treating retinal diseases because the sclera and choroid may pose a formidable obstacle to drug diffusion. Some subconjunctival implants using drugs with high scleral permeability have a reasonable potential to deliver drugs into the eye to treat retinal diseases. Passive solute diffusion through an aqueous pathway is the primary mechanism of drug permeation across the sclera.^[2] In-vitro and in-vivo flux studies have shown sclera to be quite permeable to drugs, including monoclonal antibodies, with a wide range of molecular weights up to 150 kilo Daltons.^[16-18] Trans-scleral permeability is inversely related to the drug's molecular weight; therefore, small molecule drugs are beneficial when delivering drugs from the subconjunctival space into the eye.

The solubility characteristics of a particular drug are also a major factor in determining the ability of a drug to be delivered by a particular device. For example,

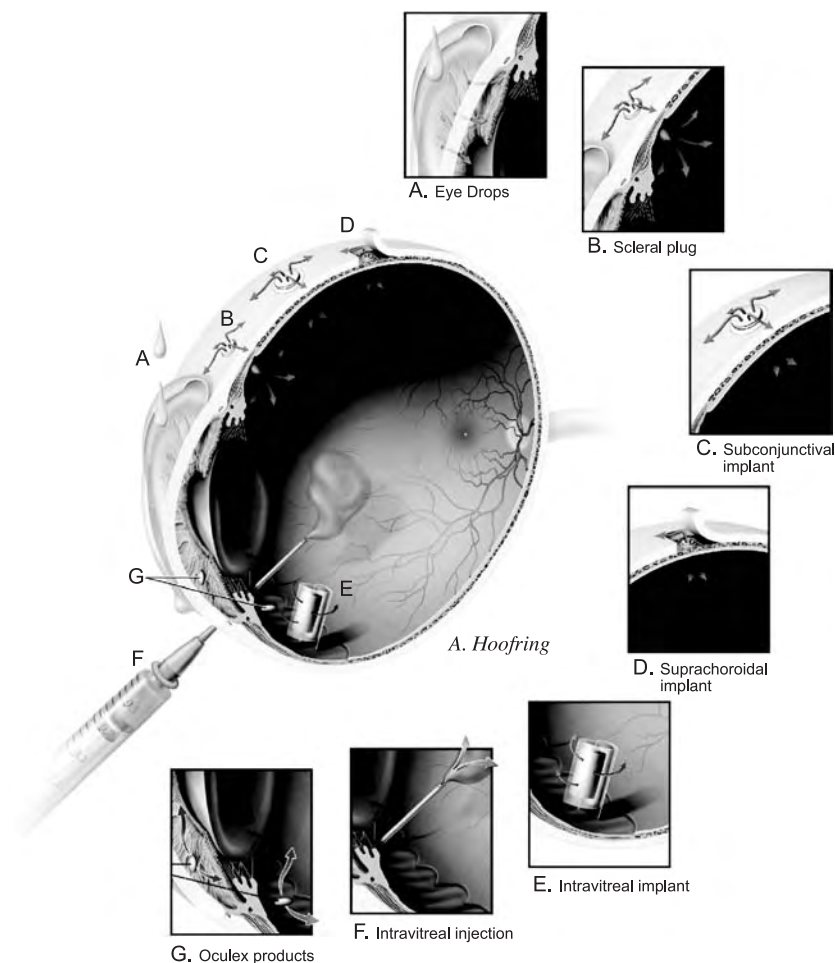

Fig. 2 Principal methods of local drug delivery to the eye.

aminoglycoside antibiotics, used in the past for gram negative bacteria endophthalmitis, are highly water-soluble and when delivered into the vitreous, have difficulty penetrating the relatively lipophilic retina leading to significant toxicity including tissue infarction and necrosis.^[10,19] In contrast, highly lipophilic drugs, like cyclosporine and corticosteroids, are cleared from the eye via a trans-retinal route and are more appropriate to use when treating diseases of the retina and choroid.^[20–22] The two main types of diffusion-based implants used in ocular drug delivery, matrix and reservoir systems, will be discussed separately.

MATRIX IMPLANTS: OVERVIEW

The matrix implant design for ocular implants typically consists of uniformly distributed drug in a nonreactive, bioerodible polymer.^[7,23] The most common polymer used is poly(lactic-glycolic acid), or PLGA, which is a copolymer of poly(glycolic acid) and poly(lactic acid). PLGA hydrolyzes into organic monomers of lactic acid and glycolic acid and is the same material used for manufacturing absorbable sutures. During the

manufacturing process of matrix implants, some of the drug dissolves in the polymeric solution, but the majority remains in solid phase (Fig. 4).^[23] The relative concentrations of the polymers, such as the lactide:glycolide ratio in PLGA, as well as polymer weight ratios can be altered to adjust the drug release rate.^[1,24,25] Furthermore, an additional polymer coating and holes in the implants can influence release rates.^[26] The polymer coating slows release rates, and larger hole diameters increase the surface area of release, which correlates with higher release rates. In addition, adjustments of drug release rate are dependent on drug properties. The use of insoluble drugs results in drug release that more closely relates to the dissolution rate of the matrix. Furthermore, the hydrophilicity of the polymer affects the release rate, as more controlled release is exhibited from hydrophobic polymers.^[27] Generally, the release of drug from bulk-eroding matrix implants follows first-order kinetics, i.e., the initial release is robust followed by a rapid decrease in release as the drug in the implant declines.^[7,28] Therefore, matrix style implants are most appropriate for eye conditions with acute onset, such as infectious endophthalmitis or postoperative inflammation, because these conditions are best treated with

Fig. 3 (A) External photograph of the eye showing injection of an antiviral medication into the vitreous cavity to treat CMV retinitis in a patient with advanced HIV-infection. These injections are repeated twice per week. (B) External photograph of rabbit eye showing front of the eye with pupil widely dilated. A corticosteroid medication (arrow) had been injected a week before and positioned in the vitreous cavity behind the lens.

an initial loading dose of antimicrobials or corticosteroids followed by a gradual tapering of the medications over a defined period of time, generally ranging from one day to three months.

MATRIX IMPLANTS: OCULAR INSERTS

Examples of matrix implants that are placed on the outside surface of the eye are ocular inserts. The ocular inserts are bioerodible, solid matrix implants that are composed of hydrophilic polymers, including poly(vinyl alcohol) (PVA) and hydroxypropyl methylcellulose (HPMC), and drug. Inserts are placed beneath the lower eyelid (i.e., lower conjunctival sac), mix with the patient's tears, and dissolve within 12 to 24 hours. Drugs used in inserts include atropine, pilocarpine, and antibiotics and are used to apply drug to the surface of the eye to treat glaucoma or a variety of other eye diseases that affect the anterior segment of the eye. In addition, the polymer matrix alone can offer therapy to patients with dry eye. An example is the manufacturing of rod-shaped hydroxypropylcellulose (HPC) inserts that are placed in the lower conjunctival sac and undergo gradual dissolution, coating the surface of the eye with a tear/HPC lubricant continuously for approximately 24 hours.^[29] To further prolong the release of a drug from an ocular insert matrix system, use of nonbiodegradable polymers such as silicone can be employed.^[30] In addition, blending cellulose polymers with carbomer and creating the Bioadhesive Ophthalmic Drug Insert (BODI) can be done to increase release of drugs in the inferior conjunctival sac for >24 hours.^[31] Aside from delivering drugs to treat eye diseases, ocular inserts made of an absorbable gelatin foam have been employed in the inferior conjunctival sac to deliver insulin systemically to treat diabetes mellitus.^[14]

MATRIX IMPLANTS: SCLERAL PLUGS

Scleral plugs are an example of a matrix implant made for intraocular insertion and delivery of drug into the vitreous cavity (Fig. 2B). Scleral plugs are biodegradable, release drug, and are placed through a sclerotomy site without suture material at the completion of a pars

Fig. 4 Illustration showing a matrix implant (left) with drug (red spheres) dispersed in the polymer. When the implant is placed in an aqueous environment (right), the polymeric structure dissolves, releasing the drug. The release rate (lower-left inset) follows first-order kinetics, with an initial burst of drug followed by a rapid reduction in release.

plana vitrectomy procedure or as a separate procedure.^[32–35] These implants are composed of a matrix of PLGA and drug, and are constructed by a compression-molding technique to 1 mm in diameter. In addition, scleral plugs are heated to 80°C, thus all the drugs used must be thermally stable. Rabbit models showed that the drug diffusion into the vitreous does not impair the clarity of the ocular media. The scleral plugs may cause a mild foreign body reaction at one month after implantation, and the retina, lens, and other tissues remain normal for the entire duration of the implant. At four months, the devices are completely degraded and the sclerotomy site is replaced by loose connective tissue.^[32–34,36–38] Drug is released by diffusion from the plug during hydrolytic degradation, where the device swells and then gradually decreases in size. The drug diffusion from the polymer matrix is generally of first-order kinetics and triphasic, with an initial burst, a diffusive phase, and a second burst.^[34] Scleral plugs with drugs of smaller molecular weights release drug faster than plugs with drugs of larger molecular weights.^[36] Some controllable factors of the release profile of drugs are composition of polymers, ratio of polymers, molecular weight, shape of plug, and amount of drug.^[33,38] In addition to the release rate of the drug from the device, the diffusion rate of the drug in the vitreous and the elimination rate of the drug from the vitreous influence the concentration of drug in the vitreous.^[36] Altering the molecular weight ratio and type of polymers has been demonstrated to change the release rate of drug by producing biphasic scleral plugs. Biphasic implants produce only an initial burst and diffusive phase, and not the undesirable final burst, which may result in ocular toxicity. These pseudo-zero-order kinetics implants eliminate the adverse burst in the last phase of release. Scleral plugs contain poly (lactic acid) at two different molecular weights, PLA-70000 and PLA-5000 at a blending ratio of 80/20. These implants maintained an effective level of drug for six months without a significant burst or significant retinal toxicity.^[25,34] The biphasic release of the blended implant was largely due to ratio of molecular weights.^[25,32] Since PLA-5000 degraded faster due to its smaller molecular weight, water channels were formed connecting the surface to the inside of the implant. The drug present inside the implant was released constantly by diffusion throughout the water channels. Because water could move freely through the implant, degradation of the implant proceeded homogeneously, avoiding a final burst of drug inherent to matrix implants without blended PLGA designs.

A number of drugs have been tested in scleral plugs. PLGA scleral plugs with 25% ganciclovir have proven that ganciclovir release lasts longer in the vitreous with the implant compared with intravitreal injections.^[34,38] Ganciclovir is an antiviral medication used for the

treatment of CMV retinitis in patients with advanced HIV-infection. The scleral plug implants can release antiproliferative drugs such as doxorubicin^[32,33] that may be useful for treating proliferative vitreoretinopathy (PVR), a disease that can occur following surgery to repair retinal detachments. PVR results from a proliferation of fibroblasts in the eye that leads to scar formation on the retina and retinal detachment can recur. It is desirable to have approximately one to two months of an antiproliferative drug in the vitreous cavity to help reduce the incidence of postoperative PVR. Scleral plugs with doxorubicin maintained a therapeutic level for one month, as 25% of the drug in the plug was released.^[32] To treat fungal infections inside the eye, scleral plugs with fluconazole, a potent antifungal medication, demonstrated a maximum concentration in the vitreous to be 2.3 times higher than after intravenous injection of fluconazole, and maintained an effective level in the rabbit vitreous for three weeks.^[37]

MATRIX IMPLANTS: OCULEX DESIGNS

A biodegradable matrix implant using PLGA and dexamethasone is currently being investigated by Oculex Pharmaceuticals, Inc. (Sunnyvale, CA). The implants are rod-shaped and approximately 2 mm in length and diameter. They can be placed in the anterior chamber of the eye to treat inflammation in the front of the eye, and also in the posterior segment, to treat retinal diseases (Fig. 2G). Currently, Oculex has completed a phase II clinical trial evaluating the company's lead product, Posurdex, for the treatment of persistent macular edema related to diabetic retinopathy, retinal vein occlusion, and uveitis. The Posurdex implant releases 0.7 mg of dexamethasone over a four to six-week period and can be injected into the vitreous through the pars plana. The Oculex product, called Surodex, is placed in the anterior segment at the conclusion of cataract surgery to prevent postoperative inflammation and has been studied extensively in the United States and in Singapore where many of the clinical trials were conducted. The Surodex implant is approved for use in many countries including China where access to topical steroid drops for control of postoperative cataract surgery inflammation is limited. The Surodex implant is placed in the anterior chamber following the completion of the cataract surgery procedure and dexamethasone is released over 7–10 days.^[39,40] The 60 microgram of dexamethasone in one Surodex implant is approximately the same amount of drug in one drop of topical 0.1% dexamethasone eye drops. When compared to topical steroid eye drops in the setting of a clinical trial, the Surodex implant was shown to be at least as effective as topical steroids in reducing anterior chamber inflammation during the first month after surgery. Patient studies showed that

Surodex does not migrate in the ocular tissues and does not need to be secured using suture materials.^[40] No significant adverse complications resulted from usage of Surodex, and there was no occurrence of rebound inflammation after depletion of drug in the implant.^[39–41]

Others have investigated biodegradable implants similar to the Oculex design to deliver corticosteroids in the anterior chamber. Morita et al.^[42] have created a rod-shaped implant releasing the corticosteroid, fluorometholone. The biocompatible polymers, poly(lactic acid) and poly(vinyl pyrrolidone), were used to create a first-order pharmacokinetic release for 40 days and the release rates could be adjusted by changing the poly(vinyl pyrrolidone) content. To date, the fluorometholone implant has only been described for use in animal models.

MATRIX IMPLANTS: MISCELLANEOUS DESIGNS

Rubsamen et al.^[43] have studied a cylindrical matrix implant of PLGA and 1 mg of fluorouracil inserted at the vitreous base for the treatment of PVR. Fluorouracil, a common chemotherapy agent used in cancer trials, is a potent inhibitor of fibroblast proliferation. The fluorouracil implant swelled slightly, and then slowly degraded, with residual matrix left at 28 days. The implant prevented tractional retinal detachment in experimental PVR models, without introducing any toxicity to the adjacent tissues. The mean fluorouracil concentrations were maintained between 2.2 and 6.7 microgram/ml in the vitreous cavity for 14 days and above 0.3 microgram/ml for 3 weeks. There was minimal variation in performance among individual implants. Sustained release fluorouracil from a polycaprolactone (PCL) matrix has also been reported to be effective in preventing tractional retinal detachment in experimental PVR, without significant complications.^[44]

Investigators have employed matrix systems to deliver antifibrotic medications to improve the success of glaucoma filtering surgery. In glaucoma surgery, a communication is surgically made to redirect aqueous humor flow to the subconjunctival space near the limbus to lower the intraocular pressure. The surgical channel can eventually scar down with fibrosis occurring in the subconjunctival space and the intraocular pressure increases. Morales et al.^[45] investigated the antiproliferative agent daunomycin in a matrix system that delivered drug to the subconjunctival space to improve the outcome of glaucoma-filtering surgery in experimental models. In the Morales system, daunomycin was conjugated to hyaluronic acid by an acid labile bond. Hyaluronic acid, a high molecular-weight carrier for daunomycin, was chosen to restrict the movement of the conjugated drug from the surgical

site. It is a naturally occurring substance in the anterior segment with affinity for extracellular matrix. Daunomycin was slowly released from the hyaluronic acid with an in-vitro half life of 51 hours, and in-vivo release extending beyond 24 hours. The pharmacologically effective concentrations of daunomycin were restricted to the surgical site, making this device attractive for the delivery of daunomycin to improve the long-term success of filtering procedures. Other matrix systems that have been employed in experimental glaucoma-filtering models use polyanhydrides as the matrix polymer. Matrix disks of a polyanhydride 1,3-bis(p-carboxyphenoxy) propane and sebacic acid, with the drug etoposide, were placed in the subconjunctival region and delivered a sufficient concentration to reduce fibroblast proliferation for at least 12 days following glaucoma-filtration surgery.^[46] When considering a drug delivery system to improve the success rate of glaucoma-filtering surgery, one has to weigh the potential risks of having potent antiproliferative drugs in the eye with the potential benefits since some of these drugs have been associated with significant local toxicities.^[47]

Another novel matrix system releases daunomycin^[48,49] into the eye and was developed for use in experimental models of PVR. Poly capillary fiber (PCF) is a nonerodible, biocompatible, anisotropic ultrafiltration fiber with several desirable features for slow-release drug delivery purposes. Properties that make PCF suited for prolonged delivery include the deep macrovoids in the outer membranes that create more surface area for drug diffusion. This slow release of daunomycin reduces the potential for local toxicity without reducing its effectiveness in inhibiting fibroblast proliferation.

Applications of matrix style implants to the eye also extend to immunosuppressants, such as cyclosporine, as well as various types of polymer materials other than PLGA. A subconjunctival, PLGA matrix implant containing cyclosporine was designed for sustained immunosuppressant therapy to the anterior segment following corneal transplant therapy to prevent graft rejection.^[50] The PLGA disk is 5 mm in diameter and 0.5 mm thick, with a 1:1 polymer to drug ratio. In-vivo experiments were successful in preventing corneal rejection in animal models.

Presoaked matrices, including soft contact lenses and gels, are also simple sustained-release devices. Drug release from these devices is very rapid in the beginning and proceeds at a rate that declines exponentially with time. The basic concept of the presoaked matrix is to extend the time that the dissolved drug will continue to be effective compared with an eye drop. Soft contact lenses soaked in 2% pilocarpine can reduce intraocular pressure for almost 24 hours.^[51] Matrix implants have also been extended to oligodeoxynucleotide (ODN) therapy for the treatment of virus-related retinitis disease.^[52] These rod-shaped implants made from PLGA

release ODN following pseudo zero-order kinetics for more than 20 days in phosphate buffer solution.

Finally, injectable matrices are also effective in short periods of drug release. Fibrin sealant was found to provide a more controlled and localized release of carboplatin to treat retinoblastoma from a subconjunctival injection.^[53] The fibrin sealant, FDA-approved for facilitating blood clotting, appeared to be well-tolerated and has the potential to extend the release of multiple drugs in the subconjunctival space. Other injectable matrices that have been studied include a semisolid poly(ortho ester) that delivered fluorouracil in an experimental glaucoma-filtering model to prevent conjunctival fibrosis.^[54] The poly(ortho ester), a bio-erodible hydrophobic polymer, undergoes surface erosion confined to the polymer-water interface and can improve the duration of drug release compared with more soluble polymers like fibrin sealant.^[15]

RESERVOIR IMPLANTS: OVERVIEW

Reservoir implants deliver continuous amounts of drug over months to years, which is desirable for treatment of chronic eye diseases. These devices typically have a central core of drug, coated with a nonreactive polymer.^[23] Although polymers used for reservoir implants are generally nonerodible, there are exceptions such as a bio-erodible reservoir ciprofloxacin implant for the treatment of intraocular bacterial infections.^[7] Non-erodible silicone, ethylene vinyl acetate (EVA), and poly(vinyl alcohol) (PVA) are commonly used in reservoir devices. The primary polymers in the first extraocular implant (placed in the inferior conjunctival sac) used for drug delivery were EVA and PVA, developed by Alza Corporation (Mountain View, California)^[55,56] and marketed as the Ocusert[®] implant. The Ocusert released pilocarpine, a medication used in the treatment of glaucoma, over a seven-day period and was available in two different doses. The Ocusert improved patient compliance since pilocarpine eye drops were required

every four hours to maintain adequate intraocular pressure control.

The application of different polymers to reservoir implants is determined primarily by the permeability of a given drug through the polymer. Silicone and PVA are freely permeable to a number of drugs while providing enough support to hold the drug reservoir together. Silicone, used for the past three decades in the manufacture of a five-year releasing contraceptive implant (Norplant[®], Wyeth Pharmaceuticals, Collegeville, Penn.), has been very attractive for use in eye implants because it is biocompatible, inexpensive, easy to handle, and has a long track record of safety in the medical field. PVA, a commonly used polymer in commercial eye drops, can be used in high concentrations (5 to 50%) to coat drug pellets. PVA can be heated up to 200°C to cross-link the polymer, rendering it less soluble to drugs. The duration and temperature of the heat treatment can be varied to control the diffusion of drugs through the PVA. EVA is impermeable to most medications and used as a coating around the drug pellet to provide more controlled diffusion of the drug from the implant. The drug delivery depends on the water that diffuses through the polymer coating and dissolves part of the pellet, forming a saturated drug solution (Fig. 5). The drug then diffuses back out of the device and as long as the solution inside the device is saturated, the release rate is constant.^[57] This mechanism allows the device to deliver a small burst of drug, followed by a steady-state release rate that persists until greater than 90% of the drug pellet has diffused through the polymer. The movement of drug through the polymer in reservoir implants is governed by Fick's Law of Diffusion, where the release rate is directly proportional to both the surface area of the implant, the diffusivity (i.e., ability of a particular drug to transit through the polymer), and indirectly proportional to the thickness of the polymeric coating.^[23] The most important determinant of the longevity of a reservoir implant is the solubility of the drug in the pellet in the surrounding media. Typically, relatively insoluble drugs will give

Fig. 5 Illustration showing reservoir implant (left) with compressed drug pellet (red spheres) surrounded by a polymer. When the implant is placed in an aqueous environment (right), water diffuses through the polymer wall and dissolves the periphery of the drug pellet. The solubilized drug diffuses out of the implant through the permeable polymer. The release rate (lower-left inset) shows an initial small burst of drug followed by sustained release following zero-order kinetics.

reservoir implants the longest release rates lasting from six months to five years. Chronic eye diseases such as AMD and diabetic retinopathy are optimally treated with a constant level of drug release, or zero-order kinetics, delivered using reservoir implants.

RESERVOIR IMPLANTS: VITRASERT (GANCICLOVIR IMPLANT)

The advent of the acquired immunodeficiency syndrome in the 1980s was a challenging time for ophthalmologists. Patients with profound immunodeficiency developed opportunistic infections including a blinding condition known as CMV retinitis. Although there were no effective treatments for CMV disease, pharmaceutical companies began investigating specific anti-CMV medications such as ganciclovir. Ganciclovir was effective when administered intravenously; however, ocular penetration was poor, leading to the development of resistant CMV isolates and rapid progression of the retinitis.^[58] Further problems with intravenous ganciclovir included systemic complications including neutropenia, anemia, and renal failure. Since a central intravenous catheter was required to administer the required daily infusions, complications from the indwelling catheter in these fragile patients included sepsis and death.^[59] Investigators started investigating the use of a ganciclovir implant that would be inserted into the vitreous cavity and attached to the inside of the sclera at the pars plana using suture material (Fig. 2E). The pars plana is an ideal area in the eye to access the vitreous cavity since it is anterior to the insertion of the retina and posterior to the lens. As a result, implants inserted through the pars plana will not damage the lens, causing a cataract, and will not damage the retina, which may lead to a retinal detachment. The ganciclovir implant was the first intraocular drug delivery implant available for humans and had a profound impact on treatment of CMV retinitis.^[60] Clinical trials using the implant were started in 1990 and approval from the FDA occurred in 1996. Marketed under the trade name of Vitrasert[®] (Bausch and Lomb, Rochester, NY), the implant was constructed by coating a compressed ganciclovir pellet with PVA, which is permeable to the drug, and then partially coated with EVA, which is impermeable to the drug, to reduce the release rate (Fig. 6). The pellet complex was attached to a PVA suture stub, heated to partially cross-link the PVA and adjust the in-vitro release rate to 1.4 microgram/hr. In vivo, the intravitreal drug levels were 4.1 microgram/ml, considerably higher than those levels achieved following intravenous therapy (0.93 microgram/ml).^[61,62] The device was capable of delivering drug for approximately eight months. Clinical studies showed that the median time to progression of retinitis

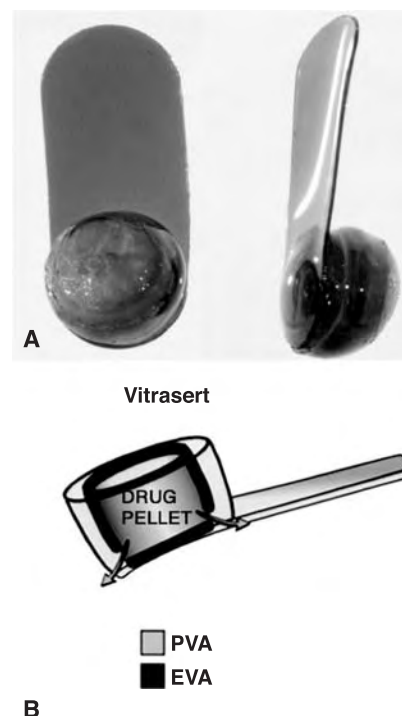

Fig. 6 (A) Vitrasert implant showing front and side views. The drug pellet contains ganciclovir, a potent antiviral agent to treat CMV retinitis. The long suture stub is trimmed and used to fixate the implant to the sclera at the pars plana, allowing the drug reservoir to release drug into the vitreous cavity. (B) Schematic drawing of Vitrasert implant showing the drug pellet surrounded by two polymers, PVA and EVA. Ganciclovir is freely permeable to PVA; however, to reduce the release rate, EVA (not permeable to ganciclovir) coats approximately 90% of the pellet and drug is released (arrows) at the base of the implant.

in untreated patients (controls) was 15 days, compared with 226 days for patients assigned to immediate treatment with the implant. This compared favorably with reported times to progression in patients treated with intravenous ganciclovir, which was 71 days.^[12,63] Vitrasert implant has emerged as the most efficacious method of treating CMV retinitis and the patient acceptance is high, given the alternatives of frequent biweekly intravitreal injections or daily drug infusions (Fig. 7). Because the device eventually runs out of drug and must be replaced, appropriate implant exchange practices have been adopted. The optimal time for exchanging the ganciclovir implant is dictated by the predictability of the duration of release of each device, the location of retinitis, and the overall health of the patient. The duration of release of each implant is dependent on the original quantity of drug, the rate of drug release from the device, and the rate of tissue clearance of the drug.^[64] The prototype ganciclovir

Fig. 7 (A) External photograph of the eye showing the sclera above and cornea below. This patient has two Vitrasert implants placed in the eye. The fixating suture material (arrows), using nonresorbing prolene material, is visible in the subconjunctival area. (B) External photograph of right eye showing the patient looking down to the right. The pupil is widely dilated and the top edge of a Vitrasert implant (arrow) is visible inside the vitreous cavity. (C) Photograph of the back of the eye of a patient with CMV retinitis. The retina is visible with areas of hemorrhage and necrosis (arrows) at the location of the CMV lesion. (D) Photograph of the CMV lesion in Fig. 7C following the insertion of a Vitrasert implant. Note the areas of hemorrhage and necrosis have resolved, and a large retinal scar is present in the area of previous infection.

implants had drug reservoirs of 5 mg and in-vitro release rates of either 1 microgram/hr or 2 microgram/hr. Therefore, expected duration of release from each prototype was 208 days and 104 days, respectively, assuming the in-vivo release rates were similar to the in vitro. Multiple reentries into the vitreous cavity through the same wound may be associated with an increased risk for vitreous hemorrhage and retinal detachment; thus, an implantation site in the eye is used no more than twice. There are acceptable ocular complications that occur in patients receiving the Vitrasert implant including a temporary decrease in visual acuity lasting a few weeks after surgery.^[63] Also, the intraocular surgery entails risks such as endophthalmitis, vitreous hemorrhage, retinal detachment, extrusion of the strut, and improper placement of the implant in the suprachoroidal space that occur in <5% of cases.^[12,60,65] Endophthalmitis can possibly be prevented by using a modified surgical technique with a scleral flap covering the incision.^[66] Patients treated with implants also may be at higher risk for developing extraocular CMV disease; thus, the combination of implantation and systemic administration of ganciclovir using the oral prodrug formulation is most effective in combating CMV infection.

RESERVOIR IMPLANTS: CORTICOSTEROID IMPLANTS

Corticosteroids are important in the management of ocular inflammatory disease that involves inflammation and/or fibrovascular proliferation such as PVR and uveitis. Experiments with dexamethasone showed that an intraocular injection of dexamethasone can successfully inhibit fibrous proliferation in the vitreous cavity, so dexamethasone was one of the first corticosteroids to be placed in a sustained release reservoir device.^[67] The dexamethasone implant contained a 5 mg drug pellet, and released at 1.5 microgram/hr in the vitreous, maintaining a vitreous concentration of approximately 2–3 microgram/ml.^[68] The implant was well tolerated, with no signs of ocular toxicity; however, since the implant would last for only five months, corticosteroids with less solubility were studied in reservoir implants. A reservoir implant releasing fluocinolone, capable of delivering drug for three years in the vitreous cavity, rapidly moved from preclinical testing^[69] to clinical human trials (Fig. 8A and B). A pilot study using fluocinolone acetonide reservoir implants in patients with refractory uveitis proved to be effective in reducing ocular inflammation and significantly improving

Fig. 8 (A & B) A fluocinolone implant showing front and side views. (C) Cyclosporine implant showing side view of a double-pelleted implant (left) and a single-pelleted implant (right). The implant with two pellets will deliver approximately twice the release rate of a single-pellet implant. Two implant doses are standard for clinical trials examining the efficacy of an implant for treating an eye disease. (D) External photograph of right eye showing the patient looking down to the right. The pupil is widely dilated and a double-pelleted implant (arrow) is visible inside the vitreous cavity.

vision.^[22] Complications included glaucoma and some patients required topical antiocular hypertension drops to lower the eye pressure. Larger multicenter trials using the fluocinolone implant are in progress internationally for uveitis, diabetic macular edema, and choroidal neovascularization associated with AMD.

RESERVOIR IMPLANTS: CYCLOSPORINE IMPLANTS

Oral cyclosporine, a potent immunosuppressant used to prevent allograft rejection, is an effective treatment for chronic uveitis.^[70] However, side effects including renal insufficiency and hypertension often limit its long-term use. Cyclosporine reservoir implants have been designed to release drug into the eye for a number of years to treat chronic uveitis.^[21] The implants were constructed using a core of 5 mg cyclosporine,

measuring 2.5 mm in diameter, coated with medical grade silicone, cured at 104°C for one hour, then attached to a PVA suture tab for placement in the vitreous cavity through the pars plana.^[20] Experimental studies have shown that devices releasing cyclosporine at a rate of 1.3 microgram/day can achieve intravitreal levels over a six month period of 500 ng/ml, which is five times the therapeutic level needed to suppress T-cell activation. These implants can theoretically release for three–five years, which is appropriate for the disease that can be active for decades. In both equine^[71] and rabbit^[21] models of uveitis, the cyclosporine implant showed reduced inflammation compared to the control eyes. A pilot study using the CsA implant for refractory cases of uveitis in humans is currently underway at the National Eye Institute in Bethesda, MD (Fig. 8). Reservoir implants for both intravitreal and subconjunctival (Fig. 9) placement have also been used to deliver angiostatic agents including 2-methoxyestradiol

Fig. 9 (A) Reservoir implant (red asterisk) containing investigational drug to treat retinal disease will be placed through previous incision made through conjunctiva (arrow) of rabbit eye. (B) Implant is placed through conjunctival incision and will be sutured closed to prevent implant extrusion.

and thalidomide in models choroidal neovascularization associated with age-related macular degeneration.^[23,28,72] Long-term safety studies on animals are mandated by the FDA and are a prerequisite to human trials to minimize the risk to the patient (Fig. 10).

RESERVOIR IMPLANTS: CODRUG IMPLANTS

The combination of the anti-inflammatory effects of corticosteroids and antiproliferative properties of an antimetabolite, such as fluorouracil, is the basis of codrug reservoir implants that can target several processes of a disease process such as PVR. Delivering multiple drugs simultaneously requires the conjugation of one of more drugs with a covalent carbonate bond linkage and compressing the codrugs into a pellet to be placed in a reservoir device. The drug conjugation makes the codrug complex less soluble, increasing the half life of each drug moiety.^[67] Codrug release into solution occurs in two steps. First is the codrug dissolution from the pellet, which is determined by the solubility of the compound, and is the principal rate-limiting step. The second step is

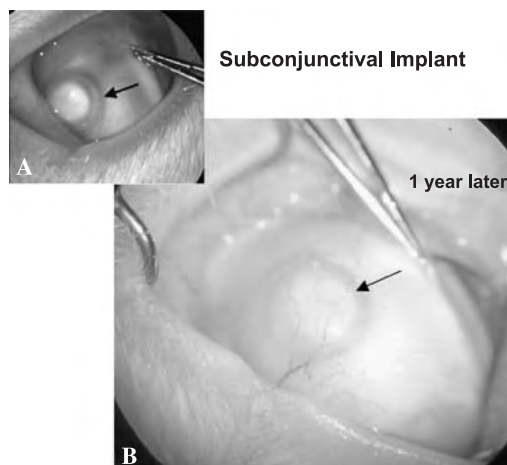

Fig. 10 (A) Reservoir implant (arrow) in subconjunctival space of rabbit eye three months after implantation. Tissues surrounding implant are intact and there are no signs of toxicity. (B) Same reservoir implant (arrow) seen in Fig. 10A after one year showing reduced drug reservoir and no long-term toxicity visible on the surface of the eye.

codrug hydrolysis, which occurs rapidly, and releases the drug moieties into equimolar quantities. It had been demonstrated that sustained release of triamcinolone and fluorouracil codrug was effective in the inhibition of a rabbit model of PVR without toxic effects evident on clinical or histopathologic examination.^[73] Codrug reservoirs that have been developed also include a CsA-dexamethasone implant to treat ocular inflammation,^[74] and a dexamethasone-fluorouracil codrug implant that was effective in a model of PVR.^[67] Other approaches have been described to release multiple drugs simultaneously without the use of codrug technology. Zhou et al. reported a multiple drug delivery implant prototype that had been designed and prepared to test a local controlled-release strategy and multiple-drug regimen approach for intravitreal treatment of PVR.^[75] The device was composed of PLGA, in three contiguous cylindrical segments, each containing 5-fluorouridine, triamcinolone, and human recombinant tissue plasminogen activator (a thrombolytic agent). The first two drugs were used as antiproliferative agents to inhibit fibroblast proliferation and the third drug dissolves hemorrhage that may have occurred in the vitreous during the surgery.

RESERVOIR IMPLANTS: LIVE CELL IMPLANTS

Reservoir implants for ocular delivery have generally used small molecular weight drugs that are stable under the curing conditions of the polymer and the biologic effects of the drug are not altered during implant

construction. Large molecular weight compounds such as cytokines, proteins, and monoclonal antibodies have not been successfully incorporated in reservoir implants for the eye. To overcome these obstacles, Neurotech USA (Lincoln, Rhode Island) developed a novel approach to release proteins into the vitreous using encapsulated cell therapy implants. The implants contain cells that are genetically engineered to secrete therapeutic factors for long-term delivery into the vitreous. Neurotech constructed an implant to release ciliary neurotrophic factor (CNTF), a protein that may be a potential treatment for neurodegenerative diseases of the eye such as retinitis pigmentosa. The titanium implants (10 mm length and 1.0 mm diameter) are loaded with mammalian cells that are genetically engineered to secrete CNTF. Genetically modified cells are packaged in a hollow-fiber, semipermeable membrane, mostly of polyether sulfone. The hollow-fiber prevents immune molecules and host immune cells from entering the device, but allows nutrients and therapeutic molecules to diffuse freely across the membrane. The encapsulated cells are in a matrix material and derive nourishment from the host milieu. The device is anchored to the sclera at the pars plana by a small titanium wire loop. In one study, CNTF was delivered through encapsulated cells directly into the vitreous of the eye in a canine model of retinitis pigmentosa.^[76] The CNTF implant had a protective effect as demonstrated by a higher photoreceptor density in eyes treated with CNTF compared with controls. No adverse effects were observed on the retina in the treated eyes. Protection of photoreceptors appeared to be dose-dependent, with minimal protection at CNTF doses of 0.2–1.0 ng/day and greater protection at higher doses. The implants were well tolerated and the cells remained viable for the seven-week implantation interval. Clinical studies in humans are currently in development to use the CNTF implant in patients with advanced retinitis pigmentosa.

RESERVOIR IMPLANTS: OSMOTIC PUMP SYSTEMS

Osmotic pumps have been investigated for the last three decades at Alza Corporation (Mountain View, California) principally for systemic drug administration.^[77] Alza Corp. gained FDA approval in 2000 for the Viadur[®] implant that releases leuprolide to treat patients with advanced prostate cancer. Small-size osmotic systems are also an effective drug delivery mechanism for eye disease.^[1,27,78] However, these pumps are too large to be placed in the eye, but attempts at fixating the drug reservoir under the skin near the eye or on the external eyelid, with a tube leading from the reservoir into eye tissue, have been performed in experimental models. In a model of endophthalmitis, an osmotic

pump was placed subcutaneously, which infused gentamicin sulfate into the vitreous over a 4.5-day period, releasing at approximately 0.1 mg/hr, and proved to be effective in treating the infection. Ambati and colleagues^[18] showed a similar pump could deliver antivascular endothelial growth factor antibodies through the sclera into the choroid and subretinal space to potentially treat choroidal neovascularization in AMD.

CONCLUSION

Drug delivery implants have had a profound impact in clinical ophthalmology, especially in the management of retinal diseases that can lead to blindness. Ocular implants have been engineered to avoid the barriers that often impede the delivery of drug via traditional methods. Matrix implants, with drug release generally lasting less than three months, are being investigated to treat acute eye diseases, while reservoir implants, with drug release lasting up to five years, are used for chronic eye diseases. The investigation and clinical use of ocular drug implants requires a multidisciplinary approach including biomedical, materials, and chemical engineers interacting with ophthalmologists. This team approach will facilitate the development of ocular implants for drug release, thus providing more treatment options to reduce the severity of sight-threatening diseases.

Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.

INTRODUCTION

Optical coherence tomography (OCT) is an emerging biomedical imaging technology, which is capable of performing cross-sectional imaging of internal microstructures of biological tissues *in vivo* and in real time.^[1–4] OCT is analogous to ultrasound B-mode imaging except that OCT uses near infrared light rather than sound. The optical echo delay time (related to depth) and intensity of light backscattered from biological tissues are measured using a technique called low-coherence interferometry. The backscattered light intensity versus the echo delay time (or depth) and the transverse position forms a cross-sectional image that can be displayed on a gray or false-color scale. An axial resolution of 1–10 μm has been achieved using advanced low-coherence light sources. Different from other medical imaging modalities such as X-ray computed tomography (CT), positron emission tomography (PET), magnetic resonance imaging (MRI), and ultrasound, OCT image contrast arises from optical scattering and absorption properties of biological tissues. OCT imaging depth is governed by optical attenuation (dominated by optical scattering), and imaging depths of 1–2 mm can be achieved in most highly scattering tissues using a near infrared light source in the 800–1300 nm wavelength range. Therefore, OCT is ideal for imaging the skin, and the epithelial/endothelial linings of internal luminal organs. OCT is very attractive in biomedicine because imaging can be performed in a noninvasive, non-contact fashion with a resolution approaching that of histology, but without the need for tissue removal or processing. OCT is a fiber-optically-based technology, making the OCT system very compact and potentially cost-effective. Flexible fiber-optic OCT imaging probes permit imaging of internal organs and integration with many medical instruments. In addition to structural imaging, OCT can also perform high-resolution, high-sensitivity imaging of blood flow and tissue birefringence.^[5–9] Studies have demonstrated OCT can assess tissue structural morphologies and functional processes in a variety of organs and/or systems including the eye, skin, gastrointestinal tract, oral cavity,

and cardiovascular system etc.^[10–19] OCT is becoming a clinically viable imaging modality for early detection of diseases, precision guidance of surgical interventions, and repeated monitoring of treatment. In the following sections, we will discuss the operating principles technological aspects and advances of OCT and representative clinical and biomedical applications.

PRINCIPLE OF OCT OPERATION

OCT is analogous to ultrasound except that near infrared low-coherence light is utilized instead of acoustic waves. A schematic of a typical OCT system is shown in Fig. 1A. The OCT system is based on a fiber-optically implemented Michelson interferometer. The interferometer contains a fiber-optic coupler (e.g., a beam splitter/combiner), which splits the low-coherence light (e.g., light with a broad spectral bandwidth) into two parts. One part is delivered to the tissue to be imaged through one of the two interferometer arms called the sample arm; the other part is sent to the reference arm, where the optical pathlength is scanned. The light backscattered from the tissue will be recombined by the coupler with light from the reference arm with a known delay, and directed to a photo detector. The echo delay time and backscattered light intensity are detected by measuring the interference signal at the detector. The interference signal only occurs when the distances traveled by the light from the sample and reference arms match to within the coherence length of the light source (see Fig. 1B). The frequency of the interference signal (or the beat frequency) is determined by the Doppler frequency shift induced by optical pathlength scanning in the reference arm. OCT essentially performs heterodyne optical detection and therefore extremely high sensitivity exceeding 100 dB can be achieved, meaning OCT can detect the backscattered light from the tissue at a level of one part in 10 billion of the incident light intensity. The echo delay time and intensity of light backscattered at different depths in the tissue can be measured by scanning the optical

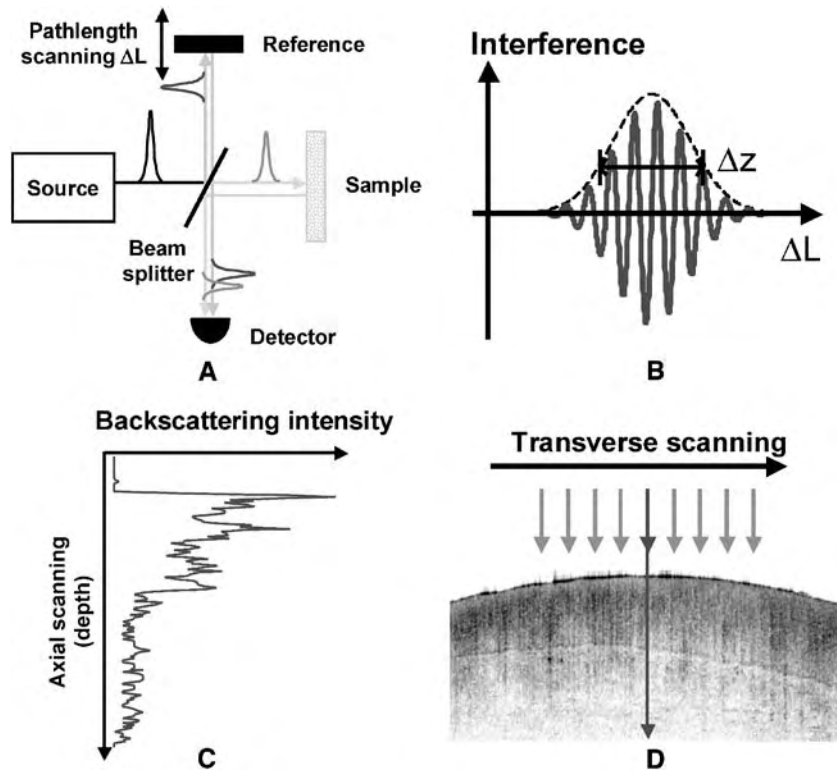

Fig. 1 (A) Schematic of a fiber-optic OCT system. (B) Localized interference occurs when the distances traveled by the light in the OCT reference and sample arms match to within the coherence length of the low-coherence light source (e.g., the two pulses returned from the reference and sample arms overlap at the detector). (C) Intensity versus the optical echo delay time (or depth) forms an axial scan. (D) A cross-sectional tomographic image is formed by multiple adjacent axial scans acquired at different transverse positions.

pathlength in the reference arm. The echo delay time is translated into imaging depth, and the backscattering intensity versus depth forms an axial scan (see Fig. 1C). A two- or three-dimensional data set consisting of multiple adjacent axial scans at different transverse positions can be acquired by laterally scanning the optical beam across the tissue (see Fig. 1D). The cross-sectional image can be displayed using a false-color or gray-scale in a Cartesian or polar coordinate system depending upon the application.

In order to analyze the OCT signal, we assume that the optical pathlength (or depth) scanning is performed in the reference arm by translating a mirror with a scanning velocity of v_s . For a given color of light with an optical frequency, f , the Doppler frequency shift in the reference arm is $f_d = (2v_s/c)f$, where c is the speed of light in a vacuum. The input light intensity and electrical field to the Michelson interferometer are $I_o(f)$ and $E_o(f)$, respectively. The E-field reflection coefficients (which are in general complex numbers) for the scanning mirror in the reference arm and the tissue in the sample arm are denoted by $r(f)$ and $s(f)$, respectively. For simplicity, we assume the 50/50 beam splitter has a wavelength-independent splitting ratio. At the detector, the E-field of the light returned from the reference arm is given by $E_r(f) = r(f)E_o(f)/2$, and the E-field of the light backscattered from the tissue is $E_s(f) = s(f)E_o(f)/2$. The interference signal measured at

the detector is thus

$$\begin{aligned}
 I_f(t) &= \langle |E_r(f)e^{i2\pi ft} \\
 &\quad + E_s(f)e^{i2\pi(f+f_d)t}|^2 \rangle_{\text{Time Average over } 1/f_d \gg t \gg 1/f} \\
 &= \frac{I_o(f)}{4} \left[|r(f)|^2 + |s(f)|^2 \right. \\
 &\quad \left. + 2|r(f)s(f)| \cos(2\pi f_d t + \phi_o) \right] \quad (1)
 \end{aligned}$$

where $t = z/v_s$ is the scanning time related to the scanning depth z and the scanning velocity v_s , and ϕ_o is the phase difference between the two beams returned from the reference and sample arms. In general, the reflectivity in the reference arm is flat and independent of the wavelength within the range of interest (e.g., when using a perfect retroreflecting mirror). Therefore, $|r(f)| = r$ will be a constant and its value represents the optical attenuation in the reference arm. In many cases, we are only interested in the AC component of the interference signal, $I_f^{AC}(t) = [I_o(f)/2]r|s(f)|\cos(2\pi f_d t + \phi_o)$, which is the beating term of two beams at the difference frequency. The constant reflectivity, r , of the reference arm functions as a heterodyne gain for the AC component. Hereinafter, without further specification, the interference signal means the AC component of the interference signal.

Since OCT uses a low-coherence light, the total interference signal will be an integral of Eq. 1 over the entire spectrum of the light source, and the OCT interference signal is then given by:

$$\begin{aligned} I_{\text{All}f}^{AC}(t) &= r \int_f \frac{I_o(f)}{2} |s(f)| \cos(2\pi f_d t + \phi_o) df \\ &= \frac{r}{2} \int_f I_o(f) |s(f)| \cos\left(\frac{4\pi v_s t}{c} f + \phi_o\right) df \end{aligned} \quad (2)$$

Assuming the phase difference, ϕ_o , is wavelength-independent, the previous equation can be rewritten as:

$$\begin{aligned} I_{\text{All}f}^{AC}\left(t' = \frac{2v_s t}{c}\right) &= \text{Re}\left\{\frac{r}{2} \int_f I_o(f) |s(f)| \exp[i(2\pi f t' + \phi_o)] df\right\} \\ &= \frac{r}{2} \text{Re}\{\exp(i\phi_o) FT[I_o(f) |s(f)|]\} \end{aligned} \quad (3)$$

Equation 3 indicates the OCT interference signal is related to the Fourier transform (FT) of the product of the source power spectrum $I_o(f)$ and the tissue reflectivity $|s(f)|$. For a majority of OCT signal processing, Eq. 3 is the starting point for analyzing the tomographic envelope, Doppler flow, and spatially resolved spectroscopy.

OCT TECHNOLOGY

In this section, we discuss some of the key technological aspects of OCT, which include imaging resolution, speed, beam delivery, and collection probes, and data processing for obtaining spectroscopic and functional information. As in any imaging technology, resolution is one of the most important parameters and therefore we consider this first.

OCT Imaging Resolution

Unlike confocal microscopy, the transverse and axial resolutions of OCT are determined independently by different physical mechanisms. The transverse resolution ΔX is governed by the focusing optics and determined by the transverse focused spot size $\Delta X = (2\lambda/\pi)NA$, where $NA = d/2f$, d is the beam spot size on the objective lens, and f is the focal length. The axial resolution ΔZ of OCT, however, is given by the coherence length of the light source, which can be derived from Eq. 3. To simplify the derivation, we assume the backscattered spectrum from the tissue does not change and the spectrum $|s(f)| = s$ is thus wavelength-independent. Under this condition, Eq. 3 indicates

the OCT interference signal is simply the Fourier transform of the power spectrum of the light source, which is the field temporal correlation function according to the Wiener-Khinchin theorem.^[20] Consider a low-coherence light source with a Gaussian spectrum, e.g.,

$$I_o(f) = I_o \frac{2\sqrt{\ln 2/\pi}}{\Delta f} \exp\left[-4 \ln 2 \left(\frac{f - f_o}{\Delta f}\right)^2\right] \quad (4)$$

where Δf is the full-width-at-the-half-maximum (FWHM) of the source power spectrum, f_o is the center frequency of the light source, and I_o is a constant (e.g., the total power of the light source over the entire spectrum). The Fourier transform of a Gaussian spectrum can be easily calculated and Eq. 3 then becomes:

$$\begin{aligned} I_{\text{OCT}}(t') &= \frac{rs}{2} \text{Re}\{\exp(i\phi_o) FT[I_o(f)]\} \\ &= \frac{rs}{2} \exp\left[-\frac{(\pi\Delta f t')^2}{4 \ln 2}\right] \cos(2\pi f_o t' + \phi_o) \end{aligned} \quad (5)$$

After substituting the variable t' with time t (e.g., $t' = 2v_s t/c$), we have the following time-dependent OCT interference signal:

$$I_{\text{OCT}}(t) = \frac{rs}{2} \exp\left[-\frac{(2\pi\Delta f v_s t/c)^2}{4 \ln 2}\right] \cos\left(\frac{4\pi v_s f_o t}{c} + \phi_o\right) \quad (6)$$

As can be seen from Eq. 6, the OCT interference signal is amplitude-modulated. The exponential part forms the modulation envelope, and the free-space axial resolution is then given by the FWHM of the envelope multiplied by the reference arm scanning velocity v_s , i.e.:

$$\Delta Z = \Delta t \cdot v_s = \frac{2 \ln 2 c}{\pi \Delta f} = \frac{2 \ln 2}{\pi} \frac{\lambda_o^2}{\Delta \lambda} \quad (7)$$

where λ_o is the center wavelength of the light source and $\Delta \lambda$ is the spectrum bandwidth. It should be mentioned that the axial resolution in tissue is the free-space axial resolution divided by the tissue index of refraction. From Eq. 7, we see that the OCT axial resolution is inversely proportional to the spectrum bandwidth of the light source. A light source with a broader spectrum bandwidth produces a finer resolution. White light, which has a very broad spectrum, would be a good source for achieving high axial resolution.^[21,22] However, conventional white light sources such as an arc lamp have a poor spatial coherence, and the coupling efficiency of white light into a single-mode optical fiber is extremely low, making it difficult to use a white light source in a fiber-optic OCT system. Therefore, an ideal light source for high-resolution fiber-optic OCT imaging should have a

Fig. 2 (A) Spectrum of a short-pulse Ti:Sapphire laser (7–8 fs, transform limited, plus ~ 5 –10% spectrum broadening when launched into a single-mode fiber). (B) The OCT interference signal, of which the FWHM of the envelope determines the OCT axial resolution.

short temporal coherence length, and be spatially single mode. Other requirements for an OCT light source include emission in the near-infrared range (e.g., 800–1500 nm for deeper imaging penetration in highly scattering tissues), high irradiance power (e.g., 5–15 mW for a better signal-to-noise ratio), and a nearly Gaussian spectrum shape (e.g., for minimizing side lobes on the interference signal). Super luminescence diodes (SLDs) are commonly used for OCT imaging. SLDs with a center wavelength at 800 nm or 1300 nm are commercially available and can achieve an axial resolution of about 5–20 μm . The SLDs are compact, making the fiber-optic OCT system very portable.

Recently, advanced low-coherence light sources have been developed including short-pulse femto-second (fs) solid-state lasers and continuum generation in nonlinear photonic crystals.^[23–26] Representative fs lasers are 5–9 fs Ti:Sapphire lasers operating at a center wavelength of approximately 800 nm and a 14–20 fs Cr:Forsterite laser operating at a center wavelength of approximately 1400 nm.^[23,24,27] The resultant axial resolution is about 1.5–5 μm .^[28,29] Most of the high-performance short-pulse lasers rely on specially designed and expensive chirped or double-chirped mirrors for intracavity dispersion management.^[23,27,30] Recently, our group at the University of Washington has built a cost-effective, 7–8 fs transform-limited Ti:Sapphire laser with a moderate footprint (75L \times 28W \times 18H cm) using off-the-shelf optical components. As shown in Fig. 2, the laser has a broad spectrum of more than 150 nm smooth providing a free-space axial resolution of 2.5 μm .

Another type of advanced broadband light sources for OCT is continuum generation in microstructured or tapered nonlinear photonic fibers. A super-broad optical spectrum can be generated, ranging from the visible to the near-infrared (500–1600 nm).^[25,26]

In addition to the broad spectrum, the continuum light source provides high spatial coherence, high power, and can be potentially made very compact. The challenges of using the continuum include the requirement of using a short-pulse pump laser, careful polarization management, and spectrum shaping. It has been demonstrated that a 2- μm axial resolution can be achieved using the continuum with a center wavelength of approximately 1200–1300 nm.^[31,32] Figure 3 illustrates an OCT image of in vivo hamster cheek pouch using the continuum light source centered at 1300 nm.^[31] Microstructures such as the epithelium, muscle layer, and a blood vessel can be clearly identified.

When using a broad spectrum for OCT imaging, the dispersion between the sample and the reference arms

Fig. 3 In vivo OCT image of a hamster cheek pouch acquired with an ultrabroad continuum generated in a microstructure crystal fiber. Structures such as the epithelium (E), lamina propria (Ip), muscle layer (M), and a blood vessel (V), can be clearly identified. (Adapted from Ref. [31].)

needs to be carefully matched in order to achieve the optimal resolution provided by the light source.^[33,34] Unmatched dispersion will cause broadening of the temporal envelope of the interference signal in time domain, or cause out-of-phase summation of the interference signals at different wavelengths in the frequency domain, which will degrade the resolution offered by the light source.

OCT Imaging Speed

OCT imaging speed depends on how fast the optical pathlength in the reference arm can be scanned except when spectral domain techniques are employed.^[35–39] The typical scanning range required is about a few millimeters. Many OCT systems perform optical pathlength scanning by mechanically translating a retroreflector in the reference arm. This is one of the simplest ways to scan optical pathlength. As shown in Fig. 4A, the retroreflector can be translated reciprocally by a galvanometer to achieve a few-millimeter scan with a micron precision and a constant scanning velocity. A constant scanning velocity is advantageous because the Doppler frequency shift at a given wavelength is constant. Thus, heterodyne detection can be performed at a fixed center frequency with a fixed frequency bandwidth, resulting in a better signal-to-noise ratio than those where the center frequency changes with the scanning depth. This simple, mechanically translated scanner can be very compact and perform optical pathlength scanning at a velocity up to 100 mm/s with a repetition rate up to 100 Hz. An image of 500 axial scans can be acquired in about five seconds using this scanner. The most attractive feature of the retroreflecting scanner is that it does not induce extra dispersion during pathlength scanning, thus making it suitable for scanning an optical beam with an ultra broad spectrum without degrading the resolution.

Real-time OCT imaging became possible when the rapid-scanning optical phase delay line (RSOD) was developed.^[40–42] As shown in Fig. 4B, the delay line is based on a grating-lens pair, similar to those used for

ultrafast pulse shaping.^[43,44] The working principle of RSOD is elegant, and it relates to the time-shift theorem in the Fourier transform.^[45] The grating-lens pair first performs an optical Fourier transform; the scanning mirror adds a phase shift linear to each optical frequency (or color). The phase-shifted light is then sent back to the lens-grating pair, and a group time delay is generated after the inverse Fourier transform. As the mirror scans, the slope of the linear phase shift varies, resulting in a varying group delay or an equivalent pathlength scanning. With a RSOD, real-time OCT imaging at 2000 axial scans per second over a 2–3 mm depth is feasible. This corresponds to an imaging speed of four frames per second for an image size of 500 axial scans. Imaging at a higher repetition rate of 4000 scans/s is possible by using a resonant scanner.^[42] However, in this case the scanning velocity has a sinusoidal time-dependence, requiring a broader detection bandwidth. The RSOD has become the most commonly used pathlength scanner for real-time OCT imaging. The center Doppler frequency is tunable by choosing the offset of the beam incident on the scanning mirror relative to the scanning axis, which can be extremely convenient, depending on the applications and detection hardware.

Other high-speed optical pathlength scanners include a rotating glass slab,^[46] and a rotating cube driven by an air turbine.^[47] The fastest scanning velocity achieved to date is about 175 m/s with a repetition rate at 28,600 scans/s. The trade-off of fast scanning is the increased complexity of detection electronics and the reduced signal-to-noise ratio.

One challenge still remains with the aforementioned fast scanners. The RSOD and rotating cube scanners are dispersive. Extra dispersion is introduced in the reference arm during depth scanning, which causes dispersion mismatch between the sample and the reference arms. Due to the high scanning speed, dynamic dispersion compensation is extremely difficult, if not impossible. To overcome this difficulty, a rapid scanning all-reflective optical delay line (RSAD) has been recently developed^[48] which does not introduce scanning-depth-dependent dispersion. As shown in the schematic (Fig. 5), the RSAD only uses three reflective

Fig. 4 (A) Schematic of a retroreflecting optical pathlength scanning delay line. The scanning repetition rate is up to approximately 100 Hz. (B) Rapid-scanning optical phase-controlled delay line (RSOD) based on a grating-lens pair and a scanning mirror. The scanning repetition rate is in the kHz range.

Fig. 5 Schematic of a rapid-scanning all-reflective delay line (RASD), which is nondispersive and suitable for real-time ultrahigh resolution OCT imaging when using an ultrabroad spectrum. Optical pathlength scanning is in the kHz range. (See Ref. [48] for details.)

mirrors, one curved and two flat mirrors. The collimated beam is incident on the scanning mirror with an offset relative to the scanning axis. Compared to another elegant all-reflective pathlength scanner based on a reflective rotary mirror array,^[49] the RSAD is extremely simple and easy to implement. Compared to the multiple-pass Herriott-cell-based scanner,^[50] RSAD is easy to align and has a high and flat coupling efficiency during the depth scanning. The overall size of the RAD is about 2.5×2.5 inches, and it can perform 1–1.2 mm depth scanning at a 4000-Hz repetition rate. The fluctuation of the light intensity in the reference arm is less than $\pm 5\%$, which keeps the heterodyne gain relatively flat over the imaging depth. A larger scanning range is possible by using a double-pass configuration or by using a large scanning mirror.

OCT Imaging Probes

A variety of OCT applications have been made possible by the development of novel OCT imaging probes. The OCT imaging probes deliver and focus a single-mode optical beam to the sample, and collect the beam backscattered from the sample. These imaging probes include a microscope-type device for imaging the skin and the eye,^[51–53] a scanning handheld probe for open-field imaging or surgical guidance,^[54,55] a flexible fiber-optic catheter/endoscope for intraluminal imaging of hollow organs,^[56–59] a Doppler catheter for imaging blood flow and a rigid microneedle for interstitial imaging of soft solid tissues.^[60,61] The flexible OCT catheter/endoscope was first reported in 1996,^[56] which greatly expanded OCT applicability for imaging internal organs including the gastrointestinal (GI) tract, bladder, female reproductive tract, and cardiovascular system.^[18,62–67] Figure 6 shows the schematic and a photo of the distal end of an OCT catheter/endoscope. It consists of a single-mode optical fiber, a graded-index (GRIN) lens to focus the beam, and a miniature prism to deflect the beam by 90° . The entire catheter is encased within a speedometer cable and has an overall diameter of about 1 mm (3 French). The catheter can be rotated by a motor at its proximal end in order to perform circumferential (or radial) imaging; it can also be longitudinally translated in order to perform imaging in a rectangular plane. The OCT catheter/endoscope has no active components and can be used directly to image hollow organs. Forward-imaging endoscopes have also been developed based on magnetically actuated fibers, MEMS scanners and piezo-driven fiber-optic scanners.^[59,68,69] The forward-imaging catheter/endoscope can be used in a wide range of applications and potentially attractive for guiding surgery or excisional biopsy since it permits

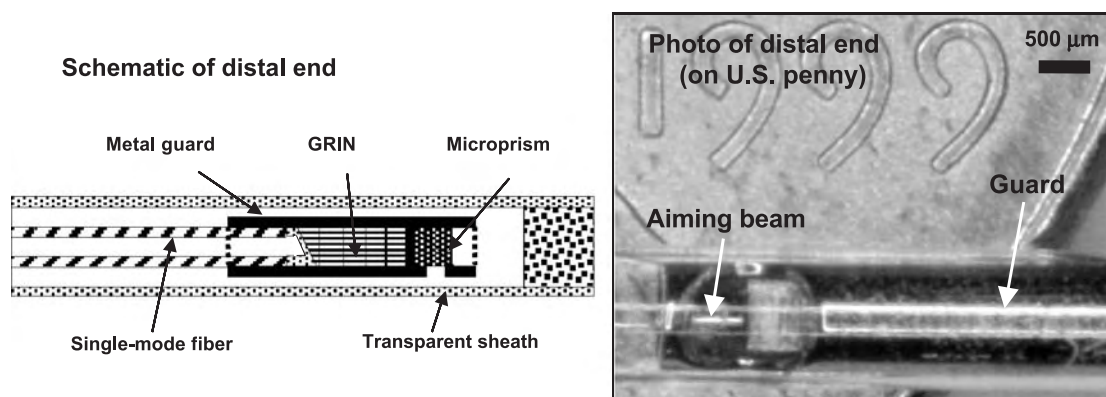

Fig. 6 Schematic and photograph of an OCT catheter/endoscope. The catheter scans the beam in a circumferential or longitudinal direction to cross-sectionally image hollow organs or vessels. A flexible speedometer cable encases a single-mode optical fiber, distal lens and a microprism. The beam is emitted perpendicularly to the catheter axis. (From Ref. [65].)

Fig. 7 (A) Photo of a 27-gauge OCT needle for interstitial imaging of internal tissue microstructures. (B) In vivo OCT image of a hamster leg muscle acquired with the OCT needle. Muscle fiber bundles can be identified as indicated by the arrow (F). (From Ref. [60])

imaging of tissues ahead of the device. Development of novel OCT endoscopes/catheters is still an area of active research. The small diameter of these imaging devices permits interfacing the catheter/endoscope with a wide range of medical instruments such as standard endoscopes by introducing the OCT device through the accessory channel. To prevent the polarization state of light from changing due to the torque on the fiber during circumferential imaging, a polarization-insensitive OCT endoscope with a built-in Faraday rotator at the distal end has been developed.^[58]

Due to the strong optical attenuation, OCT imaging depth is limited to 1–2 mm from the surface. Internal imaging of solid tissues was not possible prior to the development of a 27-gauge OCT imaging needle.^[60] The schematic of an OCT needle is similar to the OCT catheter and Fig. 7A shows a photo of a prototype OCT imaging needle. The overall diameter is about 410 μm (27-gauge) and devices with an even smaller diameter are possible. The relative distances between the optical components are set to achieve desired beam parameters including the focused spot size and the working distance. The distal tip of the needle is sharpened to facilitate interstitial delivery. Figure 7B illustrates an in vivo OCT needle image of the hamster leg muscle, from which the muscle fiber bundles can be clearly identified. The needle diameter is smaller than most excisional fine aspiration needles, so that tissues can be imaged with minimal trauma. Compared to a core biopsy needle, which generally samples the tissues with a diameter of 1 mm, the OCT imaging needle can have a sampling diameter of 2–6 mm (which is twice the imaging depth). This represents a 4- to 36-fold increase in the sampling volume. In addition, OCT needle imaging does not require tissue removal. Applications include fine needle optical biopsy and image-guided excisional biopsy.

Spectroscopic, Doppler, and Polarization OCT

In addition to structural imaging, OCT can also perform spectroscopic imaging, Doppler flow imaging,

and tissue birefringence imaging with a micron scale spatial resolution. As can be seen in Eq. 3, the wavelength-dependent E-field reflection coefficient, $s(f)$, contains information on tissue optical scattering and absorption. The backscattered optical spectra at different depths can be obtained by taking a short-time Fourier transform or wavelet transform of the interference signal followed by normalization with the source spectrum.^[70,71] Unlike conventional spectroscopy, OCT provides a spatially resolved reflection spectrum with a micron spatial resolution. Wavelength-dependent tissue optical attenuation due to scattering and/or absorption at different depths can be obtained by using the spectroscopic OCT. The spectral information can enhance optical contrast similar to staining employed in histology. Some pathologic changes involve cellular level variations such as nucleus enlargement in premalignant or early cancer, which result in changes in tissue scattering properties. Therefore, spectroscopic OCT could potentially reveal early pathologic changes.

Doppler OCT (or DOCT) is similar to Doppler ultrasound. It utilizes coherence gating to localize and resolve the flow volume where the backscattered light experiences a Doppler frequency shift (in addition to the known Doppler shift induced in the reference arm). Different from clinically viable laser Doppler velocimetry—which has been applied to many clinical scenarios for more than two decades^[72–74]—Doppler OCT provides depth-resolved quantitative flow information.^[5,6] In principle, the signal processing technique for DOCT is very similar to the spectroscopic OCT. The flow in the imaged tissue volume alters the heterodyne frequency, f_d , which will be the sum of the projected Doppler blood flow velocity along the optical beam and the pathlength scanning velocity in the reference arm, i.e., $f_d = 2fv_s/c - 2nfv_b \cos\theta/c$, where n is the index of refraction of the blood (or fluid in general), θ is the angle between the flow and the optical beam, and v_b is the blood flow velocity. Many methods have been developed to extract the depth-resolved flow velocity including the Short-time Fourier transform, Hilbert transform or phase-resolved method.^[6,75,76] Doppler OCT has been demonstrated for noninvasive

Fig. 8 Endoscopic and OCT images with corresponding pinch histology of normal (a–c) versus Barrett’s esophagus (d–f) of a patient. The OCT images were acquired at four frames per second using the longitudinal scanning scheme with $11 \times 30 \mu\text{m}$ (axial \times trans) resolution at a 1300 nm center wavelength. ep: epithelium; lp: lamina propria; mm: muscularis mucosa; sm: submucosa; mp: muscularis mucosa; g: gland. (From Ref. [65].)

assessment of blood flow on human skin and small animal skin-flap, and for evaluating the effect of photodynamic therapy and hemostatic therapy in rats.^[77,78] One area of particular interest is to quantify the blood vessel density using Doppler OCT, which might quantitatively reveal the angiogenesis process associated with tumor progression.

Many biological tissues such as muscle, tendon, cartilage, and tooth that contain organized collagen and elastin fibers exhibit birefringence, and the polarization state of light propagating within these tissues can be altered. Because the OCT interference signal represents the cross-correlation of two vector E-fields, it will be sensitive to the polarization states of light backscattered from the tissue and returned from the reference arm. Polarization-sensitive OCT (or PSOCT) was developed to quantitatively evaluate the depth-dependent tissue birefringence by measuring the birefringence effect on the interference signal.^[7–9,79] By changing the incident light polarization state and measuring the backscattered light polarization state, PSOCT can fully quantify the depth-dependent Jones or Muller matrix of biological tissues. Local changes of the polarization state of the light backscattered from thermally damaged skin have been revealed by PSOCT.^[80] It has also been demonstrated that PSOCT can enhance the imaging contrast compared to the standard envelope OCT images.^[81]

OCT APPLICATIONS

In a broad sense, OCT can be applied for diagnosis of diseases, guidance of surgical interventions, and monitoring of therapeutic effects. Optical coherence tomography was first developed to image the relatively

transparent tissues in the eye.^[1,10–12,51] Diagnostic ophthalmic OCT systems have been commercially available since 1996.^[82] With technology advances in the past half-decade, OCT has been successfully applied for imaging highly scattering tissues such as the skin, GI tract, and cardiovascular system. Although strong optical attenuation limits OCT imaging depth to 1–2 millimeters, this scale is ideal to cover the epidermis and the dermis of the skin and the epithelial/endothelial linings of the internal organs, from which many diseases originate such as neoplasia,^[13,14,57,63–65,83] and high-risk atherosclerotic plaques.^[17,18] In addition, the 1–2 mm imaging depth is comparable to (if not larger than) excisional biopsy depth, with the advantages that OCT provides image information in real time without the need to remove and process the specimen.

Clinical OCT studies in several organs and systems including (but not limited to) the skin, GI tract, female reproductive tract, joint, and cardiovascular system have just begun.^[13,14,18,57,63–65,83] It is beyond the scope of this article to describe the detailed findings for each disease that has been studied with OCT. In addition to the eye, the GI tract is the second organ that has been most extensively studied among all clinical OCT applications. Figure 8 illustrates representative OCT images acquired with an OCT imaging endoscope showing the normal and Barrett’s esophagus.^[65] During a routine GI endoscopy procedure, a 3.2-french OCT imaging probe was passed down the accessory port of a standard GI endoscope to the patient’s esophagus. Linear OCT images were taken at four frames per second by longitudinally scanning. As shown in Fig. 8, layered structures in the normal esophagus including the epithelium (ep), lamina propria (lp), muscularis mucosa (mm), submucosa (sm),

Fig. 9 OCT image and corresponding H&E histology micrograph of wounded skin of a diabetic mouse at day 10 post full-thickness skin punch biopsy. The thick, regenerated epidermis (E) bridges the wounded area and the dermis-epidermis junction can be clearly identified on the OCT image (as indicated by arrows). The OCT image correlates well with the corresponding histology (Details can be found in Ref. [95]).

and muscularis propria (mp) can be clearly distinguished from the alternating low and high back-scattering. The tissue within the epithelial layer is uniform, correlating very well with the histology of the pinch biopsy specimen. In contrast, normal layered structures were disrupted in the Barrett's esophagus and glandular structures became dominant. Again, the glandular metaplastic characteristics observed on the OCT image correlate well with the histologic findings. Recently, OCT imaging, in conjunction with quantitative tissue scattering analysis, has shown that OCT can differentiate normal tissues, metaplasia, dysplasia, and early cancer in the GI tract, and the findings are statistically significant.^[84] In the area of cancer diagnosis with OCT, efforts are being focused on detecting neoplasia at early stages when cancer is still curable. Promising approaches for detecting early neoplasia include the aforementioned quantitative method, spectroscopic OCT,^[84] the combination of angular-dependent light scattering with OCT,^[85,86] and integration of OCT with confocal microscopy.

Preliminary clinical studies have shown that OCT is capable of assessing structural changes in hard tissues such as the joint cartilage and teeth.^[16,55,87,88] Potential applications include detecting osteoarthritic cartilage degeneration, dental caries, and evaluating dental restoration. The micron resolution also makes OCT very promising for identifying high-risk atherosclerotic plaques in the cardiovascular system,^[18,89] in particular for those with a cap thickness of approximately 60 μm or less.^[90] The cardiovascular OCT application would require catheterization, similar to the intravascular ultrasound (IVUS) procedure, but provides a resolution of almost an order of magnitude higher than IVUS.^[18,91]

In addition to clinical applications, OCT has many applications as a basic research tool as well. Optical coherence tomography permits repeated assessment of the same animal *in vivo* and in real time. This can be particularly valuable for developmental biology.^[92-94] OCT can also be a useful tool for monitoring disease

progression and/or treatment outcome on an animal model over the entire time course, avoiding interanimal variance when using a large colony of animals. Recently, one example to use OCT for assessing impaired cutaneous wound healing on a diabetic mouse model.^[95] After a full-thickness cutaneous wound was created by skin punch biopsy, the wounded skin was repeatedly monitored by OCT imaging. Optical coherence tomography images at different time points during the healing process depict the formation of granulation tissue, the bridging of the regenerated epidermis over the wound, and the thickening of the regenerated epidermis. Figure 9 shows a representative OCT image of the cutaneous wound 10 days post-wound induction. The regenerated epidermis that bridges over the wounded area, the thickening of the new epidermis, and the dermis-epidermis (DE) junction can be clearly identified on the OCT image. Optical coherence tomography findings correlate very well with corresponding histology. Longitudinal OCT imaging of the same animal also reveals that the diabetic mouse exhibits a retarded wound healing process compared to the normal mouse (littermate). Preliminary results strongly suggest that OCT can be a valuable noninvasive tool for objectively evaluating the wound healing process. This research can be closely related to biomaterials and tissue engineering^[96,97] The effects of various growth factors on wound healing and the control mechanisms used for releasing the growth factors can be systematically studied using OCT on an animal model *in vivo*.

CONCLUSION

Optical coherence tomography is emerging as an attractive, noninvasive imaging modality, which is viable for clinical diagnosis and basic biomedical research. The past decade has witnessed rapid advances of the OCT technology. At present, OCT is well positioned for laboratory-based research. Except in

ophthalmology, widespread clinical OCT applications in other areas will be boosted by further technology development for improving resolution, beam delivery/collection, and imaging speed. Functional integration of structural, Doppler flow, birefringence, and spectroscopy would potentially enhance OCT image contrast and specificity for diagnosis of diseases at early stages. Development of image processing algorithms and firm understanding of the theoretical foundation of OCT—in particular about resolution degradation due to light-tissue interaction, chromatic dispersion, and the nature of OCT contrast—could lead to another level of image quality.

Optical Detection of Cancers

Xin-Hua Hu
Jun Qing Lu

Department of Physics, East Carolina University, Greenville, North Carolina, U.S.A.

INTRODUCTION

The American Cancer Society estimates that approximately 570,000 cancer deaths will occur in 2005 in United States.^[1] The key to achieving the desired patient prognosis is to detect cancer in the early stages. Among various diagnosis modalities, optical detection stands out for its potential of safety to patients and health professionals with nonionizing radiation, non-invasive nature of detection, high spatial resolution, and modest cost of equipment. Optical detection of cancers is a vast subject that has attracted intensive research efforts over the last few decades. It is therefore impossible to survey the field in a relative short essay like the current one. Instead, we will focus on the in vivo results that may lead to the noninvasive staging of dysplasia and cancers. Some in vitro data will be included here to reflect the historical development of a method or when in vivo results are not available.

It has been widely accepted that cancer originates from the accumulated mutation of DNA molecules within a cell or cells that tips the balance of cell cycle toward proliferation.^[2] Cancerous cells multiply without regulation to form a morphologically distinctive mass of tissue consisting of their clones in a local organ, often termed dysplasia, before the mass grows in size and eventually metastasizes into other organs to become a malignant tumor. Nearly all cancers develop in a staged fashion and the gold standard of cancer diagnosis and staging is the histopathologic analysis of biopsied tissues.^[3] Even with this very invasive and time-consuming technique, the criteria for staging of the dysplasia or the precancer stages are still not well defined and diagnosis varies significantly among pathologists. As a result, optical diagnosis of dysplasia lacks some clear standards to be validated against albeit greatly desired by physicians.

Optical detection of lesions was called “optical biopsy” in various publications in reference to the hope that a noninvasive replacement of biopsy and histopathology could be achieved optically. To reach this goal, one must identify the optical signatures of dysplasia and subsequent stages of cancer development, which may be correlated to three different types of variations: the mutation at the molecular level, the morphological variations at the cellular level, and

variations in tissue and vasculature (blood volume and oxygen saturation) structures at the tissue level. Optical detection of these changes at the three levels has been pursued with different regimes of measurements to acquire light signals from the ultraviolet to the infrared regions. These measurement regimes are sketched in Fig. 1 according to the wavelength relations between the excitation and the measured light signals. The following sections are divided on the basis of these relations.

THE RADIATIVE TRANSFER METHOD

Response of a biological system such as cells or tissues to an incident light field can be categorized into different types, as shown in Fig. 1. In the spectral region from about 300 to 2500 nm wavelength, elastic scattering of incident light by various components of tissues including the cells is often the dominant form of interaction. The measurement of optical signals as a result of elastic scattering and absorption is denoted here as the radiative transfer method because of the modeling methodology to be described below.

The light absorption and scattering can be understood fundamentally through the theory of classical electrodynamics in terms of the local fluctuation of the dielectric coefficient $\epsilon(\mathbf{r}, \omega)$ or the related index of refraction $n(\mathbf{r}, \lambda_h) = [\epsilon(\mathbf{r}, \omega)]^{1/2}$ at the scales of intracellular organisms, where \mathbf{r} is the position vector and $\lambda_h = 2\pi v/\omega$ is the wavelength, v and ω are the speed and angular frequency of incident light in the host medium, respectively. To demonstrate this point quantitatively, consider the scattering of an incident light field ($\mathbf{E}_i, \mathbf{B}_i$) with a wave vector \mathbf{k}_i by a biological cell. The scattering configuration and the intracellular structure, given by $\epsilon(\mathbf{r}, \lambda_h)$, are schematically presented in Fig. 2. Using Maxwell's equations, the scattered light field ($\mathbf{E}_s, \mathbf{B}_s$) along the direction of the wave vector \mathbf{k} in the far-field region can be defined by an amplitude function $\mathbf{F}(\mathbf{k}, \mathbf{k}_0)$ as^[4]

$$\mathbf{E}_s(\mathbf{r}, \lambda_h) = \mathbf{F}(\mathbf{k}, \mathbf{k}_i) \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{r} \quad (1)$$

where \mathbf{k} and \mathbf{k}_i are related to the wavelength as $k = |\mathbf{k}| = |\mathbf{k}_i| = 2\pi/\lambda_h$. The amplitude function $\mathbf{F}(\mathbf{k}, \mathbf{k}_i)$

O

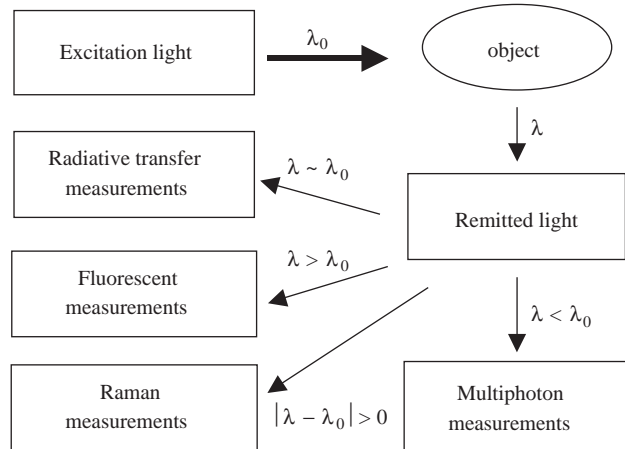

Fig. 1 Different approaches of optical measurements.

and the total field \mathbf{E} , the incident plus the scattered, are to be solved from the following equation:

$$\mathbf{F}(\mathbf{k}, \mathbf{k}_i) = \frac{1}{4\pi} \int_V (k^2 + \nabla \nabla \cdot) \times [\varepsilon(\mathbf{r}', \omega) - \varepsilon_h] \mathbf{E}(\mathbf{r}', \omega) e^{-j\mathbf{k} \cdot \mathbf{r}'} d^3r' \quad (2)$$

where V is the cellular volume in which $\varepsilon - \varepsilon_h$ is a spatial function of \mathbf{r} . These relations show that light scattering is caused by the local inhomogeneity in terms of the deviation of the dielectric coefficient $\varepsilon(\mathbf{r}', \lambda)$ from the background value ε_h of the host medium. Further, light absorption can be accounted for by using a complex dielectric coefficient or complex refractive index $n = n_r + jn_i$, where $j = \sqrt{-1}$ and n_i causes attenuation of the incident wave in addition to scattering. Although analytical solutions can be obtained for scatterer of regular geometric shapes and structures, numerical solutions are the only feasible methods for scatterers of irregular but realistic shapes and inhomogeneous internal structures.

Fig. 2 Light scattering by a biological cell.

Biological tissues consist of many types of cells and extracellular components and usually possess no long-range orders or symmetry. The structural complexity of tissues renders the first-principle approach demonstrated in Eqs. (1) and (2) impractical. Even numerical solutions of tissue optics problems are impossible at the present time owing to the prohibitive computing cost. For modeling tissue optics problems, radiative transfer theory is a much preferred approach in which only the distribution of light radiance, $I(\mathbf{r}, \hat{s}, t)$, instead of the electromagnetic fields, is to be solved. The light radiance $I(\mathbf{r}, \hat{s}, t)$ is defined as the electromagnetic energy propagating along the \hat{s} direction per unit solid angle and per unit area at location \mathbf{r} and time t . The distribution of the radiance I can be obtained from a radiative transfer equation based on energy conservation:^[5]

$$\frac{1}{v} \frac{\partial I(\mathbf{r}, \hat{s}, t)}{\partial t} + \hat{s} \cdot \nabla I = -(\mu_s + \mu_a) I(\mathbf{r}, \hat{s}, t) + \mu_s \int_{4\pi} p(\hat{s}, \hat{s}') I(\mathbf{r}, \hat{s}', t) d\Omega' + S(\mathbf{r}, \hat{s}, t) \quad (3)$$

where \hat{s} is a unit vector of direction, μ_s and μ_a are the scattering and absorption coefficient, respectively, $p(\hat{s}, \hat{s}')$ is the scattering phase function, and S is the source term. In principle the optical parameters of tissue, μ_s , μ_a , and $p(\hat{s}, \hat{s}')$, can be derived from the scattering theory presented in Eq. (2) if the details of the optical inhomogeneity ε or n are completely known.^[6] It has recently been proved experimentally that the complex refractive index of microspheres, relative to the known refractive index of water as the host medium, can be determined accurately from optical measurements of the microsphere suspensions based on Eq. (3) and the Mie theory of light scattering by spheres.^[7] For complex turbid systems such as the biological tissues, it is nearly impossible to solve analytically the practical boundary problems described by Eq. (3). Instead, numerical solutions have to be resorted to and a statistical method of Monte Carlo simulation has been widely adopted for its algorithm simplicity and ease of implementation of the parallel computing technique.^[8,9]

If scattered light can be neglected or removed from the measured data using techniques such as spatial filtering, Eq. (3) can be solved for a source-free medium by simple integration to yield the modified Beer-Lambert law:

$$\frac{I(\mathbf{r}, \hat{s})}{I(\mathbf{r}_0, \hat{s})} = \exp \left\{ - \int_{\mathbf{r}_0}^{\mathbf{r}} \mu_t(\mathbf{r}') dr' \right\} \quad (4)$$

where we define the attenuation coefficient $\mu_t = \mu_s + \mu_a$, neglect the second term on the right-hand side of Eq.

(3) because it produced scattered light only, and consider only the steady-state solutions to drop the time variable. Eq. (4) yields a “shadowgram” principle to relate the projection image data in the transmission mode to the distribution of μ_t in the imaged object and forms the foundation for computed tomography (CT).^[10]

At the other extreme of approximation, the radiative transfer equation can be simplified to a diffusion equation of a “diffuse photon density wave,” represented by $\rho_d(r, t) = \int_{4\pi} I_d(\mathbf{r}, \hat{s}, t) d\Omega$, by considering only the portion of radiance that has been multiply scattered, i.e., I_d . Once the propagation directions of these photons are randomized by multiple scattering, the distribution of ρ_d is no longer related to the detailed form of the scattering process and depends only on the absorption coefficient μ_a and a reduced scattering coefficient $\mu_s' = \mu_s(1-g)$, where $g = \int_{4\pi} (\hat{s} \cdot \hat{s}') p(\hat{s}, -\hat{s}') d\Omega'$ is the first moment of the scattering phase function. The diffusion approximation breaks down in two cases. The first case arises when μ_a becomes appreciable in comparison with μ_s because the multiply scattered portion I_d is significantly reduced by absorption and thus may not dominate in the light distribution I . The second case is in the region near a light source where most incident photons do not yet experience multiple scattering.

Continuous-Wave Imaging Studies

One of the earliest attempts to detect pathological conditions of tissues has been reported by Cutler, who observed projection images of breasts with visible light in the transmission mode in a dark room.^[11] Projection imaging of the breast or diaphanography has been actively studied in the 1970s and 1980s by using both visible and near-infrared light sources with films or video cameras as the recording devices.^[12] These studies employed the shadowgram principle for image interpretation and often were compared with x-ray mammography.^[13] Unlike the case of x-rays in which the photons that undergo volumetric trajectories due to scattering can be effectively removed from the projection data, light scattering dominates over absorption in interaction of the visible or near-infrared photons with the breast tissues. Consequently, blurring is inherent in the optical projection images. Both contrast and spatial resolution of these images, for discriminating different types of breast tissues and lesions, have been shown to be poor in comparison with x-ray mammography and research interest has diminished.

For organs other than breast, transillumination imaging is not practical and imaging in the reflection mode is the only way to measure the optical response

from tissues noninvasively. Several low-magnification microscopes or endoscopes have been routinely used in clinics by physicians as the cancer screening tools to enhance their ability of visual inspection. These include dermoscopy in detection of skin cancers, colposcopy in cervical cancers, colonoscopy in colon cancers, and bronchoscopy in lung and airway cancers. Recently, multispectral imaging has been investigated for early diagnosis of dysplastic nevi and melanoma.^[14] Quantitative modeling of the projection data in the reflection mode to obtain tomographic images, however, is extremely difficult because these signals originate from the refractive index mismatch at the tissue surface and scattered photons in the bulk tissue. Researchers have followed two directions: 1) to extract patterns and statistical features from image data and/or spectroscopy data to correlate with the pathology for cancer detection and 2) to determine the local tissue optical parameters from multipoint measurements of the reflectance with a tissue optics model. These will be discussed in this and the following sections. Elbaum et al. acquired in vivo images from 246 pigmented skin lesions, ranging from benign nevi to dysplasia to melanoma, with 10 wavebands between 430 and 950 nm using a dermoscope.^[15] The multispectral images were processed with different algorithms of patterns analysis to extract about 25 image parameters in two groups. Comparison of the two-parameter groups as classifiers with the histopathology analysis demonstrated good sensitivity (100% or 95%) and relatively poor specificity (84% or 68%). A similar in vivo method for melanoma diagnosis has been investigated on 237 pigmented skin lesions and 80% sensitivity and 51% specificity (with lesion dimension considered) were reported.^[16]

Spectroscopy Measurements

For noninvasive in vivo detection of cancer, reflectance spectroscopy with a continuous-wave (cw) white light source has been the preferred mode of measurements by researchers for its instrumental simplicity. A technique of spatially resolved diffuse reflectance has been introduced to determine μ_a and μ_s' from the spatial dependence of reflectance signals. The spatially resolved signals are acquired with multiple fibers and fitted to calculated curves based on a diffusion model of a homogenous tissue.^[17] The wavelength dependence of the parameters μ_a and μ_s' can be obtained from the spectroscopy data to analyze the chromophores in the tissue. But clinical application of this spatially resolved technique is limited because the homogeneity should not be assumed in tissues with cancerous regions. As a result, published in vivo spectroscopy studies up to this time have combined only the

single-point detection with pattern analysis of data based on various statistical methods. Improvement in modeling accuracy with Monte Carlo simulations has been reported.^[18]

Mirabal et al. investigated reflectance spectroscopy in the regions from 390 to 590 nm and from 350 to 650 nm to evaluate its potential for diagnosis of cervical tissue conditions in patients with abnormal Pap smears.^[19,20] They analyzed the spectral data statistically to extract classifiers for correlating with pathological diagnosis and compared the correlation with that determined with 355-nm-excited fluorescence spectroscopy measurements. It was concluded that fluorescence spectroscopy provided better specificity and sensitivity in the detection of cervical intraepithelial neoplasia.^[19] In vivo measurements of the reflectance spectral data and statistical analysis have been performed in an attempt to detect breast cancers, lesions in ovarian tissues, skin lesions including dysplastic nevi and basal cell carcinomas, and adenomatous colon polyps.^[21–24] Recently, Johnson et al. reported the study of spectral reflectance data, between 340 and 900 nm, acquired from 139 cancerous and normal sentinel nodes removed from 68 patients with breast cancers.^[25] Statistical analysis of the spectral data yielded scores for discriminating different types of nodes with sensitivity and specificity comparable to those of frozen section histology.

In the above studies, the measured light signals included those photons that are scattered only once or a few times in the backward directions and others that are scattered multiple times. Detection of singly backscattered photons can be realized experimentally with a single fiber of small diameter of about 200 μm for both launch and detection of light. Because multiply scattered photons in the remitted light are most likely to migrate away from the fiber, the detected signal is dominated by singly backscattered photons from the superficial layer of the tissue.^[26] Georgakoudi et al. compared three types of in vivo spectral data to evaluate their potentials for detection of dysplasia in 16 patients with Barrett's esophagus: singly backscattered light; diffuse reflectance; and intrinsic fluorescence of multiple excitation wavelengths. It was found that singly backscattered light spectroscopy data provided the best overall sensitivity and specificity among the three techniques in separating different degrees of dysplasia.^[27]

Frequency-Domain Measurements

Intensity modulation of a cw laser beam at a megahertz frequency adds "signatures" to the beam in terms of amplitude demodulation M and phase shift ϕ . When such a beam is launched into tissue, the local optical

properties of the tissue cause variation in M and ϕ in the detected signals relative to the source. With a diffusion model, M and ϕ can be inverted to obtain tissue's optical parameters μ_a and μ_s' at selected wavelengths if multiple laser sources are used.^[28] Further, several fibers can be employed to launch and measure at different locations to reconstruct tomographic images with contrast built on M , ϕ , their spatial derivatives, or μ_a and μ_s' . An early study of one breast cancer patient using the frequency-domain method at 690 and 825 nm was reported by Fantini et al., who also determined μ_a and μ_s' for normal and tumor tissues.^[29] Their very limited in vivo result suggested that μ_a and μ_s' of tumor tissues are both larger than those of the normal tissues at both wavelengths. A similar method has been used to determine μ_a and μ_s' at the sites of lesions and normal tissues on one patient with lung carcinoma and subcutaneous tumors and 10 patients with cervical carcinoma in situ at four wavelengths from 674 to 956 nm.^[30,31] The results, however, exhibited significant overlap in the values of these parameters between the normal tissue sites and lesion sites at the four wavelengths. The frequency-domain method can be further improved to enhance the image contrast of the blood oxygenation by incorporating a spatial derivative algorithm.^[32] This technique was used for an in vivo study conducted on four patients with ductal carcinomas and fibroadenoma in their breasts. Transmission images were obtained at four wavelengths by scanning the source and detection fibers in tandem and image data yielded evidence of a correlation between the lesion locations, identified by x-ray mammography and histopathology, and those of abnormality in the oxygenation index images.^[32]

Time-Resolved Measurements

The significant blurring in the cw imaging data due to the dominant presence of multiply scattered light causes substantial deterioration in the contrast of images interpreted through the shadowgram principle. As ultrashort pulsed solid-state lasers and fast photodetectors became routinely available, research interest in shadowgram imaging for cancer detection has been revived since the early 1990s. Various time-gating methods have been devised to extract the early-arrival photons, which are either not scattered (ballistic photons) or only weakly scattered (snake photons).^[33] Optical parameters μ_a and μ_s' can be obtained with a diffusion model or Monte Carlo method from the time-resolved signals of reflectance or transmittance at the wavelength of excitation.^[34,35] An in vitro study of 20 excised breast samples consisting of either fat (lipid) or fibrous tissues with a streak camera of 2 psec time

resolution has shown that the mean value of μ_s' is about 0.5 mm^{-1} for lipid tissue and 0.9 mm^{-1} for fibrous tissue at the wavelength of 800 nm.^[36] Patients with breast cysts or tumors have been studied with the time-resolved technique to obtain transmission images by scanning the source fibers connected to a diode laser generating 400 psec pulses and a photomultiplier detector on the opposite side of the compressed breast.^[37,38] Even though lesions or tumors of a few centimeters in size can be identified from the images, with the prior knowledge from MRI and x-ray mammography, no significant reduction in blurring can be observed in the time-resolved images when compared with the cw images, which may be attributed to the low time resolution of the above optical systems.^[12]

Diffuse Optical Tomography

Unlike its x-ray counterpart, optical tomography remains an open problem despite intensive research efforts. The complexity of the problem arises from the fact that the measured light signals from a turbid object are dominated by photons with volumetric trajectories in the imaged region as a result of light scattering. Inverse algorithms for reconstructing 2D images of optical parameters from the projections have been investigated in phantoms with simple-shaped structures embedded. The existence of unique solutions in practical cases, however, is unknown.^[39] Most published studies on optical tomography employed the method of fiber-based multipoint detection in the frequency domain to obtain measured data, instead of the cw or time-resolved techniques, for instrumental simplicity and large dynamic range. In diffuse optical tomography (DOT), the diffusion model is used for forward calculations of the measured data from trial values of optical parameters based on simplified models of tissue heterogeneity. Even though DOT possesses the ability to exhibit the distribution of blood oxygen saturation in tissues, fast and robust inverse algorithms for image reconstruction remain to be developed. Existing inverse algorithms for DOT are iterative processes of least-squares type or of Bayesian type using an objective function and their solutions are practical only if the number of unknown optical parameters is kept small by either using a priori structural information as constraints or reducing the number of voxels (or spatial resolution).^[40] Consequently, recent research efforts have been concentrated on the development of DOT as an auxiliary modality to other high-resolution imaging modalities such as x-ray CT or MRI to enhance the functional imaging capacity.^[41] A preliminary in vivo study of a breast tumor with DOT demonstrated the overlapping of the abnormal

locations in the images of μ_a and μ_s' at multiple wavelengths with the biopsy identified tumor site.^[42]

Optical Coherence Tomography

Reconstruction of tomographic images of an object in optical coherence tomography (OCT) is accomplished in reflection mode by combining the single-point measurement using a converging light beam of broad spectral bandwidth with 2D or 3D scanning. The OCT signal is based on the light backscattered from the focal point and is separated from the background noise by interference of the signal beam with a reference beam. High spatial resolution can be achieved in the longitudinal (depth) direction, ranging from 2 to 20 μm , using a light source of short coherent length.^[43] The resolutions in the transverse directions relate to both the imaging optics and the size of the scanning step. The OCT image contrast depends on two factors: the attenuation of the incident beam along its trajectory toward the focal point and the local gradient of the refractive index at the focal point. As a result, OCT signals are attenuated exponentially as $\exp\{-2 \int_0^d \mu_t dr\}$ within the interrogated tissue, where d is the pathlength from tissue surface to the focal point.

Optical coherence tomography has been employed successfully for detection of intraocular tumors because μ_t for most ocular tissues is much less than 1 mm^{-1} in the visible and near-infrared regions.^[44] For turbid biological tissues such as the human skin and mucosa, μ_t typically ranges from 1 to 10 mm^{-1} and the penetration depth of OCT in these tissues is limited to about 1 mm or less.^[45] The small penetration depth in turbid tissues is the major factor limiting the application of OCT for cancer detection. In a recent study, two patients with diagnosis of invasive basal cell carcinoma in their skin have been imaged with a polarization sensitive OCT method to identify structural changes in the superficial layers of the sites.^[46] The OCT images showed variations in both tumor sites, which were attributed to the local changes in the refractive index due to the loss of normal tissue structure by the invasive growth of dense tumor stroma. An in vivo study of OCT in the detection of oral tumors has been conducted in an animal model of 35 hamsters with squamous cell carcinoma and it was found that in 80% of cases the OCT-based diagnosis correlates with those based on histopathology.^[47]

Optical coherence tomography can also be implemented in the endoscopic form for in vivo imaging of luminal cancers by passing a catheter-based fiber probe through the biopsy channel of an endoscope.^[48,49] Examination of upper gastrointestinal tracts has been performed with endoscopic OCT in 32 patients suspected of Barrett's esophagus and esophageal

adenocarcinoma, followed by the endoscopic mucosal biopsies.^[50] The OCT images were compared to the histopathology analysis of the biopsied tissues and it has been found that OCT images provide sufficient contrast to differentiate among the normal esophagus, Barrett's esophagus, and esophageal adenocarcinoma. A similar *in vivo* study of 19 patients with Barrett's esophagus and esophageal adenocarcinoma confirmed that the abnormal morphologic changes in the mucosa tissues can be identified from the OCT images.^[51]

THE FLUORESCENCE METHOD

Fluorescence signals from biological macromolecules depend on the structure of electronically excited states of these molecules. This relation allows the possibility to discriminate molecules in cancerous cells or tissues from those in the normal counterparts. The strong signals, assuming the existence of either intrinsic or extrinsic fluorophores, and the ability for molecular imaging or detection have made the fluorescence method a popular approach to probe biological systems. These advantages, however, can be significantly reduced owing to the overlapping of spectral features in the broadband fluorescence spectra from different biological fluorophores and the dependence of the spectral shape on the tissue optical parameters resulting from the transport of fluorescence light in the interrogated tissues. This typically leads to poor specificity as the barrier for cancer detection in clinical settings. Future research efforts have to be invested for translation of the fluorescence method into clinical applications with much improved signal-to-noise ratios. We review here only the measurements of fluorescence signals emitted by intrinsic fluorophores, which is also called autofluorescence.

Spectroscopy Measurements

Measurements of fluorescence signals are usually carried out with cw excitation at wavelengths λ_0 in the ultraviolet and blue regions because of large absorption cross sections and often, high-fluorescence quantum yields. The distinctive features of cw fluorescence signals are given by the excitation and emission spectra and associated quantum yields or signal intensities.

Alfano et al. compared the difference in fluorescence spectra by intrinsic fluorophores of normal and tumor tissues of animals and humans.^[52,53] The fluorescence spectra were obtained with an argon laser beam at 488 nm and power of up to 100 mW focused on a spot of about 0.1 mm in diameter. These fluorescence spectra were shown to be dominated by a broadly

peaked curve in the wavelength range from 500 to 650 nm with no significant structure. It has been suggested that the signal differences at selected wavelengths in the emission spectra between tissues pathologically classified as normal and cancerous may provide the means for cancer detection.^[52,53] These early spectral measurements did not provide sufficient evidences, however, for cancer detection because the contrast or signal-to-noise ratio was small and sample-to-sample fluctuation was not considered. Additional studies of fluorescence with ultraviolet excitation from 300 to 460 nm on breast tissues provided statistically significant results, which demonstrated that spectral features are very similar among the normal and tumor tissues but the fluorophore concentration and/or fluorescence efficiency may differ in certain spectral regions.^[54,55] Even though these researchers reported that features of emission spectra can be utilized in the form of ratios of fluorescence signals at two wavelengths to differentiate cancerous tissues from the normal breast tissues, the spectra presented in these results vary from each other with no explanation provided. The technique of fluorescence emission ratio has been used for *in vivo* investigation of bronchial tissues with excitation between 350 and 495 nm. After correcting the effects of probe-tissue distance and intensity variation of excitation, it has been found that the normal bronchial tissue exhibits slightly stronger emission than the dysplasia tissue with nearly identical spectral shapes, while those of the cancerous ones were much weaker than both tissues.^[56] Similar *in vivo* study of emission ratio differences has also been reported for distinguishing nasopharyngeal carcinoma and normal tissue.^[57]

The similarity in the shapes of emission spectra between the normal and cancerous tissues significantly reduces the reliability of this technique for cancer detection. Several methods have been investigated to address this problem by either statistical analysis of spectral data to decrease the noise or employment of multiwavelength excitation to increase the signal content. Multivariate analysis methods based on principal component analysis (PCA) and support vector machines were introduced to identify spectral features that can be correlated to the pathology condition of tissues.^[58,59] A method of excitation–emission matrix (EEM) with multiple excitation wavelengths was applied to colonic mucosa tissue analysis.^[60] For over 10 yr, a research group led by Richards-Kortum has studied the fluorescence detection of cervical cancer with methods of both EEM and PCA.^[61,62] Brewer et al. collected the *in vivo* emission spectra of ovarian tissues with 18 excitation wavelengths from 330 to 500 nm from patients suspected to have ovarian cancers.^[63] On the basis of EEM analysis, it has been suggested that certain spectral patterns in EEM plots

may be correlated to the pathological conditions of the ovarian tissues for cancer detection.

Time-Resolved Measurements

One valuable method to differentiate molecules with overlapping spectra and/or reduce the effect of tissue optical parameters on the spectral shapes of fluorescence signals is to determine the relaxation times of fluorescence signals with a time-resolved technique. Time-resolved measurements probe directly the relaxation of electronically excited fluorophores back to their ground state in the time domain. Typical lifetimes of transitions between the singlet excited and ground states are 1–10 nsec. Hence, subnanosecond light pulses from pulsed lasers such as nitrogen lasers are required for excitation and detectors with similar time resolution must be used. Single- or multi-component fitting with exponential decay curves can be used to extract relaxation times from the fluorescence data. An *in vitro* study of 18 normal, benign, and malignant human breast tissues has been performed with excitation at 310 nm and emission at 340 nm.^[33] By fitting the measured data with two-component exponential curves, a large difference was found in the ratio of the two decay components among the samples: the malignant tumor tissues have the largest portion of the slow component (with relaxation time about 2 nsec) among the three types. A similar assessment of fixed but unstained breast tissues from six patients with benign or malignancy-associated collagenous stroma has been recently reported with a fluorescence lifetime imaging system of 2 nsec time resolution and excitation at 415 nm.^[64] A seemingly opposite trend, however, has been observed in the above study: pixels of benign stroma show larger relaxation times than those of malignancy-associated stroma. Further studies are obviously needed.

OTHER METHODS

Owing to the limitation of space, we have to exclude certain optical methods from discussion, which nevertheless have the potential for cancer detection. Among these, three are briefly presented here: confocal microscopy, Raman spectroscopy, and multiphoton techniques. Confocal microscopes have become a standard imaging tool in biology laboratories since the early 1990s for reconstruction of 3D images of cells and other microscopic agents. Its optical principle is similar to that of OCT except for the collection of backscattered light through spatial filtering with a microscopic objective of large numerical aperture. Confocal images of turbid tissues typically exhibit contrasts superior to the OCT images.^[65] *In vivo* applications of confocal

imaging in clinics have been investigated mostly in dermatology for the detection of skin structures and lesions.^[66] In comparison with the very active research on radiative transfer and fluorescence methods, the study of Raman spectroscopy and multiphoton techniques received relatively less attention for *in vivo* optical detection of cancers in tissues. The major challenge relates to the detection of weak signals, which requires intense light sources and sensitive detectors. Lasers are necessary to meet the requirement of high irradiance for nonlinear measurements and both high irradiance and narrow frequency bandwidth for Raman measurements. These methods have been studied for cancer detection with Raman spectroscopy and multiphoton microscopy and for analysis of the skin dermis by the second-harmonic signals.^[67–69]

CONCLUSIONS

Compared with established diagnosis modalities, such as x-ray, CT, and MRI, noninvasive optical detection of cancers has been regarded to have considerable advantages, which include patient safety, high spatial resolution, and low equipment cost. These advantages have attracted intensive research efforts over the last two decades and substantial strides have been made toward modeling of light–tissue interactions and instrumentation development for data acquisition. Despite this progress, optical detection of cancers has not yet achieved the status of the established imaging modalities. The fundamental barrier impeding the translation of optical technology from the laboratory to wide applications in clinics, in our view, relates to the lack of efficient modeling tools and algorithms to invert the measured data from turbid human tissues to the spatial distribution of optical parameters that is inherently heterogenous at the scale of millimeters or lower. It is, therefore, hoped that this barrier can be significantly reduced in the near future with interdisciplinary efforts contributed by researchers from multiple fields including the biomedical, computational, engineering, and physical sciences.

Physiology Department, McGill University, Montreal, Quebec, Canada

INTRODUCTION

Optical mapping of electrical activity with the voltage-sensitive dye-fluorescence technique in the excitable tissues such as heart and brain has become a common research tool. These techniques are especially powerful in studies of spatiotemporal organization of electrophysiological activity in complex multicellular preparations, cell cultures, and organs.

Optical recordings of transmembrane potentials can be performed in a wide range of spatial resolutions from the subcellular level to the whole heart. The response time of fast voltage-sensitive dyes lies in the microsecond range, and the temporal resolution of the technique can potentially exceed that of conventional microelectrode recordings. Spatial resolution is defined by optical magnification and ranges from micrometer to millimeter range. Progress in modern computer technology permits simultaneous optical recordings from multiple sites, providing high-resolution spatiotemporal maps of electrical activity, unachievable by electrode-based techniques. One of the pioneers of fluorescent methods in neurophysiology, B.M. Salzberg, wrote many years ago that voltage-sensitive dyes “could, we believe, provide a powerful new technique for measuring membrane potential in systems where, for reasons of scale, topology, or complexity, the use of electrodes is inconvenient or impossible”. Based on our current experience in cardiac electrophysiology Salzberg’s list needs to be extended to recordings of action potentials in the presence of external electric fields during stimulation and defibrillation, which were impossible with extracellular and intracellular electrodes.

While intracellular microelectrode technique still represents the gold standard for recording single-cell transmembrane action potentials, the chief disadvantage of this technique lies in the impossibility of maintaining stable recordings over longer periods of time from more than two or three sites, especially if the preparation is moving. Similarly, monophasic action potential recordings can be maintained only at a few sites for short periods of time. Thus, spatiotemporal mapping by either method requires the use of a roving probe, limiting the application of either method to the

study of periodic activation patterns. Extracellular contact and non-contact multielectrode arrays are excellent for recording activation maps from the heart *in vitro*, and they also remain the only techniques for *in vivo* mapping. Problems do, however, exist concerning the precise interpretation of the electrogram data, the determination of repolarization times being particularly unreliable. Thus, optical mapping is the only technique capable of recording high-resolution maps of cardiac repolarization and uninterrupted artifact-free registration of the transmembrane potentials during electrical stimulation and defibrillation.

BASICS OF FLUORESCENCE

The general mechanism underlying fluorescence is the absorption of photons of certain energy by a fluorescent compound molecule, which creates an excited unstable energy-rich state, $S1^*$. Then the energy of $S1^*$ is partially dissipated, resulting in relaxed excited state $S1$ from which fluorescence emission originates. When the molecule falls back to the ground state $S0$, it emits a photon of a lower energy than the exciting photon. The wavelength of a photon being a function of its energy, the emitted light always has a longer wavelength than the exciting light, the so-called Stokes’ shift.

So called fast voltage-sensitive dyes that are used in cardiac electrophysiology have response time in the range of microseconds. The mechanisms of voltage-sensitivity for fast dyes are not fully understood. According to the electrochromic theory, the spectral shift is voltage dependent if the photon excitation of the chromophore molecule is accompanied by a large shift in electronic charge distribution in the direction of the electric field. An alternative hypothesis is the solvatochromic mechanism, which is related to electric-field-induced reorientation of the dye molecule.

INSTRUMENTATION DESIGN

Fluorophore

Designers of voltage-sensitive dyes had to solve several problems: 1) to find a chromophore that is capable of

producing the largest movements of charges during quantum transition from the ground to the excited state; 2) to ensure the possibility of delivering lipophilic dye molecules to the cellular membrane; 3) to ensure the proper orientation of the dye molecule perpendicular to the membrane; 4) to maximize duration of stay of the dye molecules in the desired position; 5) to minimize photobleaching of the dye; and 6) to minimize side effects of the dye on the preparation in the presence and absence of light.

Among several types of fluorophore, styryl dyes represent the most popular family of fast dyes, RH-421, di-4-ANEPPS, and di-8-ANEPPS being the most important members of this family. The spectroscopic properties of these dyes have been shown to change linearly with membrane potential changes in normal physiological range of transmembrane voltages.^[1] The orientation of the molecules of these dyes in the cell membrane is ensured by the presence of lipophilic and hydrophilic groups at opposite ends of the molecule.

The stability of the position of dye molecule in the membrane can be improved by increasing the length of the hydrocarbon tails, as was done in the ANEPPS family (di-4-ANEPPS, di-8-ANEPPS, di-12-ANEPPS, nomenclature described by Loew).^[2] In single-layer cell-culture preparations, Rohr et al. demonstrated a significantly improved stability of optical action potentials in preparations stained with di-8-ANEPPS as compared with di-4-ANEPPS on continuous illumination for 60 seconds, presumably on the basis of the slower translocation of di-8-ANEPPS into the cell.^[3] However, di-8-ANEPPS is less water soluble; this necessitates the use of surfactants, such as pluronic acid, which could have toxic side effects. Due to difficulties of staining we failed to confirm superiority of di-8-ANEPPS in Langendorff-perfused and superfused heart preparations as compared to di-4-ANEPPS. In our opinion, di-4-ANEPPS remains the dye of choice for whole-heart and tissue preparations.

The signal-to-noise ratio in stained cardiac preparations is dependent not only on the dye itself, but also on its mode of delivery. For example, one needs to consider slow diffusion of lipophilic dyes through the layers of the heart during staining by superfusion.^[4] Staining by coronary perfusion provides more uniform dye delivery. However, the depth of optical recordings in preparations stained by perfusion is still debatable, ranging from 300 μm to 1–2 mm.

Light Sources

Four types of excitation light sources are used in optical recordings: tungsten lamps, arc lamps, laser, and light-emitting diodes (LED). The choice of a light

source depends on the required spatiotemporal resolution. Arc lamps and lasers are typically used in micrometer scale measurements; tungsten lamps are most commonly used in macroscopic preparations, where a resolution of hundreds of microns is sufficient. Emerging LED-based-light-source technology is used in microscopic cell culture studies, in whole heart experiments and as components of a fiber optical “optrode” used in microscopic and macroscopic settings.

Lasers can provide intense illumination, which can be easily and rapidly delivered to a small spot using computer-controlled scanner. However, lasers have significant instability of beam intensity, which is comparable to the average fractional signal intensity recorded from most voltage-sensitive dyes.^[5] Ratio-calculation feedback signal processing techniques have been applied during recordings to eliminate signal noise related to laser light intensity variability.^[5] In addition, lasers are more expensive as compared to alternative sources.

While the intensities of arc lamps have been reported to exceed 50–100 times that of tungsten lamps, this large difference in intensity cannot be directly translated into better signal-to-noise ratios, as arc lamps have a significant intensity only at distinct narrow lines of the spectrum. Unfortunately, the excitation frequency of the most efficient dyes, which produce the largest fractional change in fluorescence, such as di-4-ANEPPS and RH421, do not overlap with spectral lines of arc lamps. Since the absorption peaks of most of the voltage-sensitive dyes are relatively wide, the lower light output of tungsten lamps at a given spectral line can be compensated for by the use of wider band-pass excitation filters.

Tungsten lamps remains the most popular light source used for optical recordings. They provide a very stable output of light over a very wide range of the spectrum without the sharp peaks observed in the arc lamp’s spectra. Cost of tungsten lamps is lower compared with laser and arc lamp sources.

Light-emitting diodes were recently introduced for excitation of the voltage-sensitive dye by Kodama et al.^[6] Advances in technology brought to the market a variety of ultra bright LEDs for different wavelengths. The most suitable set from CREE has 460-nm 4–10-mW, 470-nm 10-mW, 505-nm 8-mW, and 527-nm 7-mW peak intensity wavelengths and power. This technology appears to be very promising.

Light Collection

Four engineering solutions have been used over the last two decades in brain and heart electrophysiology for optical multiple-channel recording systems: photodiode arrays (PDA),^[7] laser scanner systems,^[8] charged

coupled device (CCD) cameras,^[9] and optrode technology^[10] based on embedding illumination and detection into a single fiber, which allows custom assembling of photodetection arrays in an arbitrary form. These methods differ not only by their way of collecting the fluorescent output of the specimen but also by the way the excitation light is delivered.

CCD cameras were introduced into optical mapping to achieve higher spatial resolutions and avoid the complications of setting up PDA systems. However the accuracy of mapping data with CCD cameras is limited by a number of factors: 1) The signal-to-noise ratio in signals from CCD cameras is usually poor and requires spatial averaging, defeating the advantage of high pixel resolution. 2) The time resolution of fast CCD cameras is approaching 1 ms, but, it is accompanied by the need for sophisticated CCD-cooling systems and still yields inferior signal quality. 3) Many cameras do not allow subtraction of the background fluorescence, and if they do, it is a uniform offset potential subtracted from all channels. 4) Amplitude resolution is usually not more than 12 bits. In general, CCD camera-based optical imaging is a popular solution due to ease of setting up and low cost.

Laser scanning systems represent an entirely different approach.^[14] The output of a single laser is acoustico-optically deflected to scan some 100 sites of the whole preparation. The fluorescence emitted by each site at the time of illumination is collected by a single photodetector, which thus sequentially records the optical signals from all sites scanned by the laser beam. The advantage of laser scanning systems over PDAs is that they can cover a wider area and that flatness of the preparation is not an optical requirement. However, the time resolution is limited to some 1 ms per 100 scanning sites and considerable photobleaching by intense light beam results in a significant beat-to-beat decrease of the fluorescence level.

PDA have been used for optical mapping studies in neurophysiology and cardiology since 1981.^[7] With a quantum efficiency above 0.8, photodiodes are the most sensitive sensors for medium-to-large light intensities, their main drawback being the size of their dark current, which may limit their usefulness at very low light intensities, as in neurophysiological applications. Photodiodes are packaged in arrays of 100, 144, 256, or more. Each recording channel can be independently signal-conditioned before analog-to-digital conversion.

Novel approach to emission detection with fiber-optic custom geometry arrays^[3] in contrast to the commercially available photodiode array detectors with predefined layout has the following advantages: 1) the spatial resolution is not limited by the detector geometry; 2) the array can be set to a specific preparation shape; 3) the light can be collected from several

optical ports, enabling multiemission measurements; and 4) the type of sensing photodiode could be selected to suit the particular emission characteristics.

ARTIFACTS AND PROBLEMS

Pharmacological Effects of Voltage-Sensitive Dyes

The application of voltage-sensitive dyes has been demonstrated to cause side effects on preparations. Phototoxic effects have been documented under intense illumination, with alterations of electric activity both in neurons and in isolated cardiac myocytes. In the isolated cardiac myocytes, 1 min. of illumination with 1 W/cm² will first cause a gradual depolarization of the membrane resting potential and a decay of the action potential amplitude. This is followed by after-depolarizations, occasionally triggered activity, and finally cell death. Recently, we have shown that voltage-sensitive dye RH421 increases the contractility of isolated rat cardiac cells and Langendorff-perfused hearts. Similar effects were observed during staining with di-4-ANEPPS and di-8-ANEPPS. Vasoconstriction is another pharmacological side effect of potential-sensitive styryl dyes. This effect was described for the dyes RH-414 and di-4-ANEPPS.

Mechanical Motion Artifact

Faithful optical recordings of cardiac action potentials require immobilization of the preparation. Movement artifacts in optical action potentials tend to be most pronounced during the action potential plateau and during the action potential downstroke, whereas action potential upstrokes are generally well preserved. Movement artifacts can occur due to physical movement of the tissue from the field of view of one detector element into the field of view of a neighboring element leading to artifactual recordings of transmembrane potentials from different cells in different phases of the action potential or with different degree of staining. This effect is most pronounced at the edges of the preparation. Action potentials can also be distorted due to the modulation of light scattering by mechanical contraction, a phenomenon observed in monolayer cell cultures even in the absence of gross cell movement across the photodetector array.

There are three basic approaches to reduce motion artifacts: 1) mechanical immobilization, 2) use of motion-artifact-insensitive signal analysis algorithms, and 3) pharmacological immobilization.

Preparations can be mechanically immobilized by restricting the movement of the muscle between the

walls of the tissue chamber and/or pressure pads or by stretching the tissue. While mechanical immobilization is free of pharmacological side effects, this method can be used only in preparations with moderate amplitude of contractions; otherwise, the pressure needed to eliminate movements can cause ischemia. This technique has been successfully applied to guinea pig heart preparations.^[11] Yet, mechanical immobilization does not fully eliminate motion artifacts in all channels even in a guinea pig heart and special signal processing techniques^[11] should be used to measure action potential duration.

Motion artifacts can be reduced by another signal processing technique that is based on ratiometry—simultaneous recordings of optical signals at two different excitation or emission wavelengths with subsequent division of the two signals.^[12]

Pharmacological methods of producing mechanically quiescent preparations may significantly affect electrical activity. Several methods are being employed: perfusion with low calcium,^[13] Ca-channel blockers,^[14] 2,3-butanedione monoxime (BDM),^[9] and, most recently, cytochalasin D (cyto D).^[15] At the present time, low calcium solutions and calcium-channel blockers are rarely used in optical mapping because of their effect on crucial calcium-dependent cellular processes. BDM has effects on a variety of channels and gap junctions affecting the action potential duration. A decrease of action potential duration in rabbit, sheep, guinea pig, and dog hearts and an increase in the rat hearts were observed. Cyto D, an actin filament disrupter, has recently been shown to block contraction without affecting action potential shape or duration in a number of species.^[15] Thus, Cyto D is a promising new excitation-contraction uncoupling agent for optical mapping studies of cardiac repolarization. However, high cost of cyto D is a concern.

Noise

There are three major sources of noise present in optical recordings: shot noise, dark noise, and extraneous noise.

Shot noise is the natural fluctuation in the number of photons detected by a photodetector caused by the quantum-statistical nature of photon emission and detection. Thus, shot noise occurs even in the presence of an ideal noise-free light source and ideal noise-free detector and cannot be eliminated. Shot noise is estimated by the root mean square deviation of the number of photons hitting a photodetector per unit time and is equal to the square root of their number. The number of photons detected by the photodetector will finally be reduced by the quantum efficiency of the photodetector, which is defined as the number of photoelectrons per photon. Of the two types of

photodetectors used for optical recordings, photodiodes and photocathodes, photodiodes have quantum efficiencies of 0.8–1.0 and the photocathodes of only 0.15. Thus, photodiodes have a significant advantage over photocathodes, potentially yielding a signal-to-noise ratio that is nearly six times higher.

Dark noise is the noise signal emitted by a photodetector in the absence of light. Photodiodes tend to have much higher dark noise than photocathodes, which, despite their much higher quantum efficiency, limits their utility at low light intensities such as in single-cell measurements, in which case the dark noise can be comparable to or even higher than the shot noise. Thus, photocathodes may yield higher signal-to-noise ratios than photodiodes at very low light levels, and a direct experimental comparison between the two detectors is required in each case.

Extraneous noise is caused by noise sources in the laboratory environment. The following measures serve to cut extraneous noise down to acceptable levels: using a dark or DC-light-illuminated room to eliminate stray light from noisy sources, an anti-vibration table to isolate the setup from mechanical vibration generated in the building and the rest of the experimental setup, a Faraday cage to reduce radiofrequency noise, grounding equipment to a common isolated ground to eliminate 50- or 60-Hz noise picked up by ground loops, using low-noise light source, and isolating power supplies and amplifiers from computing equipment.

PHOTODIODE ARRAY OPTICAL SYSTEM DESIGN

The core of the optical mapping system (Fig. 1) is the Hamamatsu C4675 detector, which combines a 16 × 16-element photodiode array (chip size 17.45 × 17.45 mm² with 256 square 0.95 × 0.95-mm² photodiodes spaced 0.15 mm apart) with 256 current-to-voltage converters in a single compact (136 × 136 × 154 mm) enclosure. The optical system is built around a central beamsplitter cube (Oriol Corp.) bearing the illumination system, a bellows apparatus with the imaging lens, and a ground glass screen and reticule for focusing the imaging optics. The bellows, beamsplitter cube, and photodetector are all mounted on an optical rail. The excitation light is produced by a 250-W quartz tungsten halogen lamp (Oriol Corp.) powered by a low-noise direct current (DC) power supply (Oriol Corp.). After filtering out the infrared part of the spectrum, the light is controlled by an electronic shutter (Oriol Corp.), which opens for only a few seconds during each scan. The light beam is made quasimonochromatic by passing it through a 520 ± 45-nm interference filter (Omega

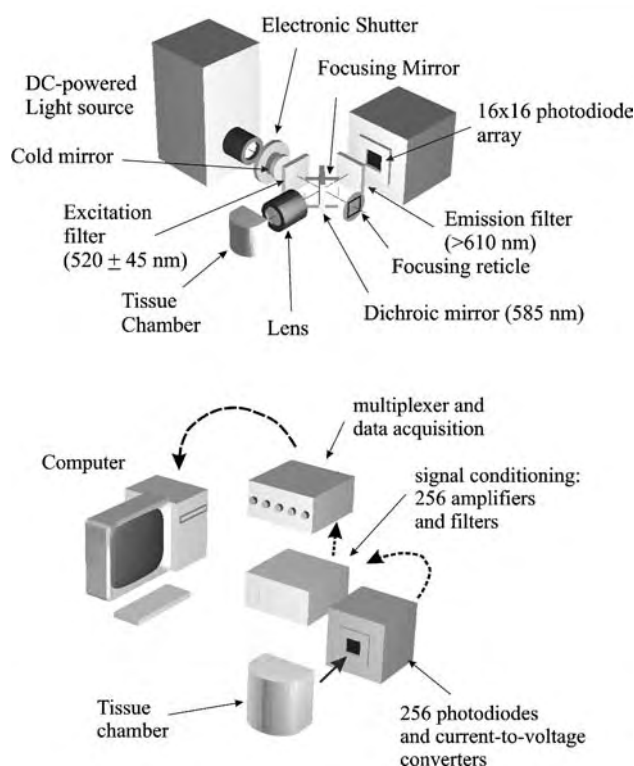

Fig. 1 Experimental setup. See text for details.

Optical), which corresponds to excitation wavelength of the dye di-4-ANEPPS. A 585-nm dichroic mirror (Omega Optical) held in the beamsplitter cube deflects the excitation light into the Nikon photographic imaging lens (50 mm f/1.2 Nikkor), which then focuses the excitation light onto the preparation. Then, the fluorescent light emitted from the preparation passes the dichroic mirror without reflection and is filtered by a long-pass filter (> 610 nm, Schott) before hitting the sensing area of the 16×16 photodiode array.

The photocurrent produced by each photodiode is first-stage amplified by its own low-noise operational amplifier inside the compact housing of the Hamamatsu C4675 detector (feedback resistors 10–100 M Ω , resulting in a gain of 10^7 – 10^8 V/A). Increasing the first stage amplification improves signal-to-noise ratios in optical signals. However, increasing the feedback resistors in the C4675 camera reduced its frequency response from 15 kHz to 1.5 kHz, which may be undesirable in some applications. The outputs of the first stage amplifiers were connected to 256 second-stage amplifiers, four 64-channel cards available from Innovative Technology, Inc., which offer computer-controlled DC coupling and AC coupling with several time constants (short time constant to remove the DC offset of the optical signals caused by background fluorescence, time constant of 30 s during data acquisition). Signals were filtered by Bessel filters with a cutoff frequency of 500–2000 Hz, depending

on the sampling rate of the data acquisition system in order to avoid aliasing errors. The signals were fed into four A/D converter boards (PCI 6033E, National Instruments). Each frame included 256 optical channels and eight instrumentation channels including surface electrogram, stimulation and defibrillation triggers, and aortic pressure, which were stored on a hard disk for off-line analysis.

An example of a raw optical signal, recorded with the described photodiode array system, is shown in Fig. 2A. Cellular depolarization during an action potential causes a reduction in fluorescence of 1 to 10% of the total fluorescence signal. Background fluorescence is caused by accumulation of dye in non-excitable cells, in the inner layer of the lipid membrane, or the lipid membranes of intracellular organelles across which there is no potential change during excitation. To reconstruct the intracellular action potential it is therefore necessary: 1) to subtract the background fluorescence, 2) to invert the signal and 3) to normalize the signals to uniform amplitudes assuming a homogeneity of action potential amplitudes in the imaged

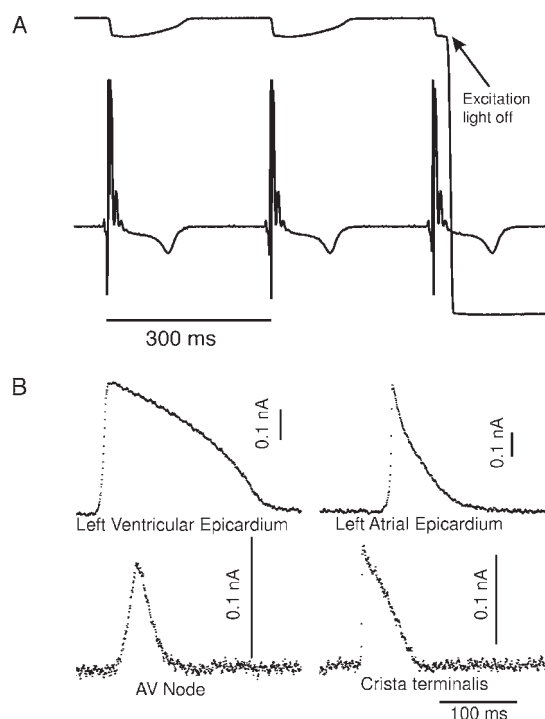

Fig. 2 Optical recordings of action potentials. A: An epicardial fluorescence recording from a rabbit Langendorff-perfused heart stained with di-4-ANEPPS (top trace) is juxtaposed with a simultaneous bipolar electrogram from the apex of the same heart. The light was turned off before the end of the recording to demonstrate the amount of background fluorescence in fluorescence signals without DC-offset subtraction. B: Photodiode optical current traces induced by the fluorescence from different heart tissues.

area of the preparation. In Fig. 2B one can see the examples of inverted optical signals detected from different areas of the heart.

EXPERIMENTAL PREPARATIONS

Experiments can be performed *in vitro* on Langendorff-perfused whole heart preparations, and isolated superfused or coronary-perfused atrial and ventricular preparations in rabbits, dogs, guinea pigs, rats, and humans, as well as in isolated cells and tissue cell cultures.

For staining, a stock solution of 5 mg di-4-ANEPPS (Molecular Probes) is prepared in 4 ml Dimethyl Sulfoxide (DMSO, Fisher Scientific) and is stored frozen at +4°C. After re-warming immediately before the experiment, it is added to the perfusate at final concentration of 0.5 $\mu\text{mol/L}$ for 5 min. during perfusion or for 40 min. during superperfusion. The method of gradual hand-injection of dye into the injection port in the bubble-trap is less cumbersome but less reproducible. Recordings started 5–15 minutes following the staining procedure.

Levels of optical signals and signal-to-noises ratios (SNR) decrease over time, presumably due to the translocation of the voltage-sensitive dye molecules into the cell interior with a half-life time about $\tau = 100 \pm 30$ min. Re-staining could be done once or twice during experiment, if needed.

Organ Mapping: Two-Dimensional Submillisecond Mapping of Transmembrane Polarization During Defibrillation Shocks in Intact Heart

Optical recordings of electrical activity are the only methods that resolve questions related to the

interaction of strong electric fields with excitable cells, conventional electrode recordings being distorted by large-amplitude artifacts.^[16,17] Using fluorescent mapping techniques, we have been able to record changes in transmembrane voltage optically with a high signal-to-noise ratio from all 256 channels. This has permitted us to acquire two-dimensional patterns of shock-induced polarization with submillisecond resolution.

Fig. 3D presents an example of optically recorded changes in transmembrane potential before, during, and after monophasic shock, which was applied at the plateau phase of a propagated action potential in rabbit heart. Fig. 3A shows the preparation photograph with a field of view of the optical mapping system. Analysis of data from all 256 channels allows reconstructing the surface map of transmembrane polarization at the end of the shock (Fig. 3B), as well as the activation map of the subsequent arrhythmia genesis (Fig. 3C). Only optical experimental techniques allow one to link together several important parameters that are responsible for arrhythmogenesis during shock-induced arrhythmia or failed defibrillation shocks: shock induced dispersion of transmembrane polarization, followed by dispersion of repolarization, and new wavefront generation, followed by formation of phase singularities and reentry.^[18]

Isolated Tissues: Conduction from the SA Node to and Through the AV Node

We recently demonstrated a nonradial spread of activation from the SA node to the AV node in isolated preparations of the rabbit right atrium.^[19] The structural complexity of the right atrial preparation, especially in the nodal areas, makes it difficult to

Fig. 3 A: Langendorff-perfused rabbit heart preparation. An optical mapping field of view is marked with a black square. B: map of the epicardial transmembrane polarization detected at the end of 8-ms, 100-V monophasic electric shock applied during plateau phase. C: Activation map of the first shock-induced reentrant beat constructed from the optical recordings. D: example of optical recording at a single optical channel (see marked position at the preparation photograph). It contains optical action potential upstroke of a propagated response during epicardial apex pacing and an arrhythmogenic response induced during the next action potential.

apply conventional electrode mapping techniques. While in unipolar electrograms the distinction between local and distant events is often impossible, bipolar electrograms represent complex spatial derivatives of the underlying spatiotemporal substrate of electrical activity.^[20] Since the precise field of view of both types of electrodes is unknown, interpretation of the electrograms remains challenging and requires verification by means of simultaneous microelectrode recordings.

Like electrograms, optical recordings represent the integrated electrical response of cells from a volume of tissue, the two-dimensional extent of which is precisely defined, even though the exact depth of the recording is less certain. We have previously suggested that double-component optical action potentials observed in proximal AV node and area of the bundle of His may be due to spatial averaging of electrical activity from several layers.^[19] Using microelectrode recordings we were able to demonstrate that optical recordings from the proximal part of the AV nodal area carry inscriptions of both superficial layers of transitional cells and a deeper layer of compact nodal and NH regions.^[21] Fig. 4 illustrates this finding by juxtaposition of two optical traces with conventional bipolar surface electrograms recorded from the interatrial septum and the

bundle of His during two basic and a single premature beats. Activation rapidly spread from the stimulation site on the interatrial septum toward the AV nodal area and finally conducted at the bundle of His. The optical trace recorded from the distal node shows multicomponent responses. Whereas the first component (T) in every beat represents activation of superficial transitional cells, in which conduction velocity is fast, the second component (NH) denotes activation of intranodal structures of the NH-region (NH). The increased delay between the first and the second components during conduction of the premature beat represents slowing of the intranodal conduction, which is also indicated by the His electrogram. It should be mentioned that relative amplitudes of the two components in the optical trace do not represent differences in action potential amplitudes, but rather the relative contribution of different amounts of tissues from transitional and NH regions, and different relative amplitudes of the two components can be seen in different areas of the proximal node.^[21]

Mapping Conduction in Cardiac Cell Culture

Heart cell monolayers are thin layers of tissue, grown in culture dishes from embryonic or neonatal cardiac cells, that have the capacity to form gap junctional connections with neighboring cells in culture and support propagating waves of excitation over long distances. Cardiac monolayers were popular twenty years ago as models of two-dimensional conduction. Optical potential mapping techniques have renewed interest in cultured monolayers, allowing the study of intercellular and cellular electrophysiology on microscopic and macroscopic scales with several advantages when compared to intact tissue. Signals from individual cells can be identified and mapped with sub-cellular resolution in cell culture while optical signals from intact tissue are compound signals from cells at the surface and deeper intramural layers. The geometry of cell cultures can be precisely controlled,^[22] allowing conduction patterns to be observed independently of the influence of micro- and macro-anatomy. Cardiac monolayers can be grown in conditions that cause cells to have similar anisotropy, connectivity, and longitudinality to transverse cell diameter ratios to cells in intact tissue. As a result of these advantages, several fundamental experiments have been performed on cell culture systems that could not easily be addressed in whole-tissue studies.

Propagation in cardiac muscle depends on both excitable and passive electrical properties of the coupled cell network. The passive properties of the tissue are influenced by factors such as discontinuities

Fig. 4 Three-dimensional (multilayer) imaging of the conduction through the atrioventricular (AV) node. The right atrium was opened through the tricuspid valve, right atrial appendage, and superior vena cava to expose crista terminalis (CrT), intra-atrial septum (IAS), AV node; and the bundle of His. The preparation was paced at IAS with a cycle length S1S1 = 280 ms, (left panel) and 274 ms (right panel), which caused partial AV conduction block. Bipolar electrograms were recorded from CrT (triangle) and bundle of His (star). Optical traces represent the superimposition of signals from the septum and the distal AV nodal areas (see rectangle on the preparation schematic). Places of microelectrode recordings are marked with black and white dots.

introduced by capillaries and connective tissue, variations in cell connectivity, and tissue anisotropy. The local structure dictates whether or not waves propagate, block, or form reentrant circuits. Control of cell orientation by brushing the collagen substrate, and cell position using photolithographic techniques, allows studying the effects of geometry on propagation.

Optical mapping of propagation in monolayers plated as strands of different widths connected to a large tissue area demonstrated that impulses propagating into the site of expansion are blocked if the strand diameter is less than 200 μm .^[23] The instability at the expansion site may be modulated by electrophysiological characteristics: rapid pacing, which reduces excitability by lowering $I(\text{Na})$, results in conduction-block in wider strands, while gap junction-block, which lowers the number of cells directly driven by cells at the expansion, permits propagation through narrower strands. Tissue geometry may also act to stabilize propagation. Propagation through a culture plated as a main strand with many side branches is slowed due to the current load imposed by the branches and is stable at speeds down to 1 cm/sec,^[23] explaining how diseased myocardium, which is a complex patchwork of healthy and dead tissue, supports stable reentry at small space scales.

Theoretical studies have demonstrated that depolarizing and hyperpolarizing regions develop at resistive barriers in the presence of a large extracellular defibrillation field, initiating waves that terminate the arrhythmia. Whether such secondary sources occur at each cell-cell boundary or at larger anatomical structures is still debatable. Optical mapping experiments in cell culture indicate that secondary sources do not form at cell boundaries in densely packed strands of cultured myocytes, but are observed at the boundaries of cell strands and at larger intracellular clefts^[24] increasing as a function of cleft length and electrical field gradient. Additional studies with monolayers without clefts but with bifurcations, abrupt curves, and sudden expansions reveal that secondary sources form at the site of geometric nonlinearities. These results suggest that the target of defibrillatory extracellular shocks is heterogeneous or anatomically complex myocardium.

Monolayers of cardiac cells monitored at macroscopic scales (~ 1 cm) over long time periods (> 10 s) have been used to monitor activation patterns associated with arrhythmia. Depending on culturing conditions, monolayers of rhythmically beating cells display periodic target waves, stable spiral waves, or spiral waves that spontaneously initiate and terminate^[25] (Fig. 5), providing a model of stable and paroxysmal reentrant tachycardias in diseased tissue. A model of reentry in quiescent, excitable tissue was developed where waves propagating around an anatomical obstacle were terminated using extracellular

The image was obtained using calcium-sensitive dye (Calcium Green) and a cooled CCD camera (Roper Scientific, EEV 576 \times 384-frame transfer CCD). Each panel shows calcium fluorescence from a 1-square centimeter region of tissue. Panels are separated in time by 150 ms.

shocks.^[26] Ectopic arrhythmias were investigated in a system where a small area of the monolayer was transiently exposed to a solution that induced ischemialike response. Washout of ischemia inducing solution resulted in arrhythmic episodes lasting up to 200 s originating from ectopic sources located at the border of the ischemic zone.^[27]

CONCLUSION

Fluorescent imaging methods developed and refined in many laboratories have proven to be valuable tools extending the frontiers in cardiac electrophysiology.^[28] We believe that recent technological advances will make these experimental techniques available for a larger number of research institutions. However, future development of the fast fluorescent mapping will have to solve several limitations and challenges.

A major limitation of current techniques of potential imaging is the lack of absolute calibration. Unlike many ratio-metric fluorescent probes for calcium imaging, voltage-sensitive dyes can provide only relative information about changes in transmembrane voltage. Although the changes in the absolute amount of fluorescence excited at one wavelength linearly depends on transmembrane voltage of the viewed cells, accurate calibration has so far been impossible because the number of cells contributing to the signal is unknown. Monatana et al. demonstrated that measurements of fluorescence ratios excited at two wavelengths can provide such information.^[29] They have shown that the ratio between di-4-ANEPPS fluorescence levels excited at 440 and 505 nm linearly depends upon transmembrane potential in a lipid vesicle in the range from -125 mV to $+125$ mV. Similarly, the ratio of di-8-ANEPPS fluorescence from N1E-115 neuroblastoma cell excited at 450 and 530 nm linearly depends on transmembrane voltage. Similar efforts are now being made to measure absolute changes in membrane potentials in the heart.

Another area of application is the simultaneous recording of voltage and other intra- and extra-cellular characteristics using combined staining with voltage-sensitive dyes and other fluorescent probes. We demonstrated that voltage and cytosolic calcium can be measured from the same Langendorff-perfused guinea pig heart stained with the voltage-sensitive dye RH421 and the $[Ca^{2+}]$ -sensitive dye Rhod-2, which have close excitation frequencies, but different emission spectra.^[30] Similar imaging studies of multiple fluorescent probes have been presented by several laboratories, involving different voltage- and calcium-sensitive dyes. In the future, such multispectral measurements can be done with a novel liquid crystal or standing-wave, fast-switching filter technology.

Department of Biomedical Engineering, Tufts University, Medford, Massachusetts, U.S.A.

INTRODUCTION

Biomedical optics is a multidisciplinary field that embraces the studies of light propagation in biological samples, processes of light/tissue interaction, and applications of optical techniques in biology and medicine. Application areas of biomedical optics range from medical therapy, monitoring, and diagnostics, to microscopy studies of biological samples. Here we describe the fundamental properties of light, the optical properties of tissue, the basic mechanisms of light-tissue interaction (and their role in therapeutic applications of light), and a physical model that describes light propagation in tissue. We also describe a number of optical spectroscopy and imaging approaches that find applications in medical monitoring and diagnostics and in the study of biological samples at a tissue, cellular, and subcellular level.

NATURE OF LIGHT

Wave Description of Light

Light is one form of electromagnetic radiation, which is specified in terms of two vectors, the electric field \mathbf{E} and the magnetic field \mathbf{H} . Both vectors obey the wave equation:

$$\nabla^2 \mathbf{E} = \frac{\mu_r \varepsilon_r}{c_0^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} \quad (1)$$

and

$$\nabla^2 \mathbf{H} = \frac{\mu_r \varepsilon_r}{c_0^2} \frac{\partial^2 \mathbf{H}}{\partial t^2} \quad (2)$$

where ∇^2 is the Laplacian operator, μ_r and ε_r are the permeability and permittivity of the medium, respectively, relative to those of vacuum (so that μ_r and ε_r of vacuum are 1, by definition), and c_0 is the speed of light in vacuum (2.998×10^8 m/s). Eqs. 1 and 2 imply that light propagates with a speed $c = c_0 / \sqrt{\mu_r \varepsilon_r}$ in a medium characterized by relative permeability μ_r and relative permittivity ε_r . For simplicity let's consider a one-dimensional case, where the fields \mathbf{E} and \mathbf{H} vary in

only one direction, say z . Then, it can be shown that the following functions of z (spatial coordinate) and t (time):

$$E_x = E_{x0} \cos \left[2\pi \left(\frac{z}{\lambda} - ft \right) + \phi_x \right] \quad (3)$$

and

$$E_y = E_{y0} \cos \left[2\pi \left(\frac{z}{\lambda} - ft \right) + \phi_y \right] \quad (4)$$

are solutions to the wave equation for the x and y components of \mathbf{E} , respectively, and similar cosinusoidal functions are solutions for the H_x and H_y components of the magnetic field. Here, E_{x0} (E_{y0}) is the amplitude of the E_x (E_y) oscillations, λ is the wavelength, f is the frequency, and ϕ_x and ϕ_y are arbitrary phase shifts. The solutions to the wave equation provided by Eqs. 3 and 4 represent the particular case of a plane harmonic wave, which is important in optics and contains the key parameters used to describe the wave nature of light. The wavelength and the frequency are not independent, as their product is equal to the speed of light propagation in the medium ($\lambda f = c$). Therefore, the wavelength and the frequency can be used interchangeably to describe the color of light.

In biomedical optics the choice of wavelength depends on the particular application. A wide range of wavelengths is used, extending over the ultraviolet (UVC: 100–290 nm; UVB: 290–320 nm; UVA: 320–400 nm), visible (400–700 nm), near-infrared (IR) (0.7 to ~ 5 μm), mid-IR (~ 5 to ~ 40 μm), and far-IR (~ 40 to ~ 300 μm) spectral regions. For example, the fluorescence excitation and emission of chromophores found in proteins and nucleic acids (tryptophan, tyrosine, phenylalanine, adenine, guanine, cytosine, uracil, etc.) are typically in the UV region of the spectrum; proteins containing prosthetic groups such as hemes, flavins, etc., present absorption bands (associated with electronic transitions) from the near-UV to the near-IR, and vibrational spectroscopy of molecules is performed at wavelengths in the mid- to far-IR.

In the wave description of light, the energy density associated with the electric and magnetic fields are $0.5 \varepsilon_r \varepsilon_0 \mathbf{E}^2$ and $0.5 \mu_r \mu_0 \mathbf{H}^2$, respectively, where $\varepsilon_0 = 8.854 \times 10^{-12}$ F/m is the permittivity of vacuum and $\mu_0 = 4\pi \times 10^{-7}$ H/m is the permeability of vacuum.

The intensity of the wave (I), i.e., its energy per unit time and unit area, is given by $c\epsilon_r\epsilon_0\mathbf{E}^2$ or, equivalently, $c\mu_r\mu_0\mathbf{H}^2$. The wave description of light lends itself to the treatment of interference and diffraction phenomena. In fact, both phenomena can be described in terms of the superposition of individual waves among which there is a well-defined phase relationship.

Polarization is also typically explained using the wave description of light. The phase relationship between the x and y components of the electric field (i.e., the difference between ϕ_x in Eq. 3 and ϕ_y in Eq. 4) determines the time evolution of the amplitude and direction of the electric field. If $\phi_x - \phi_y$ is zero or 180° , then the light is linearly polarized. If $\phi_x - \phi_y = \pm 90^\circ$ and $E_{x0} = E_{y0}$, the light is said to be circularly polarized, whereas if $\phi_x - \phi_y = \pm 90^\circ$ and $E_{x0} \neq E_{y0}$, the light is said to be elliptically polarized. For values of $\phi_x - \phi_y$ that are not 0 , $\pm 90^\circ$, or 180° , light is also elliptically polarized.

Particle Description of Light

Quantum theory has led to the description of light in terms of quanta of energy, or photons, which behave as particles with a given energy and momentum. The relevance of this representation is in the fact that the exchange of energy between light and matter can occur only through discrete amounts, the photons. The energy associated with each photon depends on the frequency of the light and is equal to hf , where $h = 6.626 \times 10^{-34}$ J s is Planck's constant, and the momentum of a photon (along the direction of propagation) is h/λ . Using the particle description, light propagation in tissue can be represented in terms of a collection of individual photon trajectories. In this picture, the energy density is given by the number of photons per unit volume U multiplied by the energy per photon hf .

The use of intensity-modulated light sources in the optical study of tissue induces time oscillations in the photon density, and the propagation of these temporal oscillations of energy density can be described in terms of photon-density waves.^[1] Photon-density waves differ significantly from electromagnetic radiation waves in that they are strongly damped over a fraction of a wavelength, so that they are intrinsically confined to the near field. Nevertheless, photon-density waves in tissue exhibit refraction,^[2] interference,^[3] and diffraction^[4] phenomena similar to those of optical waves in the far field.

The momentum of a photon changes direction every time the photon is scattered or is refracted at an interface between two media. This change in momentum is associated with a force that is used to trap small particles or cells by laser tweezers.

Radiation Parameters

Using the particle description of light, the following parameters describing the radiation field as a function of position (\mathbf{r}), direction of propagation ($\hat{\Omega}$), and time (t) are commonly used in biomedical optics. These definitions can be extended to describe radiant energy (instead of photon number) by replacing the word "photon" with "energy," and by introducing a factor hf in all definitions (where hf is the energy per photon, of which h is Planck's constant and f is light frequency). A complete nomenclature for quantities used in biomedical optics can be found in Ref. [5].

- Angular photon density is represented by $u(\mathbf{r}, \hat{\Omega}, t)$, with units of $\text{m}^{-3}\text{sr}^{-1}$. $u(\mathbf{r}, \hat{\Omega}, t)d\mathbf{r}d\hat{\Omega}$ represents the number of photons in $d\mathbf{r}$ that travel in a direction within $d\hat{\Omega}$ around $\hat{\Omega}$.
- Photon radiance is represented by $L(\mathbf{r}, \hat{\Omega}, t) = \nu u(\mathbf{r}, \hat{\Omega}, t)$, with units of $\text{s}^{-1}\text{m}^{-2}\text{sr}^{-1}$. $L(\mathbf{r}, \hat{\Omega}, t)d\hat{\Omega}$ represents the number of photons traveling per unit time per unit area (perpendicular to $\hat{\Omega}$) in a range of directions within $d\hat{\Omega}$ around $\hat{\Omega}$.
- Photon density is represented by $U(\mathbf{r}, t) = \int_{4\pi} u(\mathbf{r}, \hat{\Omega}, t)d\hat{\Omega}$, with units of m^{-3} . The photon density is the number of photons per unit volume.
- Photon fluence rate is represented by $E_0(\mathbf{r}, t) = \nu U(\mathbf{r}, t) = \int_{4\pi} L(\mathbf{r}, \hat{\Omega}, t)d\hat{\Omega}$, with units of $\text{s}^{-1}\text{m}^{-2}$. The photon fluence rate is defined as the number of photons traveling per unit time per unit area (perpendicular to the direction of propagation) over all directions.
- Photon current density, or photon flux, is represented by $\mathbf{J}(\mathbf{r}, t) = \int_{4\pi} L(\mathbf{r}, \hat{\Omega}, t)\hat{\Omega}d\hat{\Omega}$, with units of $\text{s}^{-1}\text{m}^{-2}$. The photon flux is a vector that represents the net flow of photons. Its direction points in the direction of the net flux, and its amplitude gives the net number of photons transmitted per unit time per unit area in that direction.

OPTICAL PROPERTIES OF BIOLOGICAL TISSUE

Refractive Index

The refractive index of a medium (n) is defined as $n = \sqrt{\mu_r\epsilon_r}$, so that the refractive index of vacuum is 1. As a result of this definition, the speed of light in a medium of refractive index n is given by $c = c_0/n$. Usually, the refractive index depends on the frequency of light, typically increasing with frequency. Consequently, red light travels faster than blue light. In isotropic media, there are no preferential orientations and the refractive index is independent of the orientation of the electric field. However, anisotropic tissues

may present different indices of refraction for different directions of the electric field. This phenomenon is called birefringence. In birefringent media, the refractive index, and therefore the speed of light propagation, is different for different directions of polarization of linear polarized light.

Absorption Coefficient

Absorption processes consist of the transfer of energy from the light beam to the medium. In the UV, visible, and near-infrared portions of the spectrum, this typically involves electronic transition in tissue macromolecules and pigments, whereas in the mid- and far-IR, vibrational states are involved. Absorption results in an attenuation of the light intensity according to the Beer-Lambert law:

$$I = I_0 e^{-\mu_a L} \quad (5)$$

where I_0 is the incident intensity, μ_a is the absorption coefficient, and L is the distance traveled by the light in the medium. Using the particle description of light, the absorption coefficient μ_a can be defined as the inverse of the average distance traveled by a photon in the medium before being absorbed. The absorption coefficient for a given chromophore is given by the product of its concentration times its molar extinction coefficient. The absorption spectra of three important absorbers in tissue, namely, oxyhemoglobin, deoxyhemoglobin, and water, are shown in Fig. 1. These spectra were obtained from compiled absorption data for water^[6] and hemoglobin.^[7]

Scattering Coefficient

When light travels through tissue, it can be scattered elastically (i.e., without a change in wavelength) or inelastically (i.e., with a change in wavelength, such as in Brillouin or Raman scattering). The definition of the scattering coefficient refers to elastic scattering. Elastic scattering causes a change in the direction of propagation of light and thus an attenuation in the light intensity along the optical axis. Such attenuation is described by the following equation, which is formally identical to the absorption Beer-Lambert law of Eq. 5:

$$I = I_0 e^{-\mu_s L} \quad (6)$$

where μ_s is the scattering coefficient. Similar to the absorption coefficient, μ_s can be defined as the inverse of the average distance traveled by the photons before being scattered.

Fig. 1 Spectra of the absorption coefficients (μ_a) vs. wavelength (λ) for three chromophores commonly found in tissue, namely, oxyhemoglobin (HbO_2), deoxyhemoglobin (Hb), and water (H_2O). The concentrations of Hb and HbO_2 are assumed to be $50 \mu\text{M}$. These spectra were obtained from compiled absorption data for water^[6] and hemoglobin.^[7]

Reduced Scattering Coefficient

In most biological tissues, individual scattering events are not isotropic. In other words, the angular distribution of scattered photons is not uniform. The angular distribution of scattered light is described by the probability density $p(\theta)$ that a photon is scattered by an angle θ , which is defined as the angle between the direction of propagation of the scattered photon and that of the incident photon. The anisotropy factor g is defined as the average value of the cosine of the scattering angle, i.e., $g = \langle \cos\theta \rangle$. The value of g in tissue typically ranges from 0.7 to 0.99, indicating forward scattering at angles between 8° and 45° . A g factor of 1 indicates purely forward scattering, a g factor of 0 indicates isotropic scattering, and a g factor of -1 indicates purely backward scattering. In tissue optics the angular distribution of scattering is commonly described with the Henyey–Greenstein phase function.^[8]

$$p(\theta) = \frac{1 - g^2}{2(1 + g^2 - 2g \cos \theta)^{3/2}} \quad (7)$$

The reduced scattering coefficient μ_s' , which is defined as $\mu_s' = \mu_s(1 - g)$, can be interpreted as the inverse of the distance over which the photon loses memory of its initial direction of propagation, so that $1/\mu_s'$ is a measurement of the distance between effectively isotropic scattering events.

LIGHT-TISSUE INTERACTIONS AND RELATED APPLICATIONS

The interaction of light with tissue depends on many parameters, including the optical power and energy density, the optical properties of tissue, and the thermal properties of tissue such as heat conductivity and heat capacity.^[9] Different mechanisms of light-tissue interaction form the basis for a variety of applications of biomedical optics.

Fluorescence: Detection of Metabolic Changes

There are a number of fluorophores in tissue—both in cells (nicotinamide adenine dinucleotide (NADH); flavins; and aromatic amino acids such as tryptophan, tyrosine, and phenylalanine) and in the extracellular matrix (collagen, elastin), that account for endogenous fluorescence, also called autofluorescence. The spectral properties and relaxation times of autofluorescence may be different in normal and cancerous tissue,^[10] thus providing indications toward the detection and diagnosis of cancer. NADH is highly fluorescent (excitation maximum: 340 nm; emission maximum: 450 nm), but its deprotonated form NAD^+ is not. Consequently, fluorescence can be used to measure the NADH/NAD^+ ratio, which depends on the cellular oxidative energy metabolism.

Photochemical Interactions: Photodynamic Therapy

There are several light-induced processes that involve a chemical reaction. Some of these processes are photoaddition, photofragmentation, photo-oxidation, photohydration, *cis-trans* isomerization, and photo-rearrangement.^[11] These processes typically occur at relatively low optical power densities of the order of $1 \text{ W}/\text{cm}^2$ and long exposure times of seconds or more^[9] (Fig. 2). In photodynamic therapy, a photosensitizer (for example, hematoporphyrin derivatives or 5-aminolevulinic acid) is introduced into the bloodstream and distributes over most soft tissues. Its clearance in healthy tissue is faster than in cancerous tissue, so that after 3–7 days most of the photosensitizer is localized at the cancer. At this point, irradiation with light of the proper wavelength (usually in the red spectral region) excites the photosensitizer and triggers a series of processes that result in the generation of cytotoxic singlet oxygen, which induces necrosis of malignant cells. Another biomedical application of low-power (mW) light irradiation, called biostimulation, is believed to be based on photochemical processes. Biostimulation refers to a broad class of benefic effects (wound healing, anti-inflammatory effects, pain relief,

Fig. 2 Different mechanisms of laser-tissue interactions map onto different regions in the power-density/exposure-time space. These regions are schematically represented here. (Reproduced from Ref. [9] with permission.)

etc.) induced by low-level optical irradiation. Biostimulation remains controversial because of a lack of systematic clinical protocols that prove its efficacy and a lack of studies aimed at understanding the specific photochemical processes responsible for the therapeutic effects.

Thermal Interactions: Laser Tissue Welding

Thermal effects refer to the conversion of optical energy absorbed by the tissue into thermal energy as a result of nonradiative relaxation processes. The local heating of tissue depends on the properties of light irradiation as well as the optical and thermal properties of tissue. Depending on the local increase in temperature, four effects can be produced: coagulation, vaporization, carbonization, and melting.^[9] Coagulation requires a local temperature in excess of 60°C and is associated with necrosis. At temperatures above 100°C , the vaporization of water induces thermo-mechanical effects that are responsible for thermal tissue ablation. Carbonization, i.e., the release of carbon, occurs when the tissue temperature exceeds 150°C . At even higher temperatures, tissue melts as a result of the denaturation of tissue proteins (for example, collagen). The latter effect is used in laser tissue welding, in which proteinoous or dye-enhanced solder may also be used. Thermal interactions are typically induced with optical power densities of $10\text{--}10^6 \text{ W}/\text{cm}^2$ and pulse durations of $10^{-6}\text{--}10 \text{ s}$ ^[9] (Fig. 2).

Photoablation: Laser In Situ Keratomileusis (LASIK)

Photoablation refers to the photochemical decomposition of cellular and extracellular components by direct breaking of molecular bonds by UV photons. Photoablation is confined to the irradiated area so that it results in a well-defined area of tissue removal. Excimer lasers (for example, ArF, XeCl, XeF, etc.) emitting at UV wavelengths of 193–351 nm are typically used for photoablation. Power densities are relatively high, in the range 10^7 – 10^{10} W/cm², and pulse durations range from 10 to 100 ns (Fig. 2). LASIK is a routine laser-based method that uses photoablation to flatten the cornea to correct for myopia.

Plasma-Induced Ablation and Photodisruption: Lithotripsy

At high optical power densities of 10^{11} – 10^{13} W/cm², which are typically delivered over relatively short times (10^{-13} – 10^{-10} s), the electrons in the tissue are subject to an electric field that induces forces higher than the atomic attractive forces, thus causing breakdown and the formation of ionized plasma. On the one hand, this plasma of free electrons strongly absorbs optical radiation leading directly to ablation (plasma-induced ablation). On the other hand, at even higher pulse energies, shock waves and cavitation (formation of microscopic gas bubbles) may also take place leading to photodisruption. A key difference between plasma-induced ablation and photodisruption is that the former is spatially confined to the illuminated spot, whereas the latter affects adjacent tissue as well because of the propagation of shock waves. Photodisruption finds applications in the rupture of urinary calculi (lithotripsy).

LIGHT PROPAGATION IN TISSUE

Transport Theory

The description of light propagation in tissue is usually based on the particle description of light in terms of photons. Transport theory treats the flow of particles that experience scattering and absorption in the media where they propagate. The radiative transport equation for the angular photon density u (defined earlier in the section on Radiation Parameters) as a function of position (\mathbf{r}), direction of propagation ($\hat{\Omega}$), and time (t)

is written as follows:^[12]

$$\begin{aligned} \frac{\partial u(\mathbf{r}, \hat{\Omega}, t)}{\partial t} = & -c\hat{\Omega} \cdot \nabla u(\mathbf{r}, \hat{\Omega}, t) \\ & -v(\mu_a + \mu_s)u(\mathbf{r}, \hat{\Omega}, t) \\ & + c\mu_s \int_{4\pi} u(\mathbf{r}, \hat{\Omega}', t)p(\hat{\Omega}', \hat{\Omega})d\hat{\Omega}' \\ & + q(\mathbf{r}, \hat{\Omega}, t) \end{aligned} \quad (8)$$

where $p(\hat{\Omega}', \hat{\Omega})$ is the phase function describing the probability density of scattering from direction $\hat{\Omega}'$ to $\hat{\Omega}$, and $q(\mathbf{r}, \hat{\Omega}, t)$ is the source term, representing the number of photons injected by the light source per unit volume, per unit time, per unit solid angle at position \mathbf{r} , time t , and direction $\hat{\Omega}$. The first term on the right-hand side of Eq. 8 represents the net gain of photons at position \mathbf{r} and direction $\hat{\Omega}$ due to the flow of photons. The second term represents the loss of photons at \mathbf{r} and $\hat{\Omega}$ as a result of absorption and scattering. The third term represents the gain of photons at \mathbf{r} and $\hat{\Omega}$ due to scattering. Finally, the fourth term represents the gain of photons due to the light sources. The transport equation forms the basis for a general treatment of light propagation in absorbing/scattering media. However, it cannot be solved in analytical form even for the simplest geometries and homogeneous media, so that simplified approaches are commonly in use.

Diffusion Approximation

In biomedical optics, a common simplified approach to describe light propagation in tissue is the diffusion approximation, which requires a strongly scattering medium (i.e., $\mu_a \ll \mu_s'$), time variations of the photon density that are slow with respect to the average photon interaction rate $c(\mu_a + \mu_s')$, and distances from sources and boundaries that are much greater than $1/\mu_s'$. Under these conditions the transport equation reduces to the diffusion equation:

$$\frac{\partial U(\mathbf{r}, t)}{\partial t} = D\nabla^2 U(\mathbf{r}, t) - c\mu_a U(\mathbf{r}, t) + S_0(\mathbf{r}, t) \quad (9)$$

where $U(\mathbf{r}, t)$ is the photon density, D is the diffusion coefficient defined as $D = c/[3(\mu_s' + \mu_a)]$, and $S_0(\mathbf{r}, t)$ is the spherically symmetric component in the expansion of the source term $q(\mathbf{r}, \hat{\Omega}, t)$ into spherical harmonics.

Optical studies of tissue are performed using continuous-wave (CW), time-domain (TD), or frequency-domain (FD) techniques. CW studies employ a light source whose emission properties are time-independent, TD techniques employ short (compared to the photon time-of-flight in tissue) pulses, and FD

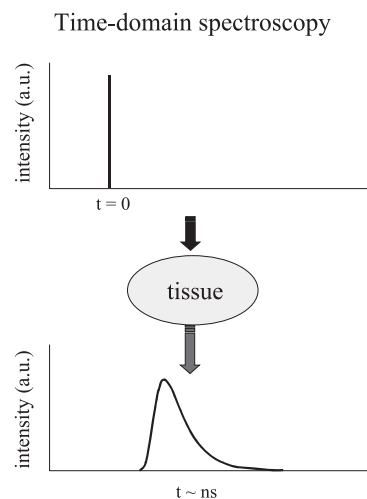

Fig. 3 In time-domain spectroscopy, the tissue is interrogated with a short pulse of light (at time $t=0$), and the temporal distribution (over a timescale of nanoseconds) of the optical pulse that has propagated through tissue can be examined.

techniques employ intensity-modulated light sources, with a modulation period that is comparable to the photon time-of-flight in tissue. The TD and FD techniques are pictorially illustrated in Figs. 3 and 4, respectively. The CW, TD, and FD solutions to the diffusion equation for a point source at $r=0$ in an infinite medium are the following:

$$U_{CW}(r) = \frac{P_0}{4\pi D} \frac{e^{-r\sqrt{3\mu_a\mu_s'}}}{r} \quad (10)$$

$$U_{TD}(r, t) = \frac{N_0}{(4\pi Dt)^{3/2}} e^{-\frac{3\mu_s'^2 r^2}{4ct} - \mu_a ct} \quad (11)$$

and

$$U_{FD}(r, \omega) = \frac{P(\omega)}{4\pi D} \frac{e^{ikr}}{r} \quad (12)$$

where P_0 and $P(\omega)$ are the CW and modulated source powers, respectively, N_0 is the number of photons emitted in the pulse for time-domain studies, and $k = \sqrt{(i\omega - c\mu_a)/D}$ (where the imaginary part of k is positive, so that $^{[12]}$ describes a wave that attenuates rather than amplifies as a function of the distance from the source r). Solutions to the diffusion equation for semi-infinite, slab, cylindrical, and spherical geometries are available in analytical form,^[12] and solutions for irregular geometries and inhomogeneous media are usually obtained using numerical methods.

Diffusion theory is often used to model light propagation in tissue, and its solutions in CW, TD, and FD (Eqs. 10–12) are used to translate optical

Fig. 4 In frequency-domain spectroscopy, intensity-modulated light is used to illuminate the tissue. The measured parameters are the average value (dc), the amplitude (ac), and the phase of the modulated signal.

measurements into measurements of the absorption and scattering properties of tissue.

BIOMEDICAL OPTICAL SPECTROSCOPY

An optical spectroscopy experiment consists of illuminating a sample with light of a known wavelength (or wavelength range) and measuring some properties of the light that emerges from the sample after having interacted with it. Absorption spectroscopy and elastic scattering techniques measure the fraction of the optical radiation dissipated or scattered, respectively, by the sample; fluorescence, phosphorescence, and inelastic light scattering measure the emitted intensity at wavelengths that are different from the wavelength used for illumination; some spectroscopic techniques involve the measurement of light polarization, for instance, optical rotatory dispersion, circular dichroism, and fluorescence polarization.

Absorption Spectroscopy

The measurement of absorption of UV, visible, and near-IR light, which is associated with transitions between electronic molecular energy states, is a common spectroscopic technique in biomedical optics. IR spectroscopy, which is associated with vibrational transitions, is less common because of the lower absorption of tissue constituents in the IR compared with the UV and visible spectral ranges, and the strong IR absorption of water. Absorption spectroscopy can give indications on the concentrations of specific

chromophores or provide structural information. A specific chromophore is associated with an absorption coefficient per unit concentration (ϵ), also called molar extinction coefficient, so that a measurement of the absorption coefficient (μ_a) yields the chromophore concentration $C = \mu_a/\epsilon$. The absorption properties of a protein or nucleic acid in a polymer are affected by the conformation (three-dimensional arrangement) of other residues in the polymer; thus absorption spectroscopy can provide structural information. A number of features of the absorption spectra of many chromophores (intensity, band shape, wavelength of absorption peak) are also sensitive to local environment (solvent).

Light-Scattering Spectroscopy

The wavelength dependence and the angular distribution of scattered light in tissue allows for the determination of the population density and size distribution of epithelial cell nuclei.^[14] This technique—called light-scattering spectroscopy—provides histological information about tissue *in vivo* and has shown the potential to diagnose early cancerous and precancerous conditions on the basis of the enlargement of dysplastic or malignant nuclei.

Measurements of the optical reduced scattering coefficient (μ_s') of tissue have been correlated with the concentration of glucose in the blood.^[15,16] An increase in the glucose concentration decreases the index of refraction mismatch between the extracellular fluid and the cellular membranes, resulting in a smaller value of μ_s' . It has also been shown that the scattering properties of brain tissue are affected by cell swelling^[17] and by events occurring at the neuronal membranes as a result of brain activity.^[18]

Fluorescence Spectroscopy

The radiative decay from an optically excited electronic state is referred to as luminescence. Fluorescence is the emission associated with a transition from a singlet excited state, and it occurs on a typical time scale of tens of nanoseconds. Because the excitation energy provided by the absorbed photons is partially dissipated through nonradiative relaxation processes, the emitted photons have a longer wavelength (i.e., are red-shifted) with respect to the excitation photons. Fluorescence measurements provide information on the structure, interactions, and dynamics of biological samples at the molecular and cellular level, and are commonly used for the study of biological specimens. In addition to the measurements of excitation and emission spectra, fluorescence techniques also involve measurements of the lifetime of the excited state, the

quantum yield (i.e., the ratio of the number of photons emitted to the number of photons absorbed), and the depolarization (i.e., the loss of polarization of fluorescence induced by dynamical processes of the fluorescent molecule). The fluorescence lifetime can be measured in the time domain by directly measuring the fluorescence decay in response to a pulsed excitation, or in the frequency domain by measuring the phase difference between an intensity-modulated excitation and the fluorescence signal, which is also modulated at the frequency of excitation.

Raman Spectroscopy

Raman spectroscopy is an inelastic scattering technique that probes molecular vibrational energy levels, as in IR spectroscopy. In the case of centrosymmetric molecules, there are vibrational modes that are either Raman-active or IR-active, so that Raman spectroscopy and IR spectroscopy provide complementary information. Raman spectroscopy is typically less sensitive than IR spectroscopy, and Raman signals may be overwhelmed by fluorescence signals in the case of samples that display autofluorescence. However, Raman spectroscopy presents a number of advantages in that it is applicable to aqueous media (because water contributes a small Raman signal, whereas it strongly absorbs IR light), it does not require special sample preparation, and it can be used to obtain spectra on microscopic areas and even on single cells. Raman spectroscopy has been applied to intact tissues for the identification of cancers and precancers.^[19]

BIOMEDICAL OPTICAL IMAGING

Fluorescence Microscopy

Fluorescence microscopy is a powerful bioimaging technique. It is based on measuring the spatial distribution of endogenous fluorophores or exogenous fluorescent molecules that label a specific tissue, cell, or cellular organelle. Fluorescence microscopy is typically performed in epi-illumination, i.e., using the same objective lens to focus the excitation light on the sample and to collect the fluorescence emission from the sample. The excitation light and the emission light are separated using a dichroic mirror, which reflects excitation light at a shorter wavelengths and transmits fluorescence emission light at longer wavelengths. The problem associated with the signal generated at out-of-focus regions in the sample is addressed by confocal microscopy.

In confocal microscopy,^[20] a pinhole is used at the focal plane on the detector side (see the left side of

Fig. 5 Schematic diagrams of confocal and multiphoton microscopy. Confocal microscopy (left) achieves z -sectioning by suppressing light generated out of the focal plane by means of a confocal aperture. Multiphoton microscopy (right) achieves z -sectioning by exciting fluorescence only at the focal plane. PMT: photomultiplier tube. (Reproduced from Ref. [11] with permission of John Wiley & Sons, Inc.)

Fig. 5). Objects on the sample at out-of-focus regions are equivalent to extended sources on the illumination focal plane, so that their off-axis emission is rejected by the limited aperture of the pinhole at the detector. Depending on the wavelength used and the size of the pinhole, the size of the optical section in the z direction is on the order of $0.4\text{--}0.8\ \mu\text{m}$. By scanning the focused spot of illumination, confocal microscopy provides three-dimensional optical imaging. Some potential limitations of confocal fluorescence microscopy are the relatively high excitation power required to compensate the signal suppression of the confocal pinhole and the limited optical penetration in tissue of UV/blue light used to excite most biologically relevant fluorophores. In particular, the high power level and the fluorophore excitation over the whole cone of illumination may lead to photobleaching (i.e., the light-induced chemical degradation of a fluorophore) over a relatively large sample volume. These potential problems are overcome by two-photon microscopy.

In two-photon microscopy (right side of Fig. 5) the fluorophore is excited by the simultaneous absorption of two photons, whose individual energy (wavelength) is half (twice) that of photons used for one-photon excitation.^[21] As a result, excitation light for two-photon excitation is typically in the red/near-IR region of the spectrum (where penetration depth in tissue is relatively high) as opposed to the UV/visible spectral range commonly used for one-photon excitation. Furthermore, two-photon excitation is confined to the focal spot of illumination because of the relatively small cross-section for two-photon excitation and the quadratic dependence of the fluorescence intensity on the incident photon flux. First, this fact results in a z -sectioning effect similar to that achieved by confocal microscopy, but without using any emission pinholes. Second, by limiting the fluorophore excitation to the focal spot, two-photon microscopy achieves a spatial confinement of photobleaching and photodamage to the sample.

Fluorescence lifetime imaging microscopy (FLIM) measures the spatial distribution of the fluorescence lifetime within the sample.^[22] Fluorescence lifetime is a sensitive indicator of the environment of the fluorophore and is independent of the excitation intensity and fluorophore concentration. As a result, FLIM is a powerful tool for bioimaging and it has been implemented by using both one-photon and two-photon excitation.

Optical Coherence Tomography (OCT)

Optical coherence tomography is an interferometric, backscattering imaging technique that provides cross-sectional structural images of tissue.^[23] OCT uses low-coherence interferometry to achieve depth discrimination. The basic idea is to split the light emission from the source into a sample beam and a reference beam. The sample beam is focused onto the tissue, whereas the reference beam is reflected by a scanning mirror. The light backscattered by the tissue on the sample arm of the interferometer and the light reflected by the reference mirror on the reference arm are mixed at the optical detector. The two signals produce a well-defined interference pattern only if the difference between the sample and reference pathlengths is within the coherence length of the light source. A short coherence length results in a high level of depth discrimination by scanning the reference mirror so that low-coherence sources are used in OCT. Because the coherence length is inversely proportional to the bandwidth of the light source, broadband light sources such as superluminescent diodes or mode-locked Ti:Sapphire lasers are suitable light sources for OCT. The source of contrast in OCT images is the high-frequency spatial variation (over a few wavelengths) of the coherent backscattering cross-section,^[24] as determined, for example, by discontinuities in the index of refraction. However, additional sources of contrast can be investigated with OCT by combining polarization,

Doppler shifts, or absorption information with the depth-discrimination feature of OCT.

Reflectance Optical Imaging

The spatially-resolved collection of light that is back-scattered/backreflected from biological tissue under pencilbeam or broadbeam illumination conditions is referred to as reflectance imaging. In contrast with the cases of confocal microscopy, two-photon microscopy, and optical coherence tomography, reflectance imaging provides limited capabilities of depth discrimination. However, there are applications that aim at imaging the collective optical features of superficial tissue layers, where depth discrimination is not a requirement. The basic approach is to illuminate the sample either directly with a laser beam or with light guides coupled to a variety of light sources. The light collection is usually performed with charge coupled device cameras. The detection of cutaneous melanoma^[25] and functional imaging of the exposed brain cortex^[26] are two examples of applications of optical reflectance imaging. By combining the spatially-resolved information of optical imaging with wavelength-resolved information, one obtains reflectance spectra at each image pixels. This spectrally- and spatially-resolved technique, which is called spectral imaging, requires tunable bandpass filters (for example, liquid crystal tunable filters or acousto-optic tunable filters) to sequentially select specific spectral regions (as narrow as 1 nm) over the visible/near-IR spectral range of 400–1000 nm.^[27]

Diffuse Optical Imaging

Most biological tissues are optically turbid media, and light propagates inside them in a diffusive regime. This diffusive mode of light propagation (also referred to as photon migration) results in the fact that light loses its polarization, coherence, and memory of the initial direction of propagation over distances on the order of millimeters. Nevertheless, optical imaging can be performed over optically thick tissues by detecting multiply scattered light; this technique is called diffuse optical imaging or diffuse optical tomography.^[28,29] The choice of the spectral region for diffuse optical imaging is dictated by the requirement of achieving an optical penetration depth on the order of centimeters, which in turn requires a relatively small absorption coefficient of tissue. Figure 1 shows that the absorption of hemoglobin and water, two of the dominant light-absorbing substances in tissue, is minimal in the near-IR band of 700–900 nm, which is the spectral range of choice in diffuse optical imaging. Continuous-wave, frequency-domain, and time-domain techniques are all used for diffuse optical imaging, according to a

reflection geometry or transmission geometry. The diffusive nature of light propagation inside tissue poses an intrinsic limit to the spatial resolution that can be achieved with this imaging modality. However, the high optical contrast provided by the spatial distribution of the concentration and oxygen saturation of hemoglobin (see Fig. 1) accounts for the effectiveness of diffuse optical imaging in areas such as tissue oximetry, breast cancer detection, and functional imaging of the brain.

CONCLUSIONS

Biomedical optics, also called biophotonics, is a very active field of research that integrates basic sciences, engineering, and clinical practice for the development of new and more effective tools in medicine and biology. Recent developments point to applications of biophotonics on a nanoscale level, for which the term bionanophotonics has been used. For example, nanoparticles such as quantum dots (fluorescent nanocrystals of semiconductors whose emission wavelengths depend on their size) and metallic nanoparticles are used for optical bioimaging and biosensing, respectively. Even BioMEMS (micro-electro-mechanical system designed for biomedical applications) is moving to the nanoscale. Biomedical optics thus covers applications that range from the macroscopic study of whole organs to the microscopic study at the cellular, subcellular, and molecular level, and to the new developments in the nanoscale world involving nanotechnology and nanophotonics.

Organic and Inorganic Matrices

Adele L. Boskey

Musculoskeletal Integrity Program, Hospital for Special Surgery, New York, New York, U.S.A.

INTRODUCTION

Mineralized tissues such as bone, tooth, and shell are composites, consisting of one or more inorganic mineral phases deposited in an oriented fashion upon an organic matrix. The mechanical properties of the composites are markedly different from those of the individual components. To understand the mechanical performance of these tissues, as well as to design tissue engineered replacements for them, it is crucial to be aware of the properties of these tissues, how they are formed, and how they function. This article focuses on bone organic and inorganic matrices, but provides illustrations and examples from teeth and shells.

Definitions

Most mineralized tissues, specifically those mineral-containing extracellular matrices formed in biologic systems, are composites consisting of an organic matrix and an inorganic one. These matrices are produced under cellular control, and together provide their component tissues with mechanical and compressive strength as well as elasticity that far exceeds that of their individual components.^[1-3] By definition, the organic matrix refers to those components made by the cells that consist predominately of proteins, sugars, and lipids, while the inorganic matrix refers to those components that are not made of hydrocarbons. A common feature of the mineralized tissues is their highly anionic organic matrices; these matrices control the deposition of biominerals upon an oriented structural support. Both soluble and insoluble matrices do this, in part, by acting as “templates.” Templating in biomineralization is generally provided by an insoluble matrix, soluble macromolecules, and precipitating ions. The insoluble template provides supramolecular architecture, while the soluble macromolecules associate with the precipitating ions, facilitating crystal nucleation on the template surface. The same soluble macromolecules, having the ability to bind to and stabilize the precipitate, can also regulate crystal growth (size, shape, and aggregation) and the extent to which these crystals proliferate. Copying these naturally occurring tissues and the processes by which they

form (biomimetics) is a fundamental technique in tissue engineering.

In bones, teeth, and a limited number of shells, the inorganic material is an analogue of the naturally occurring mineral, hydroxyapatite (HA). The chemical formula for pure HA is $\text{Ca}_5(\text{PO}_4)_3\text{OH}$, but in biologic tissues, the calcium-to-phosphate molar ratio is often quite different from the stoichiometric 1.67:1 predicted from this formula.^[4] Examples of the inorganic materials found in different tissues within the same species and in different species are listed in Table 1.

Even when the same mineral phase is present, the properties of the mineral may differ with tissue type, animal and tissue age, animal health and disease, and tissue function. The mineral in shells is most frequently a calcium carbonate, but the crystalline phase present may be aragonite, calcite, or vaterite, and often is a mixture of these phases.^[5] Some shells contain non-crystalline (amorphous) calcium carbonates.^[6] Here we review these inorganic components, their organization in the different mineralized tissues, the ways in which they can be analyzed, how the organic matrix on which they are deposited influences their formation, and how this knowledge is being used to design tissue-engineered constructs for bone and tooth repair.

BONE

Structure and Function

The bones of the body are categorized based on shape (long and flat), structural arrangement (cortical and trabecular/lamellar, woven, and compact), or by their mechanism of development (endochondral and intramembranous ossification). Some of these classifications are illustrated in Fig. 1. Flat bones (with flat as distinct from rounded cross-sections) are typified by those in the skull or ribs. They consist of a layer of spongy/lamellar bone between two thin layers of compact/cortical bone. Flat bones do not have a bone marrow cavity, but they do contain marrow. Long bones such as the femur or tibia (Fig. 1) have a shaft and two cartilage covered ends. They are dense bones providing strength, structure, and mobility. Covered by the cortex (compact bone), the long bones have a marrow

Table 1 Inorganic matrix constituents

Mineral phase and chemical formula	Found in biology
Calcium phosphates HA $\text{Ca}_5(\text{PO}_4)_3(\text{OH})$	Bones, dentin, cementum, enamel Phosphatidic shells
Brushite $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$	Salivary and kidney stones; ? embryonic bone
Octacalcium phosphate $\text{Ca}_8\text{H}_2(\text{PO}_4)_3$	Enamel
Tricalcium phosphate $\text{Ca}_3(\text{PO}_4)_2$?
Calcium pyrophosphate $\text{Ca}_2\text{P}_2\text{O}_7 \cdot x\text{H}_2\text{O}$	Pathologic deposits
Calcium carbonate Aragonite Calcite Vaterite	Shells, pancreatic stones
Iron oxide	Magnetobacteria
Silicates	Diatoms

cavity and contain both yellow and red marrow. (The red marrow produces blood cells.) The cortical bone consists of unique structural units (osteons or Haversian systems). Each osteon has a central vascular channel

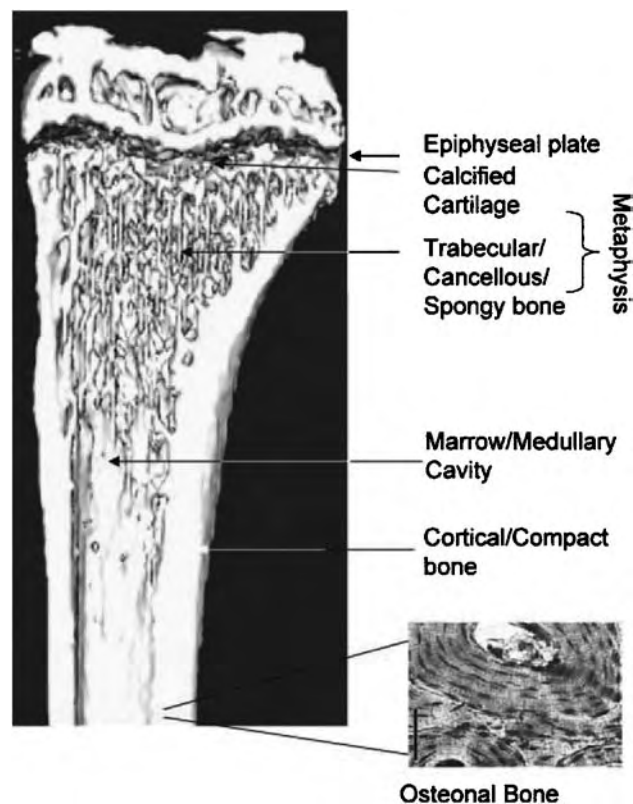

Fig. 1 The structure of a long bone. The anatomic areas are identified on a microcomputed image of a mouse tibia. The pull out shows a cross-section of compact bone, demonstrating the presence of concentric circles of mineral around a vascular cavity (Haversian canal).

(Haversian canal) surrounded by concentric layers of mineralized bone (lamellae). Distinct from cortical/osteonal bone is the trabecular/cancellous bone. It is found in metaphyseal and epiphyseal regions of the long bones. Much of the bone surface contains this less dense, more elastic, high turnover trabecular bone. Its arrangement is mesh-like (Fig. 2). Trabecular bone forms the interior portions of the bones, and is rigid but “spongy,” consisting of short parallel strands of bone, which fuse together.

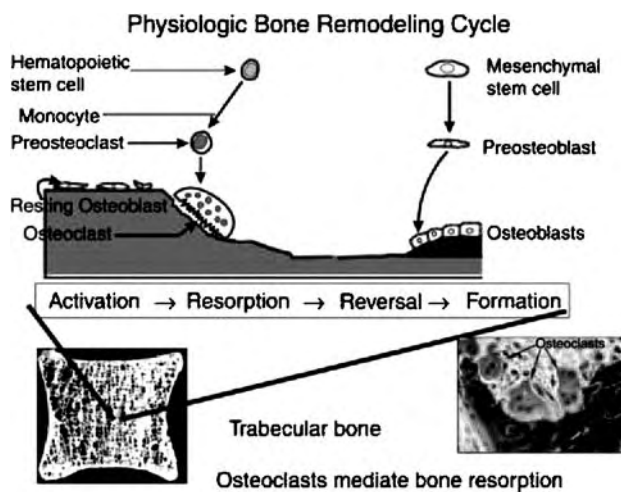

Fig. 2 The process of remodeling in bone is characterized by the coupling of osteoblasts (derived from mesenchymal stem cells), and osteoclasts (derived from hematopoietic stem cells). The pull out shows a segment of a vertebral body showing the individual trabeculae, and a stained image of osteoclasts (multinucleated giant cells) on a bone surface. (Courtesy of Dr. Steven Goldring, Harvard University School of Medicine.)

The entire bone structure provides strength and rigidity, enabling mobility while protecting internal organs. Bone is also the storehouse for calcium and phosphate (and other less abundant) ions required for the metabolism. Bone is constantly in a dynamic state, being formed by the bone-forming cells (osteoblasts) and removed by the macrophage-derived bone-dissolving cells (osteoclasts). These processes are coupled, as illustrated in Fig. 2. When the coupling is defective, i.e., when there is an imbalance between bone remodeling and bone formation, the mechanical properties of the bone composite are impaired. Examples of such uncoupling associated with increased risk of bone fracture include osteoporosis (too much remodeling resulting in loss of bone tissue), osteopetrosis (too little remodeling resulting in rock-like bones), or osteomalacia (too little mineralization).

Composition—The Mineral

The extracellular matrix of the bone composite in the adult animal consists in decreasing order of HA mineral, collagen, non-collagenous proteins, lipids, and water. The amount of mineral is usually determined by measuring the ash content (determining the gravimetric yield after the organic matrix is removed from dry-weighed bone by heating to 600°C). Radiographic methods such as backscatter electron imaging,^[7] quantitative microradiography,^[8] and dual photon absorptiometry^[9] provide two-dimensional estimates of ash content, while quantitative micro-computerized tomography can be used to calculate “mineral tissue density,” a three-dimensional parameter.^[10] While each of these methods provides insight into the amount of mineral that is present and how it is distributed in the tissue, none of them provides information on the nature of the inorganic mineral present.

The nature of the mineral phase present is generally determined by X-ray powder diffraction analysis (XRD).^[4] For this technique, the material in question is ground to a homogeneous powder and exposed to collimated X-rays that are diffracted (reflected) off the surface of the sample. The peaks that are detected (by a radiation detector or classically by a film) occur at positions determined by the spacing between the atomic planes, and are described by Bragg's Law

$$n\lambda = 2d \sin \theta$$

where n is the order of the reflection, λ , the wavelength of the radiation, d , the spacing between the planes, and θ , the angle of incidence (or reflection). The diffraction pattern provides a “fingerprint” of the phase present or if a mixture of the relative amounts of components

based on values published in the powder diffraction files.^[11] Fig. 3A presents a typical XRD pattern of large crystals of HA, such as are found in sintered apatite implant materials. The c -axis (002) reflection used to estimate particle size with the Scherrer equation (below) is indicated. Other spectroscopic techniques such as infrared, Raman, and nuclear magnetic resonance can also provide insight into the environment of molecular constituents, and hence can also provide “fingerprints” of structures;^[4,12] however XRD is the “gold standard.”

The XRD pattern not only allows phase identification, but also provides information on the relative crystal size and perfection of the crystals being examined. This is because the Bragg's equation presented above assumes that the crystals are perfect, all the planes are aligned, and the resultant diffraction peaks are sharp. But for biominerals such as HA, the peaks are broadened. The Scherrer equation can be used

Fig. 3 Illustration of techniques for identification of the inorganic phase. (A) X-ray diffraction of a synthetic HA. The c -axis 002 peak used to estimate crystallite size in biologic tissues is indicated. (B) Infrared spectrum of adult human bone, the absorbances corresponding to vibrations discussed in the text are indicated.

to calculate the average “size and perfection” of component crystals.^[13]

$$t = K\lambda/\beta_{1/2} \cos \theta$$

Where t is the thickness of the particle along the plane being examined, K a constant (usually set at 0.9, $\beta_{1/2}$ is the line width at half maximum for the peak at θ degrees).

Crystallite size can be determined directly by electron microscopy^[14] or atomic force microscopy (AFM).^[15] AFM measurements and electron microscopy provide crystal sizes for individual crystals, rather than the averages as determined by X-ray or electron diffraction. However, for bone, the values determined by all methods are in relative agreement, with the smallest dimension of the crystals being 11–30 nm, and the longest (c -axis length) dimension being 10–60 nm.

The chemical composition of the mineral can also provide insight into the nature of the phase(s) present. However, for calcium phosphates, the data is difficult to interpret not only because there are a variety of calcium phosphates in mineralized tissues (Table 1), but also because the small size of the physiologic HA crystals (and their high surface/volume area) leads to both the inclusion and the surface adsorption of foreign ions. However, at the electron microscopic level using quantitative microprobe analyses, localized compositional changes can be determined, and this can provide unique information on variations in composition within the tissue.^[16]

Infrared microscopy and infrared imaging microscopy can provide spatial information not only on the amount of mineral present (mineral/matrix ratio) but also on the crystallinity, carbonate content, and acid phosphate contents based on comparisons with X-ray diffraction data.^[17] A typical infrared spectrum of adult human bone is shown in Fig. 3B. In infrared microscopy, an infrared spectrometer is coupled to a light microscope, and thin sections of tissue examined with a spatial resolution of as little as 7 μm . Raman microscopy, which has a spatial resolution of as little as 1 μm , can provide complimentary information.^[18] Both these techniques require sections of tissues to be provided for analyses, but while the Raman analyses can be performed on hydrated tissues of variable thickness, the infrared analyses are affected by the presence of water, and require thin (2–4 μm) sections to allow light to be transmitted. Both imaging techniques provide information on the spatial distribution of mineral (and matrix) properties.

Fig. 4 illustrates the application of Fourier transform infrared imaging (FTIRI) to the study of biopsies obtained from human iliac crest bone. The images show the mineral/matrix ratio in (A) trabecular and

(C) cortical bone, along with the pixel distributions corresponding to these images. Using the same spectral data, other parameters can be determined, and Fig. 4B and 4D show the crystallinity distributions for the same trabecular and cortical bone. These data were from a biopsy of a premenopausal woman, with no evidence of bone disease as described elsewhere.^[19] As shown here, in normal healthy bone, there is heterogeneity in the distribution of the mineral properties, with the most recently formed bone having the lowest mineral content, the highest acid phosphate content, the lowest crystallinity, and the lowest carbonate content.^[18,20,21] With age, in the absence of disease, these parameters are altered, such that older bone has higher mineral content, lesser carbonate and acid phosphate contents, and increased crystallinity. However, there normally is a broad distribution of these parameters. In diseases such as osteoporosis, the mineral/matrix ratio is decreased (pixel histograms shift to the left), and the crystallinity of the residual bone is shifted to the right.^[21–24]

Composition—The Organic Matrix

The organic matrix of bone consists predominately of type I collagen (the structured template upon which mineral crystals are deposited in an oriented fashion). Collagen is a unique triple helical molecule that provides the tissue with strength and flexibility.^[25] There are more than 27 types of collagen; however, type I collagen is the most abundant, and is the major constituent of the organic matrix of bone, tendons, lung, dentin, ligaments, and skin.^[26] The collagen gene is one of the more complex in the body; more than 50 intervening sequences have to be spliced out for each of the three triple helical chains and the mRNA respliced, thus although the structure of the protein is quite simple (Glycine-X-Y) $_n$, with X and Y being proline and hydroxyproline most frequently processing of the collagen protein is extremely complex. There are numerous posttranslational modifications (synthesis of hydroxyproline and hydroxylysine, glycosylation of hydroxylysine and collagen propeptides, assembly of the triple helix, and removal of non-helical domains). Once the collagen fibrils are secreted from the cells, they are stabilized by the formation of cross-links, a process that is partially dependent on enzymes and partially non-enzymatic.^[25] This complexity leaves room for errors, and there are various diseases associated with bone fragility, which are either owing to, or associated with, mutations in the collagen gene,^[27–30] improper processing,^[31,32] or impaired collagen degradation.^[33]

The next most abundant components of the organic matrix of bone are a group of proteins that can be extracted without removing the collagen, the so-called

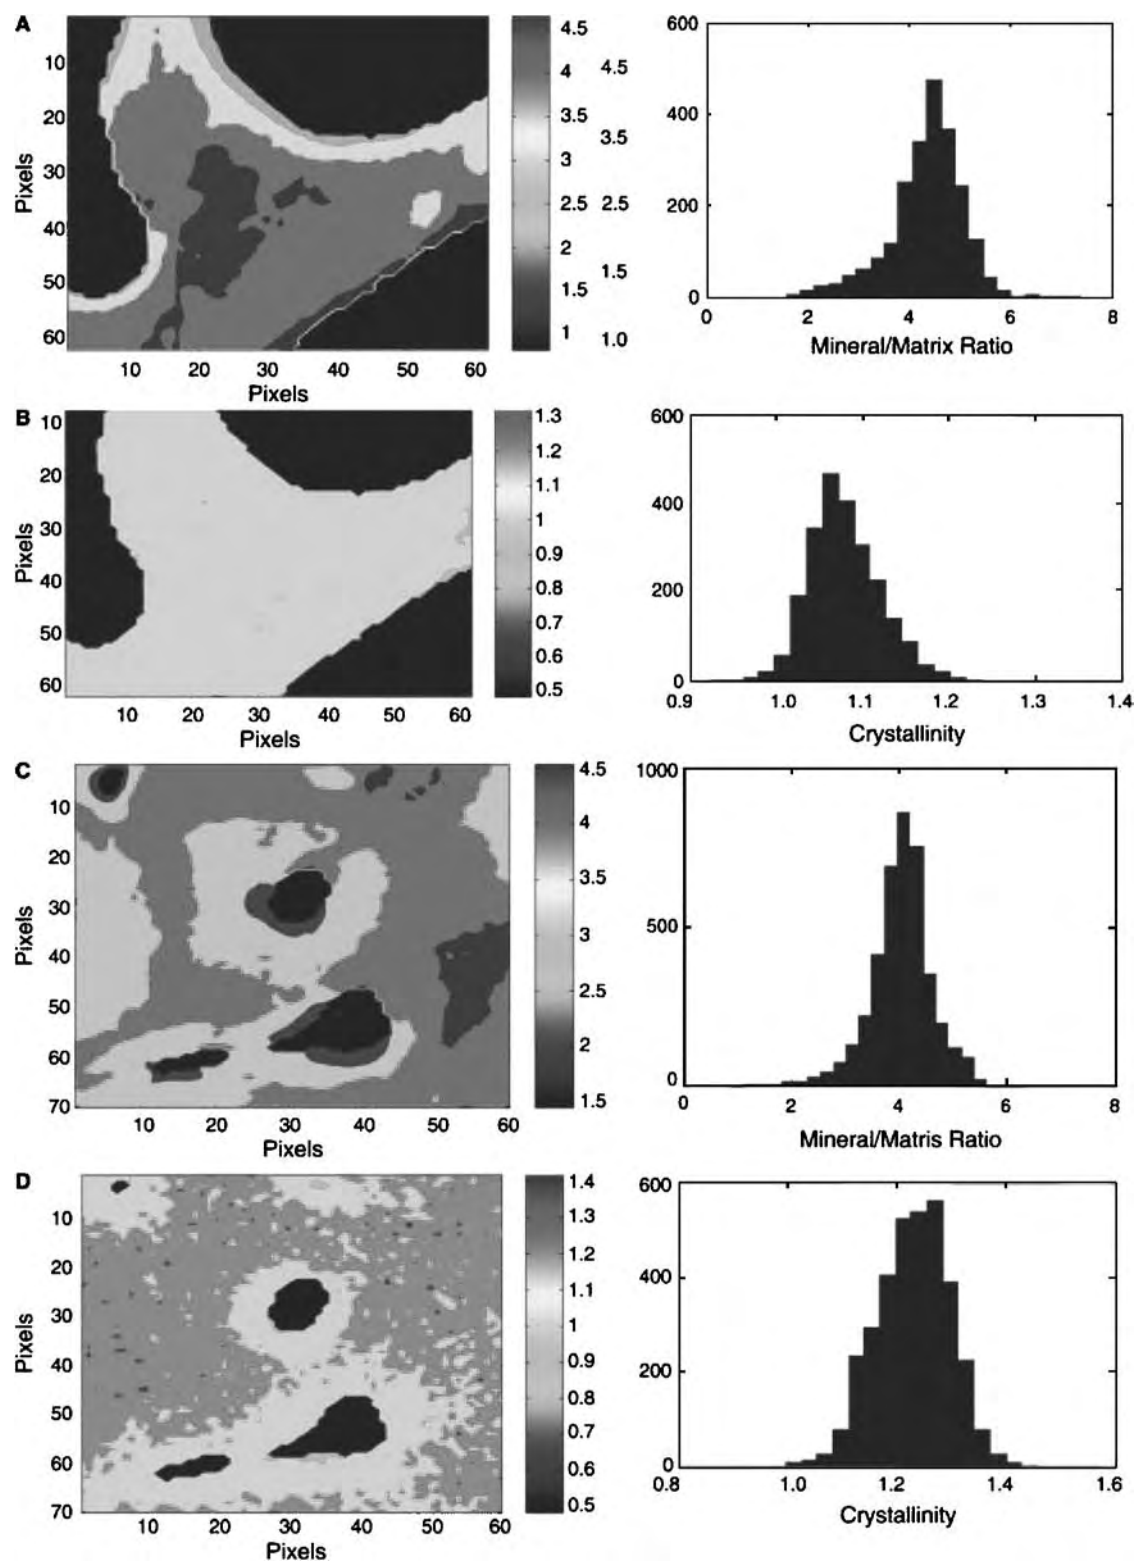

Fig. 4 Infrared imaging of bone in a human iliac biopsy. (A) Mineral/matrix ratio in trabecular bone; (B) crystallinity in this same section; (C) mineral/matrix ratio in cortical bone; and (D) crystallinity in the same cortical section. Pixel histograms are presented on the right of each image describing the distribution of parameters in the image shown.

non-collagenous proteins.^[34] These proteins are highly anionic, interact with collagen, and while these only account for about 5% of the total tissue weight, are involved in regulating the properties of the matrix, and controlling both the initial deposition of the mineral and the growth of the mineral crystals.^[35] Many of these proteins (Table 2) associate with collagen fibrils, are cell binding, and can act as growth factors to stimulate cellular responses. The properties of these proteins have been reviewed extensively elsewhere,^[33,34] and the major components of the bone matrix, along with the effect of these proteins on mineralization in solution, in culture, and/or in animals in which the proteins have been genetically ablated are summarized in Table 2. In addition to the non-collagenous matrix proteins, there are also cell-bound enzymes and intracellular enzymes that are crucial for the function, remodeling, and turnover of the tissue. These enzymes are listed in Table 3. Also in the matrix of bone, in addition to proteins and glycoproteins, are lipids derived from cell membranes, some of which associate with collagen,^[44] and some are components of other extracellular organelles. These lipids serve to regulate cell function and cell shape, and also play roles in mineralization.^[44]

Collagen provides the oriented template upon which the mineral crystals deposit. This deposition is regulated by the cells, which control the flux of calcium and phosphate ions, and by the non-collagenous proteins, which serve as nucleators, and facilitate the deposition of the apatite mineral crystals onto the collagen.

Bone Functional Properties

The most important functional property of bone from an engineering (or health) point of view is its ability to support loads. This load-bearing capacity is dependent on the composite structure^[1] and on the heterogeneity of these structures. Bone strength is determined by a combination of geometric (architecture, number of struts, and wall thickness), and by material properties including the presence of microcracks, mineral content, and crystallite size.^[45] Neither the decalcified organic matrix nor the deorganified mineral matrix has the ability to withstand loads comparable to the composite tissue. It is for this reason that bone tissue engineering seeks to develop scaffolds that can mimic the properties of the healthy bone composite. To make tissue-engineered constructs (scaffold and cells), one requires an understanding of the bone formation process.

Table 2 Organic matrix components^a in vertebrate bone, dentin, and cementum

Protein	Proposed function	Knockout phenotype
Collagen type I	Structural stability/mechanical strength	Brittle bones
Bone sialoprotein	Nucleation of HA	?
Osteopontin	Inhibition of mineralization/ osteoclast recruitment	Impaired remodeling
Dentin matrix protein-1	HA nucleator/cell signaling	Osteomalacia
MEPE	Regulator of mineralization; cell signaling	?
Osteonectin	Regulates collagen fibrillogenesis	Thinned bones, decreased bone density, cataracts, impaired wound healing
Phosphophoryn ^b (PP)	Initiation of dentin mineralization/ cell signaling	?
Dentin sialoprotein ^a (expressed as <i>dspp</i>)	Cell signaling, HA nucleation	Impaired enamel formation; impaired dentinogenesis
Osteocalcin	Recruitment of osteoclasts; inhibitor of mineralization	Increased bone density
Matrix gla-protein	Mineralization inhibitor	Extensive vascular and smooth muscle calcification
Biglycan	Regulates collagen fibrillogenesis; HA nucleator	Thin bones
Decorin	Regulator of collagen fibrillogenesis; inhibits HA formation	?

^aThis list is not comprehensive and only includes those proteins for which functions have been described.

^bFound in dentin only.
(From Ref. [4].)

Table 3 Examples of enzymes that regulate the matrix composition of bones and teeth

Enzyme	Substrate	Function
Alkaline phosphatase ^[36]	Organic phosphate esters	Stimulate mineralization
ANK progressive ankylosis ^[37]	Membrane transport	Transport pyrophosphate
PC-I ^[38]	Pyrophosphate	Hydrolyze inhibitor of mineralization
Casein kinase II ^[39]	Serine rich peptides	Phosphorylate matrix proteins
Matrix metalloproteases ^[40]	Collagen, proteoglycans, matrix proteins	Tissue remodeling
Cathepsin K ^[41]	Extracellular matrix	Osteoclast enzyme that degrades collagenous matrix
Acid phosphatase ^[42,43]	Matrix phosphoproteins	Matrix degradation by osteoclasts and chondroclasts
Carbonic anhydrase ^[43]	Carbon dioxide	Transports protons from cells—important for mineral degradation

Bone Formation

Bones growth occurs by two distinct processes, endochondral ossification and intramembranous ossification. In the first pathway, mesenchymal cells differentiate into chondrocytes and develop a cartilage matrix that is then mineralized and eventually replaced by the bone. These processes occur under the influence of a variety of hormones and growth factors reviewed elsewhere.^[46,47] The cells deposit a matrix consisting, in order of appearance as best we know today, of fibronectin, type I collagen, and non-collagenous proteins. The calcified cartilage that is formed is removed by specialized cells (osteoclasts); bone-forming osteoblasts then deposit a matrix of type I collagen and non-collagenous proteins (osteoid). Key to this process is the invasion of blood vessels, which is why vascular endothelial growth factor (VEGF) is viewed as crucial in the scheme of bone development.^[48,49] Intramembranous ossification or appositional bone growth occurs on an already formed bone matrix, and includes the coupling of resorption and bone formation. Many of the same factors that regulate endochondral ossification also play a role in intramembranous ossification, but the controlling factors are not identical.^[50] In both cases, the final bone composite is similar, although, as noted above, there are slight variations in bone mineral crystal size and composition, depending on the tissue location and age, and on the mechanism of formation.

The first step in bone formation is the formation of a matrix (osteoid in bone and cartilage in the growth plate). This is followed by maturation of both cells and matrix, including modification of the matrix to prepare it for mineral deposition. Because the properties of the mineral crystals and the mechanical properties of the tissues in which they deposit differ, there must be

distinct factors that regulate mineralization in different tissues. However, the general principles are similar. Once an appropriate matrix (which includes the template upon which the crystals will be deposited) is present, a variety of factors lead to the formation of the first insoluble mineral particles (nuclei). Nucleation may occur homogeneously, a very slow process requiring a great deal of energy to arrange the component ions in a structure that will persist as a stable “critical nucleus,” or may occur heterogeneously, on surfaces that resemble the structure of the crystals to be formed. In bone, within which crystals deposit at relatively the same time within multiple sites throughout the entire collagenous matrix, it is thought that the process must be heterogeneous. The collagen, as stated above, provides the template. Non-collagenous matrix proteins associated with the collagen (either on its surface or within its fibrils) can stabilize clusters of ions as they organize to form HA, or, because of their anionic nature, can actually serve as a substrate upon which the ions deposit. Once the HA nuclei are present, when the ion concentration in the solution remains above the solubility of the crystal (i.e., the solution is supersaturated), additional ions can add to the surface of the nuclei, and the crystals can grow in all dimensions, can form branches that support further growth, and can clump together (agglomerate). The same matrix proteins that stabilized the critical nuclei, or served as surfaces for initial crystal deposition, also are involved in the regulation of the shape, proliferation, and agglomeration of the crystals.

Tissue Engineering of Bone

While bone repairs itself by recapitulating the process of endochondral ossification^[51] or intramembranous

ossification, there are often situations where this process fails. Failure of the bone to repair may be because of the presence of neoplasms, extensive trauma, or loss of the vascular supply. In these cases, tissue engineers^[52] working with orthopaedic surgeons seek to replace the bones with scaffolds made of inorganic matrix materials, organic matrix materials, or composites that combine one or more organic matrix component with an inorganic component (Table 4).

The concept is that the scaffold will serve as a substitute template and allow the ordered deposition of mineral. However, in many cases, the inorganic materials do not mimic the poorly crystalline HA of bone, but contain larger crystals. The matrix may consist of a single component or multiple components. Composites with collagen and HA mineral are also being evaluated^[70–73] as substrates for growing bone cells. The inorganic matrix materials used include sintered HA, ceramics, mixtures of HA with bioglass, and mixtures containing other calcium phosphates. None of these has the crystallite properties of bone mineral and none to date has been reported to produce a structure with the mechanical strength of healthy bone. According to Mistry and Mikos^[74] “an ideal

biomaterial scaffold will provide mechanical support to an injured site and also deliver growth factors and cells into a defect to encourage tissue growth” while degrading in a controlled manner “without causing a significant inflammatory response.” Understanding the properties of the healthy bone mineral and matrix should help provide such a material.

Many of these scaffolds are combined with growth factors and cytokines to stimulate the influx of cells. In some cases, the growth factors are adsorbed to the scaffold matrix, in others, cells engineered to express the growth factor have been added. These factors have included, among others, bone morphogenetic proteins, parathyroid hormone, VEGF, and transforming growth factor β (TGF β).^[75,76] The challenges to using these approaches for engineering bone have been reviewed in detail elsewhere,^[77] and include limitations on cell source, problems with developing a scaffold or implant with sufficient porosity that lacks an immunogenic response, the need for a material whose mechanical properties will eventually match those of the tissue to which they are inserted, and the necessity of having a vascular network in the tissue. While most of these materials work well in cell culture experiments,

Table 4 Examples of templates being used for the development of biominerals

Template	Soluble components	Phase formed
Natural Mineral		
HA ^[53]	Simulated body fluid	HA
Polycaprolactone-HA composite ^[54]	Culture media	HA
Amino acid-coated HA nanoparticles in dextran sponge ^[55]		
HA–amelogenin composite ^[56]	Culture media	HA
Calcium carbonate ^[57]	Mollusk proteins	Aragonite (CaCO ₃)
Alumina ^[58]	Osteoblast culture	HA
Collagen		
Patterned Films ^[59]	Fibrinogen and cell culture media	HA
DMP-1 on Collagen ^[60]	Calcium and phosphate ions	HA
Polymers		
PolyHEMA–carboxylate surface ^[61]	Calcium and phosphate ions	HA
Poly(β -hydroxybutyrate-co- β -hydroxyvalerate) ^[62]	Culture media	HA
1-vinyl-2-pyrrolidinone– <i>n</i> -butyl methacrylate co-polymer ^[63]	In vivo	HA
Nanofibrils of L-lactic acid ^[64]	Culture media	HA
Oligolactone macromers ^[65]	Culture media	HA
Porphyrins on glass ^[66]	Calcium and bicarbonate ions	Calcite (CaCO ₃)
Carbon dioxide ^[67]	Carboxymethyl chitosan	Vaterite (CaCO ₃) in flower shaped clusters
Chitin ^[68]	Amino acids in vivo	HA
Chitosan–gelatin composite (\pm HA) ^[69]	Culture medium	HA

their effects in animal models and humans are very variable, and few have been evaluated *in vivo*.

Based on knowledge of the organic components involved in mineralized bone formation, recently there have been some successful attempts to produce biomimetic scaffolds that act like the collagen template, and yield a relative oriented mineralized construct *in vitro*. One of the most promising is the use of scaffolds made of self-assembling molecules by Stupp's group.^[64,78,79] Taking advantage of the need to have a construct with the adsorbed protein-providing sites for cell anchorage, nutrition, signaling to the cells, as well as regulation of mineralization of the scaffold, Stupp's group forms self-assembled biodegradable poly-L-lactic acid fibers bonded by mechanical compression along with a variety of peptides and hydrophobic components. One type of fibrils containing a long alkyl tail, a flexible region, and a single phosphoserine residue was able to orient HA deposition along their long axes *in vitro*.^[64] These materials have not yet been evaluated in animal models, but clearly demonstrate the advantage of providing a mimetic substrate that can serve as a template for HA deposition. Several of the polymers have a cholesteryl component, L-lactic acid, and a flexible protein to which other functional groups can be linked. Another group has used a similar approach with poly (DL-lactic acid) tethered with cholesterol to promote osteoblast attachment and growth *in vitro*.^[80] Song, Malathong, and Bertozzi^[61] similarly used a polymeric hydrogel (polyHema) functionalized with glutamate, aspartate, or phosphoserine. Each of these anionic groups was equally effective in promoting *in vitro* HA deposition.^[61] Table 4 lists additional materials that have been used as templates to form mineral composites and unique structures that have the potential for use in repair of mineralized tissues or induction of new tissue

formation, along with other applications far from biomedical.

A quite different approach to the use of scaffolds was recently reported,^[81] in which the problems of immunogenicity, lack of a vascular supply, and shortage of cell supplies were circumvented by using a space within the host bone as an "in vivo bioreactor." The bioreactor is formed within a space between the long bone and the periosteum that covers it. Using a calcium-rich alginate gel implanted in a space created below the periosteum of rabbits, compact bone formation (via intramembranous ossification) was reproducibly observed. The size of the new bone was dependent on the space into which the alginate was implanted. The implant material functioned equally well with or without growth factors, yielding within six weeks compact bone containing osteons surrounded by lamellar bone. More importantly, the new bone could easily be retrieved and implanted in other sites in the rabbit where it healed defects successfully.

Although many of these tissue-engineered constructs are still in the development stage, there are some already available commercially (Table 5) for repair of bone defects. These are subject to the same limitations as the experimental constructs described above, cell source, immunogenicity, vascularization, and porosity, and thus have restricted usages.

TEETH

Dentin—Composition

Dentin is similar but not identical in composition to bone.^[83] The mineral of dentin is HA, the crystals tend to be slightly larger, and the relative amount of mineral

Table 5 Examples of products for bone repair made from organic and inorganic matrices

Material	What is in it	Company and web location for further detail
Biocoral bone graft substitute	97% calcium aragonite	Biocoral (www.biocoral.com)
Bio Glass	$\text{Na}_2\text{O}-\text{CaO}-\text{CaF}_2-\text{P}_2\text{O}_5-\text{SiO}_2$	NovaBone products (www.novabone.com)
Bio-Oss	Inorganic bone matrix	Geistlich Biomaterials (www.geistlich.de)
Bio-gide	Demineralized bone matrix	
Grafton	Banked bone	Osteotech (www.osteotech.com)
Dynagraft	Demineralized bone matrix + bone morphogenetic protein ^[82]	Citagenix (www.citagenix.com)
Vitoss	Beta-tricalcium phosphate	Orthovita (www.orthovita.com)
Chronos		Synthes (www.stratec.com)
Healos	Cross-linked type I collagen microfibers coated with HA particles	DePuy (www.acumed.com)
Osteoset	Calcium sulfate	Wright Medical (www.wmt.com)

tends to be slightly greater than that found in bone. Dentin has most of the same organic matrix constituents as bone (Table 2), but their relative distribution is different, and dentin has some unique components reviewed elsewhere.^[84] The most unique are the phosphorylated dentin proteins, and, in particular, PP. PP and dentin sialoprotein, another dentin-specific protein, are expressed by a single gene (*dspp*), but the gene products are not colocalized.^[85] Unlike bone, dentin is formed directly by dentin-forming cells (odontoblasts), and in most circumstances, dentin is not remodeled. Dentin, like bone, is important for mechanical strength, and the disruption of its components (for example, the knockout of the *dspp* gene) results in abnormal dentition with impaired mechanical properties, in part attributable to the loss of the enamel coating the dentin.^[86]

Dentin Formation

Dentin, like bone, is of mesenchymal origin. The dentin-forming cells, odontoblasts, deposit their matrix around the epithelial tissue in the jaw, forming the tooth.^[87] As in bone, the mesenchymal cells differentiate, and then synthesize the organic matrix (predentin). There is progressive expression of dentin-specific phosphoproteins, and the deposition of initial mineral crystals, followed by crystal growth and proliferation.^[88] While there is little remodeling, there is an exchange of information between the epithelially derived ameloblasts (which make the enamel) and the odontoblasts. While few dentin-specific matrix components have been used for tissue engineering of other tissues, both PP^[89] and dentin matrix protein 1^[90] have promise for bone repair. A composite sponge consisting of PP and type I collagen was more effective in inducing bone formation in a rat model than collagen alone,^[89] and dentin matrix protein 1, which acts as a HA nucleator, can self-assemble, offering potential for nanoparticle development. A composite of an enamel protein (amelogenin) and HA has also been shown in culture to induce bone-like HA formation.^[56]

Dentin Tissue Engineering

Tissue Engineering of dentin to date has had limited success.^[87] While cells seeded on appropriate synthetic or natural organic, inorganic, or composite matrices can form mineralized structures, developing a structure that has the both shape and properties of an intact tooth has not yet been achieved.^[91] Recent reports indicate that cells cultured in unique dentin environments do express the *dspp* gene, unique to odontoblasts^[92] and express enamel markers. Various

components of the tooth (periodontal ligament^[93] and cementum,^[94,95] etc.) are being developed in vitro.

Enamel—Composition

Covering the surface of the dentin, the enamel composite is a much harder material.^[96] It consists mainly of HA, while the organic matrix is distinct from that of bone and dentin, containing amelogenins, enamelines, and tuftelins but no collagen.^[97,98] Adult enamel, unlike bone, has less than 3% organic matrix. Amelogenins are believed to be the initial mineral nucleators, and enamelines and tuftelins are thought to regulate the growth and orientation of the crystals.^[99] While X-ray diffraction shows that enamel is mainly HA, there is some suggestion that octacalcium phosphate may be the first phase formed in enamel.^[97] The bulk of the mineral is apatitic, and AFM has demonstrated that the crystals form long ribbon-like structures about 1 nm in diameter.^[99] These crystals are much larger crystallite size than that of dentin and bone, and have a different type of carbonate substitution.^[100] The dentin-enamel composite provides the tooth with enhanced mechanical strength—the ability to bite, grind, and chew.

Enamel—Formation

Formation of enamel (amelogenesis) is guided by specialized cells (ameloblasts).^[100] These cells, of epithelial origin, secrete amelogenin nanospheres,^[101] which control the formation of the initial HA crystals, and amelogenin and tuftelin, which help orient the crystals and regulate their growth.^[98] The details of amelogenesis have been reviewed elsewhere,^[102] but are a process quite distinct from the formation of bone and dentin. In a recent in vitro study,^[103] both full-length and a shortened (without the hydrophilic C-terminus) amelogenin inhibit crystal growth in directions other than length (the *c*-axis). In these studies, the crystals organized into parallel arrays only in the presence of the full-length amelogenin in monomeric rather than nanoparticle form. In contrast, preassembled amelogenins had no effect on organization of the crystals, suggesting that the hydrophobic portion of amelogenin regulates crystal growth while the C-terminal domain is essential for the alignment of crystals into parallel arrays. Amelogenin nanospheres thus appear to be acting both as a template and as a regulating soluble component that helps determine the ribbon-like structure of the enamel crystals. This information will be very important for designing materials for repair and regeneration of enamel.

Enamel Tissue Engineering

Enamel repair is a common process in the dental office, and is done by replacing the damaged components, either with other calcium phosphates or with HA itself.^[87,104] However to tissue engineer a tooth, the construct will have to allow for both enamel formation and dentin and cementum formation, thus there are numerous efforts to recapitulate amelogenesis.^[87] The challenge is to engineer a structure that is so distinct from those formed in other mineralized matrices, thus success has been fairly limited. Recent data indicate that enamel-like crystals can be prepared using HA scaffolds.^[105]

SHELLS

Composition

The inorganic matrix of most shells consist of calcium carbonates,^[5,106–108] while their organic matrices may include the polysaccharide chitin,^[109] a series of anionic proteins,^[108] and, in rare cases, collagen-like proteins.^[110] Four different phases of calcium carbonate may deposit, including an amorphous (non-crystalline form), calcite, aragonite, and vaterite.^[6,107,108] Some shells have mixtures of these phases.

These inorganic phases deposit on organic matrices that are highly anionic, and it is the anionic matrix that determines the site of formation of the mineral crystals, the phase formed, and their orientation.^[107,108,111–114] The nature of the phase deposited is determined by the composition of the organic matrix, and extracts of the different proteins from mollusks have been shown to determine when and if calcite or aragonite deposits.^[113,114] The previously described concept that anionic molecules provide the “template” for deposition of mineral ions was first introduced from studies of shells by Weiner and Hood.^[115] Studies of shell proteins and how they regulate mineral nucleation and growth have provided insight into the role of acidic macromolecules in biomineralization in general, and, as discussed in previous sections, have also led to a new industry where biomimetic processes are being used to engineer bone.

Tissue Engineering with Shell Components

Chitin is an abundant component of certain calcium carbonate-containing shells^[109,116] and as it is an inert polysaccharide it has been used for a variety of tissue-engineering applications including drug delivery,^[117] cartilage repair,^[42] and most recently bone repair.^[118] While coral and other inorganic matrices of shells have

been used as a bone graft material,^[119,120] few organic matrix components of shells have been tested as tissue-engineering constructs. Other components of the organic matrices of shells have not yet been tested for tissue repair and regeneration, but as suggested elsewhere,^[120] the potential for using such matrices remains to be developed.

CONCLUSIONS

The inorganic and organic matrices of mineralized tissues in vertebrates and invertebrates share several common features. The inorganic matrices often are similar, and their formation and expansion are controlled by anionic components of the organic matrices. These anionic components associate with or act themselves as templates for oriented mineral deposition. Both the inorganic and the organic matrix have potential for use in tissue repair and regeneration.

Orthodontic Wires

Eser Tüfekçi

Steven J. Lindauer

Department of Orthodontics, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

During orthodontic treatment, arch wires play an important role because they provide the force systems necessary for tooth movement. Once a wire is engaged into the bracket/band, it exerts forces on the tooth. The forces transmitted to a tooth by an arch wire depend on several parameters of the arch wire used and the relationship between the brackets in which the wire is engaged.

The mechanical force system produced depends on the appliance design and the mechanical and physical properties of the wire used. A variety of factors should be considered in the selection of a wire during a particular phase of the treatment, including the amount of force desired, the elastic range, formability, and ease of soldering or welding.

OVERVIEW

During early stages of treatment, when leveling and alignment are the main goals, a wire capable of delivering light and continuous forces is desirable.^[1] Therefore, initial arch wires are flexible and/or small in diameter, so that maximal wire deflection with light forces may be achieved. Figure 1 shows a highly flexible wire demonstrating high deflection when engaged into the brackets of malpositioned teeth. As the tooth alignment improves, wire diameter is increased by the orthodontist to provide more precise control of tooth positioning. During this stage, stiffer wires provide greater control of tooth movement—essential for the stability of the intra-arch units—while enabling inter-arch corrections (Fig. 2).

As discussed earlier, the force system required for tooth movement is transmitted by the arch wire to the teeth via brackets during orthodontic treatment. The bracket is designed to accommodate the arch wire, and ligation keeps the arch wire engaged in the bracket slot. The faciolingual and occlusogingival dimensions of the bracket slot allow the use of wires with different cross-sectional shapes and sizes. The magnitude of the forces generated in the faciolingual (first-order) and

occlusogingival (second-order) direction is in part dependent on the bracket slot size.

Forces in the faciolingual and occlusogingival directions are produced by direct contact between the wire and the bracket within the slot. Wires with either a rectangular/square or a round cross-section are able to generate couples. Besides the mesiodistal bracket width, the clearance between arch wire and slot also has an effect on the magnitude of these force systems. Wires with larger cross-sections are able to generate higher forces by more closely filling the bracket slot than wires with smaller cross-sections. As the cross-section of a wire is increased, the stiffness is also increased.

A third-order couple is another force system commonly used during orthodontic treatment to make changes in the buccolingual inclination (torque) of a tooth. It is important to note that in orthodontics, the term torque is commonly used to describe tooth inclination. A rectangular arch wire with a diagonal cross-sectional dimension greater than the occlusogingival width of the bracket slot may generate torque through two-edge contact with the slot. Therefore, large rectangular wires may be used to bring teeth to proper inclinations.

Many clinicians use the wire sequence just discussed. However, as they move from smaller, flexible wires to larger, stiffer wires, orthodontists must be aware that wire selection depends on their own treatment philosophy and the needs dictated by the presentation of individual patients.

The mechanical behavior of a ductile orthodontic wire, such as stainless steel, in tensile loading may be analyzed in a stress-strain plot (Fig. 3). Stress is the internal response of a wire to the application of external forces, defined as force (load) per cross-sectional area ($\sigma = F/A$). Strain is the deformation of the arch wire as a consequence of the stress, and is defined as the dimensional change divided by the original dimension ($\epsilon = \Delta d/d$).

The initial linear portion of the stress-strain curve represents the elastic range. The slope of this region of the plot corresponds to the modulus of elasticity (E) and expresses the stiffness of the wire material. It is a measure of the force that can be stored in a wire that

Fig. 1 A nickel-titanium wire tied to an orthodontic attachment showing high deflection.

has been deformed a certain distance. The stress at the end of the linear portion is called the proportional limit. The extreme point on the linear portion of the plot is the elastic limit, from which unloading occurs with no permanent deformation. In crystalline materials, the elastic limit is only slightly beyond the proportional limit and for this reason the two terms are often used interchangeably. If stress is removed from the wire while it is in this portion of the curve, a complete recovery of the initial shape of the wire will occur.

The working range is another important property of an orthodontic wire. It is the maximum deformation (deflection) of an orthodontic wire within its elastic range. In other words, it is the limit of how far a tooth can be moved by one adjustment of a particular wire configuration. Beyond the proportional limit, permanent deformation will take place and the wire will no longer return to its original form when the force is released. Ultimate tensile strength (UTS) is the total load that a wire can withstand before failure. Strength, stiffness, and range are the major properties of clinical importance in the choice of wires to be used. One other important property is the formability of the wire. It describes the amount of permanent deformation that a wire can withstand before it breaks.^[2]

Fig. 2 Stainless steel wire with T-loop bends incorporated to close spaces.

Fig. 3 Stress-strain curve of a ductile material in tensile loading.

The properties of an ideal orthodontic wire are as follows: 1) high strength; 2) low stiffness; 3) high working range; and 4) high formability.^[3] These important characteristics of wires are determined by a variety of factors. Alloy composition and crystal structure of the metal are important variables that are affected by the manufacturing process of the wire, including heat treatment and cold-working. Other factors that influence the mechanical behavior of a wire include the length of the wire across a certain span, or between orthodontic brackets, and the shape and cross-sectional size of the wire.

The effects of the length and cross-section of a beam on strength, stiffness, and range values in bending are shown in Table 1. Based on the engineering bending equation, for example, stiffness of a wire is inversely proportional to the third power of its length (L). Doubling the length of a wire decreases its stiffness to one-eighth.^[4] At the same time, working range is increased four times and strength is halved. The stiffness of a round wire is directly proportional to the fourth power of its cross-sectional diameter (D). Doubling the diameter of a round wire increases

Table 1 Effects of the length and cross-section on the strength, stiffness, and range of orthodontic wires

Strength	Stiffness	Range
<i>Effects of length</i>		
1/L	1/L ³	L ²
<i>Effects of cross-section</i>		
D ³	D ⁴	1/D

its stiffness by 16 times.^[4] At the same time, strength of the wire is increased by eight times, while the working range is decreased by one-half.^[4] It is important for the clinician to be familiar with the mechanical properties of the wires used so that necessary modifications during treatment can be made intelligently. For example, in order to decrease the stiffness and to increase the working range, the length of a span of wire may be controlled by the interbracket distance, which is a function of the distance between the teeth, the position of the brackets on the teeth, and the width of the bracket itself. Incorporating loops and helices into the wire can also increase the effective length of a wire between two brackets, consequently decreasing the stiffness and increasing the working range.

Orthodontic wires are manufactured by a series of proprietary steps.^[5] Usually, more than one company is involved in the manufacturing process. First, the wire alloy is cast in the form of an ingot, which is subjected to several mechanical procedures until the cross-section is small enough for the subsequent wire-drawing process. Drawing of round wires consists of several steps until the desired diameter is obtained. Rectangular wires are manufactured from the round wires by a rolling process, using a Turk's head having two sets of rollers positioned at right angles to each other. Heat treatments are a part of the manufacturing process performed to eliminate the work hardening that takes place during the wire drawing. Detailed information on how the wires are manufactured is proprietary.

In contemporary orthodontic practice, the most commonly used wires include stainless steel, cobalt-chromium-nickel, nickel-titanium, and beta-titanium (Table 2).^[6,7] Precious-metal wires such as gold were commonly used until the 1950s. However, after the introduction of stainless steel into the orthodontic profession, the use of gold wires was abandoned, primarily due to cost factors.^[5,8]

STAINLESS STEEL WIRES

In the 1950s, stainless steel alloy wires became popular because of their good mechanical properties, excellent corrosion resistance, and low cost. Today, stainless steel arch wire is the mainstay of orthodontic practice. The typical composition of the stainless steel alloys used in orthodontics is 73.75% iron, 18% chromium, 8% nickel, and 0.25% cobalt. These wires are in the austenitic phase, and they are usually referred to as 18-8 stainless steel because of the respective percentages of chromium and nickel. Chromium gives stainless steel its corrosion resistance. This element forms a thin, adherent oxide layer on the surface that prevents the reaction of oxygen with the metal below the surface.^[9-11]

The properties of steel wires can be manipulated by heat treatment.^[12] Annealing softens the steel wire, whereas cold-working hardens it. Therefore, annealed steel is very soft and formable. On the other hand, cold-worked wires are very brittle and may break when sharp bends are incorporated into the wire. During the manufacturing process, residual stresses arise which, if not eliminated, may cause breakage of the wire during clinical applications. Therefore, these wires are subjected to heat treatment after manufacturing.

Stainless steel wires may be soldered and welded if solder is used to reinforce the welded parts. This property enables the clinician to fabricate appliances more easily. Both soldering and welding may cause changes in the wire properties if the wire is overheated or underheated. Therefore, extreme caution needs to be taken during these procedures to prevent any decrease in strength of the wire.^[5] When compared to nickel-titanium and beta-titanium arch wires, stainless steel wires exhibit the highest elastic modulus and lowest springback.^[6,13] Although stiffer individually, stainless steel wires that are layered or braided exhibit greater range and lower stiffness than individual strands. That is why these wires were commonly used

Table 2 Important properties of the orthodontic wires

Property	Stainless steel	Cobalt-chromium-nickel	β -titanium	Nickel-titanium
Force levels	High	High	Intermediate	Light
Elastic range	Low	Low	Intermediate	High
Formability	Good	Good	Good	Poor
Ease of joining	Can be soldered; welding only with reinforced solder	Can be soldered; welding only with reinforced solder	Can be soldered and welded	Cannot be soldered nor welded
Friction between the bracket and archwire	Low	Low	Intermediate	High
Cost	Low	Low	High	High

during leveling and alignment before the nickel-titanium wires were available.

COBALT-CHROMIUM ALLOYS

Cobalt-chromium orthodontic wires are very similar to stainless steel in appearance and mechanical properties. Elgiloy (Rocky Mountain Orthodontics), one of the most widely known alloys, has a composition of approximately 40% cobalt, 20% chromium, 15% nickel, 15.8% Fe, 7% Mo 2% Mn 0.15% C, and 0.04 Be.^[6] Due to concerns about the toxicity of beryllium, beryllium-free Cobalt-Chromium alloys (Remaloy, Dentaaurum Inc.) have been introduced to the orthodontic profession.^[5] Cobalt-Chromium wires are available in different tempers (levels of resilience).^[14,15] The soft-temper (Blue Elgiloy) wires are popular among clinicians because they are easily formable and subsequently can be subjected to heat treatment to increase their strength and resilience. These alloys have a modulus of elasticity similar to that of stainless steel,^[6] but they feel softer (prior to the heat treatment) than stainless steel alloys because of their lower yield strength and elastic range.^[6,8]

BETA-TITANIUM WIRES

In 1980, Burstone and Goldberg introduced a beta-titanium alloy to orthodontics under the commercial name of TMA (Ormco, Glendora, CA).^[6] TMA is an acronym for *titanium-molybdenum alloy*. This alloy has approximately 78% titanium and 11% molybdenum in its composition. TMA has a modulus of elasticity approximately 40% that of stainless steel and twice that of Nitinol (nickel-titanium).^[6] This wire has an excellent resilience that provides a wide working range. The wire also exhibits high formability, which allows the clinician to bend the wire and thus incorporate stops and loops into it if desired.^[6,16] One other advantage is that it can also be spot-welded. The properties of TMA make it a wire of choice for fabrication of auxiliary springs and for intermediate and finishing arch wires.

One drawback of this wire is its high coefficient of friction.^[17] This is attributed to the high surface roughness of the wire, confirmed by scanning electron microscopic examinations.^[5,18] Surface roughness should be taken into consideration during the space closure stage of orthodontic treatment, because high friction between the arch wire and the bracket has been shown to slow down the sliding mechanism in vitro. Ion implantation has recently been used to change the surface characteristics of beta-titanium wire improving its ability to enable the use of sliding mechanics.^[19]

TMA wires are the most expensive orthodontic wires available, but their advantages make them a popular wire in current orthodontic practice. Because these wires do not contain nickel in their composition, they may be safely used in patients with a known allergy to nickel.

NICKEL-TITANIUM WIRES

Nitinol was originally developed by Buehler for the U.S. Navy in the early 1960s.^[20] The name *nitinol* was derived from its *nickel-titanium* composition with the suffix *-nol*, which stands for *Naval Ordnance Laboratory*. It was Andreassen whose vision and individual effort led to the introduction of nickel-titanium wires to orthodontics in 1971.^[21] With his collaboration, the first commercial nickel-titanium wire, Nitinol, was marketed by Unitek (3M Unitek, Monrovia, CA). This wire exhibited very important characteristics: 1) a very low modulus of elasticity (E), about one-fifth that of the stainless steel and half that of beta-titanium wires of the same length and cross-sectional dimensions; and 2) an extremely wide working range.^[22] This very first nickel-titanium wire was in a stabilized martensitic form and did not exhibit phase-transition effects. Nevertheless, because of its low modulus of elasticity and high springback, as well as its resistance to deformation, this wire offered a great alternative to braided stainless steel wires during the initial stages of orthodontic treatment.^[23]

In the mid to late 1980s, two new superelastic nickel-titanium alloys—Chinese nickel-titanium (marketed as Ni-Ti by Ormco) and Japanese nickel-titanium (marketed as Sentalloy by GAC International)—were introduced.^[5] The two remarkable properties of the nickel-titanium wires are superelasticity and shape memory.^[24] Nickel-titanium alloy is an equiatomic intermetallic compound that can exist in more than one phase. At low temperatures and high stresses, the alloy is in a martensitic phase with a monoclinic, triclinic, or hexagonal structure. At high temperatures and low stresses, a body-centered cubic (bcc) austenitic phase is present. Both superelasticity and shape memory are related to the transformation within the alloy from the martensitic to the austenitic phase.^[24–26]

Superelasticity is related to the ability of nickel-titanium wires to transform to and from a martensitic phase when subjected to stress.^[24–26] The term pseudoelasticity is also used to describe the wires' superelastic behavior.^[8]

On the stress-strain plot, stress-induced transformation is seen as a plateau where there is not much change in stress with increasing strain (Fig. 4). The austenitic-to-martensitic phase transformation occurs with increasing applied force. The initial linear portion

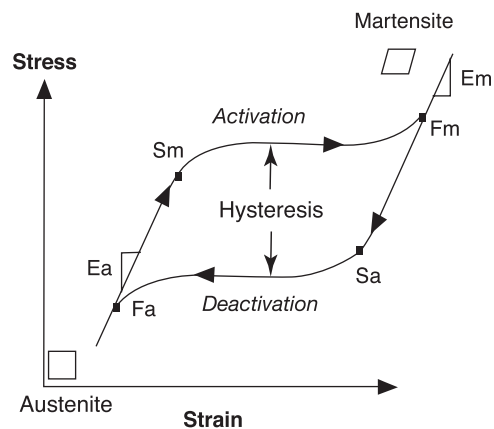

Fig. 4 Stress-strain diagram of an alloy with superelastic behavior. (From Ref. [26].)

of the stress-strain plot represents elastic deformation of the austenitic phase. The slope of this region of the plot is equal to the austenitic modulus of elasticity (E_a). Point S_m is the minimum stress at which martensitic transformation begins. At point F_m , transformation to martensite is complete. Upon unloading, there is a linear relationship between stress and strain. Point S_a is the maximum stress during unloading at which the martensitic structure can still exist, and at this point austenitic transformation begins. With further unloading, at point F_a , the reverse transformation to austenite is complete. While in this region of the curve, these wires exert relatively constant forces independent of activation within a wide range. The force subsequently dissipates once the reverse transformation takes place. The transition temperature is very important, because it determines the force levels that a wire can generate while in the plateau.^[25] By controlling temperature ranges during the manufacturing process, the transition temperature at which the martensitic transformation takes place can be manipulated.^[24-26]

Shape memory is the ability that nickel-titanium wires exhibit to undergo temperature-induced martensitic transformation (Fig. 5).^[24-26] This phenomenon is defined as thermoelasticity.^[8] Thermoelasticity allows a certain shape to be given to a wire at a temperature higher than the martensitic-austenitic transition temperature. When the wire is cooled to a temperature lower than the transition temperature it may be plastically deformed, but when it is reheated it will return to its original shape.

On the stress-strain plot, superelasticity is characterized by a loading curve differing from the unloading curve due to a loss of energy (hysteresis) (Fig. 4). This is a remarkable property, because the force that the wire delivers (unloading portion of the curve) is not the same as the force applied to engage it (loading portion of the curve). In Fig. 4, the second plateau region of

Fig. 5 Stress-strain diagram of an alloy with shape-memory behavior. (From Ref. [26].)

the unloading (deactivation) curve demonstrates how these wires are able to exert low, nearly constant forces. The ideal biological force levels exerted by the superelastic nickel-titanium alloys will move teeth with little discomfort to the patient.

One other striking characteristic of the superelastic nickel-titanium wires is that the unloading curve is affected by the degree of activation. Unloading stiffness is dependent on the level of activation; it decreases as the deflection increases. This phenomenon was first reported by Burstone et al.^[8] In their study, they showed that following an 80° activation, if a tooth moved to the 40° position, the nickel-titanium wire would exert a 380 gm-mm bending moment. However, if the wire was untied and retied, a 700 gm-mm bending moment was produced. Because of this unique behavior, therefore, the force exerted by an activated wire can be increased by simply untying and retying it.

In the mid-1990s, Ormco made a new alloy, copper Ni-Ti, available to the orthodontic profession. This new orthodontic wire is marketed in three different martensite-austenite transformation temperatures of 27°C, 35°C, and 40°C. According to the manufacturer, because shape memory behavior is obtained precisely at those specific temperatures, this wire allows the clinician to select wires on a case-specific basis.^[27] The excellent springback (working range) of nickel-titanium wires make them very useful when large deflections are necessary to engage a wire into the brackets of malpositioned teeth. The wires will generate low forces despite large deflections, resulting in less patient discomfort. These wires display springback approximately 1.4 times that of nitinol wire and 4.6 times that of stainless steel (Fig. 6).

Nickel-titanium wires have a higher coefficient of friction than stainless steel wires as a result of their higher surface roughness. This can be a major disadvantage during space closure, when sliding mechanics along a wire may be slowed down due to the high friction between the wire and the bracket.^[5,17] Nickel

Fig. 6 Activation and deactivation curves of orthodontic wires. (Adapted from Ref. [24].)

content in the composition of nickel-titanium wires is another concern regarding the biocompatibility of this alloy. Clinicians should be careful about using nickel-titanium wires when treating patients with known nickel allergies.

Although these wires offer many desirable properties, they are relatively expensive when compared to stainless steel, exhibit poor formability, and cannot be soldered or welded.^[8]

IS THERE AN IDEAL WIRE?

From this discussion, it is evident that there is not one ideal wire that would suit the needs of all phases of orthodontic treatment. This is somewhat expected, because different stages of treatment will require wires of different stiffness and range.

Nickel-titanium wires provide light forces, wide elastic range, and excellent springback, but they are expensive, offer little formability, and cannot be soldered or welded. Also, their friction is higher than that of beta-titanium and stainless steel wires.^[5,6,8] They are most often suitable for early stages of treatment, where initial alignment of malpositioned teeth is the usual goal.

Stainless steel wires are the least expensive wires and display excellent formability, weldability and soldering properties.^[5,6,8] However, they have the highest force delivery and lowest elastic range and springback when compared to beta-titanium and nickel-titanium alloys.^[5,6,8] Their high stiffness makes them suitable for the midtreatment stages to stabilize aligned teeth, while moving other teeth as required. Their low coefficient of friction allows brackets to slide along the wire—during space closure, for example—more easily than other wire compositions.

Beta-titanium alloys have force delivery, elastic range, and springback values higher than those of stainless steel, but lower than nickel-titanium alloys.^[5,6,8] They can be formed and welded.^[5,6,8] They are expensive wires and have coefficients of friction higher than stainless steel and lower than nickel-titanium alloys.^[5,8] Because of their higher springback characteristics compared to stainless steel and better formability than nickel-titanium, beta-titanium wires are well suited for fabrication of active components of orthodontic appliances. For example, springs made of beta-titanium can be formed to move individual teeth or segments of teeth, as desired. Beta-titanium wires are also often used during the finishing stages of treatment, where small bends in the wire are required to allow for precise tooth positioning.

In summary, there is not one ideal wire best for all stages of orthodontic treatment. Arch wire selection should be based on the context of its intended use.

INTRODUCTION

A large variety of materials is presently used in orthopedic procedures. These include natural tissues such as bone allografts, autogenous bone, demineralized bone and matrix, and bone morphogenic proteins; and synthetic materials such as metals, ceramics, polymers, and composites. They fill a variety of uses such as joint replacement, reconstruction or replacement of skeletal defects, augmentation of fracture repair, strengthening of arthrodeses, filling of defects, and for spinal fusion. This article describes the properties and uses of these orthopedic biomaterials.

In the biomedical industry it can be difficult to compare metals because they are usually referred to by their trademarked names (such as Zimaloy, Vitallium, Stellite, Tivanium, TiOstallo, Protasul). Often the same alloy has multiple trademark names, making it necessary to investigate the actual composition. We have presented the metals using the appropriate American Society for Testing and Materials (ASTM) standard^[2] to simplify the comparison of the commonly used metals.

METALS USED IN ORTHOPEDICS

Metals were among the first orthopedic biomaterials, and are commonly used to this day. Iron wire was reported to have been used as early as 1775 for fracture fixation.^[1] Currently, most orthopedic implants are made from either stainless steel, titanium or one of its alloys, or a cobalt-chrome alloy, although tantalum and Nitinol metals have also been used.

When selecting a biomaterial for orthopedic applications, biocompatibility and corrosion resistance are certainly important, but structural properties are more critical than in other applications. Total hip replacements, total knee replacements, and bone plates must be able to withstand loads several times the body weight of the individual. Consideration of fatigue resistance, stiffness, and surface characteristics are all critical components of the material selection process. For this reason, metals are by far the most commonly used biomaterial in orthopedics.

STAINLESS STEELS

Nickel is added to iron-chromium-carbon alloys to increase the size of the austenite field. If the carbon content is low the steel is virtually all austenite at room temperature. Austenitic stainless steels have excellent ductility, formability, and corrosion resistance (compared to other steels) and are not ferromagnetic. Reducing the carbon content increases corrosion resistance.

In 1948, Fink and Smatko described American Iron and Steel Institute (AISI) Type 302 stainless steel (UNS S30200) as the ideal biomaterial for orthopedic applications.^[3] Today, most orthopedic implants made from steel are manufactured of AISI 316 or its low-carbon form, AISI 316L (ASTM F138 and F139). These stainless steel alloys contain a smaller percentage of carbon than type 302 as well as a small percentage of molybdenum, which improves its corrosion resistance in biological fluids. The compositions of these stainless steels are given in Table 1 and the mechanical properties of the commonly used stainless steels are given in Table 2.

In a study of retrieved 316L stainless steel implants, Weinstein and coauthors found that all implants

displayed some type of corrosion (either crevice, pitting, or fretting).^[4] The severity of the corrosion had no apparent correlation to the amount of time in situ. There have been many other studies demonstrating that these implants are prone to corrosion in biological environments.

COBALT-CHROME ALLOYS

Cobalt alloys have better corrosion resistance than steels and better abrasive wear resistance. Alloying

elements produce high strength, resistance to creep, and corrosion resistance. In 1924, Zierold reported that a cobalt-chrome alloy (Stellite) was the best-tolerated metal in a study of biocompatibility using dogs.^[5] A derivative of Stellite is Vitallium (ASTM F75), which continues in use today for orthopedic and dental implants. There are basically two type of cobalt-chrome alloys used in medical implants: the castable alloy (ASTM F75) and the alloy that is usually wrought by forging the hot metal (ASTM F90). The compositions of these alloys are listed in Table 1 and the mechanical properties are listed in Table 2.

Table 2 Mechanical properties of metals used for implants

	Ultimate Tensile Strength (MPa)	Yield Strength (0.2% offset) (MPa)	Elongation (%)	Density (g/cc)
AISI 316L Stainless Steel (ASTM F138)	490–1350	190–690	12–40	7.95

TITANIUM AND ITS ALLOYS

Titanium is a relatively lightweight metal that provides excellent corrosion resistance, high strength-to-weight ratio, and ductility. Its ultimate strength is lower than stainless steel or CoCr alloys and it has poor shear strength. Titanium is the ninth most abundant element, making it readily available. Cobalt and chrome are critical alloying elements in the biomedical industry but are in lower supply; the availability and price of these elements are highly variable. In the early 1950s, Leventhal reported on the use of titanium for bone screws and plates.^[6] Although commercially pure titanium (ASTM F67) is still used today, titanium alloys—especially those made from titanium, aluminum, and vanadium (ASTM F1108 and F136)—are more commonly used. The compositions of these alloys are given in Table 1 and the material properties in Table 2.

TITANIUM-NICKEL ALLOYS (SHAPE-MEMORY ALLOYS)

This special class of titanium alloy is generally about 50% titanium and 50% nickel. Titanium-nickel alloys (Nitinol, ASTM F2063) demonstrate a shape-memory effect. That is, after deformation the metal can return to its original shape upon heating. This property makes the metal interesting for many orthopedic applications. If the material is worked into a new shape while cold, the implant will regain its original shape upon heating to body temperature. This property has allowed the material to be used for suture anchors (which expand upon heating) and fracture compression staples and wires (which contract upon heating), as well as other medical applications, including cardiovascular stents. The composition and material properties of nitinol are given in Tables 1 and 2.

TANTALUM

Tantalum (ASTM F560) is a biocompatible metal but its mechanical properties make it unsuitable for most orthopedic applications where strength is required. However, it has good biocompatibility and is corrosion-resistant. Recently, this metal has been manufactured as a porous material that allows bony ingrowth. The material is formed by depositing tantalum onto a spongelike carbon structure using vapor deposition techniques. The resulting structure looks like trabecular bone and has mechanical properties similar to trabecular bone, while allowing either soft- or hard-tissue ingrowth.^[7]

POROUS COATING

Metallic implants for joint replacement applications can either be cemented into the body or placed by press-fit or interference-fit techniques. In the case of uncemented implants, the surface of the metal is often treated to allow for bony ingrowth or gripping of the implant. Often, coatings of a ceramic (ASTM F1609) or metal beads or fibers are deposited onto the implant. The metal coatings can be made from either titanium, titanium alloys (ASTM F1580), or cobalt-chrome alloys (ASTM F1377). The coatings can be placed on implants made from either titanium alloys or cobalt-chrome alloys. The coatings can be applied using sintering or plasma spraying techniques.

POLYMERS

Biodegradable Polymers

Most of the biodegradable polymeric products on the market are made from only a few polymers, many of which were first used in sutures. The most common suture materials are the polylactic and glycolic acid polymers and copolymers, the trimethylene carbonate copolymers, and polydioxanone. The advantages of the biodegradable polymeric products include the following: They disappear, so long-term stress shielding is not a concern; there are no long-term device or materials problems; and no second operation is required for removal. The biodegradable polymeric products can be used for drug delivery. There are, however, several disadvantages associated with these materials. Most resorbable polymers degrade too fast. As they degrade, the degradation products accumulate and often result in an inflammatory reaction and sometimes seromas. This appears to be due mostly to the acidic degradation products of the most common biodegradable polymers. The polymers are not high-strength, making load-bearing implants rare. A good review of the mechanical and degradation properties of biodegradable polymers has been published by Daniels et al.^[8]

The rate of polymer degradation depends on a variety of factors. These factors may be broadly subdivided into the following categories: implant features, material characteristics, mechanism of degradation, and recipient characteristics such as age and metabolic condition. Implant features include the size and shape of the implant, material composition of the implant, stress on the implant, and implantation site (e.g., subcutaneous tissue or bone). Material characteristics include the phase of the material, (i.e., amorphous as opposed to crystalline), the racemic mixture of the polymer, and the presence of additives or impurities.

The mechanism of degradation refers to enzymatic cleavage versus hydrolysis.^[9] In order to be biocompatible, the resorbable polymers must be not only free from potentially toxic or carcinogenic residual monomers, stabilizers, polymerization initiators, emulsifiers, etc., but the leachates, degradation products, and subsequent metabolites must also be biocompatible.

Synthetic Biodegradable Polymers

Poly(lactic acid) (PLA)

Degradation rates for PLA vary widely. Lactic acid exists as two optimal isomers, L and D, with the L isomer occurring in nature. Poly(L-lactic acid) (PLLA) is more crystalline and degrades much more slowly than poly(D-lactic acid) or racemic D,L mixtures. PLLA can retain 70% of its strength at 10 months and have significant polymer remaining after 4 years in vivo, while in a prospective study, poly(D,L-lactic acid) cylinders were reported to have resorbed within 1 month.^[10]

Fibers of PLA can be melt spun and various amounts of draw can be incorporated into the process to produce stronger, stiffer, and more crystalline fibers. The tensile strength increases when PLLA is converted from bulk (30–50 MPa) to melt spun fibers (10–70 MPa), high-speed spun and drawn fibers (400–1000 MPa), or chloroform/toluene gel drawn linear, chain extended fibers (1100–2100 MPa). The melt-spinning and hot-drawing process reduced the molecular weight of the PLLA from 480,000 to 70,000.

Self-reinforced (SR) composites are made when a fiber of a material is used to reinforce a matrix of the same material. Nonreinforced bulk PLLA has a flexural strength of 57–72 MPa and a flexural modulus of 2.7 GPa, while that of a SR-PLLA composite rod utilizing drawn fibers has a flexural strength of 180–300 MPa and a flexural modulus of 7–10 GPa.^[11]

Biomaterials composed of polylactic acid, polyglycolic acid, and their copolymers degrade in vivo by hydrolysis into lactic acid and glycolic acid, which are incorporated into the tricarboxylic acid cycle and excreted.^[14] In a comprehensive review of PLA-PGA biomaterials, Athanasiou and others^[14] report that these materials are generally biocompatible, although several studies have reported inflammatory reactions occurring 7–20 weeks after surgical placement of polylactide or polyglycolide implants.

Polyglycolic acid

Polyglycolic acid (PGA) was synthesized by Bischoff and Walden in 1893 and developed by American Cyanamid as the first absorbable synthetic suture in

1962. It has been available commercially since 1970.^[12] This material retains 20% of its initial strength after 3 weeks, but has no strength after 4 weeks. PGA screws (4.5 mm diameter with 3.2 mm core) were found to have an initial shear strength of 180 MPa, bending strength of 320 MPa, torsional strength of 0.6 N-m, and modulus of elasticity of 12 GPa.^[11] Self-reinforced PGA made by drawing has a bending modulus of 18 GPa and a bending strength of 415 MPa, whereas by sintering, the bending modulus is 12 GPa and the bending strength is 360 MPa.^[12] Polylactide, polyglycolide and poly(glycolide-co-lactide) are bioresorbable polymers that belong to the group of poly(α -hydroxy acids).^[15]

Seventeen of 67 patients treated with polyglycolide rods (3.2 or 4.5 mm diameter) between 1985 and 1987 were found to have a clinical course complicated by sudden painful swelling at the ankle, discharging spontaneously through the skin, and releasing sterile liquid with remnants of the degrading implant.^[16] The discharge lasted an average of 4 weeks. Of the 67 patients, 34 had radiographs that showed ovoid osteolytic areas in the implant channels.

Copolymers of lactic and glycolic acids

In vitro, cylinders made of poly(D,L-lactic-co-glycolic acid) 50:50 (PLA₂₅GA₅₀) started to degrade at 7 days, compared with 28 days for cylinders made of poly(D,L-lactic acid) (PLA₅₀) (see U.S. Patents 4,118,470, 3,636,956, and 4,137,921).^[10] Degradation times of 6+ years have been reported for PLLA.^[17] Because of the slow absorption of this material, clinical manifestations of inflammation, if they occur, are typically noted at 15 months to 3 years after implantation.^[17]

The degree of crystallinity of the polymer and the molecular characteristics of the R-groups prescribe the hydrophobicity. The rate of hydrolysis is affected because of the impact of the hydrophobic/hydrophilic character on diffusion of water into the material. Amorphous and hydrophilic regions of the polymer are more accessible to water. For example, in comparing the amorphous D-isomer of PLA (PDLA) and the more crystalline L-isomer (PLLA), PLLA is more biostable. However, copolymers of PLA-PGA or PDLA-PLLA are less hydrophobic and less crystalline, and tend to experience faster rates of hydrolysis.^[9]

Selected examples

Poly(ϵ -caprolactone): a semicrystalline polymer with melting point of 59–64°C,^[17] it degrades more slowly than PLA.^[18] Drug delivery devices can remain active for over a year.

Copolymer of lactic acid and caprolactone: an amorphous copolymer that has been evaluated for use in biodegradable nerve guides by the University of Groningen, The Netherlands.^[19] Two-year rat carcinogenicity tests have been conducted on a Japanese custom-synthesized copolymer of ϵ -caprolactone and L-lactic acid.^[20]

Copolymer of ϵ -caprolactone and glycolide, poly(glycolic co- ϵ -caprolactone) are reported to have a fast resorption rate, almost completely absorbed at 4–8 weeks when used as a matrix for artificial skin.^[20] The sutures made from glycolide and ϵ -caprolactone take 91–119 days to become completely absorbed.^[20]

Polydioxanone and substituted poly(1,4-dioxane-2,5diones)

Polydioxanone (PDS) $T_m = 107\text{--}112^\circ\text{C}$; $T_g = -10^\circ\text{C}$; poly-p-dioxanone: a bioadsorbable polymer that can be made into flexible monofilament surgical sutures (U.S. Patent 4,052,988, U.S. Patent 3,960,152).^[15] Degradation products and rate: hydroxyethoxy acetic acid excreted, resorbed in about 6 months with minimal tissue reaction.^[21]

Poly(ortho esters)

Poly(ortho esters) are not as strong or stiff as crystalline PLA or PGA but slower to degrade. Characteristics: Diketene acetal poly(ortho esters) are amorphous polymers made from diketene acetals.^[22–24] Intermittent cyclic loading (10.5 mm/day @ 8 N) in saline-reduced flexural strength and modulus by 75% after 40 days versus 29% and 20% for static loading at 3.6 N.^[23,24] A polyorthoester mixed with demineralized bone can be molded and contoured.^[25]

Polyanhydrides and poly(anhydride-co-imides)

Poly[bis(p-carboxyphenoxy propane)anhydride and sebacic acid anhydride]. Characteristics: Hydrolysis

results in two dicarboxylic acids.^[21] The incorporation of the imide component into the backbone of the polyanhydrides increases the mechanical strength. Imides have good mechanical properties because of their rigid units, but they are not degradable. In contrast to poly α -hydroxy esters, these polymers degrade by surface erosion.^[26] Poly(anhydride-co-imides) have been evaluated by personnel from the Massachusetts Institute of Technology, Medical College of Pennsylvania, and Drexel University for orthopedic applications. They were found to have low cytotoxicity and excellent mechanical properties.^[27]

Examples of natural biodegradable polymers are provided in Table 3.

Hydrogel Polymers

Hydrogel polymers are cross linked hydrophilic polymers that are significantly swollen in water. Typical hydrogels are hydroxy alkyl methacrylates, poly(vinyl alcohol), and copolymers of N-isopropyl acrylamide. Several hydrogel monomers have been copolymerized with stable monomers. Depending on the ratio of the monomers, this has been done in order to control the water content and mechanical properties of the resulting hydrogel polymer (high hydrogel content) or to increase the swelling and biological interaction of the resulting stable polymer (low hydrogel content).

Clear UHMWPE

Clear acetabular cups have been made from ultrahigh molecular-weight polyethylene (UHMWPE) using a high-pressure (e.g., 15,000 psi) solid-state forming operation by Polyteco Inc., Hayward, CA. This is said to produce an oriented and highly consolidated material with improved wear and creep properties.^[31] UHMWPE (molecular weight $>2 \times 10^6$ g/mol) has been used for load-bearing applications such as acetabular cup of total hip, tibial plateau, and patellar surfaces of knee joints.^[15]

Table 3 Examples of natural biodegradable polymers

Material	Characteristics	References
Collagen cross-linked with hexamethylene diisocyanate fibers	Braided into ACL ligaments	[28]
Chitin, chitosan, and chitin derivatives	Chitosan: biodegradable and partially deacetylated product of natural polysaccharide chitin, based on free and acetylated glucosamine units	U.S. Patent 4,074,366. ^[29]
Alginates	Family of copolymers based on β -D-manuronic and α -L-gluronic acid residues extracted from seaweed	
Cellulose	Partially oxidized	[30]
Fibrin	Physiologically occurring and modified proteins	

Stable Polymers for Implants

In addition to poly(aryl ether ketones) (PAEKs), several other polymers may be suitable for use in implants. One set of these polymers is the liquid crystal polymers such as Vectra. Their biostability looks second-best only to the PAEKs, based on temperature stability, resistance to solvents, and ability to be autoclaved. One study presents rabbit data suggesting that Vectra/carbon fiber composite intramedullary rods are biocompatible.^[32] One other potential criterion is the ability to bond with carbon fiber in a biostable mode, in which the PAEKs are also exceptionally good. One potential drawback of the liquid crystal polymers is their complex molecular structure, which makes it difficult to determine their potential degradation products, and to get approval from the Food and Drug Administration (FDA) for their use in implants.

Aromatic poly(ether ketones) are generally prepared by the nucleophilic displacement of activated aromatic dihalides with alkali-metal bisphenolates in polar aprotic solvents, and to a lesser extent by Friedel-Crafts acylation reactions.^[33] As early as 1967, condensation polymerizations of alkali bisphenates with activated (negatively substituted) aromatic dihalides were reported by Johnson et al. to form ether bonds via nucleophilic substitution of the aromatic dihalides—often fluorides—in tetramethyl sulfone or dimethyl sulfoxide at about 160°C.^[34,35] $\text{KO-Ar-OK} + \text{F-Ar-C=O-AI-F} \rightarrow \text{PEEK}$, but at low molecular weight. Hexafluoroisopropylidene groups have also been incorporated into the polymer backbone to give better polymer solubility.^[33] There are at least 26 synthesis-related patents for poly(aryl ether ketones) identified between August, 1978 and July, 1996. The initial Imperial Chemical Industries (ICI) patents on PEEK are as follows: U.S. Patent No. 4,105,635, U.S. Patent No. 4,113,698, and U.S. Patent No. 4,113,699.

U.S. Patent 5,294,391 (Method of Making a Fiber-Reinforced Composite Structure Including Randomizing of Reinforcing Fibers) was granted to Carl R. McMillin on March 15, 1994. Many PAEK/carbon-fiber spine cages made using this patent and U.S. Patent 5,429,863 (Fiber Reinforced Composite Structure, granted to Carl R. McMillin on July 4, 1995), have been implanted in patients.

CERAMICS AND GLASSES

Both ceramics and glass ceramics are available in various forms for use as orthopedic biomaterials. Ceramic biomaterials are essentially inert within the body. This is a result of improved resistance to corrosion due to ceramic biomaterials' resistance to further oxidation. Although exhibiting more brittle behavior

than metals, ceramics of small grain size and techniques providing full density have prompted increased use of ceramics in orthopedics.

Biostable Ceramics

Biostable ceramics neither resorb nor induce osteoblastic apposition on their surfaces within the body. Aluminum oxide (alumina, ASTM F-603) and a zirconium oxide (zirconia) compound (ASTM F-1873) are the two most common biostable ceramics. Commercial submicron zirconia and alumina powders are used to make highly concentrated aqueous colloidal suspensions that can be cast. Without fiber reinforcements, strengths in three-point bending of 900 to 1200 MPa (115,000 to 175,000 psi) are reported. Advantages are that both aluminum oxide and zirconium oxide are strong and stable (so there is no need to follow degradation products); disadvantages are having weak interface with bone or tissue, low shock resistance, high modulus, and the potential for catastrophic failures. Alumina has been used clinically for many years in Europe and Canada as matched pairs of femoral head and acetabular components in total hip arthroplasty.

Mineralized bone growth into porous calcium aluminate skeletal implants requires a minimum interconnective pore size of 100 μ . The ingrowth of osteoid tissue is said to require a minimum pore size between 40 and 100 μ and the ingrowth of fibrous tissue requires a minimum pore size between 5 and 11 μ .^[36]

Bioactive Ceramics

Certain ceramics and glass ceramics also provide osteophilic surfaces so that bone-forming osteoblasts lay down bone in direct apposition on these surfaces. These are known as bioactive materials. These ceramics (ASTM F-1538) bond to bone and soft tissue. The most common examples are bioactive glasses (Bioglass), bioactive glass-ceramics (Ceravitals A-W Ceramic). Their main advantage is good bonding to tissue and bone; their disadvantage is that they are not as strong as biostable ceramics. A-W Ceramics are being used as space fillers in the iliac crest, as vertebral body replacements in the shape of rectangular bars, and as posterior lumbar interbody fusion (PLIF) cages (used in 13 cases) similar to the Brantigan posterior lumbar interbody fusion (PLIF) cage with an open area for bone growth from top to bottom.

Flexible Ceramics

There are several approaches now available to make ceramics more flexible, including nanophase

technology.^[37] If the brittle nature of ceramics is the only drawback in the design of a new product, these technologies could be used to make tougher, more flexible implants.

Bioresorbable Ceramics

A wide variety of bioresorbable ceramics have been proposed and developed with differing rates of degradation and dissolution. The order of dissolution rates for various apatites and other calcium-containing bio-ceramics is: fluorapatite (FAp) < magnesium whitlockite (MW) < hydroxyapatite (HAp) < calcium-deficient hydroxyapatite (CDHA) < OHA < β -tricalcium phosphate (β -TCP) = α -TCP { < calcium carbonate}.^[38-40] Mixed rates of degradation have been reported. In one case, β -TCP (ASTM F-1088) particles (Biobase) showed 60% degradation in minipigs while α -TCP particles (Cerasorb) showed 30% degradation.^[41] After 20 weeks, β -TCP particles showed 70% degradation while α -TCP (ASTM F-1) particles showed 40% degradation. The Cerasorb particles showed inflammatory cellular reaction over this period. After 68 weeks, 80–90% of the Cerasorb and 90–95% of the Biobase had been transformed into bone. At 86 weeks, 5% Cerasorb and 3% Biobase were still found.^[41]

Biphase calcium phosphate made from β -TCP and HAp (ASTM F-1185) is replaced by bone with the speed of dissolution of the ceramic being related to the ratio of the components.^[42] TCP is said to be osteoconductive but not osteoinductive.^[43] Biphase calcium phosphate (60% HAp:40% β -TCP) has been used instead of allograft or autograft to assist in scoliosis fusions.^[44] In the presence of osteoporosis, calcium phosphate-coated implants have no advantage over porous coatings in the mechanical fixation achieved.^[23,24] TCP dowels compressed and became displaced in 70% of anterior cervical discectomies in 20 dogs within 6 weeks. In another study, porous HAp had similar problems because of its brittle nature.^[45] Biphase ceramic also produced good posterolateral fusions in sheep.^[46]

Plaster of paris has been used in patients as a bone substitute since 1892, and HAp (in cats and monkeys) since 1952;^[45] medical-grade calcium sulfate granules have also been used to substitute for bone. Rapidly resorbable, glassy crystalline materials based on calcium alkali orthophosphates have been studied.^[47]

Apatites and Other Calcium Phosphates

Apatites and other calcium phosphate ceramics are the most intensely studied and clinically used ceramics in orthopedics. HAp, HAp granules, and HAp-sprayed

titanium are commonly used in dental and endosteal implant applications as well as on hip and knee prostheses (more commonly in Europe than in the United States). A HAp plasma flame-spray coating has been developed by many groups. Both HAp and HAp-coated titanium have been used as iliac bone crest spacers.^[48] HAp has been successfully coated onto polymers, including the Brantigan I/F PLIF Cage. COLHAP, a mixture of TCP and HAp (Ca/P ratio 1.6–1.67), is said to have mechanical properties superior to those of HAp. HAp has been mixed with cancellous bone for alveolar ridge augmentation by many users for years in Europe and Canada, and has been added to other bone cements.^[49]

When implanted in soft tissue, calcium phosphate ceramics generate a stable fibrous encapsulation. In bone, dense or microporous CaP materials become incorporated by directly bonding to the bone without an intervening fibrous layer within 3–5 months. In bone, macroporous implants are initially surrounded by fibrous connective tissue that extends into the peripheral pores. This tissue infiltration becomes denser and more organized and extends deeper into the implant until all pores and tunnels are filled, and is accompanied by osteoblastic cellular differentiation and sprouting capillaries. From one week to a month after implantation, osteoid and then new bone are deposited along the implant-fibrous tissue interface. By 4–8 months, complete infiltration is accomplished, with mature new bone bonded directly to the implant material with mature osteons, haversian canals, and mature bone marrow and vessels, without any intervening fibrous tissue. A pore size of 200 μ is needed for mature osteons to form.^[45]

Fluoroapatite (FAp) does not appear to show the same rate of degradation as HAp;^[50] however, its bone-bonding capability is slower and may not be as strong as HAp.^[51] A bioceramic has been developed from high-molecular weight calcium phosphate material with 150 to 250 micron pores converted to HAp that is said to have strength suitable for load-bearing applications.^[52]

Solid HAp and HAp coatings (or fluorapatite) may be good where nonprecision placement of component is anticipated. HAp dissolves slowly at the surface, which enhances bone growth and replacement.^[53] However, at the HAp-metal interface, this produces a weak interface over long periods of time that may cause problems with some implants.^[54] It has been found that thick coatings of HAp do not perform well.

Ceramic Bone Cements

Ceramic bone cements are another active area of research and clinical use. Several different approaches have been taken in the development of a variety of ceramic-based bone cements. Those that consist of

mixtures of ceramics and polymers or other organic compounds are discussed in the Composites section of this article. Examples of bone cements based on ceramics are discussed in the following paragraphs.

Zinc calcium phosphorous oxide ceramic cements can be made either with aluminum calcium phosphorous oxide (ALCAP) or tricalcium phosphate (TCP) for resorbable composites, or with hydroxyapatites for relatively nonresorbable composites; antibiotics such as penicillin or erythromycin or growth factors can be incorporated into the TCP amino acid composite.

A calcium phosphate ceramic that cures in situ in 4 minutes (attaining 90% strength in 4 hrs; cured in 24 hrs) to form a carbonated hydroxyapatite with a yield stress of 25 MPa has been evaluated as an alternative to PMMA for augmentation of transpedicular screws^[54] and in a canine metaphyseal defect.^[55]

A calcium phosphate/hydroxyapatite-based SuperBone family of cements using brushite, which hardens in vivo in about 10 minutes, is under development. SuperBone is also said to be a fast-setting carbonated HAp in preclinical testing.^[56] Under the name Skeletal Repair System (SRS), the carbonated apatite starts to set in 5 minutes, is 50% cured in one hour, and is said to have a compressive strength of 55 MPa after 12 hours.^[57] SRS obtained regulatory approval in the U.S.A. in 1998. It is said to be a dry mixture of monocalcium phosphate, monohydrate, tricalcium phosphate, and calcium carbonate, and to be made into a curable paste with sodium phosphate.

A HAp cement (BoneSource) can initially be formed (like paste) into a shape that becomes hard in 20–30 minutes and converts to HAp in 4 hours. It is sculptable and resorbable because it is a nonceramic HAp, unlike other HAp bone substitutes. It is used for maxillofacial surgery.

Ceramic Foam

Ceramics can also be made into foam to allow tissue ingrowth and to provide a large surface area. Porous hydroxyapatite and porous tricalcium phosphate ceramics have been made.^[58] A fiber-based ceramic foam (made from biostable ceramics) has recently been developed. With resorbable ceramics, a large surface area makes for rapid resorption. The foam can be filled with many different materials for differing applications.

COMPOSITES

A composite is a material whose material properties are different from those of the individual starting components. Bone is a classic example of a biological

composite, in terms of both materials (collagen and apatite) and structure (i.e., the microstructural organization of osteons).^[59] Synthetic composite systems have therefore found several areas of use in orthopedics. Composite analysis is a very active area in mechanics. However, a general understanding of the behavior of composites can be illustrated by several simple algebraic relationships.

Some of the composites presently found in clinical or research orthopedics are carbon fiber-reinforced UHMWPE, PLA (matrix)/PGA (fiber) fracture plates, and carbon fiber-reinforced carbon (CFRC) fracture plates. Carbon fibers have also been used as reinforcements with either epoxy or polysulfone matrices; metal fiber-reinforced polyacetal resin plates are additional composites found in orthopedic practice and study. Apatite-collagen composites are in use as a biomimetic approach to bone replacement. Fiber composites are also under study and in use for tendon replacements.

Ceramic-Collagen Bone Replacement

Ceramic materials are combined with collagen to form an artificial bone that resorbs providing scaffolding on which the patient's bone cells will grow. Two ceramic materials are mixed with bovine collagen and the patient's bone marrow and used as bone cement. A good review of the use of ceramics and other bone graft substitutes has been published by Damien and Parsons.^[60]

A commercial collagen-HAp composite (Collagraft) has been developed and studied. This collagen-HAp composite with the addition of bone marrow, has been used in rat studies.^[61] Collagraft is reported to consist of purified fibrillar collagen, hydroxyapatite, and tricalcium phosphate, and to resorb in a canine femoral shaft defect similar to autogenous bone, with healing not yet complete after one year.^[62]

It has been reported that biphasic granules (40% TCP/60% HAp) mixed with collagen were no better than no graft in a canine spinal fusion model.^[63] However, when combined with a mixture of bone-morphogenic proteins, it was about half as good as autogenous cancellous bone.

A collagen-tetracalcium phosphate bone cement has been studied in femoral condyles of rabbits in Japan.^[48] Organoapatites made from tricalcium phosphate and polyamino acids has been reported.^[64] A soft collagen-based bone defect filler (Osteobit) is being sold in Europe.

Hydroxyapatite-Polymer Composites

A hydroxyapatite-polyethylene composite has been developed for use in orthopedic implants. The material knits together with bone, maintains good mechanical

properties, and can be shaped or trimmed during surgery using a scalpel. The material was developed at Queen Mary and Westfield College and Brunel University in the United Kingdom.^[65]

A bone-joining material for orthopedic plates has been developed in Japan combining fine particles of HAp and PLA at a weight ratio of 30:70 to 60:40. The material is said to be stronger than natural bones and to maintain its strength over 4–6 months, while becoming completely absorbed into natural bone within a few years.^[66]

PMMA-Ceramic Systems

A HAp/acrylic monomer has been prepared, composed of 80% HAp granules coated with silane-coupling agent bonded with bis-phenol-A glycidyl methacrylate, 2,2'-bis(4-methacryloxyethoxy-phenyl) propane, and triethyleneglycol dimethacrylate (35:35:30 w/w), which has a setting time of 5 minutes, a peak curing temperature of 46°C, and a tensile strength of 39.6 MPa (versus 28.6 MPa for a commercial PMMA cement).

A PMMA-HAp cement has been used in total hip replacement surgeries in Japan since 1984.^[48]

Glass-Ionomer or Polyalkenote Cements

When mixtures of boric, zinc, and aluminum oxides; zinc fluoride; tartaric acid; and polyacrylic acid were evaluated 8 of the 20 mixtures had suitable setting characteristics, and 3 produced hard cements.^[67,68] Mechanical properties of polyalkenoate cement have been presented by Canadian researchers.^[69]

Bioresorbable Composites

Bioresorbable composites of various compositions have a 15-year history of clinical use as fixation devices^[70] (e.g., as screws and plate).^[71] In an extensive study of more than 1000 operations, it was found that these materials provided a greater degree of osteogenesis than could be achieved with metallic implants.^[72] There are several potential advantages to the use of bioresorbable fixation devices. They can be impregnated with BMPs or antibacterial drugs. Osteoporosis associated with stress shielding due to the significantly higher modulus of elasticity associated with metallic devices will be reduced or completely avoided. Bioresorbable devices also avoid the need for further surgery (i.e., for their removal). However, there are also potential concerns. Metallic implants are stiffer and more rigid, thus providing better mechanical support under weight-bearing conditions. As early as 1994, research was directed at the improvement of the

mechanical properties, tensile strength, and rigidity of bioresorbable materials.^[73,74]

Other Developments

Japanese researchers have presented a chitosan, hydroxyapatite or β -tricalcium phosphate, malic acid self-hardening paste that generates little heat but is not as strong as bone cement.^[75,76] CaO, MgO, and ZnO are used to modify its properties. An α -TCP with citric acid, malonic acid, and collagen is a cement that is stronger than PMMA cement that has been prepared in Japan.^[77]

Orthopedic Fixation Devices

Jill S. Kawalec

Ohio College of Podiatric Medicine, Cleveland, Ohio, U.S.A.

INTRODUCTION

Broken bones, whether accidental (fracture) or intentional (osteotomy) must be fixed in place in order for proper healing to occur. Torn ligaments and tendons must be reattached to bone, so that proper functioning of a joint or limb may occur. Orthopedic fixation devices provide for such needs. There are two categories of orthopedic fixation: internal fixation and external fixation. Within each category are several types of devices with which to fix a fracture or reattach soft tissue. The devices may be made from metals or absorbable polymers. This section will introduce several orthopedic devices currently used by surgeons.

INTERNAL FIXATION DEVICES

Absorbable Fixation

Within the past 15 years or so, the use of absorbable polymers for internal fixation has become very popular. Absorbable polymers currently in use include polydioxanone (PDO), polyglyconate, pure poly(glycolic acid) (PGA), pure poly (L-lactic acid) (PLLA), and PGA-PLLA copolymers. Of these materials, pure PGA has the greatest strength, while PDO and polyglyconate have the least strength.^[1] The majority of studies with absorbable polymers have used pure PGA, pure PLLA, or copolymers of the two.

Complications have been observed with absorbable polymers, however, these are primarily observed with the homopolymers, as opposed to copolymers.^[1] For instance, pronounced fibrous encapsulation was observed with PLLA,^[1,2] whereas sterile sinus formation^[1,3] and bone osteolysis^[1,4] were observed with PGA. The most likely cause of these complications is the degradation characteristics of the material. PLLA absorbs slowly in the body, and thus, the formation of a fibrous capsule around the implant can occur. In addition, the amorphous regions of PLLA degrade faster than the crystalline regions, resulting in the presence of crystals at the site of the implant. This may result in the formation of a fibrous capsule around the device. Conversely, PGA absorbs very quickly, with nearly all strength lost after one month and all mass lost after six to 12 months. Thus, an abundance

of monomer in the area may lower the pH and result in osteolysis or sinus formation.

Copolymers of PGA and PLLA combine the properties of both materials to produce a device that can be used in orthopedic fixation. By varying the ratio of PGA to PLLA, the properties of the material can be varied. For instance, a study that examined the behavior of a copolymer consisting of 10% PLLA and 90% PGA found that, after three to four months, sinus formation occurred in a small portion of patients who received bone pins in the ankle.^[1,5] In contrast, a study that examined the behavior of a copolymer consisting of 82% PLLA and 18% PGA demonstrated that after eight weeks in physiological buffered saline, the peak flexural strength of the copolymer was greater than that of a 1.5-mm titanium plate.^[1] This was most likely due to the slower absorption rate of PLLA.

The ideal absorbable implant can be made with sufficient initial strength for the purpose it will serve. The rate of degradation must be predictable so that adequate strength of the device remains while healing occurs. The particles and chemicals that are leached from the implant must not have a harmful effect on the body. Finally, once the implant is completely absorbed by the body, there should be no evidence that it ever existed.^[1]

Internal fixation devices that are made from absorbable polymers currently include pins, screws, and plates for fracture fixation. Additional absorbable devices include interference screws for repair of the anterior cruciate ligaments,^[6] staples for meniscal repair, and suture anchors, tacks, and staples to aid in soft tissue fixation to bone.^[7]

Fracture Fixation

Over the past 40 years, interfragmental compression has been the most successful means of immobilization of bone fragments, whether of a fracture or an osteotomy. This can be obtained by internal fixation. The principle of AO internal fixation is “early active pain-free mobilization of the muscles and joints of the injured limbs in patients with multiple fractures.”^[8] Four conditions must be satisfied to obtain the best internal fixation and healing of the surrounding tissue: 1) anatomic reduction of the bone fragments; 2) stable

O

internal fixation with a device that is appropriate for the location and type of fracture; 3) early, active, and pain-free mobilization of the soft tissue and joints surrounding the fracture or osteotomies; and 4) preservation of the blood supply to both the bone fragments and the surrounding tissue.^[8]

There are several different types of internal fixation devices that can be used, depending on type and location of the fracture or osteotomy. The concepts behind orthopedic internal fixation devices, particularly those used for fracture or osteotomy fixation, are stress-sharing and stress-shielding.^[9] A stress-sharing device allows for partial transmission of the load across the fracture site. This allows for micromotion at the site of the fracture, and, as a result, micromotion can occur at the site. Due to this micromotion, secondary healing occurs with the formation of a callus.^[9]

A stress-shielding device protects the fracture or osteotomy from functional loads by transferring the stress from the bone to the device itself. Such devices hold the ends of the bone together in compression, allowing negligible motion at the fracture site. As a result, healing is accomplished by primary healing without callus formation.^[9] One concern that must be addressed with a stress-shielding device is the phenomena of stress protection. When a rigid device is present for an extended period of time, bone mass around the device decreases, as a result of Wolff's law. This theory states that the amount of bone present is dependent upon the need for it, and, in turn, the need for bone is based upon the amount of stress applied to the area. When a rigid device is placed adjacent to bone, the stress is carried almost entirely by the device, and the bone is protected from the stress. As a result, the bone may undergo atrophy or loss of bone mass. Another consequence of stress protection is that the neutral axis of the bone, which is normally located in the medullary canal, shifts toward the device.

Rods, pins, and wires

The simplest form of internal fixation is a single rod, pin, or wire placed across a fracture or osteotomy, resulting in partial immobilization at the site. All three devices are stress-sharing devices, and thus, more rapid secondary healing with callus formation typically occurs. Rods, pins, and wires are not recommended for fracture fixation at weight-bearing locations. If the devices are inserted in such a location, immediate weight bearing is not recommended. Often, a second type of fixation is used, such as a cast, to increase the stability of the fixation. Rods, pins and wires are commonly used in fractures of the ankle, patella, metacarpals, and olecranon.^[9] Rods and pins may be

made from metals or from absorbable polymers, such as PLLA, or composites, such as self-reinforced PLLA. Wires are typically made from stainless steel. If the device is made from metal, it is common to remove it once the fracture has healed.^[9]

Wires also are used in tension band fixation. Every bone experiences bending stresses during functional loading. As the bone bends, the convex portion of the bone experiences tension, while the concave side of the bone undergoes compression. The principle behind the tension band is that the implant absorbs the tension during functional loading, while the bone absorbs the compressive stresses.^[10,11] When a fracture occurs, a gap usually forms between fragments on the tensile side of the bone, and tension band fixation aids in compressing the bone fragments. In order for the bone to function normally, a band must be placed on the tensile side of the fracture to assist in absorbing the stress. Tension band wiring is primarily indicated for avulsion fractures, fixation of arthrodeses, and for the attachment of corticocancellous grafts.^[11]

Tension band wires can be used in conjunction with Kirschner wires, or K-wires.^[10,11] This is the most common method of fixation for a fracture of the olecranon.^[10,12] With this method, two K-wires are placed axially parallel to one another. The addition of the K-wires serves two purposes: they add to the rotational stability and also serve as an anchor for the tension band wire. It is important that the K-wires are inserted parallel to one another. If not, the bone fragments may not achieve the desired compression, and the rotational stability may be compromised.^[10,11]

K-wires can also be used alone for internal fixation. K-wires are thin, smooth metal rods.^[9] They are available in diameters of 0.6, 0.8, 1.0, 1.25, 1.6, and 2.0 mm.^[13] The K-wire can be used by passing the wire across the fracture and then cutting the wire to size. K-wires are commonly used in fractures or osteotomies of the foot. For fractures of the lesser phalanx where alignment of the fragments cannot be achieved by closed methods, a K-wire is placed across the fracture for approximately two to three weeks, during which time the foot is placed in a small cast. After the required time, the wire is removed.^[14] K-wires are used in a similar manner for fractures of the great toe phalanx, and the second, third, and fourth metatarsals. In the midfoot, K-wires are used for Lisfranc fractures when the injuries are primarily to the bone, since less time is required for healing.^[15] The patient is placed in a nonweight-bearing cast and the wires are removed after six weeks.

K-wires are also often used in the joints of the hand. This includes unstable fractures of the metacarpal shafts, and the majority of intraarticular fractures of the first and fifth metacarpals. The K-wires can be placed through the medullary canal, or through the

fracture and into the adjacent metacarpals. Fixation can also be obtained by crossing two K-wires. Based on the surgeon's preference, the K-wires can be cut off beneath the skin or may protrude through the skin. The wires are typically removed after three to four weeks.^[16]

Fixation screws

Internal fixation screws are stress-sharing devices, and thus, healing occurs by callus formation.^[9] A secondary form of fixation, such as a cast, is often used in conjunction with a single screw across a fracture or osteotomy. Once healing occurs, the screw is often removed.

There are two major types of screws: cancellous screws and cortical screws (see Fig. 1).^[10] The cancellous screw is typically wider in the thread area, in comparison to the shaft of the screw. It may be fully or partially threaded. These screws are normally used in the epiphyseal and metaphyseal region of bone. If placed in cortical bone, the cancellous screw cannot be removed. As it heals, the cortical bone grows right up to the shaft. In reverse, the threads are unable to cut through the cortical bone and the screws often break.^[10] Cortical screws are fully threaded, and the thread size is not as large as the cancellous screw.

The lag screw is one of the best ways to achieve interfragmental compression.^[9,10] The lag effect occurs when the screw gains purchase in the far cortex, but passes freely through the cortex near the screw head and the fracture or osteotomy. Partially threaded cancellous screws can inherently be lag screws, as long as the smooth shaft of the screw crosses the fracture or osteotomy. A cortical screw can only be used as a lag screw when the cortex adjacent to the head of the screw is overdrilled, such that purchase is gained in the far cortex alone.^[10]

Fig. 1 Cancellous (left) and cortical (right) fixation screws.

Fixation Plates

Fixation plates are typically metal plates with a curved surface that can contour to the shape of the bone. Because of the rigidity of the metal plate, it is considered a stress-shielding device, and thus, healing is achieved by the much slower method of primary healing without callus formation. Since the load is essentially completely absorbed by the plate, failure of the plate must be considered in selecting the proper material for the plate, and bone resorption must be taken into consideration. Often, a secondary fixation method, such as a cast, is used in conjunction with the plate.^[9]

Since the metal fixation plate is a stress-shielding device, loss of bone mass beneath the device is a concern. The weakened bone may be susceptible to fracture once the plate is removed. In addition, the screws and the edges of the plate are points of discontinuity, which may result in increased bone formation. Thus, less rigid fixation is preferred. This may be accomplished by reducing the stiffness of the metal plate by making the device thinner. Another option is to manufacture the device from a material with a modulus of elasticity similar to that of bone. These materials include polymers, such as polyetheretherketone (PEEK), or composites, such as carbon fiber reinforced PEEK.^[17] These materials, however, have not been used extensively in clinical applications.

According to the AO group, fixations serve one or more of four different functions: 1) static compression; 2) dynamic compression; 3) neutralization; and 4) buttressing.^[10] With static compression, the plate is prestressed in tension, and, when fixed into place, results in axial compression of the fracture. This is primarily indicated for fractures of the arm, since one plate without the use of a lag screw inserted obliquely across the fracture should never be used in the tibia or femur.^[9,10]

With dynamic compression, the plate serves as a tension band, and absorbs all of the tensile stresses while the osteotomy or fracture is exposed only to compressive stresses.^[9,10] This technique is not recommended for new fractures, as the location of tensile stresses cannot immediately be determined.

Neutralization is the most common function of fixation plates.^[10] Interfragmental stability is first achieved by the application of lag screws. They may be inserted by themselves or passed through the plate. Once this fixation has been achieved, a protection plate is fixed over the fracture site. The function is termed "neutralization" because the plate serves to protect the lag screw fixation from torsional, bending, and shear forces. The primary application for neutralization is fracture of the tibia, excluding transverse fractures. It should be noted that all short oblique fractures should

first be fixed with lag screws prior to application of the plate, in order to achieve stable fixation.^[10]

A buttress plate is typically a thin metal plate that serves to protect the cortex. It is a stress-sharing device, and thus, healing occurs by callus formation. Weight bearing is normally delayed.^[9] The most common function of buttressing is in conjunction with a lag screw on the proximal tibia after fracture of the tibial plateau has occurred.^[9] Buttressing can also be used to prevent a cancellous bone graft from collapsing.^[10]

Intramedullary nails

Intramedullary nails are stress-sharing rods that are most commonly used for compound fractures of the tibia and femur, and occasionally, the humerus.^[9,18,19] The devices are placed centrally in the medullary canal, at the mechanical axis of the shaft (see Fig. 2).^[18] At this location, they are not susceptible to functional bending loads that may be introduced. Intramedullary nails allow for movement of the joints above and below the fracture while preventing motion at the fracture site.^[9]

Fig. 2 Schematic of a cross section of tibia, showing placement of an intramedullary nail in the medullary canal.

There are two types of intramedullary nails: reamed and unreamed. Reamed nails have a larger transverse diameter, and thus, are a stronger device. They are commonly used in the shaft of the femur and the tibia, where functional loading is high. The reaming process, however, may result in further destruction of the blood supply to the endosteal bone, thus causing delayed healing. Unreamed nails are much thinner and have less strength than reamed nails. With unreamed nails, the bone shaft is not reamed prior to insertion of the nail, and therefore, the endosteal blood supply is maintained.^[9,18]

Both reamed and unreamed nails can be locked into place by screws that are passed transversely through the nail and two cortices both distally and proximally.^[9,18,20] Interlocking screws are primarily used when the fracture is comminuted or segmented and the fragments are not in contact.^[20] The locked intramedullary nail has become the accepted method of fixation of fractures in the femur.^[19] In this instance, the nail is locked into place to prevent rotation and sliding, and acts more as a stress-shielding device until the fracture has healed sufficiently to begin to bear weight. Once callus formation begins, the screws located either proximally or distally can be removed to create compression at the fracture site to further stimulate healing.^[9,18,20]

The screw holes in the locking intramedullary nail introduce areas of high stress concentration to the device. Thus, material selection for the intramedullary nail is very important. The nail must be made of a material that is biocompatible, with good ductility, high fatigue resistance, and high mechanical strength. The metals most commonly used are titanium alloyed with 6% aluminum and 4% vanadium, cobalt–chromium alloy, and stainless steel.^[21] Stainless steel nails have been shown to be more susceptible to failure at the screw hole compared to the other materials.^[22,23] Nails made from the titanium alloy have an increased strength and flexibility and are more biocompatible than the other metals.^[19]

Soft Tissue Attachment to Bone

Suture anchors

Suture anchors are fixation devices with an integrated suture. The suture is passed through an eyelet in the anchor and is used to secure the soft tissue in place. There are three design types for suture anchors: harpoon, wedge, and screw. The harpoon-style anchors have a smooth surface but possess arcs, or prongs, to hold the anchor in bone. There may be two or four arcs, depending on the brand of anchor. Failure of this type of device usually occurs at the

suture knot.^[24] The wedge-type suture anchor is V-shaped. When inserted, the wedge closes and then reopens when in bone, thus preventing the anchor from backing out. The screw-style suture anchors possess threads that allow the device to be screwed into position.

Suture anchors for fixation of soft tissue to bone may be made from metal or absorbable polymers. Metal suture anchors are typically titanium alloy or stainless steel. Absorbable polymers are becoming more popular for use as suture anchors. Such materials include PLLA, PGA, and PLLA-PGA copolymers. Applications for suture anchors include repair of rotator cuffs, Bankart procedures, treatment of acromioclavicular joint separation,^[25] and reattachment of the Achilles tendon.^[26] Mini suture anchors have been used for thumb ulnar collateral ligament reconstruction^[27] and correction of chronic recurrent dislocation of the mandibular condyle.^[28]

Soft tissue staples

Staples are another type of device used to attach soft tissue to bone. These devices are typically U-shaped and consist of at least two legs and a bridge between the legs. The legs are parallel or nearly parallel to one another, and serve to penetrate the bone and hold the tissue in place. The legs may possess barbs, or serrations, to enhance fixation in the bone. The cross section of the legs may be round, square, or polygonal. The bridge of the staple may be either smooth or possess barbs on the underside to enhance fixation into the soft tissue.

The effectiveness of the staple depends largely on the size and quality of the tissue being fixed to bone, differences in the contour of the bone, and the degree of osteopenia.^[29] Several complications may occur with staples, including failure of the barbed staple as a result of the spikes tearing through the soft tissue,^[29] loosening of the staple, and pain that requires removal of the staple.^[24] Impingement of the staple bridge may occur, resulting in an overlying bursa.^[29]

Staples for the fixation of soft tissue to bone may be made from metals, including cobalt-chromium alloy. Metal implants can lead to several of the complications listed above. Thus, staples are also often made from absorbable materials, including PGA-PLLA copolymers and self-reinforced PLLA (SR-PLLA). Applications of staples include repair of the meniscus in the knee and reattachment of the anterior glenohumeral ligament in the shoulder joint.^[24]

Soft tissue tacks

Tacks are also used for fixation of soft tissue to bone. They are passed through the soft tissue and into the

bone. Some designs consist of spikes on the underside of the head, or have spiked washers to enhance stability in the soft tissue. Certain designs do not require drilling or tapping prior to insertion of the tack.

Tacks are typically made from absorbable polymers. Such polymers include PLLA, PGA, and a combination of both polymers. Applications include rotator cuff repair,^[30] repair of acromioclavicular separation, Bankart procedures, superior labrum anterior-posterior (SLAP) lesion repairs,^[31] and craniofacial surgery.^[32]

Interference screws

The interference screw is another device used for the fixation of soft tissue to bone. They are available with a round or flat head, and may be fully or partially threaded. They are most commonly used for repair or reconstruction of the anterior cruciate ligament (ACL) in the knee. In fact, it has become the “gold standard” for bone-patellar tendon-bone grafts in ACL surgery.^[6,33] Other applications include bone-tendon grafts and reattachments. The screws are placed with an interference fit at the site of insertion of tendon into bone. Interference screws can be made of metal or absorbable polymers. Metals include titanium alloy, while absorbable polymers include PLLA, PLLA/PGA copolymers, and a composite of tricalcium phosphate (TCP) and PLLA.^[6]

EXTERNAL FIXATION DEVICES

Casts

Casts are the most commonly used method of stabilizing a fracture or osteotomy. A cast is a stress-sharing device, which allows for more rapid secondary healing.^[9] Typically made from plaster of Paris, they are situated such that the joints above and below the fracture are immobilized to prevent excessive motion at the site of fracture. In most cases, casts allow for early weight bearing on the fractured bone.^[9]

External Fixators

The external fixator for the stabilization of bone fragments dates back to 1902.^[34] Its function is to maintain alignment of a fracture while allowing the patient to be mobile. It is a device that allows for temporary stress-shielding to protect and stabilize the site of a fracture or an osteotomy. It can also be used as a permanent stress-sharing device, where the load is distributed both through the bone and the fixator.^[35]

There are several types of external fixators. The ring fixator was developed by Ilizarov in the 1950s. It is based on the theory that bone union can be stimulated by pulling apart, or distracting, the bone fragments, as well as by compression.^[36] It is designed to hold the bone fragments in place while allowing axial dynamization at the fracture site.^[37] The ring fixator works by passing K-wires under tension or stiff full or one-half pins through the bone segment.^[37,38] The wires or pins are then secured to a full- or semi-circular ring. The ring is then fixed by threaded rods. Hinges, telescoping rods, and spacers may also be added to the construct.^[37] With such a device, adjustments can be made to the length and angulation after initial fixation.^[39] Ring fixators are commonly used for tibial osteotomies,^[40] tibial nonunions^[41,42] and compound fractures,^[43] and angular and rotational deformities of the lower extremity.^[44]

Two other types of external fixators consist of unilateral and bilateral frames.^[45] Unilateral frames include one external rod and a minimum of two transfixing pins, which are placed above and below the fracture. The pins are inserted through the skin and into the bone, and are held in place by the external rod. Bilateral frames consist of two external rods, one on each side of the bone, and at least two transfixing pins. As with the unilateral frame, the pins are fixed on one end by one of the external rods and the pins are inserted transcutaneously into the bone. In the case of bilateral fixation, however, the pins pass completely through the bone and are attached to the second external rod.^[45]

Bilateral frames are intrinsically more stable than unilateral frames. During functional loading, the pins in a bilateral frame may bend, while the stress through the external rods is distributed evenly, thus preventing significant bending. In contrast, when the unilateral frame is loaded, the transfixing pins undergo considerable bending, resulting in observable bending of the external rod.^[45]

External fixators are most commonly used for the stabilization of complex fractures, usually in the tibia.^[35] They are very rarely used for fixation of the femur or of the upper extremities, with the exception of the bones around the wrist. An external fixator is only used under extreme conditions, where there is severe injury and contamination to the surrounding soft tissue. It is also used when there has been vascular injury and prompt stabilization is required in order to rapidly restore circulation to the limb. An external fixator can also be used to repair compound or closed fractures of the lower extremities when the patient is too ill or injured to undergo extensive surgery, and for nonunions and osteotomies.^[35]

External fixators are also used in pediatrics for staged limb lengthening. When used for lengthening

purposes, an osteotomy is created and the lengthening frame is inserted into place. As the fragments are separated, a defect is created in the bone. Once the desired length is achieved, a second surgery is needed to pack the defect with cancellous bone.^[34] Other applications of external fixators are as compression frames to hold bone fragments together after an arthrodesis or when a nonunion occurs, or as soft-tissue frames to stretch soft tissues in order to correct contractures, such as an equinus deformity about the ankle.^[34]

CONCLUSION

There are many orthopedic fixation devices available, whether to repair a fracture or fix an osteotomy, or to fix soft tissue to bone. The devices include both internal and external fixation devices. The device can be made from metals, or more recently, absorbable polymers. Research continues to find means by which to improve the performance and biocompatibility of orthopedic fixation devices.

INTRODUCTION

Osteoclasts are myeloid-derived multi-nuclear cells responsible for bone degradation in the body. Bone is composed of a highly collagenous extracellular matrix made by mesenchymally-derived osteoblasts. The matrix is mineralized by osteoblasts when they generate and release matrix vesicles that initiate crystallization of hydroxyapatite on the bone matrix. Hydroxyapatite, $[\text{Ca}_3(\text{PO}_4)_2]_3\text{Ca}(\text{OH})_2$, adds strength to the bone and serves as the main store of calcium in the body. The activity of osteoclasts is highly regulated to maintain both the structural integrity of the bone and calcium homeostasis.

Hematopoietic stem cells in the bone marrow give rise to circulating mononuclear osteoclast precursors. The resorption cycle characterizes the events in the life cycle of the osteoclast. First, the circulating osteoclast precursors are recruited to the site of resorption, where the osteoclast undergoes activation following adherence to the bone matrix. Activation is evident in morphological changes and polarization of the cell that prepare the osteoclast to degrade bone. The activated osteoclast then dissolves the hydroxyapatite crystals of the bone. Following demineralization, the organic matrix is degraded by secreted proteins from the osteoclast. The resulting enzymatically-cleaved products are removed by the cell through a transcytotic process. The final step in the cycle is the termination of osteolytic bone resorption. The processes involved in the resorption cycle are largely cytokine mediated, and many of the signaling pathways involve both stromal and myeloid cells. The signaling pathway involving the receptor activator of NF- κ B ligand (RANKL), receptor activator of NF- κ B (RANK), and osteoprotegerin (OPG) has been implicated as an important regulator of osteoclast differentiation. Other factors, such as the proinflammatory cytokines tumor necrosis factor- α (TNF α), interleukin-1 (IL-1), interleukin-6 (IL-6), are important regulators of osteoclastogenesis and osteoclast activity.

Healthy bone continuously undergoes the process of bone remodeling, which balances bone formation with

resorption. The loss of balance between osteoblastic formation and osteoclastic degradation appears to be a key feature of bone resorptive pathologies, such as rheumatoid arthritis, periprosthetic osteolysis, osteolytic malignant cancers, and others. The signaling involved in the resorption cycle of osteoclasts offers promising therapeutic targets for these diseases.

OSTEOCLAST MORPHOLOGY

Mature, multinucleated osteoclasts are formed by the fusion of mono-nuclear osteoclast precursors. Activation occurs as the nonresorbing or inactive osteoclast reaches and adheres to the bone surface. Morphological changes allow the creation of a contained compartment between the osteoclast and the bone, called the resorption lacuna, that is the site of resorption. The degraded bone fragments are then removed and secreted away from the bone surface. The specialized morphology of the osteoclast makes it extremely efficient at resorbing bone.

Sealing Zone

Active osteoclasts are highly polarized cells with specific features characterizing the surface adjacent to the bone. After recruitment, receptors on the plasma membrane interact with the bone matrix to form the sealing zone, a tight interaction that creates a sealed extracellular compartment between the osteoclast and bone. Signaling initiated by the adherence of the osteoclast to the bone is accompanied by cytoskeletal rearrangements, such as the formation of an intracellular ring of actin filaments that aligns with the sealing zone and is important for the adherence of the cell.^[1] The adherence of the osteoclast to the bone matrix is crucial for resorption lacuna formation, as well as signaling that activates the osteoclast.

Integrins are transmembrane receptors that have important function in both signaling and adhesion.

$\alpha_v\beta_3$, $\alpha_2\beta_1$, and $\alpha_v\beta_1$ integrins are expressed in mammalian osteoclasts^[2] and have been implicated in the adherence of osteoclasts to bone. $\alpha_2\beta_1$ has been shown to bind to fibronectin^[3] in avian osteoclasts, however, work with human osteoclasts has also shown a capacity of β_1 , and in particular $\alpha_2\beta_1$ integrins to bind native type I collagen.^[4] A large amount of research has focused on $\alpha_v\beta_3$, the most highly expressed integrin in osteoclasts, because antibodies to this integrin as well as soluble ligand analogs^[5,6] prevent attachment of osteoclasts to bone and inhibit bone resorption. The $\alpha_v\beta_3$ integrin, although called the vitronectin receptor,^[7] has been shown to bind to many proteins besides vitronectin. The $\alpha_v\beta_3$ integrin binds to Arg-Gly-Lys (RGD) containing proteins.^[8] Of particular interest to bone biology is the binding of the $\alpha_v\beta_3$ integrin to osteopontin,^[3] an RGD-containing protein present in bone. Despite an apparent crucial role in osteoclast adherence, studies have been unable to show the presence of $\alpha_v\beta_3$ in the sealing zone.^[9] Instead, the $\alpha_v\beta_3$ integrin has been found only in the basolateral and ruffled border membranes adjacent to the sealing zone. Although inhibition of the $\alpha_v\beta_3$ integrin has been shown to have a large effect on bone resorption, the mechanism is not totally understood.

Integrins have been shown to act not only as mediators of adhesion, but also as signaling receptors in the osteoclasts. Integrin signaling affects cellular metabolism, cytoskeletal organization, and protein phosphorylation.^[10] The $\alpha_v\beta_3$ integrin has been shown to affect cellular changes through a variety of intracellular signaling mediators, including the cytoplasmic tyrosine receptor kinase c-Src, the adhesion-dependent kinase PYK2, and phosphatidylinositol-3 kinase.^[11] Integrin signaling in other cell types is responsible for changes in gene regulation, cytoskeletal rearrangement, and cell metabolism of proteins and lipids, suggesting that integrins are at least in part responsible for the activation of osteoclasts. Integrin binding to bone appears to be a key step in the activation of osteoclasts, although the mechanism of activation is not fully characterized.

Ruffled Border

The portion of the membrane, called the ruffled border, encircled by the sealing zone undergoes changes resulting in significant endosomal character and finger-like projections of the membrane towards the bone surface. Activation of the osteoclast triggers intracellular vesicles to fuse with the membrane contained within the sealing zone. Fusion releases HCl and other vesicular contents into the resorption lacuna.^[12,13] Fusion also increases the amount of membrane encompassed by the sealing zone, leading to the development of the

folds and extensions of the membrane into the resorption lacuna. The ruffled border is significantly different from the membrane of the rest of the cell. Experiments that utilized virally infected osteoclasts to examine protein targeting showed a lack of any viral membrane-targeted proteins in the ruffled border in actively resorbing osteoclasts.^[14] The viral proteins were found in the apical and basolateral portions of the osteoclast cell membrane. Within the ruffled border, a high concentration of vacuolar ATPase were found.^[15] Osteoclasts use the many vacuolar ATPases to pump H^+ into and further acidify the resorption lacuna. Carbonic anhydrase II is up-regulated in osteoclasts and found in high levels in the cytoplasm.^[16] The carbonic anhydrase II, in conjunction with HCO_3^-/Cl^- exchangers, work to maintain a steady level of intracellular protons, in addition to supplying them for the ATPases. Palogonkas et al. found further evidence of endosomal character in the localization of other endosomal markers, including RAB7 and Igp110 in the ruffled border.^[17] Vesicle fusion and the activity of vacuolar ATPase are key functions of the ruffled border that create an environment conducive to bone resorption within the resorption lacuna.

Functional Secretory Domain

Products of the degradation of the organic matrix of the bone are endocytosed by the osteoclast and trafficked to the apical region of the cell where they are secreted into the extracellular space. The apical region is called the functional secretory domain of the osteoclast. Salo et al.^[14] showed that there are differences between the basolateral membrane and the apical membrane by utilizing viral proteins trafficked to either the basolateral or the apical membrane of infected endothelial cells. Apically directed proteins in endothelial cells were found in the functional secretory domain of the infected osteoclasts while basolaterally directed proteins were localized in the basolateral portion of osteoclasts. While degradation products are being trafficked from the resorption lacuna, they may be further degraded by enzymes within the vesicles before they are secreted to the extracellular space. The functional secretory domain again illustrates the polarization in activated osteoclasts, as well as specialized functional domains of the cell.

MECHANISM OF BONE DEGRADATION

Mineral Crystal Dissolution

Following osteoclast activation, the resorption lacuna becomes highly acidic as two mechanisms work to

decrease the pH. The first is the fusion of intracellular acidic vesicles with the ruffled border releasing acid into the area of active resorption. The second is vacuolar ATPases, which pump protons across the membrane into the resorption lacuna. The low pH achieved is necessary to dissolve the hydroxyapatite crystals surrounding the organic matrix of the bone. Mineral crystals in bone must be dissolved for the degradative enzymes secreted by the osteoclast to access to the organic matrix. Hydroxyapatite crystals in the bone store a majority of the calcium in the body and osteoclastic dissolution of the mineral component of bone is an important mechanism for maintaining serum levels of calcium and other ions contained in bone such as phosphate. Accordingly, the activity of osteoclasts is regulated in response to conditions, such as hypocalcemia to maintain suitable concentration ranges of those ions.

Organic Matrix Degradation

Following demineralization, the osteoclast secretes enzymes that further degrade the bone. The extracellular matrix made by osteoblasts and osteocytes is principally composed of collagen, but contains other extracellular matrix proteins as well. The matrix is degraded by two types of proteases, cathepsins and metalloproteinases (MMPs). Fig. 1 illustrates the regulation of osteoclastogenesis and osteoclastic bone resorption.

Several cathepsins are present in osteoclasts and are responsible for much of the degradation of the organic matrix of bone. Cathepsins are lysosomal proteases active at acidic pH. Their activity at low pH shows the importance of the osteoclast machinery responsible for lowering the pH of the resorption lacuna, in providing a suitably acidic environment for cathepsins and other acidic proteases, in addition to dissolving the hydroxyapatite. Osteoclasts produce cathepsin B, C, D, E, G, L, and K (D and E are aspartic proteases, while the others are cysteine proteases).^[18]

Cathepsin K is a lysosomal cysteine protease that has been implicated as an important bone resorptive enzyme. Immunolocalization studies have shown cathepsin K localized to the ruffled border and lysosomal vacuoles in the osteoclast and the extracellular space surrounding the cell.^[19] Cathepsin K has high enzymatic activity towards type I collagen, the main component of bone, as well as type II collagen.^[20,21] Cathepsin K also has the ability to act on non-collagenous substrates, such as osteonectin,^[22] a component of the protein matrix of the bone. Cathepsin K has also been hypothesized to cleave the tartrate-resistant acid phosphatase (TRAP) leading to the generation of a more active enzyme.^[23] Studies utilizing

Fig. 1 Extensive research has showed that the accessory cells (osteoblasts and stromal cells) express two key molecules that are essential and sufficient to promote osteoclastogenesis: M-CSF and RANKL. Osteoclasts are multinucleated giant cells deriving from hematopoietic progenitors of the monocyte–macrophage lineage. Stromal cell/osteoblast cell express RANKL, OPG, and M-CSF and their expression is regulated by factors such as 1,25(OH)₂D₃, PTH, PGE₂, and glucocorticoids. RANKL and M-CSF will interact with the cell surface receptors on mono/macrophage cells. These will trigger the osteoclastogenesis process. These postmitotic committed precursors fuse to form multinucleated osteoclasts, which are then activated to resorb bone. Osteoblasts or bone marrow stromal cells are required as supporting cells for the in vitro differentiation of osteoclasts from their progenitor cells. Source: Adapted from American Association for the Advancement of Science (see Ref. [63]); Springer (see Ref. [64]); International and American Association for Dental Research (see Ref. [65]) and American Association for the Advancement of Science (see Ref. [66]).

cathepsin K knockout mice have shown that these animals exhibit osteopetrosis due to decrease matrix degradation, while demineralization still occurs normally.^[24] Cystatin C, a secreted protein produced by osteoclasts and osteoblasts, as well as cells in the liver and kidney,^[25] is an inhibitor of cysteine proteases. The addition of cystatin C decreased bone resorption in in vitro assays.^[26] The importance of cathepsin K is illustrated by the skeletal defects present in pycnodysostosis. In pycnodysostosis, cathepsin K deficiency leaves the ability of osteoclasts to demineralize bone unchanged, but there is no degradation of the matrix, resulting in shortened stature and skeletal deformities

in these individuals.^[27] Similarly, cathepsin K knockout mice show osteopetrosis^[24] due to their inability to degrade bone. The potent resorptive activity of cathepsin K is crucial to bone degradation and is regulated by other factors, such as cystatin, to achieve the desired level of matrix degradation.

Cathepsins, other than cathepsin K, play important roles in osteoclast function. They are present in vesicles and at the resorption border. Many, but not all, of the cathepsins made in the osteoclast are present in the resorption lacuna. The cathepsins not found in the resorption lacuna are suspected to play roles in the degradation of resorbed collagen and other matrix materials, as well as in the cleavage of inactive enzyme precursors that help generate an active enzyme.

MMPs are zinc-dependent proteases produced by a wide variety of cells in the body. Many of the MMPs present in bone show activity against collagen. Several MMPs are made by osteoclasts, including MMP-2, 9, 12, 13, and 14. The role of MMPs is not entirely clear. However, they do appear to function in bone matrix degradation, as well as being important in allowing osteoclast migration. Osteoblasts, osteocytes, and cells adjacent to and associated with osteoclasts at the bone surface, are all capable of producing MMPs in addition to osteoclasts. These MMPs, particularly those made by adjacent cells, have been implicated in bone resorption and have obscured the role of the osteoclastic MMPs. However, many experiments have shown that MMPs are active in bone degradation. MMP-13 is an essential MMP, as knockouts have shown decreased bone resorption, while other MMPs do not show any change in resorption rate.^[28] The unique degradation products of MMPs, called ICTP fragments, are present at elevated levels in the serum in mice with cancer-induced osteolysis. Similar to the regulation of cathepsin activity by cystatin C, MMPs are regulated by tissue inhibitors of metalloproteinases (TIMPs). MMPs have proven to be an important pharmacological target for treating bone resorptive pathologies, as bisphosphonates are used to inhibit and downregulate MMPs in bone resorption and other diseases, such as the metastases of cancer.^[29]

Removal of Degradation Products

Degraded collagen and other matrix proteins are removed from the resorption lacuna, transported through the osteoclast, and exocytosed to the extracellular space. The degraded collagen and other tissue from the extracellular matrix of the bone are removed by vesicles that form at the ruffled border and move the degraded bone products through the osteoclast to the functional secretory domain, where they are

secreted. Immunohistology has shown the presence of TRAP in the transcytotic vesicles, along with degraded collagen. TRAP, because of its presence in the vesicles and its ability to generate reactive oxygen species, has been suggested as an enzyme that further degrades bone matrix products after they are taken into the transcytotic vesicles. Staining techniques to identify osteoclasts utilize the presence of TRAP activity in osteoclasts. The release of matrix fragments through the functional secretory domain is an important function that, as mentioned previously, allows serum detection of fragments that result from the osteoclastic specific bone resorption. A detailed description of the myeloid osteoclast lineage is illustrated in Fig. 2, which shows the molecular sequence of preosteoclast recruitment, proliferation, differentiation, cell fusion, and activation. The progression of cell surface markers and the active factors at each cell stage in osteoclastogenesis is described in the figure legend.

Osteoclast Inactivation/Apoptosis

Stopping bone resorption is necessary to avoid excessive resorption and bone loss. The mechanism of this action in the resorption cycle is currently not well understood. Both inactivation and apoptosis of the osteoclast have been proposed as mechanisms for limiting osteoclastic bone resorption. The prevalence of numerous diseases with increased bone resorption has led to great interest in understanding the mechanism of osteoclast inactivation and apoptosis as possible therapeutic targets. Apoptosis of osteoclasts has been linked to the Fas apoptotic signaling pathway.^[30] Bisphosphonates have been implicated in apoptosis of the giant cell tumors in bone that are similar osteoclasts and have been used in treating diseases that show increased bone resorption.^[31]

SIGNALING IN OSTEOCLAST DIFFERENTIATION AND ACTIVATION

RANKL/RANK/OPG

RANKL, also known as TRANCE, ODF, and OPGL, is a membrane-bound protein that is a potent activator of osteoclast differentiation.^[32] RANKL is a protein in the TNF family that is synthesized by bone marrow stromal cells, activated T cells, fibroblasts, and osteoblasts.^[33] Expression of RANKL is increased in the presence of such factors as 1,25-dihydroxyvitamin D₃ (1,25-(OH)₂-D₃), Parathyroid Hormone (PTH), Prostaglandin E₂ (PGE₂), and glucocorticoids. RANKL, in the presence of another cytokine, macrophage colony stimulating factor (M-CSF), causes the differentiation

Fig. 2 The molecular mechanisms underlying osteoclast differentiation and function have been thoroughly studied by an osteopetrotic mouse model. It was found that PU.1, a transcription factor present in B-lymphoid cells and macrophages, which binds to a purine-rich sequence that contains a central core with the sequence 5'-GGAA-3' deficiency was lethal since the mice had no early macrophage precursors. Mice lacking M-CSF generated immature macrophages though the number was reduced. This suggests that M-CSF exerts its role at a later stage than does PU.1. In c-Fos, NF- κ B and RANKL mutants, normal macrophage development was evident, but with impaired osteoclast differentiation. Mutations in $\alpha_v\beta_3$ -integrin, TNF receptor associated factor (TRAF)-6 or c-Src mutants were normal in terms of osteoclast numbers, however osteoclasts in these models did not polarize and did not have ruffled membrane close to the bone side. In contrast, cathepsin K, carbonic anhydrase II, and H⁺-ATPase mouse mutants showed normal polarized osteoclasts but these cells failed to resorb bone. This was due to the fact that carbonic anhydrase II, and H⁺-ATPase are required to acidify the microenvironment between the bone and osteoclast, while cathepsin K is necessary for degradation of the organic matrix of the bone. Source: Adapted from Endocrine Society (see Ref. [67]); American Association for the Advancement of Science (see Ref. [63]) and From Nature Publishing Group (see Ref. [68]).

of macrophages/monocytes, and dendritic cells to osteoclasts.^[34,35] RANKL can be cleaved by TNF α -cleavage enzyme (TACE) to generate a soluble form of the protein. RANKL appears to induce osteoclast differentiation through the activation of the NF- κ B and c-Jun signaling pathways in osteoclast precursors.^[36]

RANKL expressed on stromal cells leads to osteoclast differentiation through RANK, a TNF receptor family member. RANK is a transmembrane receptor expressed primarily in cells of the monocyte/macrophage lineage, including B and T cells, dendritic cells, and osteoclast precursors.^[37] RANK is also expressed by differentiated osteoclasts,^[38,39] where RANKL binding is capable of activating the osteoclast.

The third player in the RANKL intercellular signaling pathway is OPG, also called osteoclastogenesis inhibitory factor (OCIF). OPG is a soluble, secreted protein that binds RANKL^[32,40] acting as a decoy receptor. By binding RANKL, OPG blocks RANKL-RANK

binding and the signaling that leads to osteoclastogenesis. By preventing osteoclast differentiation, OPG has potent bone protective effects. In several bone resorptive pathologies, an increase in the RANKL/OPG ratio has highlighted the importance of RANK/RANKL/OPG triad in regulating bone resorption.^[41,42] The protective effects of OPG have made it an attractive target for treating bone resorptive diseases, such as arthritis and metastatic cancers.

In addition to OPG, other aspects of the RANKL/RANK/OPG signaling system are being investigated as therapeutic targets. By using synthetic analogs of OPG and antagonists, or inhibitors of RANKL signaling, investigators are searching for ways to decrease the RANKL/OPG ratio. Another avenue being investigated is the ability to block RANK signaling to inhibit osteoclastogenesis.^[43] The discovery of the RANKL/RANK/OPG signaling triad has led to a better understanding of the mechanisms involved in bone remodeling.

Macrophage Colony Stimulating Factor

M-CSF is a growth factor/cytokine that is essential for osteoclast differentiation and survival. Kodama et al.^[44] demonstrated the necessary role of M-CSF in osteoclast differentiation. It is now known that M-CSF also has a role in promoting survival of both osteoclasts and osteoclast precursors.^[45] Osteoblasts and other stromal cells produce both membrane-bound and secreted forms of M-CSF, although only a small portion is membrane bound. M-CSF works to promote survival and differentiation of osteoclast and osteoclast precursors through the c-Fms receptor, a member of the tyrosine kinase growth factor receptor family. Signaling through the c-Fms receptor activates several pathways that promote osteoclast survival, including the mitogen-activated protein kinase (MAPK) cascade that turns on AP-1 and I κ B-kinase (IKK), leading to nuclear translocation of NF- κ B.

Interleukin-1

Interleukin-1, prior to the discovery of RANKL, was thought to be the main cytokine mediator involved in bone resorption and is still recognized today as an important signal in bone resorption. Interleukin-1 signaling is the result of three proteins of the same gene family: Interleukin-1 α (IL-1 α), Interleukin-1 β (IL-1 β), and Interleukin-1 Receptor agonist (IL-1Ra). IL-1 α and IL-1 β have largely the same effects in bone, but they are not the same in all regards. IL-1 α is more frequently found intracellularly and is released in significant amounts following cell death. Accordingly, serum concentrations of IL-1 α are very low. IL-1 β is synthesized, like IL-1 α , as a precursor that needs enzymatic cleavage for activation. Removal of a small peptide fragment by IL-1 β cleavage enzyme (ICE) from the propeptide generates the functional IL-1 β that is secreted by the cell. IL-1Ra is similar in structure to IL-1 β , but is not capable of eliciting a response upon binding to the IL-1 receptors. There are two IL-1 receptors: IL-1 receptor type I (IL-1RI) and IL-1 receptor type II (IL-1RII). IL-1RI is capable of binding and signaling, whereas IL-1RII is capable of binding but unable to transduce intracellular signaling.^[46] Since the two receptors are concomitantly expressed, there is competition for the binding of IL-1, however only IL-1RI leads to signal transduction. IL-1RI activation is accompanied by dimerization of IL-1RI with the interleukin-1 receptor accessory protein (IL-1RAcP) that is necessary for signaling. Structural differences in IL-1 β and IL-1Ra prevent IL-1RAcP from forming the heterodimer necessary for signaling.

IL-1 acts to stimulate osteoclastogenesis indirectly by affecting stromal cell expression of RANKL. Wei

et al.^[47] have shown that IL-1 is an intermediate in TNF α -induced RANKL expression. TNF α increases both IL-1 production, as well as the expression of its functional receptor, IL-1RI in stromal cells.^[47] The presence of IL-1Ra, or the use of IL-1RI deficient mice, had the effect of decreasing TNF α -induced RANKL expression. IL-1 stimulation increased osteoclastogenesis in macrophages exposed to RANKL and M-CSF.^[48]

IL-1 also has direct effects on osteoclasts and their precursors. Through IL-1RI, IL-1 is capable of activating the transcription factors c-Jun and NF- κ B. Activation of NF- κ B seems to be particularly important as RANKL–RANK signaling also works to activate this transcription factor. To examine IL-1 signaling, Li et al.^[49] used the presence of IL-1 receptor associated kinase-M (IRAK-M), a dominant negative IL-1RI associated signaling protein expressed in monocyte-derived cells that acts to decrease signaling. In the absence of IRAK-M, marked increases in osteoclastogenesis, osteoclast survival, as well as activation of NF- κ B, were observed. IL-1 can also affect osteoclastic bone degradative machinery, such as the expression of cathepsin K.^[50] The multiple effects resulting from both direct and indirect signaling of IL-1 make it a potent osteoclastogenic cytokine.

Tumor Necrosis Factor- α

TNF α , like RANKL, is a member of the TNF superfamily and has pro-inflammatory and bone resorptive effects. TNF α is made primarily by activated macrophages as a membrane-bound protein though TACE, the same protease responsible for the cleavage of RANKL, can act to cleave and release soluble TNF α . There are two receptors for TNF α : TNF receptor I (TNF-R1) and TNF Receptor II (TNF-R2). Signaling through TNF-R1 leads to the activation of two transcription factors: c-Jun and NF- κ B. TNF α has been shown in high concentrations to promote limited osteoclastogenesis in the absence of RANKL.^[51] Zou et al.^[52] have shown a role for TNF α , not only as a stimulator of NF- κ B signaling, but also as an autocrine factor that stimulates NF- κ B signaling in osteoclasts. There is also evidence of TNF α stimulating osteoblasts to produce RANKL, promoting osteoclastogenesis in an indirect manner.^[47] Data on the role of TNF α in bone resorption point to both a direct action in conjunction with RANKL–RANK signaling in osteoclast precursors as well as an the ability to stimulate production of resorptive signals from stromal cells in bone.

Interleukin-6

IL-6 is a cytokine expressed largely by stromal cells in bone^[53] that works to promote osteoclast survival.

IL-6 promotes osteoclast differentiation through receptors present on osteoclast precursors, however, like many of the other bone resorptive cytokines, there is an indirect mechanism that works to promote interaction of stromal cells and osteoclast precursors. IL-6 binds to the IL-6 receptor, which is composed of two subunits, the gp130 and the IL-6R α . Many of the effects of IL-6 are achieved through increases in IL-1 production.^[54] The JAK/STAT pathway is a downstream effector of IL-6 signaling that results in the eventual activation of MAPK and the transcription factor AP-1. In osteoclasts this signaling leads to differentiation and survival, while in stromal cells, IL-6 signaling results in increased expression of stromal factors, namely RANKL, that induce osteoclastogenesis through interaction with myeloid cells.^[55] IL-6 family members LIF and IL-11 are also osteoclastogenic cytokines that act through receptors utilizing the gp130 subunit for signaling. In response to resorptive signaling, the IL-6 family members act to stimulate osteoclastogenesis.

TRAF Signal Transduction

RANKL and other osteogenic cytokines activate a variety of signaling pathways, but they show a convergence of signaling to a few key transcription factors. Tumor necrosis factor receptor associated factors (TRAF) bind to TNFR family members and the IL-1R, initiating signaling cascades following receptor activation. TRAF-2, 5, and 6 have been shown to play key roles in osteoclastic signals. IL-1R, TNFR, and RANK all signal through TRAFs. IL-1R and TNFR both bind to TRAFs through adaptor proteins, while

RANK has 3 TRAF binding domains. TRAF signaling through I- κ B kinase (IKK) and the MAPK activates NF- κ B and AP-1, respectively. The TRAF binding site on RANK adjacent to the membrane is specific for TRAF-6, while the other two sites can bind either TRAF-2 or 5. In addition to interacting with RANK, TRAF-2 interacts with adaptor proteins associated with the TNFR; TRAF-6 interacts with an IRAK adaptor protein on the IL-1R. TRAF-6 knockout mice display severe osteopetrosis that shows the crucial role of TRAF-6^[56] in osteoclastogenesis. TRAF-6 works to activate the soluble tyrosine receptor kinase Src, which in turn activates PI₃ kinase and its downstream signaling partners. Signaling from the three TRAFs described above, and through IL-6, facilitates activation of MAPK and IKK, leading to further downstream activation/translocation of the two major transcription factors in osteoclastogenesis, AP-1 and NF- κ B, respectively. Fig. 3 depicts the divergent receptors and their convergence on functional differentiation and activation of the mature osteoclast.

Recruitment

In normal bone remodeling, bone formation and degradation are balanced, and a crucial part of this balance is in the recruitment, differentiation, and survival of osteoclasts. This appears to be accomplished mainly through osteoblastic signals, thereby maintaining the balance. In cases of excess resorption there is greater recruitment and survival of osteoclasts due to signaling by proinflammatory cytokines involved in osteolysis.

Fig. 3 Cytokines play a major role in regulating osteoclast differentiation and survival. Receptor mediated transduction of osteoclastogenic cytokine signaling leads to the activation of intracellular signaling cascades. TRAFs play an important role in TNFR family signaling and can activate numerous pathways to affect cellular signaling. IL-6R works through heterodimerization with gp130 to activate the MAPK cascade through JAK/STAT proteins. Signaling through the MAPK and IKK systems lead to activation of key transcription factors AP-1 and NF- κ B. Regulation of gene expression through these signaling mechanisms is responsible for the differentiation, activation and survival of the osteoclast.

BONE REMODELING

In healthy bone the process of formation and degradation is constant and balanced. The involvement of numerous cytokines from various sources in osteoclast differentiation and activation suggest that this is a highly coordinated process. Despite the activity of a myriad of cytokines and other signals, recent research has illustrated the major signaling mechanism involved in osteoclastogenesis, the RANKL/RANK/OPG molecular triad. The importance of this signaling system has been shown by the number of pathologies that exhibit some disturbance of this system. Osteoporosis is a condition that affects many people, especially women with diminished levels of estrogen. RANKL has been shown to be a major factor in periprosthetic osteolysis induced by particle wear debris surrounding joint replacements.^[57] A disturbance of the RANKL/OPG ratio has been shown in a mouse model of arthritis.^[58] Individuals with Paget's disease have been shown to express increased levels of RANKL, in part due to IL-6 signaling, as well as greater response of myeloid cells to RANKL signaling. These effects work to increase osteoclast activity in localized areas of resorption that characterize Paget's disease.^[59] One emerging area of research is the role of the RANKL and OPG in the calcification of arterial tissue in atherosclerosis.^[60] In addition, RANKL/RANK/OPG signaling has been implicated in both primary tumors of bone^[61] as well as metastases.^[62]

CONCLUSION

The regulation of osteoclast activity has become an area of significant interest as an increasing number of diseases have been characterized involving an imbalance between bone formation and resorption in remodeling. An understanding of the complex and often combinatorial effects of the cytokines that regulate osteoclast function is necessary to understand these pathologies. Elucidation of the RANKL/RANK/OPG system has provided a greater understanding of osteoclastogenesis as well as a myriad of new therapeutic targets.

Osteogenic Progenitor Cells of Bone

Richard O.C. Oreffo

University Orthopaedics, University of Southampton, Southampton, United Kingdom

INTRODUCTION

The osteoblast, the cell that is responsible for bone formation, is derived from a pluripotent marrow stromal fibroblastic stem cell, or mesenchymal stem cell, that can give rise to cells of the adipogenic, reticular, osteoblastic, myoblastic, and fibroblastic lineages. These stem cells generate progenitors committed to one or more cell lines with an apparent degree of plasticity or interconversion. However, the isolation and characterization of such stem cells has been hampered by the lack of specifically reactive antibodies and the very low incidence of these cells. A wealth of evidence has accumulated detailing the factors that regulate and modulate osteoprogenitor differentiation into the mature osteoblast phenotype using a variety of in-vitro models with different species, which has also served to provide conflicting observations and interpretations as to the fate, function, and physiology of the mesenchymal stem cell and osteogenic progenitor populations. Indeed, to date, we still know relatively little about the phenotypic characteristics, whether from a morphological or biochemical standpoint. In addition, direct in-vivo confirmation of the lineage potential and plasticity or interconversion potential that exists of mesenchymal stem cells and osteogenic progenitor cells remains unclear.

With increasing age, skeletal remodeling is altered with a resultant net bone loss as a consequence of increased trabecular and cortical bone resorption and decreased osteoblast number and bone formation. Bone formation strategies, although attractive, have yet to yield functional and mechanically competent tissues and clinical imperatives to augment and facilitate tissue lost as a consequence of trauma or degeneration, have brought mesenchymal and osteoprogenitor cell biology to center stage. This is due largely to the observation that bone has a tremendous capacity to regenerate from cells with stem cell characteristics. Thus, current approaches have centered on the isolation and expansion of mesenchymal stem cells and osteogenic progenitor cells and the modulation of their phenotype for skeletal repair using cell, gene, and tissue engineering.

This brief article outlines the concepts, properties, and current understanding in mesenchymal stem cell and osteogenic progenitor cell biology and their

potential for clinical application in tissue reconstruction, which could improve the quality of life for many as a result of advances in cell, gene, and tissue engineering.

MESENCHYMAL STEM CELL LINEAGES

Bone marrow serves as a reservoir for a variety of stem cells including the nonadherent, circulating hemopoietic stem cells and, in close contact and supporting the hemopoietic compartment, marrow stromal cells. The marrow stromal stem cell or mesenchymal stem cell exhibits multilineage differentiation capacity and has been shown to generate cartilage, bone, myelo-supportive stroma, adipocytes and fibrous connective tissue (Fig. 1).^[1–3] The capacity of bone to regenerate has long been recognized, and yet, to date, there is only limited evidence for the existence of a pluripotent mesenchymal or marrow stem cell. This is, in large part, due to their low incidence, indeterminate morphology, and, despite nearly three decades of research, undefined biochemical phenotype.

A number of criteria are required before a cell can be termed a stem cell, namely, self renewal, pluripotentiality, and the capacity for cell division maintained throughout life—terms developed from the hemopoietic system. Thus, a stem cell can be defined as a cell that maintains its own numbers (self renewal) in spite of physiological or artificial removal of cells from the population^[4] and that can differentiate into all cell types (pluripotent) or more than one differentiated cell type (multipotent).^[5] In contrast, it is important to note that (osteogenic) progenitor cells may be multipotential but cannot self-renew and thus are intermediate between a stem cell and differentiated progeny (i.e., osteoblast). Apart from a lack of morphological and defined biochemical phenotype, a certain degree of confusion has been generated by the interchangeable use of names for the pluripotent stromal cell that can give rise to osteogenic, adipogenic, fibroblastic, and reticular lineages. These have included osteogenic stem cells, stromal fibroblastic cells,^[6] stromal stem cells coined by Owen and Friedenstein,^[7] mesenchymal stem cells initiated by Caplan and coworkers,^[8] and, more recently, skeletal stem cells.^[9] Currently, mesenchymal stem cells

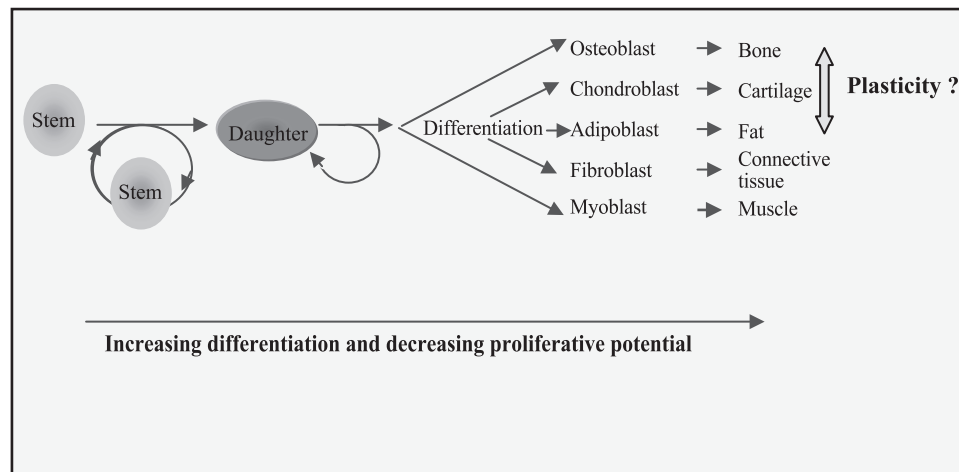

Fig. 1 Differentiation of mesenchymal stem cells from self-renewing stem cells and daughter cells to generate all mesenchymal cell lineages.

(undifferentiated pluripotent cells of the mesenchyme) appear to be the favored term adopted by many workers within the field.

Evidence for an osteoblast stem cell was provided in the early 1960s in seminal studies by Alexander Friedenstein and coworkers. Initial studies showed that bone marrow transplanted under the renal capsule of mice or within an enclosed environment (diffusion chamber) generated osteogenic tissue indicating that marrow contained osteogenic precursors.^[3,10] The mesenchymal stem cell gives rise to a hierarchy of bone cell populations artificially divided into a number of developmental stages including mesenchymal stem cell (MSC), determined osteoprogenitor cell (DOPC), preosteoblast, osteoblast, and, ultimately, osteocyte. However, it is important to note that clear and distinct boundaries between the populations do not exist and these cells exist, in essence, as a developmental continuum.

AGING AND MESENCHYMAL STEM CELLS

Aging is associated with decreased fracture repair and reduced skeletal bone mass as a consequence of a net reduction in bone formation. This can result in osteoporosis with devastating socioeconomic consequences. As indicated, bone formation depends on mesenchymal stem cells present within bone marrow that give rise to colony-forming units—fibroblastic (CFU—F), which differentiate into the osteogenic, adipogenic, fibroblastic, and reticular cell lineages.^[3,10–12] Studies on human osteoprogenitor number and age have been limited and contradictory. Nishida et al.^[13] found that alkaline phosphatase-positive colony-forming

units—fibroblastic (AP+CFU—F) were significantly reduced between 10 and 20 years of age and then gradually after the age of 20. Similarly, D'Ippolito et al.^[14] found a significant decrease with age in AP-positive CFU-F in bone progenitors isolated from human vertebrae. Other workers have recorded decreases in CFU-F colonies or AP+CFU—F in human,^[15] rat,^[16] and mouse^[17] marrow. However, Oreffo et al. in a large study of 99 patients who were osteoarthritic, osteoporotic, or showed no evidence of metabolic bone disease, found no differences in CFU—F or AP+CFU—F with age, disease state, or gender, although a significant decrease in CFU—F colony size was observed.^[18,19] Similarly, Stenderup et al. found the number and proliferative capacity of osteogenic stem cells was maintained during aging and in patients with osteoporosis.^[20] The discrepancies in these various reports may be attributable to different sample population sizes, populations selected, and laboratory protocols used. Nevertheless, the bone loss associated with aging may reflect altered proliferative capacity of progenitor cells or altered responsiveness of CFU—F to systemic or locally released growth factors^[21,22] leading to alteration in subsequent differentiation.

PHENOTYPIC CHARACTERISTICS

To date, there is a paucity of developmental stage-specific markers for mesenchymal stem cells and osteogenic progenitor cells. It is generally accepted that osteoblast is derived from a pluripotent mesenchymal stem cell.^[3,10,11,23,24] A few antibodies do exist and the isolation and expansion of these cells, while retaining

their differentiation ability, has been performed using the following monoclonal antibodies SB-10,^[25] STRO-1,^[26] SH-2,^[27] and HOP-26.^[28] Gronthos and coworkers found the heterogeneity of the stromal cell population could be reduced by isolation using the monoclonal antibody STRO-1, which recognizes a trypsin-resistant cell surface antigen present on a subpopulation of bone marrow cells.^[29] The cells expressing STRO-1 have been found to include predominantly the adherent, high growth potential, colony-forming units—fibroblastic (CFU—F).^[29] However, the epitope for STRO-1 remains to be characterized although the antibody does not bind to myeloid cells, megakaryocytes, or macrophages.^[29] The STRO-1 selected populations have been shown to give rise to osteogenic, fibroblastic, adipogenic, and smooth muscle cells, as well as cells of the osteoblastic lineage. The cells of the osteoblastic lineage, under osteogenic conditions, become alkaline phosphatase-positive, respond to $1,25(\text{OH})_2\text{D}_3$, form mineralized tissue in vitro, and, in vivo, form bone.^[29–31] Beresford and coworkers have shown, using cell sorting, that there is an inverse association between the expression of STRO-1 and alkaline phosphatase.^[30] Pre-osteoblasts or progenitor populations were observed to be STRO-1-positive and alkaline phosphatase-negative, whereas osteoblasts were observed to be STRO-1-negative and alkaline phosphatase-positive.^[30] Epitopes for a number of monoclonal antibodies shown to be reactive with early osteoprogenitor populations have been identified,^[31]—thus SB-10, which has been shown to react with osteoprogenitors at the early stages of differentiation, has been found to react with activated leukocyte-cell adhesion molecule 99 (ALCAM)^[32] and SH-2 with CD105 (Endoglin).^[33] The epitope for HOP-26, derived using human bone-marrow fibroblast cultures, has been shown to be the cell-surface and lysosomal enzyme CD63 or melanoma-associated antigen, a member of the tetraspan glycoproteins.^[34]

Studies from Verfaillie's group have shown that pluripotent mesenchymal stem cells, termed multipotent adult progenitor cells, could be derived from adult marrow by cell sorting, and the phenotype of the human mesenchymal stem cells after extended culture was observed to be CD34, CD44, CD45, c-Kit, and major histocompatibility complex (MHC) class I and II-negative.^[11] These cells have been shown to differentiate not only into mesenchymal cells, but also into cells with visceral mesoderm neuroectoderm and endoderm characteristics in vitro.^[11] Critically, it appeared multipotent adult progenitor cells engrafted in vivo when transplanted into nondamaged recipients. To date, however, issues of cell fusion, nuclear reprogramming and derivation of unique phenotypes in extended culture remain to be resolved in these and

other studies and the phenotype of the human mesenchymal stem cell in vivo is unknown.

PLASTICITY AND INTERCONVERSION POTENTIALS

The multipotentiality of mesenchymal stem cells to form bone cartilage, fat, tendon, and muscle is widely accepted as a key criterion in the definition of these cells. Studies from a number of groups have shown that bone marrow cells can be plated onto tissue culture plastic, and the initial adherent bone marrow-derived stromal colonies are derived from a single mesenchymal stem cell.^[10] These colonies are multipotent and can be induced to form bone, cartilage, and fat by simple manipulation of culture conditions.^[24,35,36] As detailed above, committed progenitors (i.e., restricted in lineage development such as bone under defined conditions) can be identified by functional in-vitro CFU—F assays.^[37] Thus, these stromal colonies retain their multipotentiality in vitro after expansion. Culture in the presence of dexamethasone, methyl isobutylxanthine, insulin, and indomethacin has been found to favor adipogenesis of human bone marrow cells, whereas culture in the absence or presence of serum with TGF β favors chondrogenesis.^[24,35] In contrast, it is well-established that marrow cells cultured in serum with dexamethasone and ascorbic acid favor osteoprogenitor differentiation with enhanced alkaline phosphatase expression, matrix production, nodule formation, and deposition of calcium, confirming the presence of osteoprogenitor cells.^[12,35] With the understanding of defined conditions required to modulate cell phenotype, the potential for cells to switch or differentiate between different phenotypes after considerable differentiation (for example, along the osteogenic lineage to give a mature osteoblast population) has led to the concept of plasticity of phenotype. It has long been known that an association between an increase in marrow adipose tissue and osteopaenia with increasing age and in a variety of experimental and pathological conditions such as disuse osteoporosis and glucocorticoid-induced osteoporosis exists,^[38] suggesting plasticity or interconversion potential between the lineages and that the adipocytic and osteogenic cells share a common lineage. Park et al.^[35] have shown the ability to isolate clonal adipogenic cells and to redifferentiate the cells into osteogenic and adipogenic lineages in vitro, while Nuttall and coworkers^[39] have shown the potential of human bone cells to transdifferentiate along the adipogenic lineage. All of these manipulations in-vitro remain to be conclusively demonstrated in vivo and the extent and physiological relevance of cell plasticity remains unclear although undeniably

clinically attractive from a tissue-engineering and -repair perspective.

DIFFERENTIATION AND PROLIFERATION—GROWTH FACTORS

A number of growth factors have been shown to affect mesenchymal stem cell and osteoprogenitor cell activity, although it is important to note culture conditions (e.g., serum-free vs. serum) and species studies (human marrow vs. mouse marrow or rat calvarial-derived populations) play a significant part in the response/interpretation observed. It is beyond the scope of this short article to cover all the regulatory factors implicated in control of mesenchymal stem cell and osteoprogenitor differentiation, but several key factors emerge in the differentiation and proliferation of mesenchymal stem cells and osteoprogenitor cells. In general, the information that follows will concentrate on data from human systems.

Transforming growth factor beta (TGF β) and other members of the TGF β superfamily, including the bone morphogenetic proteins, play a significant role in the induction and differentiation and modulation of osteoprogenitor cells.^[40,41] TGF β has complex biphasic actions on progenitors and on their differentiation. This matrix protein has been shown to act on committed or determined osteogenic precursors to stimulate proliferation and chemotaxis to generate populations of committed osteoblast cells.^[42] Locklin and coworkers showed TGF β in the absence of serum-promoted cell growth and alkaline phosphatase activity while in the presence of serum-matrix proteoglycan synthesis, and collagen synthesis was increased in human bone-marrow stromal fibroblasts.^[43] In addition, in the same model system, TGF β inhibited dexamethasone-induced adipogenesis. More recently, Walsh and coworkers found TGF β 1 limited the expansion of the osteoprogenitor fraction of human bone-marrow cells with significantly reduced alkaline phosphatase expression.^[44]

The BMPs, which like the TGF β s are sequestered within bone matrix, play a pivotal role in the initiation of mesenchymal stem cells or inducible osteogenic precursors into the osteoblast lineage (Fig. 2).

BMP-2, BMP-4, and BMP-7 have been shown to induce the mouse pluripotent fibroblast cell line C3H10T1/2 and mouse 3T3 cells to differentiate into osteoblasts, chondroblasts, and adipocytes.^[45] Similarly, Rickard et al.^[46] have shown that BMP-2 can induce osteoblast differentiation in rat bone-marrow cell cultures. In addition, differential roles for BMP receptor type IB and IA in the differentiation and specification of mesenchymal progenitor cells to either osteoblasts or adipocytes have been demonstrated by Chen and coworkers.^[41]

Gronthos and Simmons examined the growth factor requirements of selected (STRO-1) human bone-marrow stromal precursors in serum-deprived conditions in vitro and found from 25 purified recombinant growth factors examined that platelet-derived growth factor (PDGF) and epidermal growth factor (EGF) were able to initiate and support clonogenic growth of CFU—F while IL-4 and INF α inhibited colony formation.^[47] In a later study, Kuznetsov and colleagues found the initial proliferation of human and mouse marrow stromal fibroblast colony formation required at least four growth factors: PDGF, bFGF, TGF β , and EGF with differing requirements between mouse and human marrow stromal fibroblasts.^[48] More recently, Oreffo and coworkers showed INF α inhibited human osteoprogenitor cell proliferation, CFU—F formation, alkaline phosphatase expression, and HOP-26 expression, as well as modulating BMP-2 expression.^[49]

A number of studies indicate basic FGF and the glucocorticoids are potent mitogens for marrow stromal fibroblasts. FGF-2 was found to increase colony size and colony number of human stromal cells markedly although colony formation was unaffected.^[50] Furthermore, it appears FGF-2 acts on early osteogenic progenitors, possibly maintaining cells in an immature state, as in combination with the synthetic glucocorticoid dexamethasone, and further cell

Fig. 2 Differentiation of mesenchymal stem cells and daughter cells to generate bone and cartilage and site of interaction of crucial factors such as BMPs in initiating osteogenesis. The particular stages of differentiation and sites of factor interaction are imprecisely known.

maturation was observed.^[51] In vitro, dexamethasone has been shown in rat, mouse, rabbit, and human marrow stromal cultures to stimulate osteoprogenitor cell differentiation,^[43,52–57] although the known effects of glucocorticoid-induced osteoporosis and impaired fracture repair remain confounding issues.

Other factors of note include 1) PGE₂, which may act to promote osteogenesis by the recruitment of osteoprogenitor cells from the nonadherent mesenchymal precursor cells in bone marrow acting possibly via EP2 receptors,^[58–61] 2) Pleiotrophin (PTN), an extracellular matrix-associated protein, which has been found to induce human osteoprogenitor chemotaxis, proliferation, differentiation, and bone formation,^[62,63] and 3) osteoclastotropic/bone remodeling factors Il-1, Il-6, GM-CSF, and M-CSF, which have all been implicated in the modulation of osteoprogenitor proliferation and differentiation.^[64–66]

Ultimately, delineation of the growth factors and hormones required for human mesenchymal stem cells and osteoprogenitors will be needed to generate protocols for the rapid expansion, ex-vivo, of these cells (using autologous serum) while retaining their differentiation potential for tissue-engineering/regeneration applications.

STEM CELLS, GENES, AND TISSUE ENGINEERING—BONE REGENERATION AND RESTORING AGING BONES

Developments in cell and gene engineering indicate it may be possible to use osteoprogenitor cells for therapeutic use in skeletal and hemopoietic diseases. Tissue loss as a result of injury or disease, in an increasing, aging population, provides reduced quality of life for many at significant socioeconomic cost.^[67] Healthcare costs in treating patients with bone fractures, in the U.K. alone, have been estimated at £1.7 billion.^[68] With an increasing, aging population, these health costs are set to rise. To date, artificial prostheses, which are subjected to wear due to lack of integration, ultimately fail and while joint replacement surgery in rheumatoid arthritis, osteoarthritis, and osteoporosis has significantly improved the quality of life for many, biomaterial failure and incompatibility and problems with detachment of the stem coating and/or fracture of the cement–stem or cement–bone interface^[69] have led to intense research activity to exploit the potential of mesenchymal stem cells and osteoprogenitors in bone repair and regeneration.^[9,10,70] It should be noted that at present, regimes that encourage bone formation, which hold the promise of significantly increasing bone density, have yet to reach the clinic.

Each year in the U.K. there are some 150,000 fractures (wrist, vertebral, and hip) due to osteoporosis. In

particular, hip fracture is associated with high morbidity and mortality with fewer than half the patients returning home after surgery. Moreover, 30–50% of these hip operations will require subsequent revision surgery and, in a significant proportion, bone augmentation will be necessary. The lack of techniques and approaches in reconstructive surgery emphasize the number of clinical applications that would benefit from the use of mesenchymal stem cells and osteoprogenitors to augment bone formation.^[9,70] The field of tissue engineering seeks to resolve these issues through a combination of stem or progenitor cells with appropriate growth factors and tailored scaffolds. Thus, tissue engineering has been defined as the application of scientific principles to the design, construction, modification, and growth of living tissues.^[71] With regard to a source of progenitor cells, it has long been known that bone has a vast capacity for regeneration from cells with stem cell characteristics. Kadiyala and coworkers have shown that culture-expanded bone marrow cells can heal a segmental bone defect following reimplantation.^[72] A number of studies indicate mesenchymal stem cells and osteoprogenitor populations from a variety of species, including human mesenchymal stem cells, can give rise to osteogenic tissue within diffusion chambers.^[73–75] As detailed previously, human bone marrow osteoprogenitors can be isolated and enriched using selective markers, such as STRO-1, from a CD34+ fraction^[76,77] and readily expanded, indicating their potential for marrow repopulation.^[10,28,78,79] Furthermore, the lack of immunogenicity of mesenchymal stem cells^[80] has opened up the potential of these cells in cartilage and bone repair. Although true engraftment of human mesenchymal stem cells, long-term biological effects on the stem cells at the implant site, and issues of cell plasticity remain unknown, preliminary studies from Horwitz and colleagues^[81] using human bone marrow-derived osteoprogenitors transplanted into children with osteogenesis imperfecta suggest some therapeutic effect.^[82] The authors reported that donor-derived mesenchymal stem cells (albeit 2%) were capable of homing to the bone marrow and differentiating into osteoblasts. In follow-up studies an increase in bone mineral content was observed compared to age-matched controls although the precise contribution of the donor cells to the clinical improvements recorded remains to be determined.^[83] Other workers, Connolly^[84] and recently Quarto and coworkers^[85] have indicated the efficacy of autologous bone marrow stromal cells in the treatment of large bone defects. Although mesenchymal stem cell/osteoprogenitor delivery, whether by injection or with a matrix, is attractive and carries a reduced risk of morbidity, for large skeletal defects, these cells will need an appropriate, designed or smart vehicle/scaffold/matrix tailored to the shape and size of

the defect that will provide mechanical competence. To aid this process, advances in scaffold technology and gene delivery offer the possibility of genetic modification of isolated and expanded cells in constructs to produce populations of progenitor cells over-expressing selected signaling molecules for bone regeneration.^[9,83,86-88] Lieberman and coworkers have shown regional cell and gene therapy using BMP-2-producing bone marrow cells on the repair of segmental bone defects in rats.^[89] Similarly, Breitbart and colleagues have cultured periosteal cells retrovirally transduced with BMP-7 in a polyglycolic-acid scaffold in a critical-sized calvarial defect model in rabbits.^[90] Several studies indicate human bone marrow stromal cells expressing BMP-2 by adenoviral infection may prove efficacious in bone regeneration (Fig. 3).^[31,91-93]

Musgrave and coworkers^[94] reported on the use of direct adenoviral-mediated gene therapy to deliver active BMP-2 and produce bone in skeletal muscle, thus circumventing problems associated with delivery of BMP-2 and the requirements for cell expansion. However, limitations associated with immunogenicity *in vivo*, the fate of adenoviral cells, long-term safety, and the requirement for cell expansion in culture prior to viral infection and reimplantation remain significant hurdles before clinical use.

A variety of materials have been used for bone regeneration with mesenchymal stem cells and osteoprogenitors including ceramics or materials based on hydroxyapatite, ceramic forms of β -tricalcium phosphate, and composites of both hydroxyapatite and β -tricalcium phosphate.^[88] However, these materials are not osteoinductive and are resorbed relatively slowly *in vivo*. In addition, developments in recent years have sought to exploit and mimic biological cues that are necessary to mimic the cell-bone matrix interactions with the generation of biomimetic scaffolds.^[95] The development and use of synthetic materials such as poly(lactic acid) (PLA) poly(lactic-co-glycolic acid)

(PLGA), polyglycolic acid (PGA), polyanhydrides, polyimides, and polyphosphazenes, which can be surface-modified with biological agents, has made the development of such biomimetic scaffolds a realistic objective (e.g., Fig. 4).^[95,96] These synthetic materials, approved and widely used in the formation of resorbable sutures, scaffolds, and drug delivery devices, are 1) biocompatible, 2) processable into a three-dimensional structure and, 3) eventually degradable. Healy and coworkers^[97] and Dee and coworkers^[98] have reported on the ability to modulate the adhesion of osteoblasts selectively and significantly by immobilized -Arg-Gly-Asp- (-RGD-) and -Phe-His-Arg-Arg-Ile-Lys-Ala- (-FRRRIKA-) and Lys-Arg-Ser-Arg peptides (KRSR). Recently, Yang et al. have shown the potential to promote human osteoprogenitor differentiation on RGD-coupled biodegradable scaffolds.^[99] Continued advances in gene delivery combined with development of smart designer scaffolds and materials in combination with selection of mesenchymal stem cell and osteoprogenitor populations are needed to deliver on the promise of tissue engineering for skeletal repair.

FUTURE PERSPECTIVES AND SUMMARY

Given the demographic challenge of an aging population, developments in our understanding of mesenchymal stem cell and osteoprogenitor biology are paramount. From a patient's perspective, the ultimate goal will remain the utilization of mesenchymal stem cells and osteoprogenitors in simple, safe, and reproducible strategies for the augmentation of bone, cartilage, and tendon repair to address the pressing orthopedic clinical imperatives of many. Tissue engineering could provide suitable, efficacious, alternative therapies for orthopedic applications and is attractive on a number of fronts: 1) The ability to engineer tissue *in vitro* for transplantation would reduce

Fig. 3 Bone formation using selected and genetically modified osteoprogenitors. A) Cultures of adherent STRO-1+ cells immunostained using FITC conjugate and ethidium bromide nuclear stain ($\times 50$). B) Growth of STRO-1+ osteoprogenitors transduced with adenoviral BMP-2 and grown on PLA scaffolds demonstrating extensive penetration, colonization, and growth ($\times 25$). C) Alcian blue/sirius red-stained sections of STRO-1-selected cultures transduced with adenoviral BMP-2 and implanted *in vivo* demonstrating extensive new bone formation and organized collagen formation ($\times 25$).

Fig. 4 Bone formation in vivo (A) and in vitro (B, C) using human osteoprogenitor cells on PLA scaffolds. the requirement for donor tissue, as the number of skeletal cells required could be expanded ex vivo prior to implantation, 2) treatment of diseased tissue at an early stage with mesenchymal stem cells could alleviate or even cure the disease, reducing the need for life-long treatment and improving the quality of life of the patient. Thus, cell delivery vehicles, composite tissue engineering protocols, and smart materials that can orchestrate the bone formation cascade will all undoubtedly have their place. However, it is clear that many strategies are unlikely to reach clinical evaluation for the most basic of structural, biological, or safety issues and that this discipline is still in its infancy. Nevertheless, the ability to select, expand, and differentiate these cells and the potential for ex vivo gene transfer suggests the potential future use of human osteoprogenitors for gene therapy of metabolic bone diseases. Clearly, harnessing the homing potentials of such cells and channeling their development into the required human tissues for regeneration is a significant challenge, and it will be necessary to gain a greater understanding of the continuum of cell development of mesenchymal stem cells to osteoprogenitor to preosteoblast and ultimately osteocyte and the role of the matrix microenvironment and factors that control their fate and plasticity. While development pathways are clearly delineated from in vitro observations, their relevance in vivo and the extent of physiological population modulations (adipocyte to osteoblast, for example) are unclear. Ultimately, the need to define the phenotype of the mesenchymal stem cell, to generate a phenotypic finger print, will enable

isolation and expansion of populations for clinical use, which ultimately may improve the quality of life for many as a result of strategies to augment skeletal regeneration.

Work in the author's laboratory is supported by grants from the BBSRC, EPSRC, and Research into Ageing. The work presented and many useful discussions are derived from all at University Orthopaedics: Daniel Howard, Rahul Tare, Xuebin Yang, David Green, Kris Partridge, Nicholas Clarke, and Trudy Roach, as well as fruitful collaborations with Professors Shakesheff and Howdle (University of Nottingham), Professor Mann (University of Bristol) and Dr. Julian Chaudhuri (University of Bath). The author apologizes to those authors whose valuable work it was not possible to cite due to restrictions of space.

INTRODUCTION

The meaning of scientific technical terms changes from time to time, depending on progress in the field. Osteoinduction in the field of biomaterials is one example. In dictionaries of biomaterials, osteoinduction is defined as the “act or process of stimulating osteogenesis.” In this article, the authors define osteoinductive substances and materials as biological molecules such as proteins, cytokines, etc., as well as materials that induce bone formation. This does not include osteoconductive substances and materials, such as hydroxyapatite. In this article, representative osteoinductive substances and materials are described.

OSTEOINDUCTIVE SUBSTANCES

BMP (Bone Morphogenetic Protein)

BMPs are multifunctional, low-molecular weight proteins belonging to the extended transforming growth factor superfamily.^[1] In 1965, Urist isolated an osteoinductive extract from adult bone, which can induce new endochondral bone formation at ectopic sites in rodents.^[2] Currently, several BMPs are known to belong to the TGF- β (transforming growth factor β) superfamily. Members of the BMP subfamily show a pattern of seven conserved sequences in the mature protein. Mature BMP proteins are synthesized as precursor molecules, which are processed to approximately 30 kDa dimers before their secretion from the cells. The BMP family express their function by binding to transmembrane serine/threonine kinases that are named type I and type II receptors. BMPs can bind to type I and type II receptors, but the affinity is low. However, when both receptors exist, BMPs bind strongly. The binding of BMPs to the receptors is regulated by extracellular antagonists that bind to BMP and prevent BMP from binding to the receptor. Representative antagonists are noggin, GDF5, GDF6, chordin, and follistatin. Osteogenic activities of BMPs

have been demonstrated using ectopic and orthotopic implantations, which indicates BMP-2, 4, 5, 6, 7, and 9 are osteogenic molecules.^[3-6] A basic understanding of BMP functions has been achieved.^[7,8] In this section, the clinical utility of BMPs is focused on.

First of all, osteoinductive BMPs are expected to be clinically useful for orthopedic surgery. This is because only small amounts of osteoinductive BMPs are necessary for producing substantial amounts of bone. Osteoinductive BMPs such as BMP-2 and BMP-7 were found to heal large defects in rats, rabbits, dogs, and monkeys using the large, segmental long bone defect model.^[9] Results confirmed the potent osteoinductive ability and demonstrated that BMP induced the formation of bone intimately associated with preexisting surrounding bone and remodeled depending on its location. The spinal fusion procedure utilizes a large amount of autogeneous bone graft and provides a case for the application of BMP as a bone graft substitute. RhBMP-2 (recombinant human bone morphogenetic protein-2) and RhBMP-7 have been successfully examined in preclinical animal models of the intertransverse process and interbody fusion.^[10-13] Clinical studies utilizing spinal fusion applications are underway.

Osteoinductive BMPs are potential mediators of fracture repair when sufficient repair cannot be expected. Studies have demonstrated that BMP-2 and BMP-7 accelerated fracture repair in rabbit, goat, and dog models.^[14-17] Clinical studies are also in progress.

Several studies have used demineralized dentin powder, which is like demineralized bone powder and will be described later in this article. Demineralized dentin implanted into dental pulp induced mineralized tissue formation.^[18-21] Although it is known that BMPs induce dentinogenesis, the mode of action and molecular understanding of dentin BMP is not very well understood. However, recombinant BMPs are expected to induce dentinogenesis. Recently, Nakashima reported that recombinant BMP-2 and BMP-4, but not TGF- β , induced reparative dentinogenesis in dogs when placed on partially amputated dental

pulps.^[22] Similar results were obtained using recombinant human BMP-7.^[23,24] For utilizing osteogenic BMPs, bioresorbable collagen matrices are usually chosen as a delivery substance. However, a biodegradable, synthetic polymer delivery system may prove to be a more useful tool.

Recently, BMP gene therapy has attracted much attention in orthopedics and the tissue engineering field. The BMP gene is introduced directly into the body or into cells and is then followed by *ex vivo* infection and reintroduction into the body. Adenoviral vectors carrying BMP-2, BMP-7, and BMP-9 have been used directly in animal models for enhancing fractures and promoting spinal fusion.^[25–29]

Bone Proteins

Collagen type I, osteopontin (OPN), BSP (bone sialoprotein), osteocalcin, and osteonectin are typical bone proteins in bone matrix, which regulates bone metabolism.^[30] Among them, OPN is not only a differentiation marker of osteoblasts but also a regulating molecule of osteoblasts. OPN is a highly acidic secreted phosphoprotein that binds to cells via an RGD cell adhesion sequence that recognizes $\alpha_v\beta_3$ integrin. The signal transduction pathway of OPN-integrin binding in osteoblasts was studied by our group regarding osteoblast differentiation.^[31–36] The production and autophosphorylation of FAK (focal adhesion kinase), the expression of alkaline phosphatase (ALP) at the transcription level, and their kinetics were examined through OPN-integrin binding compared with collagen type I and integrin binding. Results suggested that the OPN acts as a trigger in the early differentiation of osteoblasts. In this regard, OPN is categorized as an osteoinductive substance. We examined the effect of a coating of OPN on the hydroxyapatite (HA) scaffold for a cultured bone transplantation model.^[37] According to the method of Yoshikawa et al., we subcutaneously implanted OPN-coated HA/bone marrow-derived osteoblast constructs and noncoated constructs (control) into Fischer rats. At 18, 32, and 46 days after implantation, the marrow cell/HA constructs were harvested, and their ALP activities were measured. The ALP activity of the marrow cells/OPN-coated HA construct showed a similar maximum at around 18 days with 40% higher activity than the control group (marrow cells/noncoated-HA). This indicated that the OPN coating resulted in greater bone formation with the marrow cell/HA construct *in vivo*. This result means that OPN activates osteoblast differentiation for bone formation. On the other hand, secreted OPN on HA inhibits further growth of HA.^[38] These properties of OPN might regulate the HA formation *in vivo* in a complex way.

Phosphophoryn

The process of mineralization in vertebrates involves a sequential and localized series of events that leads to the formation and growth of carbonate containing apatite mineral within an organic matrix. The matrix network into which the mineral of bone, dentin, and cementum is deposited is primarily type I collagen.^[39] Acidic, noncollagenous components of the matrix directly associated with the collagen network are thought to regulate collagen mineralization.^[40] This regulation includes control of the nucleation and the postnucleation growth of the crystals and the structural organization of the tissue. Several of the noncollagenous components might have more than one function in the regulation of mineralization.^[41,42] Notably, dentin phosphoprotein (phosphophoryn), a synthetic product of the odontoblast, is accumulated at the mineralization front of the dentin matrix and is strongly associated with the mineral phase.^[43] It has high affinity to calcium ion at physiological pH.^[44] Moreover, it binds about 1.5 additional calcium ions in the presence of phosphate ion.^[45]

The pattern of mineral deposition in dentin is correlated with the structure of the collagen fibrils.^[46] Therefore, one would expect that a mineral nucleator would have a strong association with the collagen fibrils of dentin and have a fixed distribution on the fibrils. Stetler-Stevenson and Veis^[47] found that phosphophoryn binds to collagen molecules and the surface of type I collagen fibrils from skin but not to heat-denatured collagen. The phosphoprotein from egg yolk, phosvitin, competed with phosphophoryn to bind to collagen, but other phosphoproteins such as bovine serum albumin, fibronectin, and osteonectin did not. The bound phosphophoryn enhanced the binding of calcium to collagen fibrils and was considered to have the potential to nucleate apatite crystals oriented with respect to the collagen fibrils. Electron microscopic observations showed that phosphophoryn is adsorbed by collagen fibrils near the gap region and might regulate mineral deposition in the gap region of collagen fibrils.^[48] Fujisawa and Kuboki^[49] confirmed that phosphophoryn bound to type I collagen fibrils from skin, but they found that the phosphoprotein also bound to heat-denatured collagen and that calcium sharply reduced the amount of bound phosphophoryn.

Recently, we established an *in-vitro* mineralization system.^[50–52] First, bovine phosphophoryn was immobilized on reconstituted skin type I collagen fibrils or agarose beads by adsorption or covalent cross-linking. In some samples, the ester phosphate was removed from the covalently cross-linked phosphophoryn by treatment with acid phosphatase. All samples were incubated at 37°C in metastable solutions that do not spontaneously precipitate. Reconstituted

Fig. 1 Mineral formation on phosphophoryn cross-linked to agarose beads.

collagen fibrils alone did not induce mineral formation. The phosphophoryn adsorbed by the agarose beads or the collagen fibrils was desorbed when the mineralization medium was added, and mineral was not induced. The mineral induced by the cross-linked phosphophoryn was confirmed as apatite from the X-ray diffraction pattern, and the crystals were confined to the surface of the agarose beads (Fig. 1) or the collagen fibrils (Fig. 2).^[50,51] With decreasing medium saturation, the time required for mineral induction increased.^[51] The interfacial tensions calculated for apatite formation by immobilized phosphophoryn was about the same as that found for phosphatidic acid liposomes. This similarity in values for the interfacial tension might indicate that the nucleation potential of each of these highly phosphorylated organic surfaces is the same.^[50,51] We concluded that phosphophoryn must be cross-linked to collagen for the mineralization of the collagen fibrillar network in solutions that do not spontaneously precipitate. The phosphate esters of phosphophoryn are required for mineral induction, and the carboxylate groups of phosphophoryn are not sufficient.

Fig. 2 Mineral formation on phosphophoryn cross-linked to collagen fibrils. Bar = 0.5 μm .

On the basis of the above study, we expected the phosphophoryn/collagen composites to be a good scaffold for bone tissue engineering and examined the formation of bone in orthotopically transplanted phosphophoryn/collagen and bone marrow osteoblast composites in Fischer rats.

Osteoblastic primary cells were obtained from the bone shaft of femorae of 344 seven-week-old male Fischer rats, according to the method of Maniatopoulos et al.^[53] The cell suspension of marrow cells was distributed through a T-75 flask with 15 ml of standard culture medium and incubated at 37°C in a humidified atmosphere containing 95% air and 5% CO₂. When culture dishes were near to confluent, after 10 days, they were treated with 0.1% trypsin and then concentrated by centrifuge to 10⁶ cells/ml and sub-cultured onto the synthesized phosphophoryn/collagen sponge and collagen sponge (control). After 14 days in culture with standard medium supplemented with 10 nM Dexamethasone, 10 mM β -glycerophosphate, and 50 $\mu\text{g/ml}$ ascorbic acid, the composites of phosphophoryn/collagen and osteoblastic cells and control composites were transplanted into holes that were 2 mm in diameter in the bone of Fischer rats. Then, the wounds were sutured. The composites were harvested at one, two, six, and eight weeks after implantation, fixed with 4% paraformaldehyde and 0.25% glutaraldehyde, decalcified, embedded in paraffin, and stained with hematoxylin and eosin.

Results clearly showed that more bone formed in the phosphophoryn/collagen sponge and osteoblasts composites than control composites from one week to eight weeks,^[54] which suggests that the phosphophoryn/collagen sponge is a good candidate as a scaffold for bone tissue engineering.

OSTEOINDUCTIVE MATERIALS

Bioglass

Bioglass in the Na₂O–CaO–SiO₂–P₂O₅ system is a bioactive material that has been clinically used as an important bone substitute.^[55] Bioglass and bioglass-type glasses have gained over a million successes in periodontal bone repair.^[56] As the clinical application of bioglass progresses, its limited mechanical properties are becoming apparent. Currently, several studies are under way to improve this mechanical weakness (e.g., Kokubo et al.^[57]).

Demineralized Bone

Osteogenesis can be induced in experimental animals using demineralized matrix of bone or dentin.^[2,58,59]

Mulliken and Growacki showed that demineralized human bone induced osteogenesis in the rat.^[60] When implanted into subcutaneous sites, the demineralized bone matrix causes connective tissues to produce endochondral bone.^[58,61] Furthermore, demineralized bone powder can bridge large defects in long bones in rats.^[62] Demineralized bone implants were examined for craniofacial,^[63] maxillofacial,^[64] periodontal,^[65] and phalangeal^[66,67] defects. Thus, demineralized bone has applications for several bone defects.

Biodegradable Ceramics

Calcium phosphates, which are used clinically in orthopedic surgery, have attracted attention as bone substitutes due to their good biocompatibility and osteointegrative properties.^[68–77] The application of hydroxyapatite (HA) for this purpose has the advantage of stability and maintenance of compressive strength, especially when block-shaped implants are used.^[69] However, the use of a rigid nonresorbable HA for skeletal reconstructions is associated with potential long-term interference with mechanical stress and strain in load-bearing areas. Furthermore, HA cannot be replaced by new bone. Therefore, a fracture might occur either in the HA itself or at the interface with the host bone. The clinical application of HA has thus been restricted due to its poor absorbability and brittleness. Consequently, a degradable material that can eventually be replaced by bone tissue is needed for bone repairs. A suitable macroporous structure is important to obtain good implant incorporation through rapid vascularization and bone ingrowth.^[78–80]

Recently, porous tricalcium phosphate (TCP) has been attracting attention due to its good biodegradability and biocompatibility.^[71,75,77,81] However, while some reports on biodegradable porous TCP alone implanted at extraskeletal sites suggest that degradation occurred quickly with no formation of bone,^[70,72] at least one study on porous TCP implanted at skeletal sites found that the bone that formed during the initial stages was resorbed later on so that bone repair after one year was not significantly enhanced.^[82] Moreover, some solid β -TCPs have been reported to be completely resorbable at skeletal sites; although they were not porous but granular.^[76,83]

Owing to the rapid degradation and weak mechanical properties of TCP, much research has focused on mixed calcium phosphates (mixtures of TCP and HA or TCP and polymer).^[73,77,79,84–88] However, the purity of β -TCP also influences bone formation and biocompatibility.^[89]

To try to overcome these difficulties, a highly pure porous β -TCP was manufactured as an implantable material, Osferion. This biodegradable β -TCP was

combined with bone marrow-derived osteoprogenitor cells (BMO) and cultured in osteogenic medium in vitro. We hypothesize that this composite of β -TCP and BMO could improve bone formation and slow down the degradation of β -TCP. The results are shown in the following section.

Application of Porous β -TCP for Bone Tissue Engineering

In this section, our application of porous β -TCP for bone tissue engineering is introduced. A schematic diagram of a cultured bone transplantation model is shown in Fig. 3. The cultured bone transplantation is clinically important; however, several problems remain to be solved before any clinical applications. First of all, appropriate materials are necessary for cell scaffolding. Our study focuses on the improvement of

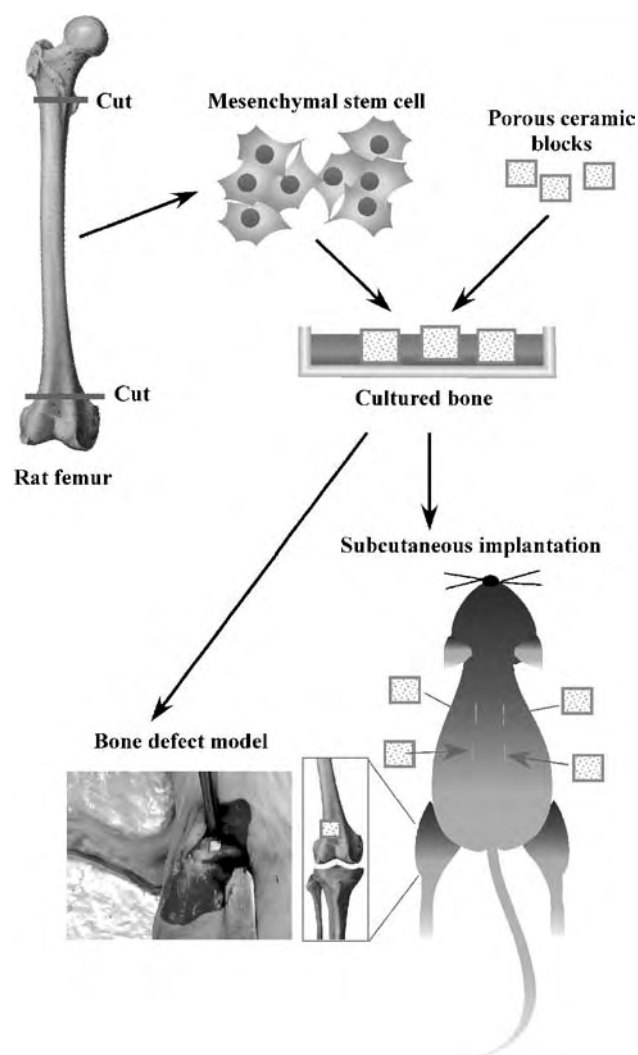

Fig. 3 Schematic diagram of cultured bone transplantation model.

Fig. 4 HE (a,c) and TRAP (b,d) staining of subcutaneously implanted (a,b) and orthotopically implanted (c,d) β -TCP and BMO composites at eight weeks postimplantation.

scaffolds and the in-vitro culture method. Several kinds of porous ceramic scaffolds have been examined for this transplantation. For clinical usage, the ideal scaffold would be a porous ceramic material not only with good biocompatibility and osteointegrative properties but also with high mechanical strength and high biodegradability. Some ceramics have the former two properties; however, no porous scaffolds satisfy both of the latter two properties. We combined blocks of porous β -TCP with rat BMO to obtain TCP/BMO composites. The composites were cultured in osteogenic medium for two weeks and then implanted at subcutaneous sites in syngeneic rats. After implantation, the composites were harvested and prepared for biochemical, histological, and biomechanical analysis. We examined the methodology, the ability of bone formation, absorbability, and biomechanical properties of the TCP/BMO composite. We also evaluated this β -TCP porous material as a scaffold for bone tissue engineering.

Alkaline phosphatase activity and osteocalcin content were maintained at high levels for at least 16 weeks. In the light microscopic analysis, decalcified sections stained with HE showed immature bone had formed in some pores of the implant at two weeks postimplantation. At four weeks, areas of mature bone existed in the pores. At eight weeks, the amount of mature bone had increased in the pores. Fig. 4 shows the HE-stained and TRAP-staining of subcutaneously implanted composites and orthotopically implanted composites at eight weeks postimplantation. Blood vessel formation was observed, which supported bone formation. Rich bone formation was observed in the pores. At the same time, TRAP-positive osteoclasts were observed, which suggested a rapid remodeling is under way. These results also suggest that the β -TCP

porous materials are good candidates for scaffolds in bone tissue engineering. The most serious problem for clinical application is the mechanical weakness of β -TCP porous materials with 2 MPa of compressive strength. Many orthopedic surgeons have doubts over clinical applications due to the rapid degradation of β -TCP in vivo. In some reports, it is suggested that bone formation cannot follow the degradation of β -TCP. However, this difficulty proved to be overcome by tissue engineering treatment of the β -TCP materials. The compressive strength of β -TCP/BMO before implantation was weak at 2.25 MPa; however, it had improved to 4.92 MPa at 12 weeks postimplantation. Moreover, it reached 11.2 MPa at 24 weeks postimplantation. These results suggested that tissue engineering treatment using porous β -TCP increased the mechanical strength of the composites in vivo.^[90]

Particulate Matter and Host Reactions

Edward M. Greenfield

Department of Orthopedics, Case Western Reserve University, Cleveland, Ohio, U.S.A.

INTRODUCTION

Wear particles from orthopaedic implants stimulate a local inflammatory process that induces proresorptive cytokine production, osteoclast differentiation, bone resorption, osteolysis, implant loosening, pain, loss of implant function, and, ultimately, the need for revision surgery. This review will focus on four aspects of the host reaction to the particles: first, the role of particles themselves compared with other factors, including implant motion, mechanical forces, fluid pressure, and bacterial endotoxins; second, the ability of macrophages and other cell types to detect the particles; third, the actions of osteoclasts and osteoblasts as effector cells; and fourth, future directions for research in this area. The 12 major conclusions of this review are that: (i) wear particles are the primary inducers of aseptic loosening; (ii) the effects of the wear particles are increased by other factors, including implant motion, mechanical forces, fluid pressure, and bacterial endotoxins; (iii) the most important type of wear particle in an individual patient is likely to be the type that is the most abundant; (iv) the macrophage is the primary cell type that detects and responds to the wear particles; (v) the wear particles activate multiple signal transduction pathways in the macrophages; (vi) the wear particles induce macrophages to produce proinflammatory cytokines [tumor necrosis factor- α (TNF- α), interleukin (IL)-1, IL-6, etc] that synergistically induce osteoclast differentiation and osteolysis; (vii) the primary role of fibroblasts and other mesenchymal cells in aseptic loosening is to produce proresorptive cytokines [RANKL and macrophage colony stimulating factor (M-CSF)] in response to the proinflammatory cytokines produced by the macrophages; (viii) lymphocytes likely do not play a major role in aseptic loosening except, perhaps, in a subset of patients with metal sensitivity; (ix) increased osteoclast differentiation is the primary cause of osteolysis; (x) decreased bone formation plays an important, but secondary, role in aseptic loosening; (xi) a better understanding of the genetic regulation of aseptic loosening may lead to better methods for identifying higher risk patients; and (xii) approaches to accelerate osseointegration or to inhibit bacterial growth, wear particle migration, or osteoclast differentiation are promising future directions that deserve further study.

BACKGROUND

Wear particles are the primary cause of aseptic loosening of orthopaedic implants.^[1,2] Aseptic loosening, a major problem in clinical orthopaedics, is defined as loosening, in the absence of clinical or microbiological evidence of infection, owing to osteolysis or local bone loss. The overall process is summarized in Fig. 1. Motion between the implant components generates metallic and polymeric wear particles. The most abundant type of particle in most patients is ultrahigh molecular weight polyethylene (UHMWPE) derived from the bearing surfaces. Although the rate of generation of these particles will likely be reduced by the recent development of cross-linked UHMWPE, aseptic loosening will likely remain a major problem because cross-linking does not eliminate the production of wear particles^[3] and, in fact, leads to the production of smaller, more biologically active, particles.^[4] Moreover, many other sources of wear particles exist, including third-body wear, impingement, backside wear, polymethylmethacrylate bone cement, hydroxyapatite coatings, corrosion, fretting, misalignment, and Morris tapers.^[1]

The wear particles stimulate a local inflammatory process that induces proresorptive cytokine production, osteoclast differentiation, bone resorption, osteolysis, implant loosening, pain loss of implant function, and, ultimately, the need for revision surgery (Fig. 1). This review will focus on four aspects of the host reaction to the particles: first, the role of particles themselves compared with other factors, including implant motion, mechanical forces, fluid pressure, and bacterial endotoxins; second, the ability of macrophages and other cell types to detect the particles; third, the actions of osteoclasts and osteoblasts as effector cells; and fourth, future directions. For details on other aspects of the process, readers are referred to other recent reviews.^[1,2,5,6]

THE ROLE OF PARTICLES AND OTHER FACTORS

Many types of studies have led to the consensus that wear particles that are phagocytosable (i.e., $<10\mu\text{m}$ in size) initiate aseptic loosening of orthopaedic

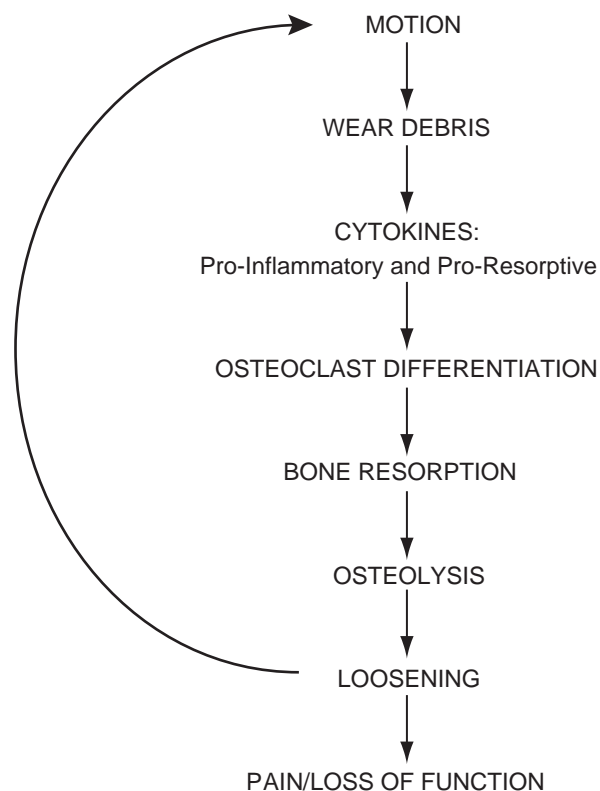

Fig. 1 Overview of the aseptic loosening process.

implants.^[1,2] Moreover, the rate of UHMWPE wear correlates with the risk of aseptic loosening.^[7,8] Despite the importance of wear particles in stimulating implant loosening, it is likely that other factors also contribute to the process.^[6] For example, a number of studies have shown that implant motion, mechanical forces, fluid pressure, and bacterial endotoxins can increase the biological responses induced by wear particles.^[6] We have been especially interested in the potential role of bacterial endotoxins in aseptic loosening.^[6] Although this might seem to be a contradiction in terms, aseptic loosening is defined as osteolysis in the absence of clinical or microbiological evidence of infection, which does not exclude a role for subclinical levels of infection or for molecules derived from bacteria located in other sites in the body. The three most likely sources of bacterial endotoxins during aseptic loosening are the implants themselves; systemic endotoxin derived from gut flora, minor infections, or dental procedures; and the bacterial biofilm found on many implants retrieved from patients with aseptic loosening. Of these three possibilities, the bacterial biofilm is likely to be quantitatively most important.^[6]

Although the most abundant type of particle in most patients with aseptic loosening is UHMWPE, numerous particles can also be generated from the polymethylmethacrylate bone cement and the metallic components of the implants (Fig. 2). Multiple studies

Fig. 2 Hematoxylin and eosin-stained periprosthetic tissue from a loose knee implant. *Black arrows* indicate metal wear particles; *white arrows* indicate UHMWPE wear particles visualized using polarized light microscopy. (Courtesy of Dr. James Anderson, Department of Pathology, Case Western Reserve University.)

have revealed conflicting results on the relative potency of the particles of the different materials (Ref. [9] and references therein) and we have recently shown that titanium and UHMWPE particles induce osteolysis by indistinguishable mechanisms.^[10] Important but hard to control factors such as particle size, shape, and the adherence of biologically active molecules make these studies difficult to interpret. Nonetheless, taken together, the studies suggest that the most important type of wear particle in an individual patient is likely to be the type that is the most abundant in that patient. Consistent with this, the most important effect of oxidation of UHMWPE appears to be the stimulation of particle generation rather than the stimulation of biological activity of the particles (Ref. [10] and references therein).

MACROPHAGES AND OTHER CELL TYPES AS PARTICLE DETECTORS

Abundant evidence indicates that macrophages are the primary cell type responsible for detecting the wear particles, and that the initial response to phagocytosis of the particles by macrophages is the increased production of proinflammatory cytokines.^[1,5,6] One active area of research examines the roles of the individual proinflammatory cytokines produced by macrophages in response to wear particles. As reviewed in Ref. [11], TNF- α is the proinflammatory cytokine with the best evidence for a role in aseptic loosening. In support of this conclusion, pharmacological or genetic inhibition of TNF- α signaling reduces wear particle-induced osteolysis in cell culture and animal models.^[11]

Moreover, a polymorphism in the TNF- α gene promoter is associated with an increased rate of aseptic loosening.^[12] IL-1 also likely plays a role as a polymorphism in the IL-1 receptor antagonist also is also associated with an increased rate of aseptic loosening.^[13] Moreover, we have found that neutralizing antibodies directed against either IL-1 α or IL-1 β inhibit wear particle-induced osteoclast differentiation by ~75% (Fig. 3A). In the same series of experiments, neutralizing antibodies directed against either TNF- α or IL-6 inhibited osteoclast differentiation by ~65% (Fig. 3A). Because the sum of the inhibitions induced by the four antibodies (75% + 75% + 65% + 65%) substantially exceeds 100%, it is most likely that the four cytokines act synergistically to induce osteoclast differentiation in response to wear particles. In agreement with this conclusion, we have also found that IL-1 β , IL-6, and TNF- α can synergistically stimulate osteoclast differentiation in the absence of wear particles (Fig. 3B).

Another area of research examines the macrophage intracellular signal transduction pathways that are activated by wear particles. This is undoubtedly an extremely complex and only partially understood response. Our current working model of signaling pathways activated by wear particles is depicted in Fig. 4. This working model indicates that wear particles bind to a complex of receptor molecules that includes toll-like receptors.^[6] The receptor complex, in turn, strongly activates many signal transduction pathways. The nuclear factor- κ B (NF- κ B), ERK1/2, and PI3K/Akt pathways all contribute to the production of TNF- α in response to wear particles.^[11,14] TNF- α , in turn, is one of the proinflammatory cytokines that stimulate osteoclast differentiation and the resultant osteolysis (reviewed in Ref. [11]). The p38 and c-Jun amino-terminal kinase (JNK) pathways are also activated by wear particles.^[11] Although these pathways do not appear to contribute to TNF- α production, they may be responsible for the production of other proinflammatory cytokines.^[11] All of these results are based on our studies of titanium particles with adherent endotoxin; “endotoxin-free” titanium particles are much less potent at inducing the downstream events such as the activation of all examined signal transduction pathways, the production of proinflammatory cytokines, osteoclast differentiation, and osteolysis.^[6,11,14] “Endotoxin-free” particles likely do not activate toll-like receptors because they are the primary receptors used by the host immune system to detect bacteria and other pathogens.

Cells besides macrophages may also play a secondary role in responding to wear particles. For example, recent studies have shown that mesenchymal cells at various stages of differentiation along the osteogenic pathway (fibroblasts, stromal cells, preosteoblasts, and

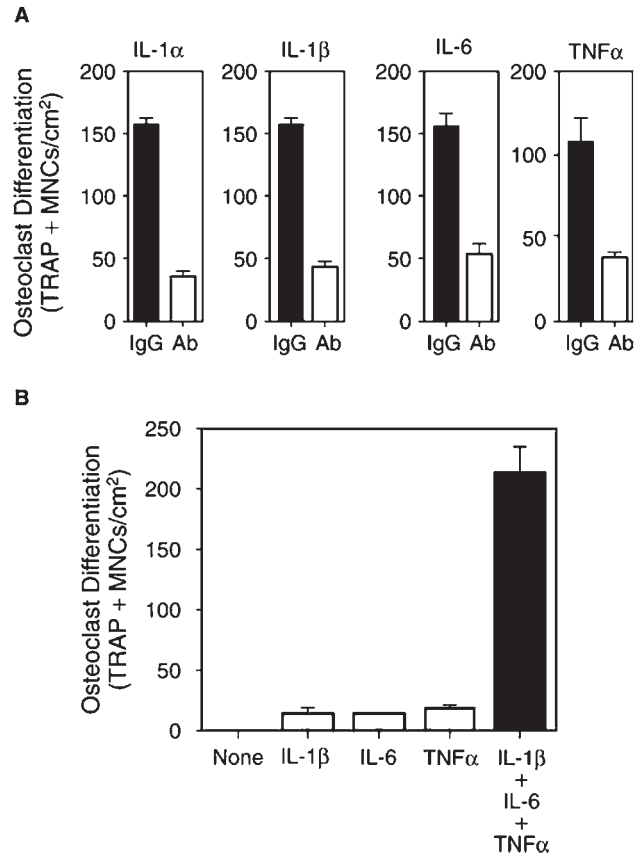

Fig. 3 Proinflammatory cytokines synergistically stimulate osteoclast differentiation in response to titanium particles (panel A) and when added directly to the cell cultures (panel B). In panel A, maximally effective concentrations of neutralizing antibodies to the indicated cytokines were added to osteoclast differentiation assays containing conditioned media from macrophages incubated with titanium particles (open bars). Control groups received equal amounts of isotype-matched IgG (filled bars). In panel B, submaximal amounts of IL-1 β , IL-6, and TNF- α were added either alone (open bars) or in combination (filled bars) to osteoclast differentiation assays in the absence of macrophage conditioned medium. Panel A is modified from Lowe, R.; Nalepka, J.; Van De Motter, R.; Goldberg, V.; Bi, Y.; Greenfield, E. Stimulation of osteoclast differentiation by wear debris depends on synergistic interactions between IL-1 α , IL-1 β , IL-6, and TNF- α . *Trans. Orthop. Res. Soc.* **2001**, *26*, 959. Panel B is modified from Ragab, A.A.; Nalepka, J.L.; Bi, Y.; Greenfield, E.M. Cytokines synergistically induce osteoclast differentiation: support by immortalized or normal calvarial cells. *Am. J. Physiol. Cell Physiol.* **2002**, *283*, C679–C687.

osteoblasts) can produce proinflammatory and pro-resorptive cytokines in response to wear particles (Ref. [15] and references therein). In most patients, however, it is likely that the production of resorptive cytokines in response to inflammatory cytokines produced by macrophages is quantitatively more important (Fig. 5).

Fig. 4 Signal transduction pathways activated in macrophages by orthopaedic wear particles. (Modified from Ref. [11].)

This conclusion is based on two types of data. First, macrophages are the most abundant cell type surrounding most loose implants and, second, macrophages produce much higher levels of cytokines per cell than are produced by mesenchymal cells. Moreover, a histological, in situ hybridization, and immunohistochemical study by Jiranek et al.^[16] of the periprosthetic tissue surrounding aseptically loose implants showed that macrophages and foreign body giant cells were the only cell types that phagocytosed the wear debris. In addition, these monocyte-derived cells were the only cells that produced IL-1 β mRNA. In contrast, immunohistochemistry showed IL-1 β protein bound to both macrophages and fibroblasts, indicating that IL-1 β protein binds to receptors on both cell types but that macrophages are the primary producers of the proinflammatory cytokine.^[16] The primary role of fibroblasts and other mesenchymal cells would then be to produce proresorptive cytokines, such as RANKL and M-CSF, in response to the proinflammatory cytokines

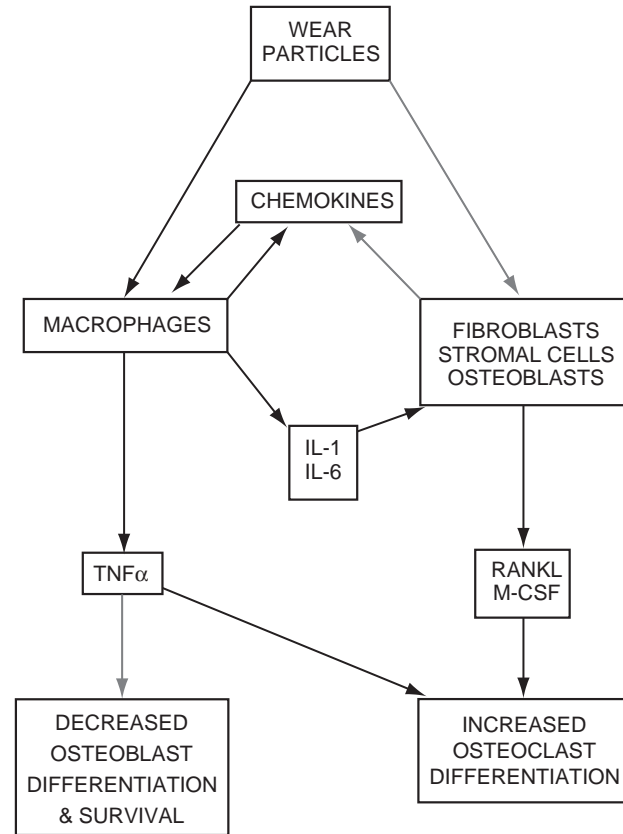

Fig. 5 Cellular responses to orthopaedic wear particles. *Black arrows* indicate primary responses; *gray arrows* indicate secondary responses.

produced by macrophages (Fig. 5). It should also be noted that TNF- α is an exception in that it primarily acts directly on osteoclast precursors to induce their differentiation into mature bone resorptive cells (Fig. 5).^[6] Fibroblasts may also be important in the production of chemokines that recruit macrophages to the periprosthetic environment (Fig. 5).^[2] As wear particles induce macrophages to produce abundant levels of chemokines that recruit additional macrophages (Fig. 5),^[5] the fibroblast-derived chemokines are likely to be quantitatively important only during the initial stage of host responses to wear particles, prior to substantial macrophage recruitment.

The lymphocyte is another cell type suggested to contribute to the responses to orthopaedic wear particles.^[17] In support of this possibility, lymphocytes from a subset of patients with aseptic loosening exhibit sensitization to metals.^[17] However, this presents the classical chicken-or-egg question: do the increased metal levels in patients with loosening contribute to the increased sensitization and/or does sensitization contribute to aseptic loosening? Only the latter possibility would indicate that lymphocytes contribute to aseptic loosening. Evidence against a role for lymphocytes was obtained in animal and cell culture studies that found

that lymphocytes do not detectably contribute to cytokine production or to osteolysis induced by wear particles (Ref. [10] and references therein). Moreover, the study by Jiranek et al.^[16] discussed above failed to show the phagocytosis of wear particles by lymphocytes in periprosthetic tissue. However, three studies have recently shown that the periprosthetic tissue from patients with aseptic loosening of metal-on-metal joint replacements contains high levels of T and B lymphocytes.^[18–20]

OSTEOCLASTS AND OSTEOBLASTS AS EFFECTOR CELLS

Osteoclasts are the cells that resorb bone in response to the local inflammatory process initiated by wear particles.^[5] So, osteoclasts are the primary effector cell type responsible for wear particle-derived osteolysis. Wear particles have little effect, however, on the activity or the survival of mature osteoclasts.^[5] Instead, the recruitment of osteoclast precursors to the periprosthetic environment and their subsequent differentiation into mature bone resorbing cells are both potently upregulated by the inflammatory response initiated by wear particles (Fig. 5 and left side of Fig. 6).^[5] The recruitment and differentiation of osteoclast precursors thus represent attractive targets for the pharmacological treatment of aseptic loosening.

Osteoblasts are the cells that form bone, and decreases in osteoblast number or activity induced by wear particles likely play a secondary role in implant loosening (right side of Fig. 6).^[6] The inhibition of osteoblast number and activity by wear particles appears to be much more potent *in vivo* than *in vitro*,^[6] indicating that this inhibition is likely owing to the inflammatory process induced by the wear particles rather than to direct effects on the osteoblasts themselves. TNF- α may be especially important in this process because it inhibits differentiation of osteoblasts and stimulates their apoptosis (Fig. 5).^[21] Although the decreased bone formation plays a secondary role in the pathogenesis of implant loosening, patients with high rates of bone formation have lower rates of aseptic loosening.^[7] In this regard, we have found that the high rates of bone formation in young mice lead to the rapid repair of osteolytic areas.^[6] Moreover, increased bone formation is responsible for the ability of osteogenic agents, such as growth factors and parathyroid hormone, to increase the osseointegration of orthopaedic implants.^[6,22] Osteogenic agents represent an especially attractive pharmacological approach, because accelerated osseointegration would allow patients to return more rapidly to activities of daily living and would lead to a lower incidence of aseptic loosening in subsequent years.^[6]

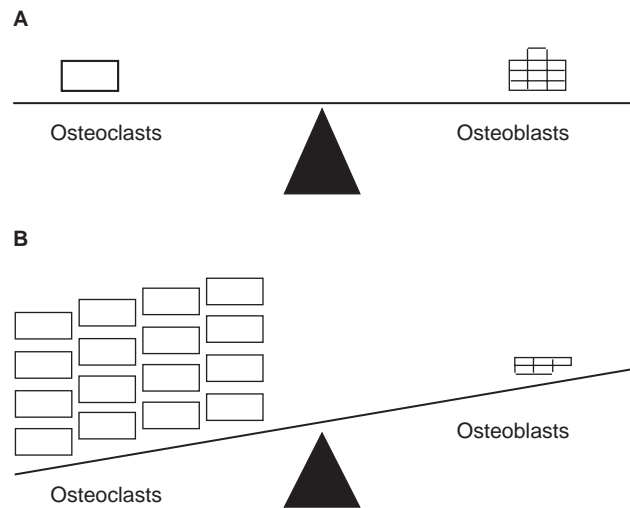

Fig. 6 Osteoclasts and osteoblasts as effector cells responsible for implant loosening. During normal homeostasis (A), the action of the two cell types are balanced with ~10 osteoblasts required to form new bone equivalent to that resorbed by one osteoclast. During implant loosening (B), bone resorption exceeds formation primarily because the number of osteoclasts increases 10–20-fold. The ~50% decrease in the number of osteoblasts is a smaller, secondary response. (From Ref. [5] and Kadoya, Y.; Revell, P.A.; Al-Saffer, N.; Kobayashi, A.; Scott, G.; Freeman, M.A.R. Bone formation and bone resorption in failed total joint arthroplasties: histomorphometric analysis with histochemical and immunohistochemical technique. *J. Orthop. Res.* **1996**, *14*, 473–482.)

FUTURE DIRECTIONS

The inhibition of the inflammatory process, either pharmacologically or by gene therapy, would likely reduce aseptic loosening. However, the long-term systemic inhibition of inflammation may lead to increased infections and other serious complications.^[23] As discussed above, the inhibition of osteoclast differentiation or the acceleration of osseointegration represents more attractive approaches, which would not necessarily require the local delivery of the pharmaceutical or gene construct. Moreover, these approaches would potentially have the additional benefit of reducing osteoporosis in the treated patients. An example is the potential use of bisphosphonates in patients with orthopaedic implants. By inhibiting osteoclastic bone resorption, bisphosphonates can increase the osseointegration of implants in animal models when administered either systemically^[24] or bound to the implants.^[25] Moreover, in patients, bisphosphonates can reduce the increase in local bone turnover and the resultant local bone loss that

occurs in the first few years after total hip arthroplasty.^[26,27]

As a more detailed understanding of the host response to orthopaedic wear particles becomes available, it may be possible to identify those patients who have high risk for aseptic loosening. As discussed above, patients with high rates of bone formation have lower rates of aseptic loosening.^[7] In addition, specific femur geometries correlate with altered rates of aseptic loosening.^[7] Although the genes involved are unknown at this time, it is likely that genetic polymorphisms contribute to both the high rates of bone formation and the femur geometries. Genetic polymorphisms also likely control the magnitude of each patient's inflammatory and resorptive responses. For example, as discussed above (in the section entitled Macrophages and Other Cell Types as Particle Detectors), polymorphisms in both the TNF- α and the IL-1 receptor antagonist genes correlate with altered rates of aseptic loosening.^[12,13] One way to appreciate the likely importance of genetics in controlling the susceptibility to aseptic loosening is to consider the role of genetics in osteoporosis: twin and family studies have shown that 60–80% of the variation in bone density between individuals is genetically determined, and many genes appear to contribute to this effect.^[28]

To the extent that bacterial molecules contribute to aseptic loosening,^[6] antibacterial agents may decrease the rate of aseptic loosening, in addition to decreasing implant infection. Data from the Norwegian Arthroplasty Registry show that both the intravenous administration of antibiotics for one to three days following implant surgery and the inclusion of antibiotics in the polymethylmethacrylate bone cement contribute to decreased aseptic loosening.^[29] The prolonged effects of these therapies likely result from favoring patient-derived cells in their “race for the implant surface” with bacteria.^[6] Covalently linking antibiotics to metal implant surfaces may provide an even longer-lived effect.^[30]

Finally, guided bone regeneration might reduce aseptic loosening.^[31] In this approach, particle migration from the joint space to the bone–implant interface is blocked with a membrane of expanded polytetrafluoroethylene. This membrane also guides bone formation to reinforce the seal and to continue to block particle migration. This approach was tested using a goat total hip replacement model in which the cobalt–chromium bearing surfaces were roughened prior to implantation to accelerate the wear of the UHMWPE.^[30] The polytetrafluoroethylene membrane substantially reduced aseptic loosening assessed radiographically and histologically 12 months after implantation.^[30] The long-term usefulness of this approach remains to be investigated.

CONCLUSIONS

The 12 major conclusions of this review are that: (i) wear particles are the primary inducers of aseptic loosening; (ii) the effects of the wear particles are increased by other factors, including implant motion, mechanical forces, fluid pressure, and bacterial endotoxins; (iii) the most important type of wear particle in an individual patient is likely to be the type that is the most abundant; (iv) the macrophage is the primary cell type that detects and responds to the wear particles; (v) the wear particles activate multiple signal transduction pathways in the macrophages; (vi) the wear particles induce macrophages to produce proinflammatory cytokines (TNF- α , IL-1, IL-6, etc) that synergistically induce osteoclast differentiation and osteolysis; (vii) the primary role of fibroblasts and other mesenchymal cells in aseptic loosening is to produce proresorptive cytokines [RANKL and macrophage colony stimulating factor (M-CSF)] in response to the proinflammatory cytokines produced by the macrophages; (viii) lymphocytes likely do not play a major role in aseptic loosening except, perhaps, in a subset of patients with metal sensitivity; (ix) increased osteoclast differentiation is the primary cause of osteolysis; (x) decreased bone formation plays an important, but secondary, role in aseptic loosening; (xi) a better understanding of the genetic regulation of aseptic loosening may lead to better methods for identifying higher-risk patients; and (xii) approaches to accelerate osseointegration or to inhibit bacterial growth, wear particle migration, or osteoclast differentiation are promising future directions that deserve further study.

INTRODUCTION

Nerve injuries can lead to clinical deficits that range from temporary loss of sensation to quadriplegia. Our understanding of nerve injury and repair has increased dramatically since the time of Galen, when nerves were first distinguished from tendons; however, the clinical application of scientific knowledge continues to be subdued, with functional results of nerve repair largely unchanged during the past 30 years. Direct approximation of proximal and distal ends of cut nerve remains the gold standard whenever possible, despite results that are less than 100% effective. When a significant nerve gap is incurred that cannot be repaired by end-to-end suturing, the current repair method involves implantation of an autograft as a conduit for axonal regeneration. However, surgical nerve grafting using a donor nerve is limited by availability and donor site morbidity, such as loss of sensation and cosmesis. Research in biomaterials and tissue engineering was recently enlisted to overcome these limitations. This article reviews historical and current understanding of surgical nerve repair and introduces alternate techniques using novel tissue engineering constructs for the repair and regeneration of peripheral nerve.

Nerve injuries complicate successful rehabilitation more than any other form of trauma. Peripheral nerve damage occurs in approximately 30% of extremity trauma.^[1] Self-care and other tasks of daily life can be severely impaired because of a lack of tactile discrimination and motor dysfunction.^[2] Pain from neuromas, sympathetic dystrophy, and causalgia often follow nerve injury, often necessitating further surgery.^[3] Causalgia has an estimated occurrence of 1–15% in sharp injuries. Causalgia and sympathetic dystrophy are commonly associated with crush injuries, whereas neuromas commonly result from transected nerve injuries.^[4,5] Improved guidance of regenerating nerves would, in theory, reduce the severity of these disabling sequelae.

RELEVANT ANATOMY

Peripheral nerves carry within them motor, sensory, and sympathetic nerve fibers (axons). Nerves comprise a neural component and a connective tissue component. (See also Sanghvi et al., “Tissue Engineering of Peripheral Nerve.”) The neural component consists of individual axons that can be myelinated or unmyelinated (Fig. 1). The non-neural component is made up of vascular and connective tissue cells and collagenous matrix organized into endoneurium, perineurium, and epineurium layers. The endoneurium is the basal membrane layer that envelops each individual axon; it is secreted by Schwann cells, which are the glial cells of the peripheral nervous system normally ensheathing myelinated axons, except at Ranvier’s nodes. The axons themselves are organized into fascicles, which are surrounded by a layer of perineurium, composed of collagen fibers and concentric layers of epithelial cells united by tight junctions. The fascicles are bundled together and surrounded by an outermost layer of epineurium composed of collagen and elastic fibers; it usually represents 50% of the cross-section of the nerve. The nerve receives its blood supply from vessels from the mesoneurium that is contiguous with the epineurium (Fig. 2).^[6]

Human peripheral nerves are subdivided into monofascicular, oligofascicular, and polyfascicular types. Monofascicular nerves (e.g., terminal branches of digital nerves) contain only one large bundle of several thousand axons with either a pure sensory or a pure motor function. Oligofascicular nerves (e.g., the radial nerve at the wrist) are composed of both sensory and motor elements. Polyfascicular nerves are composed of many small fascicles containing axons that serve a variety of functions.

Cellular Changes Associated with Injury

The most common etiology necessitating peripheral nerve repair is upper limb trauma.^[7] Nerve injuries are

Fig. 1 Rat peroneal nerve cross-section, showing myelinated axons. A, B: Scanning electron micrograph, C. Transmission electron micrograph. Diameter of myelin sheath is typically 20 micrometers. (J. Rosen, unpublished data.)

commonly associated with transection, laceration, or avulsion of the nerve trunk from surrounding tissues. Trauma causes nerves to undergo a succession of changes, not only at the site of injury but also in the brain, which tries to restructure its functional organization as a consequence of the peripheral nerve damage.

The proximal end of the transected axon generally retracts for a distance equal to several Ranvier's nodes, with the injured tip sealing off immediately and forming a proximal stump (Fig. 3). The nucleus and its associated apparatus enlarge to prepare for the regenerative process.^[8] However, in some cell bodies, transection causes cell death through an apoptotic cascade characterized by DNA fragmentation, shrinking of

the cell, chromatin condensation, and formation of apoptotic subcellular bodies.^[6] Thus, the population of neurons capable of axonal regeneration diminishes over time, although apparently never declining to zero.

Distally, transection causes the axons to disintegrate and undergo wallerian degeneration, a sequence of proteolytic processes that disintegrates the axoplasm, leaving remnant debris to be digested by invading macrophages and proliferating Schwann cells. Wallerian degeneration affects the entire distal length of the nerve; because all regenerating axons must traverse this distance, healing of trauma to nerve trunks near the body axis may take years.^[9] (See also Sanghvi et al., "Tissue Engineering of Peripheral Nerve.")

Fig. 2 Vessels from the mesoneurium, which is contiguous with the epineurium. (From Ref. [66].)

Fig. 3 The proximal end of the transected axon generally retracts for a distance equal to several nodes of Ranvier, with the injured tip sealing off immediately and forming a proximal stump. (From Ref. [66].)

The Role of Schwann Cells

Schwann cells make a crucial contribution to peripheral neural development, maintenance, and regeneration.^[10] In response to injury, Schwann cells divide rapidly, migrate from the two ends of a

transected nerve into the repair zone, phagocytose myelin debris, and create endoneurial “bands of Büngner” to guide axonal elongation through the distal nerve stump (Fig. 4).^[11,12] Schwann cells actively create the correct microenvironment for axonal regeneration by secretion of diffusible molecules such as nerve growth factor,^[13,14] ciliary neurotrophic factor,^[15] dopaminergic neurotrophic factor,^[16] and brain-derived neurotrophic factor.^[17] In vitro studies demonstrated that Schwann cell-secreted extracellular matrix containing Type IV collagen, laminin, and fibronectin^[18] potentiate regeneration.^[13,19–21] Schwann cells also secrete cell adhesion molecules (laminin, L1, N-cadherin, γ -1 integrins, and neural cell adhesion molecule)^[22] and a plasminogen activator for extracellular proteolysis.^[23]

Peripheral grafts without viable Schwann cells fail to support regeneration across peripheral nerve gaps much over 10 mm^[24] or in the central nervous system (CNS).^[25,26] If their multiple functions are not replicated artificially, Schwann cells will be needed throughout the healing nerve to remyelinate axons; if not distributed in the graft at the time of implantation, they will have to migrate from the nerve stumps, slowing the rate of maturation.^[27]

THE COURSE OF NERVE INJURY

Classification

Sir Herbert Seddon in 1943 was the first to describe three discrete types of nerve injury—neuropraxia,

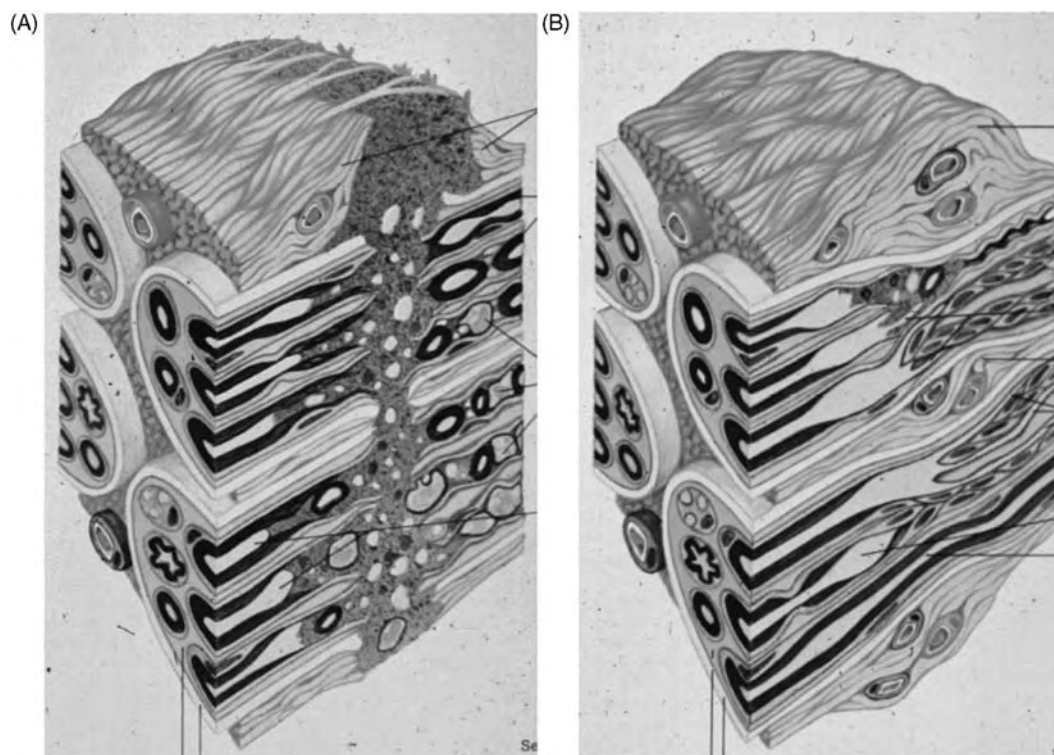

Fig. 4 The Schwann cells de-differentiate at the site of injury to form “Bands of Büngner.” A: Acute nerve injury: axons retract toward cell body, fragment distally. B. Healing nerve: Schwann cells prepare for axons regenerating across injury site. (From Bryant, W.M. “Wound Healing.” CIBA Clinical Symposia 1977, 29 (3), plates 14 and 16. Novartis Foundation.)

axonotmesis, and neurotmesis—as a basis for evaluating and predicting clinical outcome and formulating treatment plans.^[28] In 1951, Sunderland modified the classification system, adding two additional interim steps.^[29] Dellon and Mckinnon later described a six-degree rating scale of injury that dealt with clinical challenges associated with neuroma in situ (Table 1).^[30]

Clinical Assessment of Nerve Repair Outcome

Return of sensation or motor function can be assessed beginning 2 to 4 months postsurgery and continuing 6 to 18 months or longer at monthly intervals, depending on the location of the repair site and cast removal, using routine clinical tests for muscle strength, coordination, and touch. Non-invasive methods for evaluating human motor and sensory recovery include manual and automated strength testing, active range of motion, pain and touch thresholds, sudomotor (sweat gland) response, and surface electrophysiology.^[31] Tinel’s sign is a sensation of tingling felt in the distal extremity of a limb when percussion is performed over the site of an injured nerve, indicating a partial lesion or early regeneration in the nerve.^[32] Specialized equipment for clinical electrophysiology^[33] may be employed. New non-invasive methods for

assessing cross-sectional anatomy of the repaired nerve are available (i.e., high-resolution nuclear magnetic resonance^[34]).

Sensory assessment

Clinical sensory tests of hand function include touch, tactile gnosis (spatial discrimination), pain, and control of sweat glands.^[35] Touch threshold is measured with Semmes–Weinstein monofilaments and tactile gnosis using two-point discrimination. Patients’ self-report of recovery or persistent pain distal to a repair or donor nerve biopsy is significant.^[36] Temperature and vibration thresholds^[37,38] may be tested, but tend to be non-specific or duplicate results of other methods (E. Moberg, as cited by Dellon^[35]).

Recovery of sudomotor response^[39] is believed to parallel return of pain and temperature sensation, although a recent paper^[40] cautions against over-reliance on this assumption. In the ninhydrin test, ninhydrin is applied to the patient’s hand, who then places his or her hand on special paper; color will only develop in areas of innervated sweating skin.^[35] A newer method employs topical application of a known dose of capsaicin, which induces local hyperemia (evinced as reddening) only if arteriolar

Table 1 Classification of peripheral nerve injuries

Type I injury (neuropraxia) represents the mildest type of injury and is associated with full recovery of function. It involves a temporary loss of nerve conduction from ischemia-induced focal demyelination. There is no damage to the nerve itself, and clinically there is no Tinel's sign (see below) at the site of the lesion. A common example of this type of injury is "Saturday night palsy," where an intoxicated patient falls asleep with his or her arm hanging over a chair for an extended period of time, resulting in compression of the radial nerve. Experimental sham surgery, where the nerve is exposed to air without intentional trauma, can produce similar results.

Type II injury (axonotmesis) is an injury where wallerian degeneration occurs in the distal segment. Typically a crush injury, the endoneurium and perineurium remain intact; hence, scar formation is not seen. Recovery will be complete unless the distance of the injury from the motor end plate results in prolonged denervation of the receptor, causing motor recovery to be adversely affected. Nerve regeneration proceeds at 1.0–1.5 mm/day and can be followed clinically with advancement of Tinel's sign. Such injuries do not require surgical intervention.

Type III injury refers to distal wallerian degeneration with the addition of fibrosis of the endoneurium, although the perineurium remains intact. The differentiation between a Type II and Type III injury is based on the degree of recovery. Recovery will be incomplete as a result of scarring of the injury site, which blocks nerve regeneration. There may be a mismatch between regenerating fibers and appropriate end organ receptors. Regeneration occurs at a rate similar to axonotmesis. Surgery is usually not required, but in cases where there is delayed recovery, surgery may be necessary to remove the scar. Clinical recovery will be incomplete.

Type IV injury describes a nerve physically in continuity, but not functioning because of a complete blockage of nerve regeneration by scar tissue. Tinel's sign is seen at the level of injury, but there is no progression of Tinel's sign over time, indicating a lack of regeneration. Wallerian degeneration occurs distal to the injury. Surgical intervention is required for any hope of recovery. This is usually accomplished with primary nerve repair, nerve grafting, or interposition of a nerve conduit to bridge the gap left by scar excision.

Type V injury (neurotmesis) is the result of complete transection of the nerve. Surgery is required before any regeneration can occur. It is usually straightforward to diagnose these types of injuries because almost all complete nerve transactions are open injuries. Treatment is with early surgical exploration and primary repair of the nerve.

Type VI (neuroma in continuity) injury represents a combination of any of the above five levels of injury. It involves a mixed pattern of injury to the individual fascicles of the peripheral nerve, ranging from no injury to Type V injuries. Surgical intervention is usually necessary, with variable clinical recovery. Because only Type IV and Type V injuries are improved by surgery, the surgeon should make a detailed preoperative clinical assessment of the function of each fascicle or group of fascicles so as not to damage uninjured Type I–III injuries during surgery.

(From Ref. [6].)

sphincters are innervated.^[41] Noninvasive measurement of sensory nerve compound action potential is possible, although difficult to interpret.^[42–44] Sural nerve donor site evaluation should be considered in autograft patients.^[45]

Motor assessment

Standard manual anatomic evaluations consist of using a goniometer to measure joint-selected range of motion.^[46] Strengths of individual muscles are assessed non-invasively by the isometric manual motor test—preventing motion of muscles or tendons while the subject attempts motion against the therapist's restraint.^[47] Grades are assigned based on the muscle's ability to contract, total force the muscle can produce, and the amount of resistance, including gravity, against which a muscle can contract. Functional evaluations such as the Jebsen hand function test^[48] and postural assessment^[49] can provide an appraisal of the loss of function as it relates to activities of daily living. Automated strength (grip, palmar pinch, key

pinch, and tip pinch)^[50] and range of motion measurements in the hand can be made using the Greenleaf EVAL™ system.^[51]

Factors Affecting Success of Nerve Repair

Clinical results following nerve repair are influenced by many parameters such as the nature, location, and extent of the injury; the level and timing of the repair; and surgical techniques, as well as factors related to the patient's health (e.g., smoking, compliance with physical therapy).^[52] Probably most important is the prompt timing of surgery,^[6] with primary (i.e., without later secondary reentry of the surgical site) repair being preferable, if possible. Early repair circumvents major problems such as neuronal apoptosis, muscle atrophy, and scar formation, all of which increase with time. Chronic denervation (more than 3 years) leads to atrophy of sensory and motor end organs; therefore, recovery after grafting is likely to be delayed and of lesser extent than if the target tissues are intact.^[53] However, there have been occasional reports of

Table 2 Sensory and motor results after grafting

Gap grafted (cm)	No. cases	Age (yr)	% Children	Follow-up (yr)	Motor Recovery (%)				Sensory Recovery (%)					
					M2	M3	M4	M5	S2	S2+	S3	S3+	S4

(From Ref. [6].)

successful reinnervation many years after interruption of nerve transmission.^[2,54] Success in restoring motor function to preinjury levels is claimed in 33% to 46% of some series of patients, but more often achieves only a level of 3 on a 0-to-5 scale.^[30] Sensory recovery rarely (3% to 12%) is complete, with two-point discrimination only to 7 mm at best (Table 2).

Factors intrinsic to the injury itself are a significant harbinger of successful outcome. Shorter defects and uncontaminated injuries^[55] are more likely to have better functional outcomes. Meticulous surgical technique is critical to a successful functional outcome. Stretching of the distal and proximal ends of a nerve must be avoided. Coaptation must not be performed under tension because postoperative edema will cause the nerve ends to swell, resulting in poor signal conduction, increased scar formation, and reduced intraneural microvascular flow.^[56] Finally, age and other health factors are important to successful outcome. In general, young children have greater regenerative capability and elderly patients have the poorest results for nerve repair or grafting.

HISTORY OF SURGICAL NERVE REPAIR

Pre-1950s

Our understanding of nerve injury and repair dates back to the time of Ferrara in 1608, when the primary repair of a transected nerve was first documented.^[6] However, it was not until the 1800s that nerve injury and repair were seriously studied and repair techniques were reported in the literature. Before this time, peripheral nerve injuries were usually left untreated or amputated, perhaps because of a lack of antiseptic

measures or antibiotics. In 1850, Waller extensively studied the processes associated with nerve injury, carefully denoting the cellular changes to axons after transection of the hypoglossal nerve in frogs and demonstrating the reproducible pathologic changes following injury that now bear his name.^[57]

The American Civil War (1860–1864) and the resulting large number of peripheral nerve injuries provided greater opportunities for increased understanding. From examination of acute and chronic nerve injury during the Civil War, Mitchell (Fig. 5) and colleagues, in 1864, first demonstrated that partial nerve injury could lead to causalgia, in which the fingers are tapered, painful, and hairless because of a lack of innervation.^[58] From the period of the Civil War until World War II, numerous surgeons began experimenting with nerve repair and grafting. In 1873, Heuter achieved end-to-end coaptation of nerve stumps by epineural suturing, which continues to be the standard used today.^[57] Although ultimately unsuccessful, in 1878 Albert first attempted clinical nerve grafting using a donor nerve from another patient to bridge the median nerve after tumor resection.^[6] In 1898, Tornau published the largest series of nerve repair of his time, comprising 212 primary and secondary repair cases.^[6] Fascicular repair was first advocated by Hashimoto and Langley in 1917,^[59] but achieved limited use until the advent of the surgical microscope.^[60]

Post-1950s

The period following World War II saw renewed interest and experimentation in nerve repair, in part because of the explosion of war injuries now treatable with modern medicine. Woodhall and Beebe (1956)

Fig. 5 Portrait of S. Weir Mitchell from the College of Physicians of Philadelphia. From examination of acute and chronic nerve injury during the Civil War, Mitchell and colleagues first demonstrated, in 1864, that partial nerve injury could lead to causalgia.

reported on 3656 peripheral nerve repairs following war injuries, with relatively poor functional outcomes.^[61] Such poor results colored the perception and expectations of nerve repair for surgeons until a major breakthrough occurred with the work by Millesi in the late 1960s, advocating microsurgical techniques, limited tension, and the use of autografts whenever direct repair was not feasible.^[56] Since Millesi, our understanding of nerve pathophysiology has increased substantially, but there has been little translation of knowledge from experimental models into clinical practice. Millesi's techniques continue to be standard practice today for repair of peripheral injuries.

Prior to development of modern biomaterials, there were nonetheless many attempts to bridge nerve gaps with non-neural materials. Weiss (Fig. 6) cites 53 publications using nerve conduits from the late 1800s to the 1940s.^[62] For example, Forssman in 1898 observed that nerve regeneration could be guided using straw tubes as a bridge. He attributed this phenomenon to neurotropism, the theory that regenerating axons have an affinity for certain substances. This was the view posited by Ramon y Cajal, who believed chemical factors guided the proximal sprout to the distal nerve. Many years later, this concept was called into question by Weiss and Taylor in a series of experiments using Y-shape arteries. Weiss demonstrated that nerve regeneration occurred independently of the distal target, supporting the concept of nerve growth

Fig. 6 Portrait of Paul A. Weiss from the National Academy of Sciences, *Biographical Memoirs*, Vol. 72 (1997). Weiss conducted a review of the many attempts to bridge nerve gaps with non-neural materials, prior to development of modern biomaterials, in the period between the late 1800s and the 1940s.

by contact guidance.^[63] Recent work demonstrated conclusively that both neurotropism and contact guidance both play a critical role in regeneration.^[64] Other studies demonstrated further end-organ specificities, as well as fascicular-specific growth regulation.^[65] These experiments laid the foundation for the concepts of nerve guides and tissue engineering to replace the autograft.

Current Nerve Repair Techniques

The aim of nerve repair is to guide the regenerating axons successfully into the distal nerve with minimal blockage or escape. Nerve repair methods are divided into direct repair (neurorrhaphy) and graft techniques. Direct repairs can be further subclassified into epineural repair and fascicular repair. Graft repairs are performed using harvested nerve segments from autogenous sensory nerves such as the sural or antebrachial cutaneous nerve^[66] (Table 3). The surgical method selected is dependent on the nerve type and tension at the repair site, which is influenced by the gap length, timing of repair, and nature of the injury. In complicated wounds, primary treatment may consist of debridement, reestablishing a vascular supply, and skin closure, with secondary nerve and tendon repair delayed some weeks until inflammation subsides.^[67] Donor nerve excision can be performed by an open

Table 3 Common donor nerve graphs

Nerve graft	Abbreviation	Length (cm)	Morbidity
Sural		30–50	+
Medial antebrachial cutaneous	MACN (above elbow)	10–12	+
Medial antebrachial cutaneous	MACN (below elbow)	8–10	+
Lateral antebrachial cutaneous	LACN (below elbow)	10–12	++
Superficial branch radian	SBRN	20–30	++
Dorsal cutaneous branch ulnar	DCBUN	4–6	++
Lateral femoral cutaneous	LFCN thigh	15–20	+++

(From Ref. [66].)

approach or using endoscopic surgery.^[68,69] Post-surgical rehabilitation includes immediate splinting, followed by successively higher intensity exercise.

Epineural vs. Fascicular Repair

Clinical and experiment studies compared epineural repair to fascicular repair in the treatment of peripheral nerve injuries^[70] (Table 4). Theoretically, fascicular repair should be superior because of better alignment of proximal axons with the bands of Büngner, leading to their preinjury destinations; however, epineural repair is easier, faster, and demands less manipulation, thereby minimizing the disruption to the fine internal structure and critical blood supply. In the acute setting, epineural repair is sufficient where there is a sharp, clean, and clearly delineated lesion. Millesi reports advantages of microsurgical repair under favorable conditions, but the increase in surgical operative time and scar formation should be considered.^[56] If it were possible to completely align the fascicles with minimal trauma and disruption, fascicular repair would likely produce better clinical results than epineural repair.

Nerve Graft Surgical Procedure

When the direct repair of a nerve injury cannot be performed without tension, nerve grafting is recommended.^[71] The graft is a conduit for axonal progression from the proximal to the distal stump, most often being an autologous non-vascularized nerve. The surgical technique of nerve grafting is similar to direct neurorrhaphy, requiring the same microsurgical, atraumatic technique to ensure best results. When

Table 4 Epineural versus fascicular repairs

Epineural repair
Heuter's end-to-end coaptation of nerve stumps is the most traditional and commonly used method of repair for transected nerves. Sutures are passed through the epineural sheath using 8-O to 10-O non-absorbable nylon sutures under magnification. It is important to identify the fascicular pattern of the nerve so as to obtain proper anatomical alignment. Care must be taken not to disturb other intraneural contents so as to minimize subsequent fibrosis and scar formation. The epineural suturing technique is relatively simple because only low magnification is required; however, one major disadvantage is that individual fascicles may be misaligned, which in turn may result in defective reinnervation.
Fascicular repair
Fascicular repair involves the coaptation of corresponding fascicles in the proximal and distal nerve stumps to try to achieve anatomic alignment. Such manipulation became possible with the introduction of the operating microscope having over 20 × magnification and long working focus distance. Reconnection of isolated fascicles requires the suturing of corresponding fascicles in the distal and proximal stumps using 10-O and 11-O sutures. Meticulous attention must be paid to surgical technique in order to avoid tension and to prevent injury to the interfascicular content. An advantage associated with fascicular compared with epineural repair is the decreased risk of axonal misdirection; however, the risk of damage to the fascicles may increase because of microherniation of endoneural content. In addition, interfascicular sutures increase intraneural foreign body reactions and, therefore, the likelihood of intraneural fibrosis.

(From Ref. [70].)

performing nerve grafting, the surgeon tries to match the sensory and motor components of the individual fascicles at the proximal and distal repair sites as accurately as possible (Fig. 7). This can be difficult when grafting in the proximal extremity because the fascicular patterns are frequently mixed. Intraoperative identification is often necessary to differentiate the fascicular components. A variety of techniques have been used to aid identification, including electrostimulation, acetylcholinesterase staining, and carbonic anhydrase histochemistry.^[72] Most commonly, surgeons use anatomic cues such as the pattern of epineural blood vessels to properly align the nerve stumps (Fig. 2).

The standard practice of microsurgical nerve reanastomosis has been to use 9-O or 10-O nylon sutures to connect the perineurium of the nerve segments.^[70,73–75] Fibrin tissue adhesive (e.g., Tisseel[®], Baxter-Hyland) was approved for clinical use in 1998, affording a faster, less error-prone method of anastomosis. Nerve autografts and vein-to-nerve grafts

are now routinely affixed using a bead of fibrin surrounding the junction and extending several millimeters to either side. (See Carr et al., "Fibrin Sealants.")

Donor Site Morbidity

Donor nerves excised for nerve grafting are ideally expendable sensory nerves whose harvest results in

minor disability. Donor nerves include the sural, lateral antebrachial, anterior division of the medial antebrachial cutaneous, intercostal,^[76] or supraclavicular nerves^[77] (Table 2). In selecting a donor graft, it is important to consider the cross-sectional area of the nerve to be repaired, the length of the nerve gap, and donor site morbidity. Donor site morbidity involves loss of donor nerve function, hyperesthesia adjacent to the region of sensory loss, and the possibility of a

painful neuroma. Neuromas are nodular outgrowths from a damaged nerve that occur when axons escape past the remaining perineurium^[78] or encounter an obstacle such as a blood clot.^[5] Risk of neuroma is minimized if the proximal stump is tunneled into innervated muscle, which inhibits axonal sprouting. One study on harvesting of the sural nerve reported that 44% of patients complained of sensory defect around the lateral aspect of the foot and ankle, 42% of patients complained of calf tenderness, and intolerable pain associated with neuroma occurred in 16% of patients.^[6] Sensory loss in the leg as a result of excising the sural nerve can adversely affect gait and balance.^[79]

ALTERNATIVES TO NERVE AUTOGRAFTS

The greatest need for donor autograft nerve at a single injury site is for repair of the brachial plexus—the complex network of cervical nerves proximal to the upper limb.^[80] Problems with autograft repair include a second surgical site, donor site morbidity, and limited supply.^[81–83] Experimental alternatives to autografts include allo- or homografts, heterografts, and artificial materials in tubular form.^[84] An artificial nerve graft (ANG) potentially would solve autograft-associated problems and promote functional recovery equal or superior to an autograft repair.^[30]

Nerve xenografts (cross-species) and allografts (same species) entail rejection or health risks associated with systemic immunosuppression to allow graft acceptance.^[70,85,86] Recent experiments demonstrated that immunogenic compounds can be extracted from allogeneic donor nerve.^[87,88] Other grafts of biologic origin include autogenous veins^[89,90] and pseudosynovial or mesothelial tubes,^[91] experimental results were deemed acceptable but far from ideal. Chiu et al.^[89] reported clinical trials using veins to bridge nerve gaps of 15 mm and longer. Beyond 15 mm, they noted that nerve regeneration ceased and suggested that this may be because of a lack of factors needed for regeneration.^[56]

Guidance Tubes

Although autogenous nerve grafting continues to be the gold standard, one possible alternative is the design of artificial constructs to replace the elements necessary for axonal regeneration. The simplest such artificial nerve graft replaces only the perineurium with a tubular conduit; a complete tissue-engineered ANG would emulate the internal geometry, cellular population, and neurotrophic environment of the natural autograft. The ideal result of implantation of an artificial nerve graft is return of sensory and muscle function as good

or better than that of an autograft^[81] (typically 80% of the intact uninjured nerve; see Table 2). Because no substantial amount of donor nerve is required, the risk of functional loss, scarring, or neuroma at a donor site is minimized.^[92] (See also Schlosshauer and Lietz, “Nerve Guides.”)

There has been a resurgence in interest in the potential for interventions to restore lost neural cellular population, structure, and function.^[93,94] Early human trials are being conducted using relatively simple microgeometry, cell manipulation, and surgical techniques. Notable among these trials is that of Integra Life Sciences, which obtained license to the Yannas patents for collagen/glycosaminoglycan composite implants.^[95] Implantation of unfilled 2- to 5-cm collagen tubular grafts in Danish patients reportedly began in September 1998.^[96] This is a large-scale product-oriented second-stage trial, compared with one-time trials of synthetic biomaterials in relatively few patients by Mackinnon and Dellon in the 1980s.^[97]

Biomaterials for ANGs

Biocompatible materials are required for both the tubular outer conduit and the optional internal scaffold through which the axonal fibers regenerate.^[98] Natural biopolymers, insoluble synthetics, biodegradable synthetics, and electrically active materials have been used for this purpose. The limitations of natural biomaterials include immunoreactivity with the patient and non-uniformity in the graft material. It may be more feasible to alter the chemical and engineering properties of synthetic biomaterials so as to achieve the desired geometric configuration, biocompatibility, porosity, degradation, and mechanical strength.

Silicone is the most frequently employed synthetic biomaterial,^[99,100] but, like other non-resorbable materials,^[101] results in declining function after approximately 6 months as a result of constriction of the enlarging nerve.^[102] The common finding that regenerating axons detach from the wall and form a thin bundle or cable in the center of the silicone tube illustrates cellular non-adhesion; texturing the inner surface can result in a much different, looser structure.^[66] (See also Wynne and Lambert, “Silicones.”)

Experiments with synthetic resorbable materials have had some success.^[103,104] As in the case of vein grafts, clinical trials of bioresorbable tubes fabricated from polyglycolic acid (PGA) without matrix or cells in 15-mm gaps yielded results comparable to that of sutured autografts, but performed poorly in gaps of 30 mm or more.^[97,105] (See also Boland et al., “Poly(Glycolic Acid).”) Newer bioresorbable materials such as glycolide trimethylene

carbonate (GTMC, Maxon™),^[106] polydioxanone, and poly(lactic-ε-caprolactone)^[107] are less brittle and longer lived in vivo. These materials have varying time courses of inflammation and induced fibroblast proliferation.^[108] As with PGA, as long as particles of GTMC or polydioxanone remain (3–6 months), inflammation, mononuclear macrophages, multinuclear giant cells^[97] and compression of the nerve persist.^[107] (See also West, “Biofunctional Polymers.”)

The predominant natural biomaterial for nerve conduit fabrication has been Type I collagen. Type I collagen is the principal extracellular protein of connective tissue and is a polymer of triple-helical subunits.^[109] (See also Beckman et al., “Collagen.”) In human femoral nerve, Type I is present in the perineurium,^[110] whereas collagen Type III is predominantly located in the endoneurium.^[111] Dissolved collagen can be repolymerized to form gels, coatings, and microfibrillar structures,^[112] which can be strengthened by molecular cross-links.^[113]

Experiments demonstrated that silicone tubes filled with Type I collagen result in successful bridging of short nerve gaps.^[114–116] Empty tubes made of collagen support nerve regeneration equal to other biomaterials.^[117,118] This finding was recently confirmed in sites adjacent to the spinal cord as well as distally.^[119] Saline-filled bovine collagen tubes across short (4-mm) gaps in peripheral nerves in primates demonstrate slower initiation of regeneration but equal long-term results compared with autografts.^[120] The combination of collagen with other natural biopolymers such as fibrin may yield better control over resorption rate and inflammation.^[121] Some researchers concluded that regeneration in collagen is impeded,^[122] but these investigators did not compare the same collagen preparations. Parallel orientation of collagen fibrils at the molecular level promoted unidirectional axon elongation.^[123,124]

Tissue Engineering Concepts

Tissue engineering, defined as the combination of living cells with a biomaterial scaffold, holds promise for replacing tissues lost to injury or disease.^[125] (See also Auger and Germain, “Tissue Engineering.”) Whereas other approaches to tissue engineering for human implantation may use donor cells that can be rejected, our approach is based on using a patient’s own (“autologous”) Schwann cells.^[126,127] One of the critical assumptions we made in formulating the ANG is that incorporation of Schwann cells will enhance axonal regeneration by de novo synthesis of growth factors and neuron-specific adhesion factors if they are placed in a biocompatible matrix with suitable micrometer-scale geometry. Researchers working on

peripheral nerve at the Miami Project to Cure Paralysis^[128] made the same assumption. Relying on the patient’s own Schwann cells to provide neurotrophic factors entails the burden of obtaining and isolating the cells and custom-fabricating grafts for each individual patient,^[127] as well as the risk that the cells will not survive or secrete the factors in sufficient quantity (autologous Schwann cells genetically altered to hyperproduce growth factors are eventually possible^[129]).

Schwann Cell-Seeded Grafts

Much has been learned about isolation and culture of adult human Schwann cells.^[130,131] It is now known that growth factors such as heregulin preferentially stimulate proliferation of Schwann cells.^[128,131–133] Previously, we purified Schwann cells using a complement-lysis method to eliminate fibroblasts; this method has a low yield of viable cells.^[134] We since modified the successive-migration explant culture method used by the Bunge group^[130] to minimize the initial non Schwann cell population by microdissection, removing blood vessels as well as perineurium before enzymatically releasing Schwann cells; residual fibroblasts are <5% of the total cell number. More efficient methods of isolating and culturing large numbers of Schwann cells are based on immunoaffinity methods employing antibodies to Schwann cell-specific surface antigens (e.g., S-100)^[135] and on selective growth media.^[136]

Example Artificial Nerve Graft Concept

Ideally, artificial nerve grafts are composed of viable Schwann cells, a linearly oriented matrix, and an outer bioresorbable polymer conduit, emulating the native nerve after injury. The matrix distributes and maintains the donor Schwann cells inside the graft, and the conduit facilitates surgical emplacement in the host site and reduces scar-forming inflammatory ingrowth. (See also Sanghvi et al., “Tissue Engineering of Peripheral Nerve.”) A typical graft of 1- to 3-mm diameter would replace a single nerve fascicle; for large nerves, fascicles in proximal and distal stumps would be reconnected with individual parallel grafts. Preparation of the graft essentially consists of repolymerization of solubilized Type I collagen with added cultured Schwann cells and insertion into a GTMC or cross-linked collagen conduit. This ANG concept evolved from work by Drs. Hentz and Rosen on a sutureless method (fascicular tubulization) for nerve repair.^[137,138]

Fig. 8 Rat peroneal nerve implants 28 days post-surgery; artificial nerve grafts were tested in vivo by implantation into 10–14 mm peroneal nerve gaps in the rat. A. Cell-free artificial nerve graft at explantation. B. Sutured autograft at explantation. (J. Rosen, unpublished data.)

ANG Results

ANGs are initially tested in vivo by implantation into 10- to 14-mm peroneal nerve gaps in the rat (Fig. 8). Recovery of motor function is assessed by walking track analysis^[139] at weekly intervals. (See also Sanghvi et al., “Tissue Engineering of Peripheral Nerve.”) Repeated walking track analysis demonstrated that Schwann cell-containing ANGs are superior to collagen-only ANGs and ANGs containing dead Schwann cells or mixed fibroblast/Schwann cells in collagen, which in turn are superior to empty tubes (Fig. 9). Electrophysiology and histological analysis also demonstrate that neonatal Schwann cells favorably influence nerve regeneration if present in adequate numbers.^[140]

If nerve fibers do not reconnect across the gap, the cause is most often because one end came loose from the nerve stump; it may be reconnected by means of another surgical procedure. Another cause is interposition of sutures, blood clots, or other non-nerve tissue, thus increasing the likelihood of scar formation. Both causes also occur in autografts at about the same frequency as expected in artificial grafts.^[52]

Another cause of failure that occurs rarely in autografts is premature resorption of the graft, so the guiding sheath disappears before axons reach their destinations; this possibility is minimized by increasing conduit wall thickness and cross-linking in proportion to the length of the graft. Both in our primate study (unpublished data) and in clinical trials by Mackinnon and Dellon,^[97] failure of axons to reach the distal

Fig. 9 Repeated walking track analysis has shown that Schwann cell-containing artificial nerve grafts (ANGs) are superior to collagen-only ANGs, ANGs containing dead Schwann cells, or mixed fibroblast/Schwann cells in collagen, which in turn are superior to empty tubes. (From Keeley, R.D.; Sabelman, E.; Kadlcik, P.; Agras, J.; Eng, L.; Wiedman, T-W.; Nguyen, K.; Sudekum, A.; Rosen, J. Synthetic nerve graft containing collagen and syngeneic Schwann cells improves functional, electrophysiological, and histological parameters of peripheral nerve regeneration. *Restorative Neurol. and Neurosci.* **1993**, *5*, 353–366.)

nerve stump was probably a result of premature lysis of the sheath.

According to published reports^[141] and our experience, synthetic polymers do not dissolve uniformly, but by cracking into fragments that can interfere with regeneration. Degradation of collagen is by cell-mediated enzymolysis^[142] and its persistence is a function of cell metabolism and degree of enzyme-resistant cross-linking.^[143] Concerns about flexion-induced fragmentation or pinching of the ANG^[81] where it crosses a joint appear to be minimized by routine postsurgical immobilization for 6–8 weeks. A collagen-based ANG approximates the properties of natural veins used as nerve grafts, which are reported to perform better when subjected to flexing than synthetic polymers.^[144]

CONCLUSIONS

Despite greater understanding of the process of nerve regeneration, surgical practice and restoration of function after peripheral nerve injury have changed little for decades.^[145] The general concept of tissue engineering, or facilitated regeneration through the use of composite artificial/cellular tissues, has broad applications beyond peripheral nerve grafts. In the near future, ANGs would be most frequently used in distal nerve loss in the limbs,^[74] larger diameter multi-fascicular nerve trunks (including branching nerves as in the brachial plexus),^[146,147] facial nerve palsy^[148,149] and other craniofacial sites,^[77] and iatrogenic damage such as occurs in pharyngeal and prostate cancer surgery.

There is a high probability that a Schwann cell-seeded equivalent to a peripheral nerve autograft would find application in the CNS, particularly for bridging trauma in the spinal cord.^[25,150] Other CNS applications are based on using a matrix carrier for Schwann cells or CNS cells implanted into the brain.^[151,152] Clinical trials of peripheral nerve autografts into the CNS are already under way.^[153,154] Another therapeutic application following spinal cord injury would be to use ANGs to reroute some fascicles of nerves with intact CNS communication to denervated muscles^[155,156] as an alternative to tendon transfer to restore hand function.^[1]

ACKNOWLEDGMENTS

We acknowledge VA Rehabilitation R&D Merit Review Grants B588-1, -2, -3RA “Artificial Nerve Graft: Union of Cellular and Non-Cellular Components,” and “Clinical Trial of Artificial Nerve Graft” to J. M. Rosen, M.D., and E.E. Sabelman,

Ph.D. V.R. Hentz, M.D., provided long-term support and inspiration. We thank H. Pham and F. Zhang for animal surgery, J. Kipp, P. Kadlcik, and M. Hu for histology, R. Keeley for expert rat handling, and S. Long and R. Masher for editorial assistance.

Phosphorylcholine (PC) Technology

Andrew L. Lewis

Drug Delivery Division, Biocompatibles UK Limited, Farnham, Surrey, United Kingdom

INTRODUCTION

Terms such as biomimicry and bio-inspired have been used to describe systems that have been designed specifically by the application of principles taken from observing nature. PC Technology™ is one example of such a system. It encompasses a range of biomaterials, the chemical compositions of which are founded upon the structure of the cell membrane.

OVERVIEW

Although the lipid bilayer assembly of plasma membranes has been known for some time, it was not appreciated until the early 1970s that the lipid components composing the outer and inner halves of the bilayer are very different. It was Zwaal and coworkers who first reported in *Nature* the fact that if the bilayer is separated into its inner and outer leaflets and then individually exposed to blood, the outer layer does not cause the blood to clot, whereas the inner layer is thrombogenic.^[1] This is explained in terms of the predominant phospholipids in each layer, the outer leaflet composed mainly of those with zwitterionic phosphorylcholine (PC) headgroups (Fig. 1), as opposed to the larger proportion of negatively-charged phosphorylserine-based phospholipids found on the inside. This observation led to the seminal work of the late Professor Dennis Chapman, who demonstrated that surfaces functionalized with the PC headgroup could be rendered non-thrombogenic.^[2-6] This led Chapman to found a company in 1984 called Biocompatibles in order to develop and commercialize a range of materials and surface treatments based on PC Technology that would bring significant benefit to devices used in medicine by improving their tolerance within the body.

PC POLYMERS—EVOLUTION AND SYNTHETIC PERSPECTIVE

Early methods of functionalizing surfaces with PC included direct coupling of reactive small-molecule PC species to the desired substrate. Although the biocompatibility of the surfaces was improved, these techniques

generally required complex pretreatment steps, were inconsistent, and often were not practically viable for medical device manufacture. The first polymer-based approach was achieved using an analogue of the naturally occurring lipid dipalmitoylphosphatidylcholine (DPPC, Fig. 1) that possessed acetylenic bonds within the alkyl chains.^[7] This diacetylenic phosphatidylcholine (DAPC) could be polymerized onto a surface by use of UV or γ -irradiation, which induced cross-linking by addition across the triple bonds. The resultant coating was stable and biocompatible, but again the method of application was fraught with handling difficulties. Other polymer systems investigated included PC-based polyesters and polyurethanes made by the direct polycondensation of the PC diol glycerophosphorylcholine with appropriate diacid chlorides or diisocyanates. Although the biological properties of such materials were enhanced, the presence of the PC group resulted in a significant detrimental effect on the mechanical properties of these types of polymer.

The development in Japan of the PC methacrylate monomer, 2-methacryloyloxyethyl phosphorylcholine (MPC, Fig. 2), opened the door to a whole new area of flexible chemistry that utilizes free-radical polymerization. An improved route to the monomer synthesis allowed multigram preparations to be achieved and hence provided potential commercial viability. The monomer is prepared by the coupling of 2-hydroxyethyl methacrylate, a commonly used material in the medical industry, with 2-chloro-2-oxo-1,3,2-dioxaphospholane, followed by a ring opening reaction of the intermediate alkoxyphospholane with trimethylamine. A large family of polymers could now be prepared via a variety of free-radical techniques including:

- Conventional one-shot or monomer-starved solution methods for the preparation of linear and cross-linkable coating polymers.^[8,9]
- Specialized techniques such as atom transfer radical polymerization (ATRP) to prepare controlled architectures such as block copolymers, narrow polydispersities, and macromonomer synthesis.^[10-12]
- Emulsion methods for water-based PC latexes and suspension polymerization for PC-based microsphere fabrication.
- Bulk polymerizations for molded articles such as contact lenses.^[13,14]

Fig. 1 Cell membrane, structure of a typical phospholipid, and PC polymer analogues.

One of the first PC polymers to be synthesized using these methods was a copolymer with *n*-dodecylmethacrylate (MPC-*co*-DMA (1:2), Fig. 2) which, with two long-chain alkyl monomers for every one MPC unit, is a close structural analogue of DPPC (Fig. 1). This material is amphiphilic in nature due to the highly polar PC headgroups and the hydrophobic alkyl components, and requires the use of a subtle mixture of solvents during synthesis via a solution method due to the differences in monomer solubilities. The hydrophobic portion allows stable coatings to be formed on various substrates such as glass, metals, and a variety of plastics, by virtue of physi-adsorption through hydrophobic interaction. The PC component attracts a high water content (~60%) into the coating to form a hydrogel with remarkable hemocompatibility.^[15]

For some applications, particularly in which a change in shape or dimension of the device may ensue (for instance, in the case of an expandable stent), it is desirable to have a more mechanically robust coating. A cross-linkable PC polymer was developed for this purpose (XL-MPC-*co*-DMA, or PC1036); the polymer is synthesized and isolated from solution as a linear polymer, but with silyl groups pendent from the polymer backbone that provide a method of cross-linking after the coating has been applied.^[9] The extent of curing can be controlled by thermal treatment of the coating and further enhanced by use of a γ -irradiation cycle typical of that employed in the sterilization of

medical devices. Variations on this polymer have also been developed; they contain a cationic component that allows the coating to interact with species that carry a net negative charge, such as heparin and DNA (PC1062 & PC2028, Fig. 2). These coatings can be applied to devices where antithrombogenicity (as opposed to non-thrombogenicity) is required, or in which the ability to deliver locally large biomolecules, such as genetic material, is required.^[16]

In the case of molded articles such as soft contact lenses, adhesion to a substrate is not a requirement and the hydrophobic component of the polymer is replaced by a suitable comonomer that acts as a solvent for the MPC during the bulk polymerization.^[13,14] In the case of the Proclear[®] contact lens (PC1015, Fig. 2), the comonomer is 2-hydroxyethyl methacrylate which, together with a small amount of cross-linker, produces a 59% water content hydrogel (omafilcon A) that has excellent transparency and oxygen permeability necessary for contact lens fabrication.^[17] The lens can be produced from polymer molding buttons which are individually lathed into the various lens powers, or more commonly nowadays by direct cast molding in which the monomer formulation is polymerized directly within a mold that creates the desired shape of the lens. For applications where only a surface treatment is necessary, in-mold coating (IMC) techniques allow for the application of suitably functionalized PC polymers to the inside surfaces of a mold, after which the mold is filled with an

Fig. 2 Structure of the MPC monomer building block and various polymers that have been developed.

appropriate polymer formulation and cured.^[18] As the functional groups within the mold react, the reactive functionalities of the PC polymer become grafted into the surface of the forming article, producing a highly stable, wettable and biocompatible layer. The use of the allylic functionality is particularly useful (PC1071, Fig. 2) and can dramatically alter the surface characteristics of materials such as silicone that are classically very hydrophobic in the absence of any surface modification.

These few examples serve only to demonstrate the flexibility of the polymerization technology and by no means form an exhaustive list of the range of polymers that fall under the PC Technology umbrella. With the advent of new radical polymerization techniques such as ATRP and RAFT that allow more control over polymer architectures, there will be further advances in novel PC polymer synthesis to report in the near future.

BIOPHYSICAL CHARACTERIZATION

Surface Mobility and Swelling Properties

PC coating polymers that are based on lipidlike structures are amphiphilic due to the combination of the polar PC moieties and hydrophobic alkyl chain components. Solutions of these materials in suitable solvents can be easily applied to surfaces via any of the conventional techniques such as dip, spin, or spray coating. As the solvent evaporates from the forming film, the polymer will orientate its hydrophobic groups at the air interface in order to minimize the interfacial free energy. This has been demonstrated by the use of TOF-SIMS which shows that the PC groups are buried within the film when exposed to air or high-vacuum conditions.^[8,19] Once exposed to an aqueous environment, the coating rapidly rearranges so that the PC groups are expressed at the surface, a phenomenon demonstrated in a number of studies using contact angle measurement. These properties are important during consideration of the intended application of the coating, as a spontaneously wettable surface may be desired which requires re-engineering of the PC polymer to avoid the hysteresis effect.

Studies using spectroscopic ellipsometry and neutron diffraction demonstrate that the PC films swell very rapidly when exposed to water (some 50% of water is absorbed within the first minute).^[20,21] The kinetics of swelling and distribution of water within the coating is dependent upon whether the coating is the noncross-linked or cross-linked type. For the latter case, the swelling follows a two-stage mechanism involving a rapid, essentially diffusion-controlled ingress of water, followed by a much slower phase controlled by relaxation of the polymer chains. The hydrophilic:hydrophobic group balance and the extent of cross-linking of the polymer network dominate the swelling properties. Various estimates have placed the number of water molecules directly associated with each PC headgroup in the region of 12–18. These molecules are bound tightly to the PC; it is this attribute that provides the PC hydrogels with a level of dehydration resistance that makes them particularly suitable as contact lens materials, where on-eye dehydration can be associated with discomfort to the wearer.

Coating Stability

The stability of the PC coatings is obviously an important feature of their properties. For the simple physisorbed copolymer materials, studies in which part of the alkyl chain of the hydrophobic portion was radiolabeled with tritium showed that, once coated onto a substrate, the film was stable and did not leach.^[7] For the

cross-linkable polymers, atomic force microscopy techniques were used to demonstrate the increased force required to remove the coating from a substrate compared to the noncross-linked systems, and to show how the force of removal varied with curing and sterilization regimes. An adapted nanoindentation method also showed that the low level of cross-linking gave the coating some slightly elastic property; this ability to allow the coating to recover following deformation is particularly useful with respect to expandable devices such as stents.^[9] The stability of the coating on the *BioDivYsio* coronary stent was studied in vivo both in a porcine coronary model and on a stent removed from a human subject. Both studies showed the coating was still present, required the same force to remove, and had the same thickness, even after six months' implantation.^[23,24]

Drug Delivery Capability

The cross-linked networks formed in polymers such as PC1036 (see Fig. 2) lend themselves perfectly to drug delivery.^[25,26] Although the polymer coating is not macroporous in nature, the interstitial spaces between polymer chains are filled with imbibed water and provide a medium for drug loading, and ultimately a route for release of the therapeutic agent from the coating. Measurements made from fully cured membranes cast from this polymer indicate that the polymer has an effective molecular weight cut-off around 1200 daltons, a figure confirmed by loading and release studies of different molecular weight compounds from coronary stent coatings of this polymer.^[16,26] Furthermore, the coating has been investigated using fluorescent probe analysis to confirm the presence of hydrophobic domains within the hydrated polymer. Pyrene has a fused ring structure that gives rise to a characteristic fluorescent spectrum in which particular bands change in intensity when the molecule is in different environments. A very low level of pyrene in water gives a particular spectrum indicative of a polar environment, compared to that when the pyrene is allowed to partition from the water into the coating, during which the spectrum changes to one that is characteristic of a hydrophobic surrounding. This showed that there are hydrophobic domains within the hydrogel with which hydrophobic drugs could potentially interact and hence provide a method of controlled delivery from the coating. In point of fact, studies involving the loading and release of a range of different therapeutic agents from the PC-coated stent showed that there was a relationship between hydrophobicity and rate of release that was not explained by solubilities of the drugs alone. A weak correlation between the partition coefficient of the drug between octanol and water ($\log P_{(o/w)}$)

and the time for 90% release of the agent to be achieved was found to exist, supporting the hypothesis that the more hydrophobic compounds (higher log $P_{(o/w)}$) interact with the hydrophobic domains in the coating and hence retard their release.

As the PC1036-based coatings had a molecular weight limitation, it was necessary to develop other coatings that would allow the delivery of higher-molecular-weight species. Of particular interest for coronary stent purposes are large biomolecules such as heparin and DNA fragments. Such species carry a net negative charge, and so cationic PC coatings such as PC1062 and PC2028 were developed that are still highly biocompatible but capable of interacting with the biomacromolecules by surface ionic attraction.^[16]

In Vitro Bioevaluation

The extent of in vitro biological evaluation of various PC polymers is substantial^[27] (see Tables 1 and 2).

Many studies have focused on the first steps of any biofouling process, namely, the adsorption of proteins to the polymer surfaces. Any medical device that is placed on or within the body will illicit a response from the host, and the first test for foreign articles in this process of nonself-recognition is their interaction with proteins. When presented with a foreign surface, the proteins may change their three-dimensional shape in order to adopt a more energetically favorable conformation. This in turn exposes chemical moieties within the protein structure that are not normally accessible, and the growing protein layer takes on a higher level of biological activity which can ultimately result in adverse immunological and inflammatory responses. When proteins contact PC-based surfaces they are met by a layer of bound water molecules which act as a barrier to the permanent adhesion of the molecule. The use of circular dichroism spectroscopy has confirmed that the conformation of the protein remains unchanged, there being no thermodynamic drive for the structure to unfold, and consequently PC surfaces are largely protein-resistant.^[28] By addressing this

fundamental step in the cascade of reactions designed to rid the body of foreign bodies, PC can be used to improve the biotolerance of medical devices. Table 1 details work carried out on a range of proteins, using a wide variety of different techniques, in the analysis of their interactions with different PC-based polymer systems.^[7–9,15,18,19,29–39] In all of these studies without exception, it is shown that protein adhesion to a wide range of substrates is significantly decreased by modification of the surface with a PC polymer.

The interaction of cells with surfaces is largely controlled in the first instance by nonspecific protein adsorption. Receptors on cell surfaces rely upon the interaction with particular chemical sequences within certain proteins, which only become available when they alter their conformation. Once the cells are able to

anchor to the surface they can spread, divide, and generally orchestrate an attack against the foreign surface. By virtue of their ability to resist protein fouling, PC-based surfaces have been shown to reduce cellular adhesion of a number of different cell types in vitro^[27] (Table 2). Infection by certain bacteria is another process that may be controlled by reducing the extent of protein adhesion to a surface. For many types of bacteria, it is necessary to adhere to a surface in order to reproduce. In order to facilitate this, the organisms produce various excretions; surfaces that can resist the adhesion of these, thus preventing the bacteria from sticking, will have improved infection resistance. Table 2 outlines a number of studies that have reported successful reduction of bacterial adhesion to PC surfaces.^[7–9,15,29–48]

APPLICATION OF PC TECHNOLOGY

In the past, materials for use within the human body were selected mainly on the basis of the physical function they were to perform. With the aged population rising, there is an increasing emphasis on the duration over which these medical devices are required to serve, and thus greater focus on improving their tolerance by the recipient. This requires an understanding of the biological processes involved, with a focus on the interface between tissue and device. Over the past few decades, PC Technology has offered a proven strategy for the management of this interface in a number of different application areas.

Blood Contact

The bloodstream is a very unforgiving environment for any prospective device that must function within it. The hemostatic mechanism is responsible for minimizing the blood loss from any damaged blood vessel, but the process can educe undesirable events when the blood is presented with the artificial surface. There is a complex sequence of interdependent reactions that

begins with the adsorption of plasma proteins on the surface, and involves platelet adhesion and activation together with coagulation initiated from surface-mediated and extrinsic pathways, culminating in the formation of thrombus by cellular entrapment in an insoluble fibrin gel. In order to overcome these events, prior to any procedure involving blood-contacting devices, the anticoagulant heparin is administered, more commonly nowadays together with an anti-platelet regime. In addition to the extra cost involved, there are often problems associated with lowered platelet counts and bleeding. Devices that are therefore naturally resistant to the formation of thrombus have obvious advantages.

The *in vitro* studies described in the preceding section (see also Fig. 3) demonstrate that by mimicry of the red blood cell membrane, PC Technology is able to dramatically reduce the processes leading to thrombus formation. This exceptional hemocompatibility has led to its evaluation on a wide variety of devices used in cardiovascular applications. Initial studies of the technology were made using a variety of *ex vivo* models in which flowing blood was passed through various PC-coated tubing, with significant reduction in thrombus and platelet adhesion.^[49–52] Based on these results,

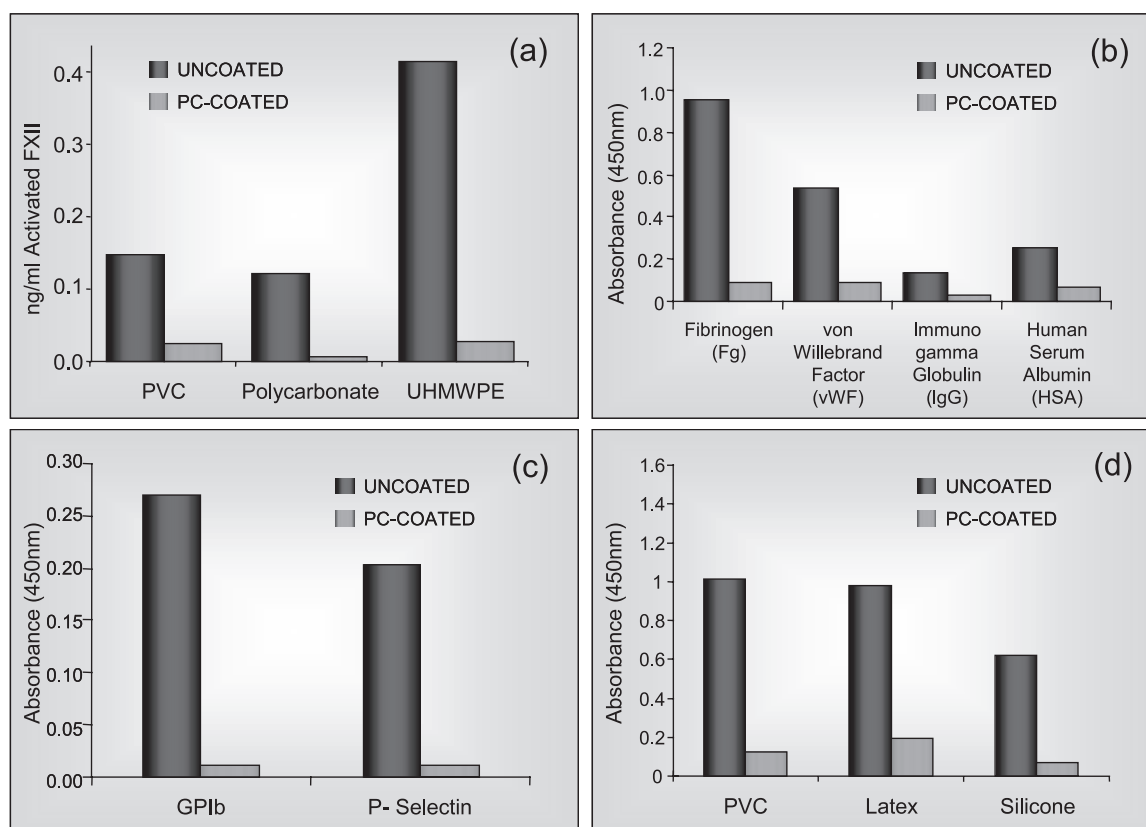

Fig. 3 In vitro performance of PC coatings: (a) reduction of contact activation; (b) reduced protein adhesion; (c) reduced platelet adhesion and activation; (d) reduced bacterial adhesion (*E. coli*). (From Refs. [9] and [15].)

Fig. 4 The problems with medical devices. Blood contacting applications: uncoated extracorporeal circuit blood filter after use (a), compared to a PC-coated filter (A); the anastomoses of a PTFE graft and the related intimal hyperplasia (circled) for uncoated (b) and PC-coated grafts (B) in a canine model; tip of an uncoated PTCA guidewire after a 28-minute procedure (c) and the PC-coated guidewire after a 108-minute procedure (C); uncoated coronary stent from an ex vivo shunt study covered in thrombus (d), compared to the PC-coated stent in the same study (D). Elsewhere in the body: a poorly wetting soft contact lens (e) compared to a PC-containing soft contact lens (E); bacterial adhesion to an uncoated latex surface (*E. coli*) (f), compared to the PC-coated latex surface (F); a PC-coated ureteric catheter after use in a patient (g), compared to an uncoated catheter from the same patient (G).

PC-coated thoracic drain catheters were the first of the various temporary in-dwelling devices to show a significant clinical advantage.^[53] In the years since these early successes, the technology has been applied to ever-more-complex devices, and is currently licensed to Sorin-Dideco for use on the entire circuitry of their cardiopulmonary bypass systems, including components such as the oxygenators, heat exchangers, tubing, filters (see Fig. 4a,A), and reservoirs. This serves to illustrate the flexibility of the coating, as these components are made from a variety of different materials including stainless steel, polypropylene, polycarbonate, PVC, and epoxy resin. Clinical data from the use of such devices show that up to 30% more blood is preserved, and many of the critical blood factors are significantly less activated, when a PC-coated circuit is employed.^[54] Moreover, the use of fully-coated circuits allows for reduced systemic heparinization of the patient, resulting in improved platelet count and lower post-operative bleeding.^[55] Future developments in this area include the use of a second-generation PC coating that has the capability of binding heparin to its surface

(see Fig. 2) in order to address areas of extreme hemodynamic flow which induce thrombosis regardless of surface contact.

Vascular grafts are another device in which potential benefit has been demonstrated by application of PC Technology. These are essentially synthetic blood vessels, commonly made of expanded poly(tetrafluoroethylene) (ex-PTFE) or Dacron (poly(ethylene terephthalate), PET), that are used to create a bypass around diseased arteries or replace damaged vessels. There are currently no suitable materials for use in the manufacture of narrow-bore vascular grafts (less than 3 mm), as conventional materials thrombose and block. Use of PC in combination with such devices is shown to be of benefit, not only from the nonthrombogenicity bestowed upon the device,^[27] but also from the fact that studies in a canine model showed reduced intimal hyperplasia at the anastomoses where synthetic graft is sutured to the tissue^[56] (see Fig. 4b,B).

Percutaneous coronary angioplasty (PTCA) is a minimal access procedure that is used to unblock the arteries of the heart without the need for bypass surgery.

It involves making a small incision in the leg or arm and, with the aid of low-intensity X-rays, advancing a steerable guidewire through the vasculature and into the affected coronary artery. The guidewire is passed through the narrowed region (known as the stenosis) and then a balloon catheter is advanced into position over the guidewire. Once in place within the stenosis, the balloon is filled with saline to pressures up to 20 atmospheres so that it inflates and opens the blockage. Upon deflation, the blood flow is reestablished and the catheter and guidewire removed prior to closure of the access incision in the artery. The guidewires are made from metals such as stainless steel and can be present within the bloodstream from minutes to hours. Even with heparinization, thrombus can form on the guidewire, which could be of potential danger to the patient if it were to dislodge and travel around the body. An *in vivo* study on guidewires coated with a simple PC copolymer (Fig. 2) showed that the coating significantly reduced platelet adhesion in a porcine model.^[57] Recently, Plante et al. reported on a clinical study using a variety of different guidewires with various coatings, and demonstrated by SEM that only the PC-coated guidewire had no sign of any thrombus present after clinical use, all other wires showing significant coverage with thrombi^[58] (Fig. 4c,C).

Clinical trials have shown that long-term outcomes after PTCA are significantly improved if a device known as a stent is placed within the reopened section of the vessel to maintain its patency. The stent can be of several types, but most popular are metal scaffolds that are crimped onto the balloon, and are then expanded into place when the balloon is inflated. Stents are also commonly made of stainless steel and, once deployed, remain in contact with the blood until such a time that the vessel heals and the stent becomes covered with a new endothelial layer. This process can take months and patients are required to remain on antiplatelet therapies over this period to prevent the risk of stent-related thrombosis blocking the treated vessel completely. The PC-coated stent was developed with the objective of reducing the risk of subacute thrombosis by masking the underlying thrombogenicity of the substrate. Initial studies of the coated stent were made *ex vivo* using an arteriovenous shunt made of silastic tubing in which the device was deployed; the shunt was then attached between a suitable artery and vein, some of the flowing blood being redirected through the shunt and over the stent. Platelets were radioactively-labeled with indium and their adhesion monitored using a gamma camera focused over the shunt. SEM was used to reveal the extent of occlusion of the shunt as thrombus formed (Fig. 4d,D). PC-coated stents displayed the expected resistance to platelet adhesion and thrombus formation,^[27] prompting more challenging studies *in vivo* in a range of more relevant preclinical models. Results from these assessments further support

the excellent hemocompatibility of the PC coating. Moreover, histological examination of the implants revealed that the tissue had no adverse reaction to the coating,^[59,60] unlike many other coatings previously studied that induced severe inflammatory reactions.^[61] Data such as these supported the clinical evaluation of the coated stent in a number of different registries and other trials, culminating in a randomized study used for U.S. approval of the device called DISTINCT (*BiodivYsio™ stent in controlled clinical trial*).^[62] This remains the only randomized trial with a coated stent to yield a 0% subacute thrombosis rate.

Although serious when it occurs, the incidence of stent-induced subacute thrombosis in the real world is reported to be around 3%, but lower in most clinical trials. This is due primarily to the introduction of more effective antiplatelet agents. A much more serious problem has been the occurrence of restenosis, in which the stented segment reblocks over time, necessitating a repeat procedure to unblock the artery again. The additional procedure not only incurs extra cost, but is further anguish to the patient and is made more difficult due to the presence of the initial implanted device. Restenosis is in essence an overactive healing response to the injury caused by balloon expansion and stent placement. The molecular biology of the process is complex, not well understood, and beyond the scope of this article. The rates of restenosis with PC-coated stents are comparable to market-leading uncoated devices, as the PC is bioinert and cannot address the injury caused during the procedure. Many approaches have been suggested to try and control the overproduction of new intimal tissue within the stented segment of the vessel (or neointimal hyperplasia, as it is known), but most recently, the delivery of drugs locally from the stent itself is proving to be the most efficacious. The PC coating has been shown to be a proven vehicle for the delivery of a range of therapeutic agents,^[25,26] and thus PC drug delivery stents were developed. The *BiodivYsio* Matrix stent systems were developed in order for physicians to load a drug of their choice onto the device by simple immersion of the stent in a suitable solution of the drug for a few minutes just prior to stent implantation.^[63] Upon removal from the solution, the stent is allowed to dry in air and then immediately deployed. Matrix LO is based on PC1036 and allows loading of drugs up to 1.2 kilodaltons. It has been used to load a range of drugs including angiotensin,^[64] the anti-inflammatory drug dexamethasone,^[65] and the healing promoter oestradiol,^[66] the latter two drugs showed promise in preclinical studies and have progressed to clinical trials (*STRIDE* (*study of anti-restenosis with the biodivYsio dexamethasone-eluting stent*) and *EASTER* (*estrogen and stents to eliminate restenosis*) for dexamethasone and oestradiol, respectively). Matrix HI is based on a cationically

modified PC coating (PC2028), and has been used in a number of preclinical studies including the study of Oliglow (radioactive oligonucleotide), DNA plasmid that codes for vascular endothelial growth factor-2 (VEGF2), and an antisense codon that codes for *c-myc*. There is currently no clinical activity based on this device, although there is a growing interest in the use of gene-based therapy to address restenosis.

Elsewhere in the Body

Outside of the bloodstream, the ocular environment is the second area of major application for PC Technology. The tear film is a complex structure composed of an aqueous mixture of proteins and lipids that bathe the eye, providing nutrients and protection against bacterial infection. Moreover, the cornea has no blood vessels and the tissue relies upon the direct absorption of oxygen from the atmosphere into the tear film where it can then diffuse into the cells. Any device that is required to function in contact with the cornea will significantly impact upon the tear film and will inevitably become a barrier toward the diffusion of oxygen. A PC-based soft contact lens material known as omafilcon A, has been developed; it falls within the soft contact classification scheme as a high-water-content nonionic material. The Proclear[®] range of soft contact lenses provides for the maintained health of the cornea on a number of different levels. Studies have shown that both protein and lipid deposition on the lens are markedly reduced when PC is present;^[38,39] this has the benefit of more comfort for the wearer throughout the day, as the deposition of biomolecules on the lens is essentially an immune response that can cause irritation to the cornea.

Once in contact with the cornea, the lens must allow for adequate permeability toward oxygen, ions, and other nutrients. The water within the hydrogel lens provides the medium through which these may be transported to the tissue. The amount of PC in the lens has been engineered to produce a bulk water content of around 59%, more than sufficient to provide more than adequate oxygen permeability, at the same time maintaining sufficient mechanical strength to allow handling. The PC also dominates the surface properties of the lens. The highly hydrophilic nature of the material ensures that the surface of the lens is easily wetted by the tear film, as demonstrated in Fig. 4e,E, in which the highlights on each lens clearly show the difference between the poor wetting characteristics of an ordinary lens (e) compared to that of a PC-based lens (E). The tear film is shown to break up more rapidly, and the lens surface wettability deteriorates, as proteins and lipids in the tears begin to adhere and spoil the lens surface. With the enhanced resistance to the spoliation processes, the PC-based lens material maintains its

excellent wetting properties—and hence a stable tear film—for much longer periods.

Furthermore, the PC helps to reduce evaporative loss of water from the lens. On-eye studies have shown that the PC-based lens dehydrates significantly less over a day's wear than other soft lenses made from conventional materials.^[67,68] In a double-blind clinical study, two lens-user groups compared the PC-based lens with an ordinary market-leading lens over a six-week period. One group wore Proclear for six weeks and then switched to the other lens, and vice versa for the other group. Each was asked to rank the lens on the basis of comfort at the end of each week, and in both groups the PC-based material was ranked significantly higher.^[69] On the basis of such data, the product has a label claim allowed by the FDA based upon potential benefits provided by the lens for dry-eye sufferers.

Elsewhere in the eye, PC Technology has been investigated on such devices as glaucoma shunts, punctum plugs, and intraocular lenses and for extended-wear contact lenses. Although there are no commercial products in these areas as yet, the benefits of PC are realized in feasibility. Its use in intraocular lenses (IOLs) in particular, as both a coating material for existing PMMA-based IOLs and as a wholly new foldable bulk IOL material, has shown great promise. Significant reductions in the adhesion of proteins such as fibrinogen and lysozyme, various cell lines such as corneal epithelia, fibroblasts, and macrophages, and bacteria such as *Staphylococcus epidermidis* and *Pseudomonas aeruginosa* have been reported (see Table 2 and references cited therein).

Infection is a common problem encountered with implants of all types, and can often result in additional trauma associated with the need to remove the device. The ability of PC Technology to resist colonization by a variety of strains of bacteria has therefore driven its application on devices used in other regions around the body. Studies in vitro have shown that the PC coating is more effective than antimicrobial silver-based treatments in reducing both *S. aureus* and *P. aeruginosa* biofilm formation on fluoroplastic tympanostomy tubes^[70] (licensed by Gyrus for the PacifiC[®] tympanostomy tubes). Other in vitro studies have shown reductions in adhesion of *E. coli*, *S. epidermidis*, *Proteus mirabilis* and *P. aeruginosa* on various coated alloplasts compared to uncoated controls (see Fig. 4f,F^[71]). Furthermore, the ability of the coating to resist the adhesion of proteins, in particular fibrinogen, is significant because of the implication of this protein in the formation of conditioning films necessary to encourage *S. aureus* attachment to surfaces. Urological devices are especially renowned for complications induced by infection due to the relative ease by which bacteria can gain access to the device surfaces. Certain of these bacterial species are known to increase the possibility of mineralization or

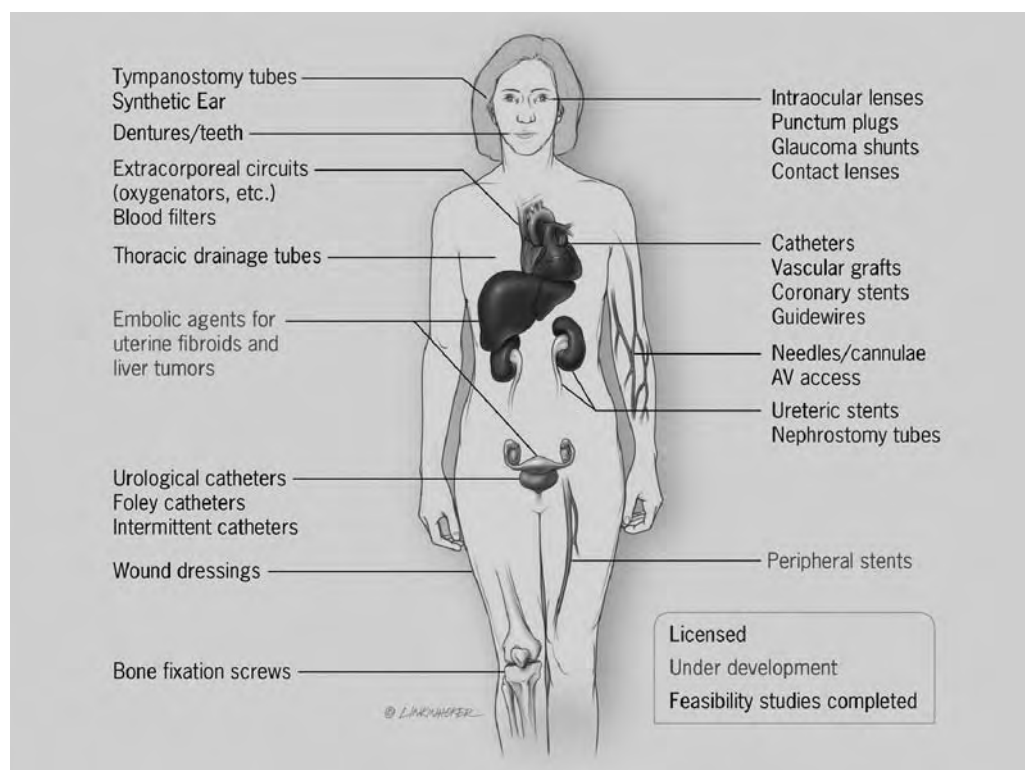

Fig. 5 The use of PC coatings and materials around the body from feasibility to commercial reality.

encrustation of the devices. Urease-secreting organisms such as *P. mirabilis* convert urea to ammonia, causing an increase in pH and initiation of crystallization of calcium and magnesium salts. These minerals encrust the lumens of the device causing blockage. Laboratory methods that mimic this encrustation process using *P. mirabilis* in artificial urine have shown that PC coatings produce large reductions in magnesium on latex and silicone substrates.^[27,71] The same effect has also been observed in vivo in a study on urological catheters, in which uncoated and PC-coated catheters were used consecutively in the same patients and the extent of encrustation assessed in each case (Fig. 4g, G^[27]). Moreover, a clinical study was performed using PC-coated polyurethane ureteral stents which were implanted for three months and then removed and analyzed for the presence of biofilm. This was compared to standard stents removed previously from the same patients and analyzed using the same techniques; the percentage of stents with biofilm visible by scanning electron microscopy was shown to be reduced from 70 to 30% for the PC-coated devices.^[71]

CONCLUSIONS AND FUTURE DIRECTIONS

PC Technology is an important addition to the field of biomaterials that has translated into significant clinical

benefit and commercial investment in a number of medical device applications. It has been studied in a vast array of indications around the body, as illustrated in Fig. 5. The current focus for the technology is on the development of improved embolic agents, materials that are introduced into blood vessels with the objective of occluding the blood flow (for instance, in order to stem flow to a tumor or block a vascular malformation). This type of minimally invasive procedure is on the increase and requires more advanced materials with improved long-term biocompatibility and the potential for drug delivery.

Medical devices have been transformed over recent years with the emphasis shifting from a purely mechanical standpoint to include consideration of the material-tissue interface. More recently, there has been a desire to introduce some form of bioactivity that will enhance the ability of the tissue to heal in the presence of the device. PC Technology is playing an important role in this biomaterials revolution, proving to be an extremely flexible platform for combining exceptional biocompatibility with the ability to deliver therapeutics in a controlled fashion. The continued evolution of the technology will be somewhat dependent upon the development of new techniques for polymer synthesis in order to allow novel architectures to be created, and subsequent device construction to convert these into useful biomaterials. Some initial advances have been

made using novel polymerization methods, such as ATRP, that have allowed well-defined, low polydispersity block copolymers to be made, which have the potential to form biocompatible stimuli-responsive structures that could find use in a multitude of drug delivery applications in the future.

Photopolymerization

Dong-an Wang

Jennifer H. Elisseff

Department of Biomedical Engineering, Johns Hopkins University, Baltimore, Maryland, U.S.A.

INTRODUCTION

Photopolymerization is defined as the reaction of monomers or macromers to produce polymeric structures by light-induced initiation (excitation of a photoinitiator) and subsequent polymerization. Fundamental research and practical applications of photopolymerization have evolved significantly over the past several decades leading to a better understanding of the mechanisms of the reaction and to numerous industrial and medical applications. The general concept of photopolymerization is to conjugate and solidify the fluid reactants into a desired stable structure using light. The procedure is usually irreversible. Complex patterns can be created using photopolymerization to print integrated circuits, wiring boards, or microfabricated biomaterial scaffolds. Photopolymerization technologies have also been applied in medicine for applications ranging from dental to lung sealants.

For the preparation of polymeric biomaterials, it is necessary to distinguish the concepts of photopolymerization, photocrosslinking and photografting. Photopolymerization refers to the polymerization of small molecular monomers or oligomers polymerizing via photoreactive moieties to generate a linear macromolecular. Poly(N-hydroxyethyl methacrylate) (pHEMA) is an example of a linear polymer created by photopolymerization. Photocrosslinking defines a process by which functional groups on linear or branched macromer chains crosslink to form a three-dimensional network. Poly(ethylene glycol diacrylate) (PEGDA) is a popular macromer used to generate hydrogels by photocrosslinking. In general terms, photopolymerization describes both linear photopolymerization and photocrosslinking. The third concept, photografting, describes the procedure of covalently incorporating functional additives to a polymeric matrix or surface using a light-induced mechanism. Photografting is an important modality for biomaterial surface modification. This article will review the mechanism of photoinitiation and photopolymerization, as well as novel applications in biomaterials and tissue engineering.

Photopolymerization causes significant changes to material physical properties, such as phase, solubility,

adhesion, color, optical index, and electrical conductivity. This technique for material synthesis has been applied to microfabrication, coating, and surface modification of devices and materials, including adhesives and sealants; printing materials; optical and electro-optical materials; and electronic materials.^[1] More recently, the benefits of photopolymerization have been utilized for numerous biomedical applications. The majority of photopolymerized biomaterials are based on acrylate systems. The prepolymers are usually water-soluble unsaturated acrylate or methacrylate-containing oligomers or macromers that can be covalently cross-linked via addition polymerization with the excitation of radical-generating photoinitiators. For dental or orthopedic applications, photopolymerization has several advantages including rapid gelation and the ability to create a moldable crosslinked structure in situ via minimally invasive injection. Furthermore, photopolymerization, enables encapsulation of cells for in-situ tissue engineering.

MECHANISMS OF PHOTOPOLYMERIZATION

Photopolymerization requires three essential elements: electromagnetic radiation ($h\nu$), chromophore-containing photoinitiators (PI), and mono/macromers with unsaturated moieties such as a vinyl group and its derivatives including styrene, acrylate, or methacrylate groups. Ultraviolet (UV: 190~400 nm) and visible light (Vis: 400~800 nm) can be harnessed for photopolymerization. Accordingly, the maximal absorption wavelength (λ_{\max}) of the PI chromophores (the carbon-carbon or carbon-oxygen π -electron conjugates in PI molecular structure) is concentrated in the relatively high energetic UV or near UV visible range.

Successful photopolymerization relies on effective initiation and propagation. The irradiated photons with proper frequency ($\nu = c/\lambda = E/h$, where c = light traveling speed, λ = wavelength, E = photon energy, and h = Planck's constant) are absorbed by the π -electron conjugates of PI chromophores that are simultaneously promoted to a higher energy orbital—PI*. This excited quantum state has a half-life of less than a μsec . It

rapidly decays back to the original state inducing photon emission or molecular lattice vibration. Numerous PI^* may also chemically decompose into reactive fragments, such as radicals $[I^*]$ or ions $[I^+/I^-]$. As reactive intermediates, these fragments are more stable and serve as direct initiators for radical polymerization or anionic/cationic polymerization (Eq. 1).

Eq. 1 Excitation of photoinitiators and process of photopolymerization.

Most of the practical biomedical applications of photopolymerization use a free radical mechanism to initiate addition polymerization of vinyl group-containing mono/macromers (Eqs. 2 and 3).

For traditional thermal radical polymerization, chain initiation and propagation usually require a temperature higher than 40°C . However, since electromagnetic radiation provides highly efficient energy for PI excitation, the photoinitiation and the subsequent polymer chain propagation can proceed at lower temperatures ($10\sim 40^\circ\text{C}$), which is compatible with physiological environments (37°C). Furthermore, chain transfer processes that terminate reactions in thermal radical polymerization are minimized. The termination of chain propagation usually proceeds by

standard radical coupling and unsaturation exchange through β -hydrogen migration involving ambient oxygen.^[2]

As described above, the primary radicals for polymerization initiation usually originate from the PI (PI^*). However, for some applications the exogenous PI is unnecessary. A typical example is the photografting strategy for the surface modification of polyurethane biomaterials. This mechanism is based on the in situ generation of primary radicals from the polymer matrix by photooxidation with a peroxide reagent and UV irradiation. The polyether moieties in polyurethane matrix can be oxidized into peroxide radicals that are capable of initiating subsequent chain propagation (Eq. 4).^[3] Another novel example of photo-oxidation is the generation of tyrosyl radicals on the tyrosine residues of collagen fibers in the superficial layer of cartilage tissue. By initiating these domestic radicals, the (meth)acrylated macromers are covalently grafted onto the tissue (Eqs. 4 and 5).^[4,5]

To study non-free radical systems, cationic photopolymerization of phenyl glycidyl ether was recently performed using two kinds of iodonium PI: diaryliodonium hexafluoroantimonate (IHA) and (tolcumyl) iodonium tetrakis (pentafluorophenyl) borate (IPB). Whereas the free radical system depends on light for both initiation and propagation, cationic photopolymerization requires light only for the initiation and creation of the cationic active center.^[6] This study demonstrates feasibilities for the dark-curing photoinitiated polymerization. However, the PI toxicity

may limit biomedical applications of this novel approach.

BIOCOMPATIBLE PHOTOINITIATORS

The role of photoinitiators (PI) in photopolymerization is to generate reactive intermediates (free radicals) to initiate the polymerization of unsaturated (vinyl) mono/macromers with the energy from electromagnetic radiation (i.e., UV or near UV-range visible light). Photo-initiation involves photon absorption, PI molecular excitation, and finally reactive fragment formation after PI decomposition. The function of photon absorption is executed by the π -electron-delocalized chromophores in the PI molecular structure and the successive light-induced PI cleavage also occurs at the boundary of the π -electron-conjugate moieties. Each chromophore has a specific maximal absorption wavelength (λ_{\max}) and a corresponding molar extinction coefficient (ϵ , $\text{mol}^{-1} \text{cm}^{-1}$), which is an experimental measure of photon absorption probability at that wavelength. The intensity of absorbance (A) can be calculated using the equation $A = \epsilon \cdot C \cdot l$, where C represents the concentration of chromophores and l represents the length of light-path. The typical units of chromophores are: $C=C$ (alkene, $\lambda_{\max} = 195 \text{ nm}$, $\epsilon = 10,000$), $C \equiv C$ (alkyne, $\lambda_{\max} = 195 \text{ nm}$, $\epsilon = 2000$), $C=C-C=C$ (diene, $\lambda_{\max} = 215 \text{ nm}$, $\epsilon = 20,000$), Benzene (benzoyl or phenyl, $\lambda_{\max} = 185 \text{ nm}$, $\epsilon = 60,000$; $\lambda_{\max} = 200 \text{ nm}$, $\epsilon = 8000$; $\lambda_{\max} = 255 \text{ nm}$, $\epsilon = 200$), RCOR (Ketone, $\lambda_{\max} = 190 \text{ nm}$, $\epsilon = 900$; $\lambda_{\max} = 280 \text{ nm}$, $\epsilon = 15$), RCOOH (Carboxyl, $\lambda_{\max} = 205 \text{ nm}$, $\epsilon = 60$), $\text{N}=\text{N}$ (Azo, $\lambda_{\max} = 345 \text{ nm}$, $\epsilon = 10$), NO_2 (Nitryl, $\lambda_{\max} = 270 \text{ nm}$, $\epsilon = 18.6$), $\text{S}=\text{O}$ ($\lambda_{\max} = 210 \text{ nm}$,

$\epsilon = 1500$), ROOR (Peroxide, $\lambda_{\max} = 200 \sim 300 \text{ nm}$).^[1,2] However, the practical value of ϵ relies on the individual chemical environments, such as the properties of adjacent groups, substituents, and local conjugates.

Commonly used thermal radical initiators, azo and peroxide initiators, are also capable of photoinitiation. The typical species are respectively 2,2'-azobisisobutyronitrile (AIBN, $\lambda_{\max} = 350 \text{ nm}$) and benzoyl peroxide (BPO, $\lambda_{\max} = 230$ and 270 nm). Light-induced radical formation is illustrated schematically in Eqs. 6 and 7. Unfortunately, these compounds suffer from low photoinitiation efficiency and cell toxicity, and are not water soluble, thus limiting biological applications. Limited photoinitiator water-solubility may lead to low initiation efficiency and toxicity. Solubility in water may be improved by dissolving the initiator in an initiator stock solution of 70% ethanol.

Toxicity of the photopolymerization system may be caused by the electromagnetic irradiation, chemical properties of the reagents, or initiator reactive intermediates. The frequency and intensity of light can be manipulated to optimize photopolymerization efficiency and reduce toxicity. A higher intensity and/or shorter wavelength of light enhances initiation efficiency at the cost of increased cell and tissue injury. On the other hand, a lower irradiation intensity will require longer exposure times for polymerization, which can also be harmful to the viability of living cells or tissues. One potential solution is to apply a biocompatible range of ultraviolet ($\lambda \geq 365 \text{ nm}$)^[7] or visible blue light ($\lambda = 420 \sim 500 \text{ nm}$). A class of photoinitiators containing benzoyl or phenyl-ketone π -electron-delocalized conjugates respond to these wavelengths of light. The typical products of UV-range PI (Ciba-Geigy) are Irgacure

family of 2,2-dimethoxy-2-phenylacetophenone (I 651, $\lambda_{\max}=365$ nm, $\epsilon=94.6$), 1-hydroxycyclohexyl phenyl ketone (I 184, $\lambda_{\max}=365$ nm, $\epsilon=7.7$), 2-methyl-1-[4-(methylthio) phenyl]-2-(4-morpholinyl)-1-propanone (I 907, $\lambda_{\max}=365$ nm, $\epsilon=120.8$), and Darocur family of 2-hydroxy-1-[4-(hydroxyethoxy) phenyl]-2-methyl-1-propanone (D 2959, $\lambda_{\max}=365$ nm, $\epsilon=6.7$). The prototypical visible-light initiating system is camphorquinone (CQ, $\lambda_{\max}=470$ nm, $\epsilon=24.8$, Aldrich) (Eq. 8a) with ethyl 4-*N,N*-dimethylaminobenzoate (4EDMAB), triethyl amine (TEA), and a popular photosensitizer, isopropyl thioxanthone (Quantacure ITX, $\lambda_{\max}=365$ nm, Great Lakes Fine Chemicals) (Eq. 8b). The mechanism of radical generation is demonstrated in Eqs. [9–12].^[7]

The potential toxicity mediated by the combined factors of chemicals and irradiation has been investigated using various cells. These experiments were performed by suspending the cells in PI solutions and

directly exposing them to light irradiation. As reported by Bryant and Anseth,^[7] with ~ 6 mW/cm² (intensity) of 365-nm UV or ~ 60 mW/cm² of 470–490-nm visible light, respectively, the UV-PI D 2959 at concentration of $\leq 0.05\%$ (w/w) or the visible-PI CQ at concentration of $\leq 0.01\%$ (w/w) is cytocompatible for NIH/3T3 fibroblast cells and also capable of initiating the photopolymerization of macromers. For chondrocytes, the use of 0.05% (w/w) D 2959 is safe with ~ 8 mW/cm² of 365 nm UV exposure for 10 minutes. According to the data reported by Williams, Malik, and Elisseff,^[8] the use of 0.05% (w/w) D 2959 with ~ 8 mW/cm², 365 nm-UV exposure for 5 minutes is also safe for goat and human mesenchymal stem cells (gMSC and hMSC). For corneal epithelial cells (SIRC cell-line), the cell viability is around 50%; for human embryonic germ cells (LVEC cell-line) and human fetal osteoblast (hFOB), the cell viability is lower than 50%.

PHOTOPOLYMERIZED BIOMATERIALS

The concept of biomaterials covers all natural and synthetic nonmedicinal matters or blends that, in whole or partially, fulfill the purposes of physically reconstituting, improving, substituting, or reconstructing defective human tissues or organs. Biomaterials include metal, ceramic, synthetic organic materials, and natural macromolecular materials, of which functional polymers are one of the largest families. For biomaterial fabrication, the process of photopolymerization has advantages of short reaction time, mild reaction conditions, in situ gelation, and biocompatibility. Hydrogels are one class of photopolymerized biomaterials. A photopolymerization system comprises mono/macromers, photoinitiators, processing additives, and functional additives in aqueous reaction medium. For tissue engineering applications, living cells are also incorporated. Mono/macromers are usually hydrophilic, with the essential unsaturated structures needed for polymerization. Degradable moieties and functional groups are frequently incorporated into the hydrogels. Members of the polyester family; poly(orthoester), poly(propylene fumarate) (PPF), polyphosphoesters, poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and polyanhydride, as well as natural macromolecules, are commonly employed as the degradation sites on the polymeric scaffold of hydrogels. Biological signals, such as proteins, peptides, sugars, enzymes, and growth factors, are often incorporated as either functional pendent groups on polymeric skeleton or functional additives physically mixed in the system. Hyaluronic acid (HA) is an example of processing additive for controlling the systemic viscosity and fluidity.

Photopolymerized Hydrogels

Photopolymerized hydrogels created from small molecular weight monomers, such as poly(2-hydroxyethyl methacrylate) (pHEMA), have unique properties. These hydrogels are composed of small-molecular-weight repeating units, and correspondingly have a small pore size and low swelling ratio (water content). High-density pHEMA hydrogels have a high degree of polymerization, which results in a higher bulk strength and adhesive capacity. As biomaterials, they are primarily used as injectable hard-tissue substitutes in the spine or as permanent dental fillers. Due to the physically condensed composition of these hydrogels, living cells may not be encapsulated.

Photocrosslinked Hydrogels

Photocrosslinked hydrogels for use as tissue engineering scaffolds are formed by larger molecular weight

monomers, macromers. The macromers are usually water-soluble polymers with photocrosslinkable moieties. Poly(ethylene glycol)-based polymers, including PEG-diacrylate (PEGDA, Eq. 13), are frequently used for tissue-engineering applications and provide a simple model for illustrating their practicality.

Eq. 13 Chemical Structure of PEGDA.

In PEGDA structure, the macromolecular poly(ethylene glycol) (PEG) is the backbone of the macromer and the diacrylate is the endgroup. After the formation of a PEG hydrogel by photocrosslinking, the three-dimensional crosslinked PEG network forms the scaffold with the acrylate endgroups saturated into chemical crosslinking points. Two or more photocrosslinkable moieties are present on one macromer chain to create a water insoluble network. Crosslinking moieties are generally acrylate derivatives, including methacrylate, methacrylic anhydride, acrylamide and propylene fumarate. The candidates for the macromer backbone are hydrophilic macromers with the molecular weight mostly varying from 10^3 to 10^5 Dalton. Examples of hydrophilic macromers include water-soluble polyethers (such as PEG), polyesters, polyols (such as PVA), polysaccharides and polyester-ether dendrimers.^[9]

Two classes of photocrosslinked hydrogels are PEG gels and polysaccharide (polyol) gels. PEG (or polyethylene oxide, PEO) is a widely used biomaterial due to its superior properties of biocompatibility, hydrophilicity, and mechanical flexibility. These attributes also make it an ideal candidate as a hydrogel scaffold. PEG macromers can be roughly divided into two categories: PEG-backbone and PEG-branched. The PEG-backbone class comprises versions of PEGDA with a template similar to a block copolymer, (meth)acrylates-*Fg*-PEG-*Fg*-(meth)acrylate, where *Fg* represents functional groups for degradation or biological signaling. The PEG-branching class generally encompasses comblike grafting (coupling) of PEG to create co-polymers. The PEG side chains with (meth)acrylate endgroups are pendent branching chains or chains with a comb attached to a backbone. Functional groups can be hybridized either on the ends of PEG chains or on the macromer backbone.

Preparing polysaccharide macromers requires the conjugation of (meth)acrylate moieties onto polysaccharide chains. A large number of sugar hydroxyl groups (OH) or other reactive functional groups such as amine (NH_2), carboxyl (COOH), or sulfonic/sulfate (SO_3/SO_4) groups are utilized as the conjugating sites. Glycidyl methacrylate and methacrylic anhydride may

be employed as the methacrylation reagents. The polysaccharide species used for photocrosslinked hydrogels include alginate, hyaluronan,^[10] dextran,^[11] chitosan,^[12] heparin,^[13] and chondroitin sulfate.^[14] As natural macromolecules, polysaccharides have the advantages of biocompatibility, biodegradation, and specific biological/biophysical functions. For example, chondroitin sulfate, a major component of native cartilage, can be methacrylated to form a hydrogel (Eq. 14, an example of a methacrylated polysaccharide).

Eq. 14 Chemical structure of chondroitin sulfate-glycidyl methacrylate.

Crosslinking

The pore size of hydrogels depends on the molecular dimensions and hydrophilicity of the macromer as well as the actual crosslinking density. The crosslinking density is determined by the (meth)acrylate density and crosslinking efficiency. In general, a highly crosslinked and/or hydrophobic polymer scaffold tends to form hydrogels with a smaller pore size. The hydrogel crosslinking efficiency, C_e , can be calculated by Eq. 15,^[15] which includes the addition polymerization efficiency of the macromer's di-acrylate endgroups.

$$C_e = \left(\frac{\overline{M}_n}{\overline{M}_c} \right) / f_n \quad (15)$$

Eq. 15 Calculation of crosslinking efficiency, C_e .

where f_n is the number of the macromer's crosslinking functionality. For example, each PEGDA macromer molecule (with two acrylate endgroups) may maximally crosslink with four other macromer molecules with acrylate endgroups. Thus f_n is 4, \overline{M}_c represents the average molecular weight shared by each crosslinking functionality of the macromer in the crosslinked network, and \overline{M}_n represents the number

average molecular weight of the macromer. \overline{M}_c can be calculated using the Peppas–Merrill model,^[16] which originates from the Flory–Rehner model and is applicable to systems with the solvent present during crosslinking. The Peppas–Merrill model is expressed by Eq. 16.

$$\frac{1}{\overline{M}_c} = \frac{2}{\overline{M}_n} - \frac{\left(\frac{\overline{v}_0}{\overline{V}_1} \right) [\ln(1 - v_s) + v_s + \chi_1 v_s^2]}{v_r \cdot \left[\left(\frac{v_s}{v_4} \right)^{\frac{1}{3}} - \frac{1}{2} \cdot \left(\frac{v_s}{v_r} \right) \right]} \quad (16)$$

Eq. 16 Calculation of average molecular weight per crosslinking functionality, \overline{M}_c .

where v_0 is the specific volume of the polymer/macromer, \overline{V}_1 is the molar volume of the swelling agent (water), v_s is the polymer volume fraction in the equilibrium-swollen hydrogel, χ_1 is the Flory polymer–solvent interaction parameter, and v_r is the polymer volume fraction in the hydrogel immediately after crosslinking but before swelling, which is equivalent to the volume concentration of the solution where crosslinking occurs. The values of v_s can be calculated by Eq. 17:

$$v_s = \frac{Q_v - W_a / \rho_{\text{water}}}{Q_v} \quad (17)$$

Eq. 17 Calculation of polymer volume fraction in the equilibrium-swollen hydrogel, v_s .

where ρ_{water} is the density of water, Q_v is the volume-swelling ratio of the gels, and W_a is the equilibrium water content (weight) in the gels. The expression $C_e \cdot f_n$ is the average number of crosslinking that occurs on each macromer molecule. If the polymer/macromer's f_n value is not greater than 2, or the system's average C_e value is not greater than 2/4, gelation will not occur. This is also demonstrated by the Peppas–Merrill model for water-soluble macromers ($\chi_1 < 0.5$) in crosslinking-swelling system ($v_s < v_r$)—the \overline{M}_c value is always smaller than $\overline{M}_n/2$.^[15]

Degradation

The in-vitro degradation of PEGDA hydrogels is based on the hydrolytic cleavage of the degradable groups into macromers (at the F_g site of the template “(meth)acrylates- F_g -PEG- F_g -(meth)acrylate”). Degradable groups that have been attached as F_g include oligo PLA/PGA,^[17] PPF,^[18] and phosphoesters.^[15] The corresponding degradation products are the water-soluble macromers and bioresorbable oligo (meth)acrylate,

PEG (when molecular weight <10,000 Da), as well as nontoxic small molecules (Eq. 18).

A second form of hydrogel degradation relies on the backbone-degradation of polyesters, polypeptides, polysaccharides, and their combinations. Polyester backbones are usually composed of PLA/PGA, poly(ϵ -caprolactone) (PCL), poly phosphoester, and PPF. Polysaccharide backbones include alginate, hyaluronan, chitosan, and chondroitin sulfate (Eq. 14) and protein backbones comprise collagen,^[19] gelatin^[13,20] and fibrinogen.^[21] The combination of polyester backbone with poly(aspartic acid)-grafted combs with methacrylate groups (Eq. 19),^[22] and the combination of polyphosphoester backbone with PEG-grafting co-polymer methacrylated with methacryloyl chloride (Eq. 20) have been reported.^[23] An example of a combination degradable hydrogel is a (meth)acrylated linear polyester-polyether (PEG) hybridized dendrimer (Eq. 21).^[9]

A traditional hydrolytic mechanism of polymer degradation occurs through cleavage of ester groups. Variation of environment temperature and pH can significantly affect the degradation kinetics of the ester groups. For example, alkaline conditions dramatically accelerate poly(phosphoester) degradation by neutralizing the acidic degradation products.^[24] When the environmental temperature and pH are stable, as in the physiological conditions, hydrogel degradation is impacted by three factors: the chemical (hydrolysis) property, the density of degradable groups, and the pore size of the gel which controls the water content and the efficiency of water-polymer interaction. These three factors can be manipulated to control degradation. For example, hydrolysis may be accelerated by increasing the density of degradable sites or the pore size. However, hydrolytic degradation can be difficult to control due to lack of specificity.

Eq. 18 Chemical structure of functionalized PEGDA-type macromers. (From Refs. [13,15,16].)

Eq. 19 Chemical structure of polyester-g-poly (aspartic acid) macromer. (From Ref. [22].)

Eq. 20 Chemical structure of polyphosphoester-g-PEG macromer. (From Ref. [23].)

The synchronization of biomaterial scaffold degradation and tissue development is important for optimizing tissue engineering systems. Biological strategies may be investigated to create a material that can specifically respond to its environment. The concept of *biodegradation* is presented as a method to enzymatically cleave polymeric scaffolds and hydrogels. Bio-responsive degradation of scaffolds is triggered by specific changes in the environment. In recent investigations of cartilage–bone tissue engineering scaffolds, chondroitinase ABC that is produced by mature chondrocytes and alkaline phosphatase that is secreted by osteocytes were respectively used for the biodegradation of chondroitin sulfate gels and phosphoester gels.^[24] Results indicate the bioresponsive relationships between the relevant tissue-produced enzymes and the degradation of the corresponding biomaterials.

Functionalization

Photopolymerized biomaterials generally play the roles of carriers or fillers for biological systems. In addition to the physical properties and functions, biomaterials are also expected to fulfill biological functions, such as promoting cell proliferation, inducing cell differentiation, or enhancing the growth of surrounding tissues for defect

regeneration. A straightforward method to incorporate function is to create directly photocrosslinkable hydrogels made up of natural macromolecules or macromolecular blends. To promote cartilage and bone healing, (meth)acrylated polysaccharide gels and blends of PEOA-type gels encapsulating extracellular matrix extracts “Matrigel”^[25] or “Cartrigel”^[26] have been developed. Hyaluronic acid (HA) was also utilized in a blend with PEOA gels with the dual roles as a process additive for the viscosity control and a functional additive for tissue concrescence (Genzyme, Inc.).

For tissue-engineering purposes, a number of enzymatic and peptide biological signals are employed as functional additives in hydrogels to improve development of engineered tissues. For hard tissue regeneration, transforming growth factor- β (TGF- β)^[27] and bone morphogenetic protein-2 (BMP-2) have been hybridized with photopolymerized hydrogels. The arginine–glycine–aspartic acid tripeptide sequence (RGD) is widely used to improve cell adhesion on biomaterial surfaces and in hydrogels.^[28] Biological signals such as growth factors can be physically encapsulated in the hydrogels with cells. TGF- β and BMP-2 have been combined into mesenchymal stem cells (MSC)—PEGDA photopolymerizing gel systems *in vitro* and *in vivo*, respectively, for chondrogenesis and osteogenesis. To prevent the loss of these additives

Eq. 21 Chemical structure of methacrylated linear polyester–polyether PEG) hybridized dendrimer. (From Ref. [9].)

from the hydrogels via water leaching or extraction, they can be covalently tethered to the hydrogel. Tethering sites can be on the reactive groups of the polymer backbone such as the double bond in propylene fumarate of PPF (Eq. 18), or at the ends of the pendent chain residues, as in the free amino groups (NH_2) of the polyphosphoester-*g*-PEG macromers shown in Eq. 20. Another choice is to synthesize the functionalized and (meth)acrylated mono/macromers separately, and then mix with the standard mono/macromers (such as PEGDA) for co-photogelation (co-photopolymerization/crosslinking). The strategy is schematically illustrated in Eq. 22 using an example of RGD-PEGDA tethering system. Methods for covalent tethering include commonly used bioconjugate techniques, such as the sulfonyl (acyl) chloride, carbonyl diimine (CDI), *N*-hydroxy succinimide (NHS), and divinyl sulfone routes.

Eq. 22 RGD-PEGDA gel tethering system by co-photogelation.

Photografting

Photografting is a technique used for biomaterial surface modification. The basic strategy is: 1) surface photooxidation of a polyether/ester matrix by UV irradiation and hydrogen peroxide to generate reactive (peroxide) radicals; 2) the surface radicals initiate in situ photografting and successive photopolymerization (usually low polymerization degree) of vinyl (acrylate) monomer/macromers with UV irradiation but without photoinitiators; 3) functional moieties (groups, compounds, or polymers) are conjugated for material surface functionalization based on the reactive pendent groups of the photografted poly/oligomers (Eq. 4). This photografting technique has been applied to the surface modification of man-made blood vessel materials and hard-tissue substitution materials. Polyurethane elastomers, including poly(ether/ester urethane)s, are employed as the matrix material for blood-contact devices for cardiovascular tissue engineering. Reactive surface modifying additives, 2-hydroxyethyl (meth)acrylate (HEMA or HEA), acrylamide (reactive amine group containing), and methacrylic diethyldithiocarbamate^[29] can be photografted using the strategy described above. Then with the reactive groups ($-\text{OH}$ or $-\text{NH}_2$),

hydrophilic polymer chains and/or biological ligands are conjugated onto the surface. PEG chains, because of their high hydrophilicity, chain-mobility, and steric exclusion, are often individually grafted as the surface inhibitors for platelet adhesion. PEG chains are also used as spacers for biological ligands, playing the roles of physical supporter and mobility provider at the water interface of the materials. Ligands include surface stearyl groups or Cibacron Blue that is capable of specifically binding blood albumins to make a surface inert and nonthrombogenic. Surface-activating signals like the RGD sequence are also used to promote the adhesion and proliferation of endothelial cells on the modified surface achieving endothelialization.^[30] For cartilage-tissue engineering, degradable PLA/PGA and PCL are often employed as scaffold matrix materials. Using similar photooxidation and photografting strategies, cell(chondrocytes)-growth-promoting ligands are covalently introduced onto the surface of the degradable polymeric scaffolds to improve cartilage tissue regeneration.

PHOTOPOLYMERIZATION FOR TISSUE-ENGINEERING APPLICATIONS

Tissue engineering is the application of the principles and methods of engineering and the life sciences toward the fundamental understanding of structure–function relationships in normal and pathological tissue and the development of biological substitutes to restore, maintain, or improve functions. Photopolymerized biomaterials have been applied to tissue-engineering applications with numerous roles including non-cell involved fillers, or dressings; cell growth guiders or promoters; and matrixes for two- and three-dimensional cell culture. Acellular photopolymerized biomaterials comprise dental fillers and defect dressings for hard tissues. Practical systems include PEGDA-HA blends for bone and cartilage dressings (Genzyme, Inc.) and hernia fixing. PolyHEMA or chondrotin sulfate gels are being used as the fillers for bone repair. Photopolymerized hydrogels are also believed to have the talent of inducing and guiding cells to regenerate tissues^[15,20] Sharma et al. are developing strategies to organize chondrocytes and hydrogels to promote chondrocyte proliferation and three-dimensional tissue production, impossible in two-dimensional systems. For applications in two-dimensional cell culture systems, photopolymerization techniques are generally utilized for surface modification. Biological signals or ligands are immobilized onto the biomaterial surfaces using photografting approaches, by which the cell–material interfaces are optimized for cell adhesion and proliferation. For example, as described in photografting section, RGD was conjugated onto polyurethane elastomers via

Fig. 1 Schematic illustration of man-made cornea using photopolymerized hydrogels. (From Ref. [33].)

photografting to construct endothelial cell-engineered surfaces for cardiovascular tissue engineering. Unlike endothelial cells, which naturally grow on two-dimensional surfaces, the native environment for most musculoskeletal cells is in three dimensions. Common methods to create a three-dimensional environment are 1) to encapsulate cells in hydrogels or 2) to place cells on porous biomaterial scaffolds. Photopolymerization strategies have been applied to the latter method as demonstrated by photografting of biological signals to optimize the material-cell interfaces. BMP or RGD-conjugated porous materials of biodegradable PLA, PGA, and PCL have been used to enhance scaffolds for cartilage repair.^[31] A unique approach for three-dimensional culture is cell encapsulation by photogelation of injectable macromer-cell-photoinitiator systems. This has been applied to hard tissue regeneration, liver engineering (with hepatocytes),^[32] and bioartificial corneas.^[33]

Applying hydrogels to tissue engineering has numerous advantages. Hydrogels are composed primarily of water, similar to the composition of biological systems. Mechanical properties and water can be manipulated to suit a particular application. The crosslinked hydrophilic polymer network is capable of suspending and immobilizing cells, whereas it also allows for the free penetration of water, nutrients, and metabolic waste, even allowing limited cell migration. A unique tissue-engineering application of hydrogels is engineered corneas. The biomimetic structures may be constructed into a multilayered structure with a superficial epithelial monolayer, deep endothelial monolayer, and a photopolymerized hydrogel encapsulating keratocytes, as a transparent substitute of cornea stroma, in the middle (Fig. 1).^[33]

Hard Tissue Repair

Among the current tissue-engineering applications using photopolymerized biomaterials, entries for hard tissue

repair are the most numerous. A significant number represent dental substitutions (fillings) and musculoskeletal repair templates. The fundamental questions lie in the construction of implants and their integration between the implants and the surrounding tissues. The formulation of the photopolymerization precursors is always composed of mono/macromers, photoinitiators and diluents. The mono/macromers are usually di(meth)acrylate compounds. For dental materials, small molecules or stiff polymers, such as the aromatic ring-containing 2,2-bis[4-(2'-hydroxy-3'-methacryloyl-oxypropoxy) phenyl] propane (bis-GMA) or 1,6-bis(2'-methacryloyl-oxyethoxycarbonylamino)2,4,4-trimethylhexane (UDMA), are applied with relatively high solid density. The system is complemented with inorganic fillers to improve compatibility and strength. The photoinitiator CQ (Eq. 8) is widely used with visible blue light. The photopolymerized (crosslinked) system has a low shape/size distortion and low water absorption, as well as good adhesion, making it ideal as a dental filler.

For the musculoskeletal dressings or implants typically used on bones or cartilage, the diluents are usually water or aqueous fluids and cells are encapsulated in the implants. The in situ injection protocol for (knee) articular cartilage repair is demonstrated in Fig. 2.^[34]

The procedure demonstrates in situ injection of the precursors for polymerization and then in situ photogelation (cell encapsulation) with UV irradiation. The in vivo trials have been performed in nude mice by transdermal injection (Fig. 3)^[35,36] and also in defects created on the articular surface of a goat model (Fig. 4).^[34]

Chondrocyts and osteoblasts are respectively encapsulated for cartilage and bone regeneration. Mesenchymal stem cells (MSC) may also be employed for three-dimensional cultivation in hydrogels. The in-vitro and in-vivo studies of chondrogenesis and osteogenesis were performed using the corresponding growth factors of TGF- β and BMP-2 to promote stem cell differentiation. Furthermore, a novel technique of separately encapsulating different cell lines or cell types within a multilayer hydrogel was developed to mimic the zonal

organization and behavior of chondrocytes respectively in the superficial, middle, and deep levels of native cartilage.^[37]

Integration of biomaterials with the body has been a longstanding problem in medicine. Lack of proper biomaterial implant integration with the body sacrifices longevity and function. Integration of biomaterials with hard tissues such as cartilage, which lacks the ability to self-repair, is particularly challenging due to the nature of the dense extracellular matrix and strong mechanical

forces that the tissue must withstand. Traditional strategies rely on adhesive primers for acellular dressings. Wang and Elisseff developed a novel strategy of tissue-initiated photopolymerization for the integration of the (PEGDA) hydrogels and the native cartilage tissue.^[5] The technique is based on: 1) enzymatic clearance of the proteoglycans in cartilage to expose the collagen network; 2) in situ generation of tyrosyl radicals by photo-oxidation of tyrosine residues on collagen with H_2O_2 under low intensity UV irradiation; and 3) introduction of a macromer solution and in situ photogelation via tyrosyl radical initiation and UV excitation. Since the reaction is initiated by components of the tissue, the macromers are covalently grafted onto the tissue and crosslinked (gelled) to form a hydrogel without exogenous photoinitiators. A cartilage-hydrogel implant created by the tissue-initiated polymerization is pictured in Fig. 5.^[5]

Step 3 has been improved for cell encapsulation by controlling the degree of photopolymerization. Instead of achieving sufficient photogelation, which needs relatively tough reaction conditions, Step 3 is terminated at the termination of photografting (also the photoinitiation) of diacrylate macromer but prior to their further propagation or crosslinking. The free acrylate groups covalently introduced onto the cartilage surface (with PEG spacers) act as the primers for integration. Then living cells can be implanted through the standard protocol with PEGDA macromers and photoinitiators. The diacrylate macromers in the implant will be gelled via self-photocrosslinking and also simultaneously crosslinked with the primer acrylate groups. Therefore, cell encapsulation and the integration with cartilage are both fulfilled. This integrating technique, besides using the principles of basic protein biochemistry (the generation of tyrosyl radicals), is due to a combined strategy of photografting and photopolymerization.

Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

This article provides a brief history and definition of piezoelectricity, followed by an introduction to a variety of piezoelectric materials, with a focus on processing, characterization, and properties. We will illustrate the impact of piezoelectricity on biomaterials and biomedical applications through a description of applications and functions.

PIEZOELECTRICITY

The piezoelectric effect is a linear effect closely related to the microscopic structure of the material. Piezoelectricity stems from the Greek term *piezo* (for pressure); it follows that piezoelectricity is the generation of electrical polarization in a material in response to a pressure or mechanical stress. This phenomenon is known as the direct effect. Piezoelectric materials always display the converse effect in which a mechanical deformation ensues upon application of an electrical charge or signal.

Piezoelectricity is a property of many noncentrosymmetric (lacking a center of symmetry) ceramics, polymers, and other biological systems. The moment-generating nature of this phenomenon makes it ideal for sensor and actuator applications, underlining its similarity to biological-type behavior in which a system senses a change in its environment and reacts to that change through a proportional response.

A subset of piezoelectricity is pyroelectricity. A pyroelectric material is a material that exhibits a change in polarization in response to a uniform temperature variation. Some pyroelectric materials are also ferroelectric; a ferroelectric material possesses a spontaneous polarization that can be reversed by application of a realizable electric field. The application of an AC field large enough to yield polarization-switching results in a hysteresis loop. A typical field-polarization hysteresis loop is illustrated in Fig. 1. One key feature of the loop is the remanent polarization P_r , indicative of the potential piezoelectric performance of the material. At moderate to large electric field levels, inherent nonlinearities (as demonstrated by the hysteresis loop) are observed. At any drive level, some hysteretic behavior is always present. However, at relatively low electric

field levels, the electromechanical response can be regarded as a linear phenomenon. It is then governed by the linear constitutive equations shown in upcoming sections.

HISTORY OF PIEZOELECTRICITY

Pierre and Jacques Curie discovered the piezoelectric effect in 1880 during their study of the effects of pressure on the generation of electrical charge by tourmaline crystals. They subsequently showed that quartz, cane sugar, and Rochelle salt also exhibited the piezoelectric effect. By building upon their work on the symmetry of crystals and their earlier observations on pyroelectricity, the Curie brothers were able to predict the classes of crystals and the conditions under which piezoelectricity would be observed.^[1] In 1881, the term piezoelectricity was first suggested by W. Hankel, and the converse effect was deduced by Lipmann from thermodynamics principles the same year.^[2] The Curie brothers immediately confirmed the converse effect experimentally and proved the complete reversibility of the electrical and mechanical responses.

In the next three decades, collaborations within the European scientific community established the field of piezoelectricity; by 1910, Voigt's *Lerbuch der Kristallphysic* was published and became a standard reference work detailing the complex electromechanical relationships in piezoelectric crystals.^[3] However, the complexity of the science of piezoelectricity made it difficult for it to mature to an application phase until a few years later. In 1916, Paul Langevin developed a piezoelectric ultrasonic detector using the first quartz-sandwich-transducer: quartz crystal sandwiched between two metal plates; as the quartz resonates, the plates emit sound waves through the water. Another quartz device measures the rebounding waves, and the time between emitting and rebounding waves is determined and used to calculate the distance to a possible reflecting source.^[4] This was clearly the forerunner to the sonar. His success opened up opportunities for piezoelectric materials in underwater applications as well as a host of other applications such as ultrasonic transducers, microphones, accelerometers, etc. In 1935, Busch and Scherrer discovered piezoelectricity in potassium dihydrogen phosphate (KDP).^[5] The KDP family was the first major

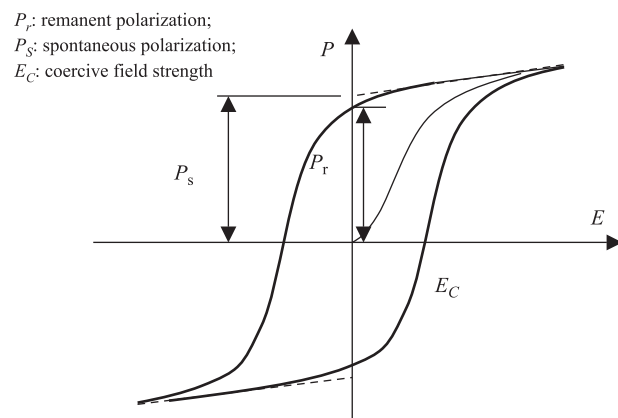

Fig. 1 Typical electric field-polarization hysteresis loop.

family of piezoelectric materials to be discovered. During World War II, research in piezoelectric materials expanded to the United States, the Soviet Union, and Japan. Until then, limited performance by these materials inhibited commercialization, but that changed when a major breakthrough came with the discovery of barium titanate (BT) and lead zirconate titanate (PZT) in the 1940s and 1950s, respectively. These families of materials exhibited very high dielectric and piezoelectric properties. Furthermore, they offered the possibility of tailoring their behavior to specific responses and applications by the use of dopants (i.e., a foreign substance added to a material in a relatively small concentration to alter its properties). To date, PZT is one of the most widely used piezoelectric materials. Most commercially available ceramics (such as KDP, BT, and PZT) are based on the perovskite structure (Fig. 2). The perovskite structure (ABO_3) is the simplest arrangement in which the corner-sharing oxygen octahedra are linked together in a regular cubic array with smaller cations (Ti, Zr, Sn, Nb, etc.) occupying the central octahedral B-site, and larger cations (Pb, Ba, Sr, Ca, Na, etc.) filling the interstices between octahedra in the larger A-site. Compounds such as $BaTiO_3$, $PbTiO_3$, $PbZrO_3$,

Fig. 2 Perovskite structure (chemical structure ABO_3).

$NaNbO_3$, and $KNbO_3$ have been studied at length, and their high-temperature ferroelectric and antiferroelectric phases have been extensively exploited. This structure also allows for multiple substitutions on the A- and B-sites resulting in a number of useful, though more complex, compounds such as $(Ba,Sr)TiO_3$, $(Pb,Sr)(Zr,Ti)O_3$, $Pb(Fe,Ta)O_3$, $(K,Bi)TiO_3$, etc. It follows that tailoring of the properties is made possible due to the flexibility the perovskite structure affords through judicious selection of dopants and substitutions.

Starting around 1965, several Japanese companies focused on developing new processes and applications, and opening new commercial markets for piezoelectric devices. The success of the Japanese effort attracted other nations, and today the needs and uses of piezoelectric materials extend from medical applications to the communications field, military applications, automotive field, and the consumer industry. Prior to that, pioneering work by Fukada et al. paved the way to extending the field of piezoelectricity to organic materials. As early as the 1950s, Fukada and coworkers investigated the piezoelectric behavior of collagen and other biological polymers, culminating in their utilization of tendon and bone as gramophone pickups in 1959.^[6] However, due to the low piezoelectric coefficient of biological polymers, the applications, and hence the interest, were very limited. This was soon changed by one significant discovery: that of piezoelectricity in stretched and poled poly(vinylidene fluoride) (PVDF) by Kawai in 1969.^[7] He showed that thin films of PVDF that had been poled exhibited a very large piezoelectric coefficient, 6–7 pC/N, a value that is about ten times larger than had been observed in any other polymer.

For more on the early history of piezoelectricity, the reader is referred to an excellent summary focusing on the 19th- and early 20th-century developments by Trainer.^[8] Two other notable works are a text by W. G. Cady^[9] and the 1971 Jaffe, Cook, and Jaffe book *Piezoelectric Ceramics*,^[10] still one of the most referenced works on piezoelectricity.

PIEZOELECTRIC CLASSES

The unit cell contains the smallest grouping of atoms representing the chemical formula of the crystalline material. The specific symmetry of a unit cell determines the possibility of piezoelectricity in the crystal under consideration. For example, if the unit cell has no center of inversion, an external stress causes a displacement of charges, and the charge distribution is no longer symmetric. A net polarization develops and results in an internal electric field. In general, the shapes of the unit cells fall into seven general crystal systems: cubic, tetragonal, trigonal, monoclinic, triclinic, orthorhombic, and

hexagonal. Crystallographers further classify crystal systems based on point groups. All crystals can be divided into 32 classes or point groups, emerging from three types of symmetry elements: pure rotation axes of symmetry (one-, two-, three-, four-, and sixfold), planes of reflection (mirror) symmetry, and axes of rotary inversion (rotation followed by inversion through a center). The point groups determine the form and symmetries of the elastic, piezoelectric, and dielectric matrices that appear in the constitutive relations (more on that in subsequent sections). Table 1 shows the seven crystal systems and the 32 point groups. As illustrated in the table, of the 32 point groups, 20 are both non-centrosymmetric and piezoelectric. The lack of center of symmetry means that a net movement of the positive and negative ions with respect to each other as a result of stress produces an electric dipole. The ceramic, being composed of the random orientation of these piezoelectric crystallites, is inactive, i.e., the effects from the individual crystals cancel each other and no discernable piezoelectricity is present. Regions of equally oriented polarization vectors are known as domains. “Poling” is a commonly used method to orient the domains by polarizing the ceramic through the application of a static electric field. The electrodes are applied to the ceramic (through painting, spraycoating, evaporating,

screenprinting, sputtering, etc.) and a sufficiently high electric field is applied such that the domains rotate and switch in the direction of the electric field. The result is never a full orientation of all domains; however the polycrystalline ceramic exhibits a large piezoelectric effect. During this process, there is a small expansion of the material along the poling axis and a contraction in both directions perpendicular to it (see Fig. 3).

PIEZOELECTRIC CONSTITUTIVE EQUATIONS

When the constitutive equation for a piezoelectric material is written, account must be taken of changes of strain and electrical displacement in three orthogonal directions caused by cross-coupling effects due to applied electrical and mechanical stresses. Tensor notation is first adopted; the reference axes are shown in Fig. 4. The state of strain is described by a second-rank tensor S_{ij} , and the state of stress is also described by a second-rank tensor T_{kl} . The relationships relating the stress tensor to the strain tensor, compliance s_{ijkl} and stiffness c_{ijkl} , are then fourth-rank tensors. The relationship between the electric field E_j (first-rank tensor) and the electric displacement D_i (also a first-rank tensor) is the permittivity ϵ_{ij} , which is a

	11 GROUPS		10 GROUPS		11 GROUPS			

Piezoelectric^a

^aThe point group 432 (cubic), although lacking a center of symmetry, does not permit piezoelectricity due to a combination of the other symmetries. (Source: Ref. [11].)

Fig. 3 Poling of a polycrystalline material, (a) unpoled, (b) poled.

second-rank tensor. The piezoelectric equations are therefore written as:

$$D_i = \varepsilon_{ij}^T E_j + d_{ijk} T_{jk} \quad (1)$$

$$S_{ij} = \underline{d}_{ijk} E_k + s_{ijkl}^E T_{kl} \quad (2)$$

where d_{ijk} and \underline{d}_{ijk} are the piezoelectric constants (third-rank tensor). Superscripts T and E denote that the dielectric constant ε_{ij} and the elastic constant s_{ijkl} are measured under conditions of constant stress and constant electric field, respectively. In general, a first-rank tensor has three components, a second-rank tensor has nine components, a third-rank tensor has 27 components, and a fourth-rank tensor has 81 components. Not all the tensor components are independent. Both of these relations (i.e., Eqs. 1 and 2) are direction-dependent; they describe a set of equations that relate these properties in different orientations of the material. The crystal symmetry and the choice of reference axes reduce the number of independent components. A convenient way of describing them is by using axis directions as given by Fig. 4. The convention is to define the poling direction as the 3-axis; the shear planes are indicated by the subscripts 4, 5, and 6, and are perpendicular to directions 1, 2, and 3, respectively. This simplifies the notations introduced above, where a 3-subscript tensor notation ($i,j,k=1,2,3$) is replaced by a 2-subscript matrix notation ($i=1,2,3$ and $j=1,2,3,4,5,6$), and a 2-subscript tensor notation ($i,j=1,2,3$) is replaced by a 1-subscript matrix notation ($i=1,2,3,4,5,6$).

Fig. 4 Reference axes.

A shear strain such as S_4 is a measure of the change of angle between the two initially orthogonal axes in the plane perpendicular to axis 1. The first subscript of the d -constant gives the “electrical” direction (field or dielectric displacement) and the second gives the component of mechanical deformation or stress.

PIEZOELECTRIC CERAMICS

Barium Titanate

Barium titanate is a perovskite with the chemical formula BaTiO_3 (see Fig. 2, where $A = \text{Ba}$, $B = \text{Ti}$). BT has a cubic structure above 120°C , which transforms into a tetragonal structure upon cooling below 120°C . Another transition is found at 0°C , going from tetragonal to orthorhombic, and a third one at -90°C , from orthorhombic to rhombohedral. The most important transition in the piezoelectricity of BT is the one that takes place at 120°C . This temperature is known as the Curie temperature T_c , and the phase transition takes BT from the paraelectric cubic structure (symmetric structure) to the ferroelectric tetragonal structure (non-centrosymmetric). In BT, the spontaneous polarization that gives rise to piezoelectricity and ferroelectricity is a consequence of the positioning of the Ba^{2+} , Ti^{4+} , and O^{2-} ions within the unit cell. The Ba^{2+} ions are located at the corners of the unit cell, the O^{2-} ions are located near, but slightly below, the centers of each of the six faces, and the Ti^{4+} ion is displaced upward from the unit cell center. The resulting dipole moment is a consequence of the relative displacements of the Ti^{4+} and O^{2-} ions from their symmetrical positions (see Fig. 5). BT was the first piezoelectric ceramic to be developed and exploited commercially. However, since the discovery of PZT a decade later, BT has been largely replaced by PZT, which has piezoelectric coefficients. Since then, use of BT has shifted to the capacitor industry, specifically the multilayer capacitor for its high dielectric constant.

Fig. 5 Tetragonal barium titanate crystal structure.

Lead Zirconate Titanate

Lead zirconate titanate has the chemical formula $\text{Pb}(\text{Ti}, \text{Zr})\text{O}_3$. Similar to BT, it has a perovskite crystalline structure. It is the most widely used piezoelectric ceramic due to the combination of properties it affords. Figure 6 shows the phase diagram for PZT.^[10] As can be ascertained from the figure, T_c (transition from paraelectric to ferroelectric) is anywhere between 240 and 480°C depending on the ratio of Ti to Zr in the solid solution. The implication is that piezoelectricity can now be exploited over a wide temperature range, which is not possible for the BT system. The phase boundary transition between the tetragonal structure and the rhombohedral structure, referred to as the morphotropic phase boundary (MPB), is nearly independent of temperature. Both the dielectric constant and the piezoelectric response increase dramatically at the MPB. Table 2 lists the in-plane coefficients of PZT. To further increase the performance of PZT, and improve its resistance to fracture, researchers have developed actuators based on the ceramic configured

Fig. 6 Phase diagram of PZT. (From Ref. [10].)

with a metal backing or other similar layers.^[12,13] Among these devices are Unimorphs[®], Bimorphs[®], RAINBOWs[™], and THUNDERS[™], to name a few. The result is a more durable and flexible actuator, in which the ceramic is often present in a state of pre-stress.

P

PIEZOELECTRIC POLYMERS

The properties of polymers are different in comparison to those of inorganics (Table 2) in that they are uniquely qualified to fill niche areas where single crystals and ceramics are incapable of performing as effectively. As noted in Table 2, the piezoelectric strain constant (d_{31}) for the polymer is lower than that of the ceramic. However, piezoelectric polymers have much higher piezoelectric stress constants (g_{31}) indicating that they are much better sensors than ceramics. The fourth column of Table 2 reveals that the electromechanical coupling coefficient k_{31} for the ceramic is almost three times that of the polymer. The electromechanical coupling coefficient describes the conversion of energy from mechanical to electrical and, vice versa, electrical to mechanical. As such, it is a measure of the piezoelectric strength in materials.^[10] One would then conclude that the piezoelectric ceramic shown has a higher piezoelectric performance than the polymer. Piezoelectric polymeric sensors and actuators offer the advantage of processing flexibility because they are lightweight, tough, and readily manufactured into large areas, and can be cut and formed into complex shapes. Polymers also exhibit high strength and high impact resistance.^[14] Other notable features of polymers are low dielectric constant, low elastic stiffness, and low density, which result in a high voltage sensitivity (excellent sensor characteristic) and low acoustic and mechanical impedance (crucial for medical and underwater applications). Polymers also typically possess a high dielectric breakdown and high operating field strength, which means that they can withstand much higher driving fields than ceramics. Polymers offer the ability

Table 2 Comparison of piezoelectric polymers and piezoelectric ceramics^a

	d_{31} (pm/V)	g_{31} (mV-m/N)	k_{31}	Features

to pattern electrodes on the film surface, and pole only selected regions. Based on these features, piezoelectric polymers possess their own established area for technical applications and useful device configurations.

Synthetic Piezoelectric Polymers

PVDF

Polyvinylidene fluoride (PVDF) is a fluoropolymer that, due to a combination of processability, mechanical strength, and good chemical resistance, has been used as an inert lining or pipework material in chemical plants. However, thanks to Kawai's discovery in 1969,^[7] it became better known for its piezoelectric properties and has been extensively investigated since. PVDF is inexpensive, flexible, and lightweight, and accounts for virtually all of the commercially significant piezoelectric polymer application.

PVDF is a semicrystalline polymer with typically 50 to 60% crystalline content, depending on thermal and processing history. Generally, PVDF is synthesized by the free-radical polymerization of 1,1-difluoroethylene, and the repeating unit is $-\text{CH}_2-\text{CF}_2-$ (Fig. 7). The amorphous phase in PVDF has a glass transition that is well below room temperature (-50°C); hence the material is quite flexible and readily strained at room temperature. There are two conditions that must be fulfilled in order to render PVDF piezoelectric, namely, the crystal structure should possess a nonzero net dipole moment, i.e., it must be polar, and the dipoles should have the same preferred orientation. PVDF has four polymorphic forms: α , β , γ , and δ phases. The α -phase is the most common and stable form of PVDF. Normally, the α -phase is obtained by melt extrusion. It is nonpolar as it produces an inversion of the dipole moments in

**Fig. 7** Structure of PVDF.

alternate chains, which leads to a cancellation of the overall dipole moment. The β -phase is the most important polymorph of PVDF because it is polar and is predominantly responsible for the piezoelectric properties. Usually, the β -phase is obtained by mechanical stretching of the α -phase film. Generally, stretching is either uniaxial or biaxial, which yield different properties. The γ -phase is also a polar unit cell. Generally, the γ -phase is obtained by solution crystallization and readily transforms into the β -phase upon mechanical deformation. The δ -phase is the polar form of α -phase. It is obtained by applying a high electric field to an α -phase film. As a result, the unit-cell dimensions and the configuration are the same as in the α -phase. As mentioned earlier, the β -phase is the form most commonly used for piezoelectricity because it results in the higher piezoelectric coefficients. After mechanical stretching to produce the polar β -phase, the poling process begins with heating of the film and application of a high electric field. During the poling process, the dipoles are aligned relative to the direction of the poling field. The polarization achieved depends on the applied field and on poling temperature and poling time. When the piezoelectric film is operating in an electromechanical or motor mode, the film elongates and contracts as the polarity of the alternating field changes. When operating in a mechano-electrical or generator mode, external forces are applied that produce compressive and tensile strain. These deformations cause a change in the surface charge density, resulting in a voltage between the electrodes, the polarity of which changes as the direction of the force is reversed.

PVDF copolymers

Copolymers of polyvinylidene fluoride with trifluoroethylene (TrFE) and tetrafluoroethylene (TFE) have also been shown to exhibit strong piezoelectric, pyroelectric, and ferroelectric effects. Here, these polymers are discussed together because they behave similarly when copolymerized with PVDF. An attractive morphological feature of the comonomers is that they force the polymer into an all-*trans* conformation that has a polar crystalline phase, thus eliminating the need for mechanical stretching to yield a polar phase.

P(VDF-TrFE) crystallizes (up to 90%) to a much greater extent than PVDF yielding a higher remanent polarization, lower coercive field, and much sharper hysteresis loops. TrFE also extends the use temperature by about 20°, to close to 100°C. Conversely, copolymers with TFE have been shown to exhibit a lower degree of crystallinity and a suppressed melting temperature as compared to the PVDF homopolymer. Although the piezoelectric constants for the copolymers are not as large as for the homopolymer, the advantages of P(VDF-TrFE) associated with processability, enhanced crystallinity, and higher use temperature make it favorable for applications.

Recently researchers have reported that highly-ordered lamellar crystals of P(VDF-TrFE) can be made by annealing the material at temperatures between the Curie temperature and the melting point. They refer to this material as a single crystalline film. A relatively large single crystal P(VDF-TrFE) (75/25 mol%) copolymer has been grown that exhibits a room temperature $d_{33} = -38$ pm/V and a coupling factor $k_{33} = 0.33$.^[15]

Nylons

Kawai et al. first reported piezoelectricity in nylons (polyamides) in 1970.^[16] In 1980, Scheinbeim reported improved levels of piezoelectricity in odd-numbered nylons.^[17] One remaining limitation is that the presence of the hydrogen bonding in the nylons renders them hydrophilic; studies have shown that water absorption can have a deleterious effect on their dielectric and piezoelectric properties.^[18] Water absorption in nylon-11 and nylon-7 can reach as high as 4.5% (by weight) and more than 12% for nylon-5,^[19] whereas it is less than 0.02% for PVDF and its copolymers.

The monomer unit of odd nylons consists of even numbers of methylene groups and one amide group with a dipole moment of 3.7 D. Nylons crystallize in all-*trans* conformations and are packed so as to maximize hydrogen bonding between adjacent amine and carbonyl groups for an even- and an odd-numbered polyamide. For the odd-numbered monomer, the dipoles result in a net dipole moment. The amide dipole cancels for an even-numbered nylon, although remanent polarizations have been measured for some even-numbered nylons.^[20] The unit dipole density is dependent on the number of methylene groups present, and the polarization increases with decreasing number of methylene groups from 58 mC/m² for nylon-11 to 125 mC/m² for nylon-5.^[17,18,20]

At room temperature, odd-numbered nylons have lower piezoelectric constants than PVDF; however, annealing of the films enhances their polarization stability through a denser packing of the hydrogen-bonded sheet structure in the crystalline regions. This results in a reduction of free volume for rotation and hence a hindrance of the dipole switching.^[18,20]

Typical values of the piezoelectric constants for some of the semicrystalline polymers discussed above are given in Table 3.

Amorphous polymers

The piezoelectricity in amorphous polymers differs from that in semicrystalline polymers and inorganic crystals in that the polarization is not in a state of thermal equilibrium, but rather a quasistable state due to the freezing-in of molecular dipoles. The result is a piezoelectriclike effect. One of the most important properties of an amorphous piezoelectric polymer is its glass transition temperature (T_g , temperature below which

Table 3 Comparison of piezoelectric properties of some semicrystalline polymeric materials^a

the material exhibits glasslike characteristics, and above which it has rubberlike properties) as it dictates temperature for use and defines the poling process conditions. Orientation polarization of molecular dipoles is responsible for piezoelectricity in amorphous polymers. It is induced, as shown in Fig. 8, by applying an electric field E_p at an elevated temperature ($T_p \geq T_g$) where the molecular chains are sufficiently mobile and allow dipole alignment with the electric field. Partial retention of this orientation is achieved by lowering the temperature below T_g in the presence of E_p , resulting in a piezoelectriclike effect. The remanent polarization P_r is directly proportional to E_p and the piezoelectric response. It is a measure of the degree of piezoelectricity in the polymer. The following linear equation for the remanent polarization results when the Clausius Mossotti equation is used to relate the dielectric constant to the dipole moment.^[21]

$$P_r = \Delta\epsilon \epsilon_0 E_p \quad (3)$$

It can be concluded that the remanent polarization P_r and hence the piezoelectric response of a material is determined by $\Delta\epsilon$, the change in the dielectric constant below and above T_g , making it a practical criterion to use when designing piezoelectric amorphous polymers. The dielectric relaxation strength $\Delta\epsilon$ may be the result of either free or cooperative dipole motion.

The literature on amorphous piezoelectric polymers is much more limited than that for semicrystalline systems.^[20] This is due in part to the fact that no amorphous piezoelectric polymers have exhibited responses high enough to attract commercial interest. Much of the previous work on amorphous piezoelectric polymers resides in the area of nitrile-substituted polymers including polyacrylonitrile (PAN),^[22–24] poly

(vinylidene cyanide vinylacetate) (PVDCN/VAc),^[25–28] polyphenylethynitrile (PPEN),^[29,30] and poly(1-bicyclobutanecarbonitrile).^[31] Weak piezoelectric activity in polyvinyl chloride (PVC) and polyvinyl acetate (PVAc) has also been found.^[32–34] The most promising of these materials are the vinylidene cyanide copolymers that exhibit large dielectric relaxation strengths and strong piezoelectricity. Table 4 shows molecular structures of the most commonly encountered amorphous piezoelectric polymers.

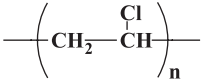

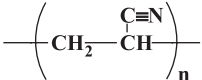

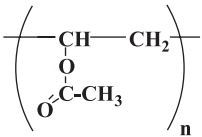

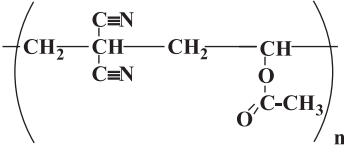

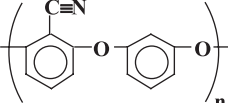

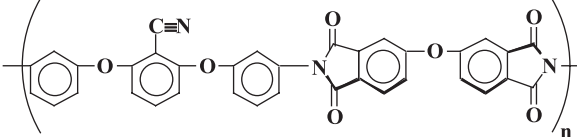

Biological Piezoelectric Polymers

Piezoelectricity of biopolymers was first reported for keratin in 1941.^[35] Consequently, other biological materials have been found to be piezoelectric, including tendon, dentin, ivory, aorta, trachea, intestine, wood, and collagen;^[36,37] polypeptides such as poly- γ -methylglutamate and poly- γ -benzyl-L-glutamate;^[38,39] oriented films of DNA,^[40] polylactic acid,^[41] and chitin,^[42] and the nucleic acids. Bone, however, has been the most frequently studied tissue. Fukada and his group investigated the piezoelectricity in bone in depth starting as early as 1957.^[43] Other researchers subsequently confirmed their findings and further contributed to this area.^[44–46] The piezoelectric coefficient d_{14} , which relates a shear stress applied along the long axis of a bone to the electric displacement that appears on a surface perpendicular to the axis (Fig. 4), is the critical coefficient in this case. The piezoelectricity of bone is of great interest to many researchers because it could shed light on bone physiology. For example, it is known that electric polarization in bone influences bone growth^[46] and, therefore, one could hypothesize that the piezoelectric signal in bone could regulate bone growth.

Because most natural biopolymers possess D_∞ symmetry, they exhibit shear piezoelectricity. As mentioned earlier, a shear stress in the plane of polarization produces electric displacement perpendicular to the plane of the applied stress, resulting in a $-d_{14} = d_{25}$ piezoelectric constant. The piezoelectric constants of biopolymers are small relative to those of synthetic polymers, ranging in value from 0.01 pC/N for DNA to 2.5 pC/N for collagen. However, investigating the piezoelectric mechanism in these biopolymers may help us develop synthetic polymers with higher piezoelectric shear coefficients, uniquely suited to some applications such as flow sensing, for example.

At present, piezoelectricity in biopolymers is an undisputable, albeit still a phenomenological, fact. The physiological significance of piezoelectricity, however, is not yet fully understood, and that opens up a whole potential of exciting and challenging studies.

APPLICATIONS

The application potential for piezoelectric and other electroactive polymers is immense. To date, ferroelectric polymers have been incorporated into numerous sensing and actuation devices for a wide array of applications. Typical applications include devices in medical instrumentation, robotics, optics, computers, and ultrasonic, underwater, and electroacoustic transducers. One important emerging application area for electroactive polymers is in the biomedical field in which polymers are being explored as potential artificial muscle actuators, as invasive medical robots for diagnostics and microsurgery, as actuator implants to stimulate tissue and bone growth, and as sensors to monitor vascular grafts and to prevent blockages.^[47,48] Such applications are ideal for polymers as they can be made to be biocompatible and they have excellent conformability and impedance matching to body fluids and human tissue. The intent of this manuscript is not to detail specific applications, but the interested reader may refer to excellent sources on applications of piezoelectric and ferroelectric polymers.^[49–51]

CONCLUSION AND FUTURE DIRECTIONS

It has been more than 120 years since the discovery of piezoelectricity. Great strides have been accomplished both on the material and on the application sides. Both piezoelectric ceramics and piezoelectric polymers have become viable for commercial purposes. Early on in the history of piezoelectricity, emphasis was on investigating and mastering the fundamental structure-property relationship in the crystals. This approach has enabled the development of numerous synthetic piezoelectric materials with properties far exceeding that of natural or biological materials. This made possible a number of applications, which further generated more interest in piezoelectricity.

As discussed previously, piezoelectricity was first discovered in biological materials; then, in the next few decades, it centered on new synthetic families of crystals with increasing piezoelectric performance. It is interesting to note that researchers have now come full circle, rediscovering biological polymers and other naturally occurring materials and working on unraveling the piezoelectric phenomenon in them and the physiological

role it plays in the function of the material. Researchers continue to diligently uncover novel ways to characterize complex electromechanical properties and, as they do so, new processing methods and applications are revealed.

ACKNOWLEDGMENT

The author expresses her most sincere appreciation to Dr. J. S. Harrison (NASA Langley Research Center) for providing technical insight in the area of piezoelectric polymers.

Plasma Modification of Materials

Ricky K.Y. Fu

Paul Kim Ho Chu

Department of Physics & Materials Science, City University of Hong Kong, Kowloon, Hong Kong

INTRODUCTION

Biomaterials are typically defined as materials that constitute parts of biomedical implants and devices. Many synthetic materials currently used in biomedical applications include metals and alloys, polymers, and ceramics. Because of their different structures and properties, these materials have different applications. The ideal biomaterials should have good physicochemical properties, while the surface should possess good biocompatibility as the environment inside the body is chemically and mechanically active. Interactions between the implanted biomaterials and body tissues take place on the materials surface and, consequently, biochemical responses and reactions depend on the surface properties. Therefore, the implanted biomaterials must have good biocompatibility and in some instances need to integrate with the surrounding biological environment to restore adequate functions without releasing harmful chemical products or inducing deleterious effects, such as skin irritation, chronic inflammatory, and hypersensitivity responses. Surface modification of biomaterials has become an interesting topic in medicine as an effective means to improve the surface functions and lifetime of biomaterials.

Plasma surface modification (PSM) not only chemically and/or physically alters the surface composition and microstructures via processes such as etching, chemical reactions, sterilization, ion irradiation and bombardment, but also can synthesize a different structure, such as a thin film on the surface of the biomaterials via coating, grafting, and thin film deposition. The new film or surface can possess very different chemical and biological properties from the bulk materials. In these ways, the surface of the biomaterials can be made more biocompatible, while the favorable bulk attributes, such as strength, can be retained. In this entry, common plasma techniques and the properties of plasma-treated biomaterials are described. A number of the examples are related to metals and polymers that are the most widely accepted materials in medical devices, such as total joint replacements, orthopedic implants, dental prostheses, cardiovascular blood vessel stents, artificial heart valves, and breast implants. In all of these cases, the

aim of surface treatment is to enhance the surface properties, such as biocompatibility, bioactivity or bioinertness, corrosion and wear resistance, wettability, adhesion, and resistance against fatigue-related failures.

PLASMA CHARACTERISTICS, PLASMA DISCHARGE TECHNIQUES, AND PLASMA–SURFACE INTERACTIONS

Plasma

Plasma is often called the fourth state of matter. A plasma can be envisioned as a collection of electrons, singly and multiply charged positive and negative ions, neutral atoms, excited particles or radicals, electromagnetic radiation, molecules, and molecular fragments. An important feature of the plasma is that the positive and negative particles are in a state of charge equilibrium and the sum of the positive and negative charges in a sufficiently large volume is equal to zero. In fact, plasma technology is dry, environmentally friendly, and cost-efficient in a myriad of applications.

Plasma Discharge

To produce a plasma, electron separation from atoms or molecules in the gas state, that is, ionization, is required. When an atom or a molecule gains enough energy from an outside excitation source or via interactions (collisions) with one another, ionization occurs. In most practical situations, plasma is produced by an electrical discharge. There are a number of different discharge techniques including radiofrequency (RF) discharge, microwave discharge, glow discharge (GD), and arc discharge. Generally, these techniques can be classified into two categories: gaseous and metallic plasma discharges.

Radiofrequency GD

Radiofrequency discharges have been widely applied to the surface treatment of biomaterials and can be classified into two types according to the method that

couples the RF with the load: capacitive coupling and inductive coupling. The hardware typically consists of an RF generator, a matching network, and an antenna. Commonly, the generator operates at a frequency of 13.56 MHz and the pressure during the discharge is between 10^{-3} and 100 Torr. The plasma density, which is defined as the electron or ion density (equal in the quasi-neutral state), in a low-pressure (10^{-3} –1 Torr) radiofrequency GD varies from 10^9 to 10^{11} cm^{-3} , whereas that at a medium pressure (1–100 Torr) can reach 10^{12} cm^{-3} . The electron temperature in a low-pressure discharge is usually between 1 and 5 eV and the plasma potential of the RF discharge is typically in the range of 10 to 30 V above the wall potential and proportional to the electron temperature.

Vacuum arc

The vacuum arc technique is used to generate a metal ion plasma. It is sustained by materials originating from a cathode. In general, a cathodic arc plasma source is composed of two parts: plasma production unit and macroparticle filter. The arc discharge is characterized by a relatively high current (10 or 100 A) and a relatively low voltage (10–80 V) between the cathode and the anode. When a feedback mechanism is established in which a very small area of the cathode surface is heated by electron emission, more materials are ejected. The materials emitted from the cathodic spot are mainly ions and macroparticles. A curved magnetic filter is commonly utilized to eliminate these macroparticles from the cathodic arc plasma.

Corona and atmospheric discharge

Corona discharge appears as a luminous glow localized in space around a pointed tip in a highly nonuniform electric field. The voltage applied to the anode exceeds several kilovolts and the magnitude of the discharge current varies from 10^{-10} to 10^{-4} A. In the plasma near the tip, the density of the charge species decreases rapidly with distance from about 10^{13} to 10^9 cm^{-3} .

The most widely used atmospheric arc plasma source in biomaterials research is the plasma spray torch. A common configuration comprises a nozzle-shaped anode serving as a constrictor. To sustain a plasma torch, the discharge current and power density are very high. The plasma is formed between the cathode and the anode by an electrically conducting gas at $T^\circ > 8000$ K at pressure of 10^5 Pa. Owing to the high plasma flow velocity (nearly 1×10^3 m/sec) and high temperature in the plasma, almost all solid particles can be melted and a high velocity is acquired. Thus, atmospheric plasma torches are widely used in plasma spraying.

Plasma-Surface Interactions

The interactions between plasma particles and sample surface are critically dependent on the working pressure, plasma parameters, and mode of operations. In general, both chemical and physical interactions have a significant effect on the outcome of the plasma treatment. The plasma–surface interactions in ion implantation and thin film deposition process are briefly described here and readers are urged to peruse other references for more in-depth discussions.^[1–3]

Ion implantation

The important considerations in any description of ion–solid interactions are the deep distribution of the implanted ions, irradiation damage and sputtering, creation of new materials, and ion alloying. The implanted ion penetrates a solid and comes to rest via electron and nuclear energy loss resulting in collision cascades. Those collisions can cause sputtering, radiation-enhanced diffusion, ion backscattering, ion-induced chemical reactions, and defect generation. Sputtering sets the limit of the maximum concentration of implanted atoms that can be retained in the target. The yield of sputtered atoms, that is, the number of sputtered atoms per incident ion, typically varies from 0.5 to 20 depending on the primary ion species, ion energy, structure and composition of the target, and sample topography. As ion irradiation is quite efficient in forming vacancy–interstitial pairs, the effects of irradiation on the ordered alloy are described by the competing processes of chemical disordering, which is induced by atomic replacements resulting from displacement and cascade damage, and chemical ordering. The process is stimulated by radiation-enhanced diffusion. Besides, ion implantation offers the ability to alloy any elemental species into the near-surface region of any substrate, irrespective of thermodynamic criteria, such as solubility and diffusivity. These considerations coupled with the possibility of low-temperature processing have prompted explorations into applications, where the limitations of dimensional changes and possible delamination associated with conventional coatings are the practical concerns.

Thin film deposition

In this process, reactants diffuse from the plasma to the substrate surface giving rise to chemical reactions and thin film deposition. Deposition process parameters, such as the type of ions and their energy, flux, incident direction, and deposition temperature, play important roles in the film composition, structure, and many related properties, such as grain size, crystallographic

orientation, defects, stress concentration, film adhesion, and surface topography, all of which alter the mechanical, electrical, optical, as well as biomedical properties of the materials. Under certain ion energy bombardment, various surface features and microstructures, such as cones, pyramids, ridges, ledges, pits, and faceted planes, can form. It should also be noted that under ion bombardment, films frequently show preferred orientation. In the case of low atom mobility or low substrate temperature, films have a tilted, voided columnar structure, and ion bombardment generally causes a reduction in the film grain size. Energetic ions displacing atoms from equilibrium sites lead to a small grain as well as a defective and stressful film. The threshold ion energies and critical temperatures often delineate the limits of the competition between lattice damage and defect annealing effects. Therefore, a proper set of plasma parameter and deposition conditions is important to yield the desirable film structure and properties.

PLASMA TREATMENT OF BIOMATERIALS

As the surface of biomaterials plays an important role in their interactions with body fluids, tissues, and cells, the surface structures and properties are of paramount importance. They can be altered by plasma-based treatment processes, such as plasma sputtering and etching, implantation, deposition, coating, and spraying. Fig. 1 illustrates some of the surface properties that can be altered by PSM.

Plasma Sputtering and Etching

In plasma sputtering and etching processes, materials are removed from the surface by chemical reactions and/or physical sputtering. Commonly, inert gases, such as neon and argon, are used as the carrier gas and are responsible for physical ablation, while reactive plasma is employed for chemical etching of the surface. The plasma used in the process generally is produced by RF GD. The sputtering rate depends on the input power of the source, working pressure, and voltage applied to the substrate.

Plasma etching is a useful method to change the surface morphology of biomaterials. For instance, polymeric materials, such as polyurethane (PU), can be treated in an argon (Ar) and sulfur dioxide (SO₂) plasma to increase the surface wettability. The fibrinogen adsorption rate is reduced because of the etching effect that renders the surface rougher.^[4] This process can also be used to create the desirable microfeatures and macrofeatures on the biomaterials. These features are capable of regulating cell functions,

such as repellency, proliferation, differentiation, and apoptosis. The effects of the substratum topography on the cellular behavior, such as cell orientation, migration, and cytoskeletal arrangements, have attracted much attention. Investigations of the grooved surface reveal that cells aligned to the long axis of the grooves, often with organization of actin and other cytoskeletal elements in an orientation parallel to the grooves.^[5] As cell behaviors, such as size, shape, density, and geometry, can provide regular signals for cell survival and growth or apoptosis, the effectiveness of cell culturing and spreading rather than rounding on the specialized surface feature can modulate or switch cells from apoptosis to survival and growth.^[6] With regard to plasma-induced surface patterning and cell culturing, Schroder et al. have introduced a plasma etching process to induce micropatterning on polymeric materials surfaces as illustrated in Fig. 2.^[7] Their results show that ammonia plasma introduces amino groups to the surface to attain good cell adhesion, whereas hydrogen plasma can be used for surface passivation. The latter process can be used to remove surface functional groups and consequently, a higher degree of cell repellence is obtained. D. Braber et al. have produced microgradient textures on titanium and silicon rubber substrates for rat dermal fibroblasts (RDFs) culturing.^[8] The RDFs cellular behavior depends on the size of the grooves, and the proliferation rate of the RDFs is much higher on titanium than silicon rubber substrate. Other studies on surface activation of polyetheretherketone reveal that the surface topography can become irregular with high roughness, and inflammatory cell responses can be spatially controlled in a manner that can be ultimately exploited to improve the biocompatibility of medical devices.^[9] Hence, the plasma-based surface patterning technique enables visualization of the effects on cell functions and spatially controls the cellular microorganization.

Plasma Implantation

In plasma implantation, ions in the overlying plasma are accelerated by a high field toward the biomaterial surface for structures and properties modification. Generally, the ion penetration depth is a function of the implantation energy and also depends on the material properties, such as electrical conductivity and density. The effects of ion implantation are different for metals, ceramics, and polymers. In metal and ceramic biomaterials, the physical changes arise from atomic and nuclear collisions often leading to the formation of highly disordered and sometimes amorphous structures. Chemical changes arise from the formation of hard-phase precipitates or surface alloys. The physical and chemical changes typically combine

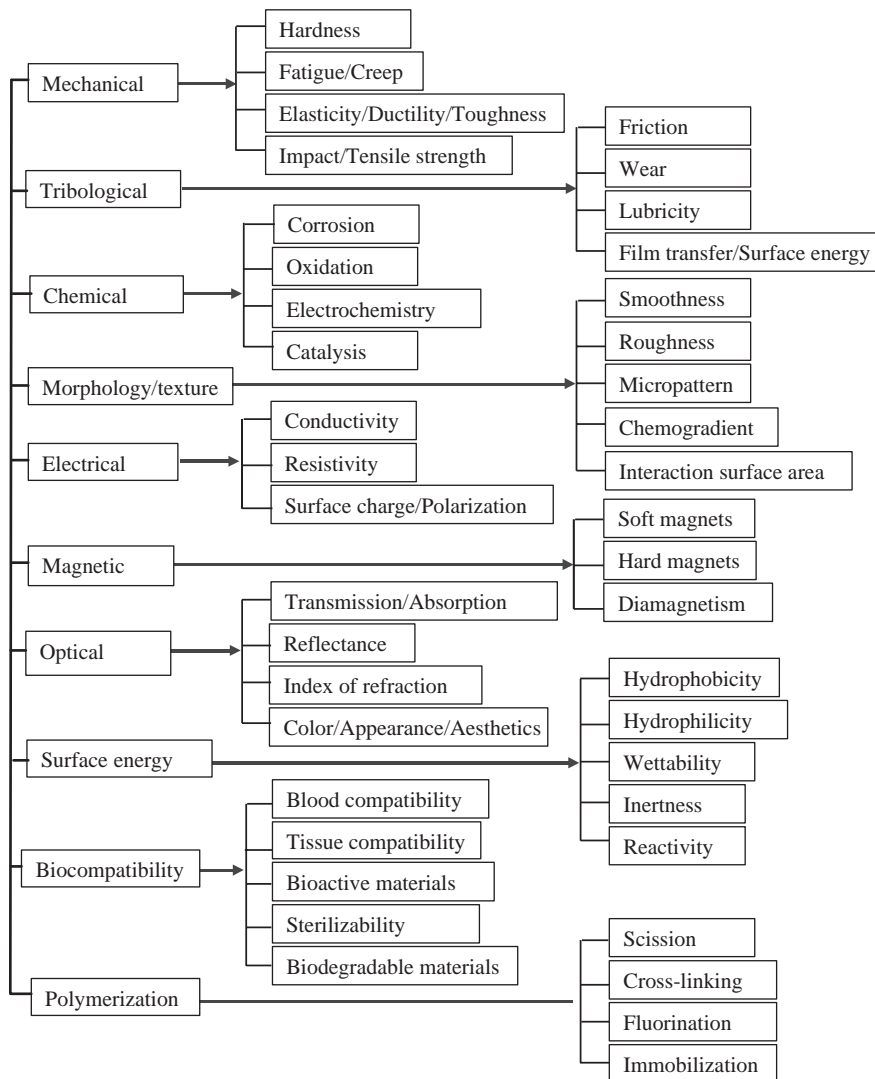

Fig. 1 Biomaterial surface properties altered by PSM.

to create surfaces that are harder and more resistant to wear and chemical attack without substantially altering the bulk properties. In polymeric biomaterials, the use of energetic ions and activated species in the ion implantation process introduces deeper ion penetration, cross-linking, and/or chain scission. It can also enhance or reduce the functional groups on the polymeric surfaces. This may thus help reduce the aging effects and degradation of the functional groups or chains. In addition, surface properties such as surface hardness, wear resistance, surface wettability, and surface tension can be improved.

Ion implantation of metallic biomaterials

Metallic biomaterials, such as stainless steels, cobalt-based and titanium-based materials, are commonly used in orthopedic devices, such as total knee, hip, shoulder, and ankle joint replacements, spinal implants, and bone fixators, dental implants to replace teeth/root

systems and bony tissues in oral cavities, as well as cardiovascular implants, such as artificial heart valves and blood vessel stents. Most orthopedic devices are designed to remove diseased areas of joints and replace them with implants designed specifically to restore stability and functions under adverse and stressed conditions. Materials chosen for the devices must meet the biocompatibility requirements of the immune system, the biological environment, corrosion issues, friction, and wear of the articulating surfaces, and implant fixation through either osseointegration or bone cement. Ion implantation using either conventional beam-line ion implantation (BLII) or plasma immersion ion implantation (PIII) can be used to modify the mechanical, physical, chemical, and biological properties of most metallic biomaterials.

Nitrogen Plasma Implantation. Metallic biomaterials after nitrogen implantation exhibit improved tribological characteristics and can better resist corrosion attacks due to changes in the surface composition and

Fig. 2 Micropatterned growth of epithelial KB cells on (A) PET and (B) PHEMA. The areas of increased cell density were treated with ammonia plasma, while the areas with suppressed cell adhesion were additionally treated in hydrogen plasma.

formation of favorable microstructures. For instance, the wear enhancement of nitrogen-implanted materials stems from the formation of hard, secondary nitride-phase precipitates in the near-surface region. The high hardness of these nitride precipitates translates into significant strength and the matrix phase is further strengthened by the presence of strain fields around the precipitates that can impede dislocation movement. Improvement in the corrosion resistance arises from the high solubility of the implanted nitrogen leading to a more compositionally homogenous surface. In steels, it is generally accepted that the chromium-depleted zone adjacent to the grain boundaries is susceptible to intergranular corrosion and galvanic attack. Nitrogen implantation can significantly enhance the wear and corrosion properties of steels by the formation of hard CrN precipitates, expanded austenite transformation

into martensite during high-temperature treatment, production of a surface devoid of grain boundaries, and formation of a protective passivating film.

Nitrogen implantation has also been used to modify titanium and titanium alloys. Damdorenea et al. have implanted nitrogen into pure commercial titanium and compared the electrochemical behavior in a media of different pH.^[10] In a neutral pH saline solution, the implantation does not affect the corrosion resistance. In an acidic solution, the implanted titanium shows higher corrosion resistance and stability up to +1.5 V. The improved electrochemical behavior can be explained by the nitride phase acting as a barrier. They screen the Ti ions from the external environment, thereby inhibiting migration of the Ti ions and formation of TiO₂ at low potentials. Ueda et al. have performed nitrogen plasma implantation to improve the surface tribological properties of Ti6Al4V as artificial heart valve materials.^[11] The results show a well-behaved nitrogen profile (~40% peak atomic concentration) and nitrogen retention layer (~50 nm). After plasma implantation, the friction coefficient is reduced by about one-third compared to the untreated alloy and the hardness is increased by about 70%.

Oxygen Plasma Implantation. Oxygen implantation into titanium can induce the formation of titanium oxide and it is known to have varying stoichiometries. The common compounds are Ti₃O to Ti₂O, Ti₃O₂, TiO, Ti₂O₃, Ti₃O₅, and TiO₂. Titanium oxides are thermodynamically very stable and the Gibbs free energy of formation is highly negative in a variety of oxidation media, such as water or oxygen containing organic molecules. Poon et al. have conducted oxygen PIII on NiTi shape memory alloys used in orthopedic applications.^[12] It is observed that the oxide barrier layers can effectively resist the release of harmful Ni ions from the implants into the living tissues. They also compare the anticorrosion efficacy of oxide films produced by atmospheric pressure oxidation with that of oxygen PIII. The results show that the oxidized samples do not possess improved corrosion resistance and are even far worse than the untreated samples, while significant improvement in the corrosion resistance can be achieved by oxygen PIII, as shown in Fig. 3. In addition, in vitro biological tests reveal that the oxygen PIII surfaces are cytologically compatible, allowing the attachment and proliferation of osteoblasts. Oxygen implantation into NiTi forms titanium oxides so that the wear loss and the corrosion attack can be mitigated and osteoblasts can grow and spread on the oxides. Tan, Dodd, and Crone also employ oxygen PIII to modify the electrochemical properties of NiTi.^[13] Their results illustrate that both the corrosion and the wear-corrosion behaviors can be improved by heat treatment and an oxygen-modified surface.

Fig. 3 Scanning electron micrograph images of NiTi surface after electrochemical tests based on the ASTM G5-94 and G61-86 protocols in a standard SBF at a pH of 7.42 and temperature of $37 \pm 0.5^\circ\text{C}$. A cyclic potential was scanned between -400 and $+1600$ mV at a rate of 600 mV/hr. (A) Untreated control, (B) atmospherically oxidized, and (C) oxygen-plasma implanted.

Metal Plasma Implantation. Biological friendly elements, such as calcium, phosphorus, and sodium, can be introduced into biomaterials to enhance the mechanical and chemical properties, surface bioactivity, and biocompatibility. Hanawa has studied calcium implantation into titanium to improve bone conductivity.^[14] A more positively charged Ca-implanted surface is achieved because of the dissociation of hydroxyl radicals and the release of Ca ions from the surface accelerates the formation of calcium phosphate, as illustrated in Fig. 4. Osteogenic cells are activated to form osteotissues and a large amount of new bone is observed to form early on calcium ion implanted titanium after implantation into rat tibia. A similar observation has been obtained from Ca PIII titanium surface.^[15] On exposure to air, the surface calcium is first oxidized and then reacts with water to form calcium hydroxide. After the Ca PIII titanium is soaked in simulated body fluids (SBFs), a bone-like apatite layer forms on the surface confirming the improvement of the bone conductivity.

Calcium ions are implanted into titanium to immobilize bisphosphonates on the surface.^[16] The

modified layer, which consists of CaTiO_3 and TiO_2 , is relatively stable so that immobilized bisphosphonate can remain on the modified surface. In the dental field, bisphosphonate prevents periodontal destruction and decreases the formation of dental calculus. Many of the bisphosphonates inhibit the crystal formation of calcium phosphate in vitro blocking the transformation of amorphous calcium phosphate into hydroxyapatite (HA) and the dissolution of these crystals. Therefore, the use of bisphosphonates is expected to promote osteogenesis at the bone tissue-implant interface by inhibiting the activity of osteoclasts, and immobilization of bisphosphonates on titanium implants is considered important.

The effects of phosphorus implantation on the corrosion resistance and biocompatibility of titanium have been investigated by Krupa et al.^[17] The process leads to amorphization of the surface layer and the formation of TiP as well as the increase of the corrosion resistance after short-term and long-term exposures. In the biological tests, osteoblasts show the ability to spread on the surfaces, but no difference is

Fig. 4 Hydroxyl radicals (A) in air and (B) in electrical charges in body fluids on unimplanted titanium and calcium ion implanted titanium.

found between the modified and the control titanium. Calcium and phosphorus-coimplanted titanium can also promote the formation of HA on the surface after backfilling with oxygen and thermal treatment as the modified surface structure containing both Ca and P is close to that of apatite.

Sodium has been implanted into titanium to form sodium titanate in the near-surface region. The process produces morphologically rugged surfaces that induce apatite precipitation from SBF in immersion tests.^[18] The surface reactivity is associated with a titania hydrogel film formed by the hydrolysis of sodium titanate. The double layer on a negatively charged titania hydrogel surface tends to increase supersaturation that fosters apatite nucleation and precipitation near the surface.

Ion implantation of polymeric biomaterials

Polymers are probably the most widely used biomaterials. They are the materials of choice in cardiovascular devices, scaffolding implants for tissues, and ophthalmic applications. However, polymers at present have many deficiencies, such as low mechanical strength and poor wear resistance. Ion implantation is a useful solution to mitigate these deficiencies and satisfactory results have been achieved by ion implantation. Several common synthetic polymers are described here.

Polypropylene. Polypropylene has an exceptionally high flex life and excellent environmental stress-cracking resistance. It is commonly used in finger joint prostheses with an integrally molded hinge design. On the other hand, PP contains only carbon and hydrogen and it is quite hydrophobic, thereby limiting its potential applications. Li and Niu have performed

carboxy ion (COOH⁺) implantation at room temperature into PP and studied the in vitro effects of ion implantation on immune macrophages, 3T3 mouse fibroblasts, and human endothelial cells (ECs).^[19] COOH⁺ ion implantation is observed to break off some pendant groups of PP and induce unbound carbon atoms to combine with the implanted COOH⁺ ions and oxygen in air to form new polar O-containing groups, such as O–H, C=O, and C–O bonds. This gives rise to a more hydrophilic surface. The ensuing cell attachment tests show that fibroblasts and human ECs can be better cultured and proliferated on the implanted surface. Low macrophage attachment with normal cellular morphology has also been observed because of the formation of O-containing groups on the surface and the diminution of cell decomposition.

Polystyrene. Polystyrene (PS) has good transparency, high thermal stability, low specific gravity, and a relatively high modulus. It is often used in cell culturing and studies of mechanisms of the interactions between cells and artificial materials. Nakao et al. have studied neon ion (Ne⁺) bombardment of PS.^[20] Ne bombardment of PS destroys the benzene ring completely and induces the formation of an amorphous carbon phase with new functional groups, such as C–O and C=O. In cell adhesion measurements, the modified PS exhibits high adhesion and spreading of HeLa cells. In addition, Bacakova et al. have reported that fluorine ion (F⁺) implantation in PS can increase the polarity, hydrophilicity, electrical conductivity, and carbonization of polymeric surface.^[21] Endothelial cell culturing tests demonstrate a significant increase of cell attachment. In ELISA tests, the modified PS is found to enhance the expression of a cytoskeletal protein, vimentin, and protein of focal adhesion plaques, and talin.

Polymethylmethacrylate. Polymethylmethacrylate (PMMA) is an amorphous material with good resistance to diluted alkaline and inorganic solution. It also possesses high transparency, high refractive index, and good weathering properties. It has been used in contact lenses and implantable ocular lenses because of their excellent optical properties, dentures, and maxillofacial prostheses due to their good physical and coloring properties. Research interests have focused on extending the lifetime of PMMA implanted into the body with respect to ophthalmic intraocular lens (IOLs) applications. Li, Cui, and Gu have reported that the cleavage of pendants, surface oxidation, and formation of F-containing groups in F⁺ ion-implanted PMMA promote the reduction of platelets, neutral granulocytes, and macrophages adhesion on the surface of the IOLs.^[22] It is believed that fluorine ion bombardment increases the surface hydrophobicity, disfavoring cell

attachment. At the same time, no appreciable changes in the tensile strength and optical transmittance of the implanted PMMA have been observed.

Polytetrafluoroethylene. Polytetrafluoroethylene (PTFE) has a very low surface tension and friction coefficient. It also has the unusual property of being able to expand on a microscopic scale into a microporous material. Microporous PTFE or expanded PTFE (ePTFE) is used as subcutaneous augmentation material in various biomedical applications, such as vascular grafts and facial surgery. As ePTFE has a highly hydrophobic surface, it limits cell adhesion. Several studies have concentrated on improving the surface properties, such as wettability as well as blood and tissue compatibility. Colwell et al. have reported that N_2^+ , Ar^+ , and Ca^+ ion implantation can induce defluorination, resulting in the increase of surface roughness and the change in hydrophobicity depending on the implantation dose.^[23] Suzuki et al. have studied Ne^+ ion implantation into ePTFE for dura mater applications. It is found that ion implantation destroys the surface chemical structure of ePTFE, thereby producing C=O bonds.^[24] The in vivo study using rabbits shows that the internodal distance, density of the nodes in ePTFE, and C=O radicals induced by ion implantation are the major factors influencing cell invasion on the ion-implanted ePTFE.

Plasma Deposition and Coating

Plasma deposition is an important area in biomaterials engineering. In this process, a layer with properties distinctly different from those of the bulk materials can be synthesized. The common techniques include PIII-deposition, plasma-enhanced chemical vapor deposition, plasma grafting, and polymerization.

Carbon-based thin films for biomedical applications

Diamond-like carbon (DLC) films possess novel properties, such as chemical inertness, electrical resistance, optical transparency, high hardness, and low friction coefficient. Some representative uses of hard DLC coatings are: 1) hard carbon films on surgical instruments; 2) implanted fittings, such as infusion devices and connecting parts; and 3) semipermanent components, such as heart valves, stents, replacement joints, and ophthalmic devices. Hard, thin, and hermetic DLC films can act as nontoxic corrosion-resistant barriers against attack by microorganisms. They also resist biodeterioration. By suitably tailoring the surfaces, protein adhesion and cell growth can be promoted or retarded as required by the applications.

Diamond-like carbon consists of carbon and hydrogen and is a metastable form of amorphous carbon containing a hybrid structure of sp^2 and sp^3 bonds. The disordered structures and properties of DLC depend very much on the deposition techniques and fabrication parameters. Fourier transfer infrared (FTIR) and laser Raman spectroscopies are the common techniques used to characterize the structure and bonding of a-C:H. Hydrogenated DLC displays a wide FTIR absorption band. The C–H stretching modes are composed of three regions, the $\text{sp}^1\text{=C-H}$ modes centered at 3300 cm^{-1} , the $\text{sp}^2\text{=CH}_n$ modes from 2975 to 3085 cm^{-1} , and $\text{sp}^3\text{-C-H}_n$ modes from 2850 to 2955 cm^{-1} . Diamond-like carbon films with a hybrid sp^2/sp^3 structure show a D band (disorder) and a G band (graphite) signal at around 1350 and 1580 cm^{-1} , respectively, in the Raman spectrum. A common way to monitor the changes in the structures or chemical states of the DLC is to compare the shift of the G band and the ratio of the intensity of D band (I_D) to that of G band (I_G).

Diamond-like carbon coatings typically have good hemocompatibility, which is typically expressed by decreased thrombus formation. When exposed to blood, an increased ratio of albumin to fibrinogen adsorption, as well as decreased platelet activation, is observed on coated surfaces.^[25] The degree of blood compatibility is related to the electronic conduction, work function, and surface energy, which are dependent on the ratio of sp^3 to sp^2 in the DLC film. There have been attempts to modify the DLC structures by doping with biocompatible elements, such as Ti, Si, P, etc. Diamond-like carbon films are usually not cytotoxic and can be applied to chronic neuroprosthetic implants. The antibacterial adsorption behavior of DLC-coated polymers presented by Wang et al. shows that reduction in bacterial adhesion is due to energetically unfavorable adhesion on the DLC surface, as the free energy of adhesion (ΔF_{Adh}) predicts whether microbial adhesion is energetically favorable ($\Delta F_{\text{Adh}} < 0$) or not ($\Delta F_{\text{Adh}} > 0$).^[26] On the other hand, in some particular applications in which no cell or bacterial attachment to the DLC surface is desirable, certain cytotoxic elements, such as Ag, Cu, or V, can be embedded into the DLC films. This allows the DLC surface to have a tunable antibacterial effect. However, care should be exercised because in a biological media, the doping elements can be released to cause toxic reactions inhibiting cell proliferation and differentiation.

Titanium-based thin films in biomedical applications

Titanium-based films are normally used in orthopedic and dental prostheses as well as blood-contacting biomaterials. Rutile titanium oxide films generally

have blood compatibility better than that of clinical biomaterials, such as low-temperature isotropic carbon (LTIC). Depending on the deposition parameters, a wide range of phases, from amorphous to crystalline rutile, can be synthesized by plasma-deposition techniques. Although the crystal structure and crystallite size of Ti–O films appear to influence the activation of the plasmatic clotting system only to a minor degree, Ti–O films exhibit superior thromboresistant properties in long-term tests. In vitro blood compatibility investigation indicates that the TiO₂ film has a longer clotting time, lower hemolytic rate, less adherent platelets, as well as less aggregation and pseudopodium of the adherent platelet.^[27] In vivo implantation into dogs shows no thrombosis on the Ti–O films after 17–90 days, in contrast to that on the control of LTIC, as shown in Fig. 5. It is suggested that the significantly lower interfacial tension between the Ti–O films and blood and plasma proteins, and the semiconducting nature of the Ti–O films give rise to the improved hemocompatibility. Other studies also show that Ti–O films have the desired properties to promote growth of ECs on the surface without protein precoating.^[28] It is believed that seeding with ECs on vascular prostheses can overcome the generation of thrombi and emboli because of the nonthrombogenic properties of the cells in the natural state in contact with blood. Moreover, doping of Ti–O films with the appropriate elements can not only change the microstructures, but also enhance their mechanical properties and biological compatibility. For instance, tantalum-doped Ti–O films exhibit changes in the semiconductivity and physical properties that preclude fibrinogen from denaturation and, consequently, prevent blood coagulation.^[29] Phosphorus-doped Ti–O films also demonstrate improved clotting behavior.^[30] It is believed that P and its oxides in Ti–O can act as the biochemical functional groups that hinder electron exchange between proteins and the surface of materials.

Plasma grafting and polymerization

When polymeric materials are exposed to plasma, radicals are created in the surface chains of the polymer because of energetic irradiation. These surface radicals can initiate polymerization reactions when put in contact with monomers in the liquid or in the gas phase. As a result, a variety of desirable properties can be obtained via graft polymerization. A specific demand for a polymeric biomaterial surface is its compatibility with organs and cells. This leads to the approach of cell seeding before implantation as the natural state of seeded cells can inhibit the generation of thrombi and emboli on the surface of implants in contact with blood. Thus, a suitable interface between

Fig. 5 Scanning electron micrographs of materials after 90 days of implantation into dogs. (A) Ti–O film and (B) LTIC.

the synthetic implants and the individual cells is required. Plasma graft polymerization is a useful technique to promote cell attachment. The cell seeding procedures are: 1) functionalization of the polymer surface with radicals by plasma irradiation, such as Ne, Ar, N₂, NH₃, or O₂; 2) immobilization of the suitable spacer molecule; 3) covalent coupling of the cell intergrin-mediator, such as extracellular matrix (ECM)

proteins of fibronectin, laminin, vitronectin, and von Willebrand factor; and (d) seeding with ECs. Fig. 6 illustrates the schematic of an interface for cell seeding.

Cell adhesion to polymeric materials is mediated by cell-surface receptors interacting with cell adhesion proteins bound to the material surface. To promote receptor-mediated cell adhesion, the polymer surface should mimic the extracellular matrix. Poly(vinylidene-fluoride) (PVDF) is a biomaterial designed for soft tissue applications, but it does not possess functional groups. Surface modification of PVDF can be performed by plasma-induced graft polymerization of hydrogels like polyacrylic acid spacer and immobilization of fibronectin.^[31] Klee et al. conclude that incorporation of fibronectin onto PVDF surface, either adsorptively or covalently, can induce cell attachment to PVDF. However, prolonged proliferation and survival of cells are seen only when the protein molecule is covalently bound to the surface. Therefore, long-term presence of the ECM protein on the polymer surface seems to be a prerequisite for successful application as a biomaterial.

Graft polymerization of functional monomers using plasma GD is very effective in increasing the immobilizing site on the segmented PU surface for heparin (Hep) immobilization. The blood compatibility of poly(ethylene oxide) (PEO)-grafted and Hep-immobilized PU has been investigated using in vitro blood interaction.^[32] Poly(ethylene oxide) is frequently used as a surface modifier or spacer, and Hep, which is well known as an anticoagulant, is often used as an immobilizing biomolecule. Kang et al. have observed that the activation of plasma proteins and platelets on PU is slightly suppressed by PEO grafting and significantly suppressed by Hep immobilization. A longer PEO biomolecule has better blood compatibility than a shorter PEO, whether or not it is directly grafted on the PU surface or used as a spacer between the PU surface and the Hep. Moreover, the release of cytokine interleukin-6 (IL-6) by the stimulation of peripheral blood mononuclear cell with Hep-immobilized PU can be highly suppressed.

Plasma Spraying

Plasma spraying includes atmospheric plasma spraying and vacuum plasma spraying. In plasma spraying, the powders of the sprayed materials are introduced into the plasma area of the plasma torch. Because of the high temperature and flux velocity of the plasma, the melted or the partially melted powders are accelerated toward the substrate at high speed forming a coating with a lamellae structure. Owing to the high temperature of the plasma core, plasma spraying offers the ability to deposit almost any metal and various combinations of materials. The high temperature enables the use of the coating materials with a high melting point, such as ceramics, cermets, and refractory materials.

Plasma spraying is widely used to produce bioactive ceramics, such as HA, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, as interfacing osseoconductive layers on metallic surgical implants. The HA is one of the most attractive materials for human hard tissue implants because of its similar chemical composition (Ca/P ratio) to that of teeth and bones. An HA coating can accelerate the process of bone growth in the vicinity of the prosthesis. Therefore, HA has been clinically applied as a dense, sintered material and as a coating on bioinert metallic implants. However, the relatively poor bonding due to high residual stress between the plasma-sprayed HA coating and prostheses is one of the main disadvantages making it unsuitable for high-load applications. To achieve the mechanical characteristics needed for biomedical applications, blending with a tough phase is essential. Titanium metal, Ti-6Al-4V alloy, yttria-stabilized zirconia, Ni_3Al , and Al_2O_3 ceramics have been considered good candidates as the reinforcing phases. Another important concern is the resorption and degradation of HA coatings in a biological environment. This may lead to disintegration of the coating resulting in the loss of both the coating-substrate bonding strength and implant fixation. Generally, the amorphous and the metastable compounds are more soluble than the crystalline HA. Some post-deposition treatment processes have been proposed to

Fig. 6 Schematic illustration of plasma graft polymerization of an interface for cell seeding.

increase the crystallinity, including furnace annealing, laser irradiation, and vapor-flame treatment.^[33]

Other common plasma-sprayed coatings used on titanium alloys are Al₂O₃, ZrO₂, and TiO₂. These coatings are being used clinically because of their excellent wear resistance and corrosion resistance. However, Al₂O₃ and ZrO₂ coatings cannot bond directly to human bone tissues because of their bioinertness, thereby limiting their applications. Attempts have been made to plasma spray bioactive ceramics onto titanium implants.^[34] Some bioglass and glass-ceramic coatings, including CaO-SiO₂, have been found to bind to living bones and some ceramics including wollastonite (CaSiO₃) and dicalcium silicate (Ca₂SiO₄) have also been reported to have excellent bioactivity.^[35]

CONCLUSIONS

Plasma surface modification of biomaterials is an effective means to modify the surface of existing materials to enhance the physicochemical properties and optimize the biocompatibility and biofunctionality. There are many types of biomaterials and the design of each type of biomaterials or devices has its own challenge based on the intended function and biological uses. Much work has been conducted and more information pertaining to surface engineering of biomaterials can be found in Refs. [36–40]. More efforts are needed to further improve the functions and lifetime of the biomaterials. As the biomaterials field is interdisciplinary in nature, there must be a close collaboration among people in materials science, plasma physics, chemistry, biology, biomedical engineering, and medicine.

INTRODUCTION

Polyamides are polymers consisting of R-CO-NH-R' monomeric units. Polyamides such as proteins, wool, and silk exist naturally or they can be made synthetically. Synthetic polyamides include nylon, Kevlar, Versamid, sodium polyaspartate, aromatic polyamides, pyrrole-imidazole polyamides, peptide nucleic acid (PNA), and peptidomimetics. A small group of polyamides are categorized in a separate group as polyamino acids to distinguish them from the proteins because of their different features of biosynthesis. Synthetic polyamides can be made by the condensation reaction of monomers and the polymer chain grows through the formation of amide bonds. The amide bond is formed by the reaction of a dicarboxylic acid or an acid chloride with a diamine. Synthetic polyamides can also be made from an amino acid or its lactam, which may be able to undergo a self-condensation reaction. Natural and synthetic polyamides are useful in modern industries and biomedical applications.

CLASSIFICATION OF POLYAMIDES

Both natural and synthetic polyamides are divided into the homopolyamides, consisting of one type of monomers, and the copolyamides, which are composed of more than one constituent. Chemically, polyamides can be divided into four categories: 1) polyamides made by the polymerization of lactams; 2) polyamides made by the condensation of a diamine with a dibasic acid; 3) polyamides made by self-condensation of amino acids; and 4) polyamides based on vegetable oil.

NATURAL POLYAMIDES

Proteins

Proteins are complex organic molecules built from 20 different amino acids, in which the amino acids are

joined through a peptide bond (an amide bond). Once linked in the protein chain, an individual amino acid is called a residue and the linked series of carbon, nitrogen, and oxygen atoms are known as the main chain or protein backbone. A typical protein consists of around 200–300 amino acids in a single chain. Titin is the largest protein in the cardiac and skeletal muscles. Titin contains 26,926 amino acid residues.^[1] The synthesis of proteins from amino acids occurs inside the cells using mRNA as a template and the process is called translation. The sequence of amino acids in a protein is defined by the genes encoded in the genetic code DNA. The structure of the protein can be determined using amino acid sequencing, X-ray crystallography, and nuclear magnetic resonance spectroscopy. Many proteins are enzymes and play a crucial role in cell metabolism. The proteins are also responsible for many physiochemical processes in living organisms, e.g., cell signaling, immune responses, cell adhesion, and the cell cycle. Proteins also play a major role in the structural support of the body as components of skin, hair, nails, tendons, muscles, and bones.^[2]

Many traditional proteins prepared by extraction of animal (e.g., collagen) and plant (e.g., soy or zein from corn) tissue are being chemically or physically modified for applications in the food and biotechnology industries. Fibrous proteins such as collagen and elastin have been used in biomaterials and tissue engineering.^[3] Using chemoselective ligation technology, chemoselective anchors can be incorporated into the protein backbone to change the pharmacokinetic properties, thus leading to the formation of new lead proteins.^[4]

In addition to the proteins, there is a small group of compounds in nature known as polyamino acids. Polyamino acids include some interesting compounds, such as polyglutamic acid (PGA), polylysine, and cyanophycin (Fig. 1). Polyglutamic acid was first detected in pathogenic Gram-positive bacterium *Bacillus anthracis* more than 60 years ago.^[5] Later it was

Fig. 1 Structures of polyglutamic acid, polylysine, and cyanophycin.

reported to be present in non-pathogenic Gram-positive strains of the genus *Bacillus*.^[6] In addition to the *Bacillus* spp., two halophilic eubacteria,^[7] a halophilic archaeobacterium,^[8] and few coelentrates (e.g., Hydra)^[9] have been found to produce PGA. PGA can act as a biodegradable and non-toxic substitute for the polyacrylate.^[10] In addition, it can be used as a biodegradable thickener, humectant, sustained release material, or drug carrier in food, cosmetics, or medicine. Among other applications, efforts have been made to convert the ammonium nitrogen present in liquid manure to a transient depot form of nitrogen using PGA-producing bacteria.^[11] Polylysine was isolated from *Streptomyces albulus* spp. around 40 years ago.^[12] Polylysine inhibited the growth of both Gram-positive and Gram-negative bacteria at lower concentrations.^[13] Furthermore, inactivation of bacteriophages was observed by this compound. Because of its antibiotic properties, polylysine can be used as a preservative in animal feed. Cross-linked polylysine is used as cationic adsorbent in pharmaceutical applications.^[14]

Cyanophycin, which is also referred to as cyanophycin granule polypeptide, a copolymer of aspartic acid and arginine, is a storage compound for carbon, nitrogen, and energy and exists as insoluble cytoplasmic inclusions in many cyanobacteria. In non-heterocyst-forming cyanobacteria, the cyanophycin granules are distributed in the protoplasts,^[15,16] whereas in heterocyst-forming cyanobacteria, cyanophycin granules are frequently present in the heterocysts, which are specialized for the fixation of molecular nitrogen. In those cells the cyanophycin

granules are primarily associated with the polar nodule and the neck, which connects the heterocyst to the adjoining vegetative cells.^[17] The cyanophycin granules were first isolated from *Anabaena cylindrica* by differential centrifugation.^[18] Purified cyanophycin can be chemically converted to a derivative with reduced arginine content, which then can be used in place of PGA in various technical processes, such as a biodegradable substitute for polyacrylate.^[19] Recently, cyanophycin synthesis has been established in several recombinant *Escherichia coli* strains harboring *cphA* from different sources, resulting in a maximum content of 26% (w/w) cell dry mass after growth on rich complex medium.^[20–22] Transgenic tobacco and potato plants accumulate high levels of cyanophycin. This could be a natural source of biodegradable, non-toxic plastic such as the polymer polyaspartate.^[23]

Silk

Silk is a natural protein fiber obtained from the larvae of the silk worm, *Bombyx mori*. Many other insects produce different types of silk, although none of them has been exploited for commercial purposes. Silk production is especially common in the Hymenoptera and is sometimes used in nest construction. Other types of arthropods produce silk, most notably various arachnids such as spiders (spider silk). Natural silk has long been used in making clothes, but it is also used for making parachutes, bicycle tires, comforter filling, and artillery gunpowder bags. Interestingly, early bullet-proof vests were also made from silk. Chinese medical

doctors have used natural silk to make prosthetic arteries. Recently, some bioengineers developed a genetically engineered chimeric material using a combination of nature's most remarkable materials, spider silk and silica. The resulting fusion protein has industrial and medical applications, such as growing bone tissues.^[24] Because of the strong and tough nature of spider silk, it has potential applications in the medical field for surgical sutures, artificial ligaments, and tendons. To test the possibility of using spider silk for surgical sutures, it was implanted subcutaneously in pigs. Within 2 weeks all the wound sites healed well, and few demonstrated any inflammation.^[25] Silk could also be used for soft body armor, oxygen-permeable contact lenses, biomaterial membranes, and even tethers for planes on aircraft carriers. Stem cell-based tissue engineering has been used to make biomaterials of silk fibroin scaffold. These biomaterials can be used as skeletal tissues like bone, ligament, and cartilage, as well as connective tissues like skin.^[26] Nexia Biotechnologies in Montreal successfully produced spider silk protein in transgenic goats. Milk produced by these goats contained the required protein.^[27]

Wool

Wool is a natural fibrous protein derived from the hair of sheep. It is also produced by other mammals, such as goats, rabbits, alpacas, and llamas. Natural wool is useful in making sweaters, gloves, coats, blankets, seat covers, boots, carpets, etc. It has been suggested that keratin extracts from hair and wool can be used as biomaterials. Further, it may be useful in biomedical applications for wound healing and bone regeneration, scaffolds for tissue engineering, and coating for medical devices.^[28]

Cyclotides

Cyclotides are unusual polypeptides found in a variety of tropical plants from the Rubiaceae and Violaceae families. They are head-to-tail cyclized through amide bonds. These cyclic polypeptides contain around 30 amino acid residues and possess strong chemical and biological stability toward enzymatic degradation because of the presence of a cyclic backbone. Cyclotides contain six conserved cysteine residues that form three disulfide bonds, which provide extra stability. These structural features make the cyclotides interesting for protein engineering. Use of stable cyclotides as templates for pharmacologically active sequences is being explored. In native medicine, cyclotides demonstrated a variety of biological properties, including antiviral (HIV), antimicrobial, and insecticidal activities, as well as neurotensin inhibition. An extract of the

plant *Oldenlandia affinis* has been used to accelerate childbirth, indicating that the cyclotide present in the plant affects contraction of the uterus. This is how the first cyclotide, Kalata B1, was discovered.^[29–31] Recently, researchers demonstrated that cyclotides possess cytotoxic activities.^[32,33]

SYNTHETIC POLYAMIDES

Nylons

The first chemical synthesis of a polyamide, namely nylon 6,6, was achieved by Carothers and coworkers at Du Pont in 1935. The polymer was produced commercially in 1939 and originally used for fibers. A year later, in 1940, Schlack discovered nylon 6 in Germany. Later, nylon 7 and nylon 9 were discovered as fiber-forming materials by Russian chemists. The production of nylon 11 and nylon 12 was reported in France in 1955 and 1960, respectively. The term nylon, originally a trade name, later became the generic name given to linear polyamides. Nylons can be made from single monomers such as amino acids or their cyclic lactams by self-polycondensation or by ring-opening polymerization, respectively. They can also be made from the polycondensation reaction of dicarboxylic acids and diamines. Nylons are designated by a numbering system. In the case of single monomer nylons, the digits that follow the nylon name represent the number of carbon atoms between two successive amide groups, such as nylon 6 and nylon 12. For nylons based on diamines and dicarboxylic acids, the numeral is composed successively of the number of carbons in the diamine and diacid molecules, respectively. Thus, nylon 6,12 is made of 1,6-hexamethylenediamine and 1,12-dodecanoic acid. The most important nylons produced commercially are nylon 4,6; nylon 6,6; nylon 6,9; nylon 6,10; nylon 6,12; nylon 6; nylon 11; and nylon 12.^[34]

Nylon 6 is prepared by hydrolytic or anionic ring-opening polymerization of caprolactam. The caprolactam is made from cyclohexane, phenol, or toluene. Nylon 6,6 is made by the polycondensation reaction of two monomers, each of which contain six carbon atoms. One of the monomers is a six-carbon acid with a $-\text{COOH}$ group at each end, hexanedioic acid (adipic acid). The other monomer is a six-carbon chain with an amino group, $-\text{NH}_2$, at each end, 1,6-diaminohexane (1,6-hexamethylenediamine).

Fig. 2 Nylon 6,6.

When these two compounds polymerize, the amine and acid groups combine, each time losing a molecule of water. Because the acid is acidic and the amine is basic, they first react together to form a salt. The salt is then converted into nylon 6,6 by heating under pressure at 350°C (Fig. 2).

Similarly, nylon 4,6 is prepared from 1,4-diaminobutane and adipic acid. Other nylon salts are synthesized in the first step from hexamethylenediamine and the corresponding dicarboxylic acids, azelaic acid (obtained from oleic acid) and 9 carbon atoms for nylon 6,9; sebacic acid (obtained from castor oil) and 10 carbon atoms for nylon 6,10; and dodecandioic acid (obtained from butadiene) and 12 carbon atoms for nylon 6,12.

Nylon 11, also called Rilsan[®], is prepared by the self-condensation of ω -aminoundecanoic acid (11-aminoundecanoic acid), a crystalline solid. The raw material for the amino acid is castor oil, a vegetable product composed of the triglyceride of ricinoleic acid. The self-condensation of ω -aminoundecanoic acid is conducted in a continuous process at about 220°C, withdrawing water continuously. The latter stages of the process are conducted under reduced pressure. Nylon 11 is highly resistant and is attacked by very few solvents and chemicals.

Nylon 12 is synthesized by the hydrolytic polymerization of dodecanelactam prepared from butadiene by a multistage reaction. The process is conducted at about 300°C in the presence of aqueous phosphoric acid.

Nylons are linear thermoplastic polymers containing highly polar amide groups separated by a flexible aliphatic hydrocarbon chain. The carbonyl group of the amide linkage of a polyamide unit can become associated with the amino hydrogen of the amide linkage of an adjacent molecule through H-bonds. H-bonding affects several properties of these polymers. They have sharp melting points, high tensile strength, rigidity, hardness, high abrasion resistance, reduced solubility, and low thermal coefficient of linear expansion.^[34,35] When exposed to light, especially in the presence of air, there is a strong tendency for these polyamides (nylons) to lose tensile strength and to discolor. This is most likely a result of oxidation of amino groups and amide groups of the polymer molecule from effects of radiant energy on the polymer in contact with oxygen. Antioxidants of various kinds

are partially effective in stabilizing the nylons against the effects of oxygen and ultraviolet light. Some of these include mercaptobenzothiazole, syringic acid, and various phenolic antioxidants, chromium, and copper salts. The oxidation of polyamides is accelerated by heat or light or both. It is noteworthy that carbon black is an effective stabilizer against exposure to light and air, presumably because it absorbs radiation and thus slows the rate of deterioration.^[35]

Around 80% of nylon production goes into fiber applications such as clothing, tire cords, ropes, and carpets. Nylon 6 is considered the best material for shock-proof parts. Nylon 6,6 is used for high mechanical loads. Nylon 11 and 12 are preferred for cable sheathing, surgical sutures, and precision engineering parts. Nylons are extensively used in the automotive industry as parts of chassis, steering wheels, bumpers, housings, rear-view mirrors, parts for electrical equipment, transmission systems, and fuel supply system parts in the engine block and the lubricating system. In mechanical engineering nylons are used in gears, cams, bearings, etc. In telecommunications they are used for circuits and relays, contact makers, drive units, cable sheaths, and plug and socket devices. Nylons are also used in water heater tanks, heat exchangers, thermostat casings, fans, chairs, tables, combs, and sterilizable moldings for medical uses. Nylon films are used in packaging pharmaceutical and food products.^[34]

Polyamides have good biocompatibility with human tissue because of its similarity in chemical structure with the collagen protein. Recently, a new kind of tissue engineering scaffold material of needle-like nano-hydroxyapatite (n-HA) and polyamide (PA66) biocomposite was prepared using the cosolution coprecipitation method. Strong molecular interactions and chemical bondings exist between the n-HA and PA66 in the composite. This new scaffold has excellent mechanical properties close to that of natural bone.^[36]

Kevlar[®]

Kevlar[®] is a brand of synthetic polyamides made by DuPont. Kwolek and Blades developed Kevlar in 1965 at DuPont.^[37] Fibers of Kevlar consist of long molecular chains produced from polyparaphenylene terephthalamide. Kevlar is similar in structure to nylon 6,6, except that instead of the amide links joining

Fig. 3 Monomer units of Kevlar.

chains of carbon atoms together, they join benzene rings. The two monomers are terephthaloyl chloride and 1,4-diaminobenzene (Fig. 3).

When these monomers react and eliminate a molecule of hydrochloric acid as a byproduct, an amide bond is formed and the chain grows in length. The structure of Kevlar is illustrated in Fig. 4.

Many interchain bonds make Kevlar highly oriented and extremely strong. Kevlar derives a portion of its improved strength from intermolecular hydrogen bonds formed between the carbonyl groups and protons on neighboring polymer chains and the partial pi stacking of the benzenoid aromatic stacking interactions between stacked strands. These interactions result in a unique combination of properties. Kevlar has high tensile strength, low electrical conductivity, and excellent dimensional stability and is chemical and flame resistant. There are three common grades of Kevlar: pure Kevlar, Kevlar 29, and Kevlar 49.

Since its discovery, Kevlar has been used for many applications such as bulletproof vests, composites for boat construction, lightweight mountaineering ropes, lightweight skis, and helmets and racquets. Kevlar has played a significant role in many critical and diverse applications: ropes that secure airbags in the crucial landing apparatus of the Mars Pathfinder; shrapnel-resistant shielding in jet aircraft engines that can protect passengers in case an explosion occurs; and gloves that protect hands and fingers against cuts, slashes, and other injuries that often occur in glass and sheet metal factories.^[37]

Because biopolymers are now being used as replacements for ligaments, Wening et al. recently tested the cytotoxicity and mutagenicity of Kevlar 49 against six strains of *Salmonella typhimurium* and Chinese hamster cells, respectively, and reported that Kevlar 49 does not exhibit mutagenic or cytotoxic activity.^[38]

Polyamides are fairly readily attacked by strong acids, but are much more resistant to alkaline

Fig. 4 Structure of Kevlar.

hydrolysis. Hydrolysis is faster at higher temperatures. Hydrolysis by water alone is so slow as to be completely unimportant. Kevlar is more resistant to hydrolysis than nylon.^[39]

Versamid

The synthetic polyamide resins made from condensation of polymerized vegetable oil acids and polyalkylene polyamines are marketed under the trade name Versamid[®].^[35] They are available in several grades, ranging from materials that are liquid at room temperature to hard, solid materials melting at temperatures as high as 185°C. The polyamide resins are considered internally plasticized by the long carbon chains and the large alkyl substituents on the chains of the dibasic acid portion. Versamids are classed as relatively low-melting, highly soluble polyamide resins of low to moderate molecular weight. Solid versamid resins are used as such or modified with plasticizers, waxes, and other resins in hot-melt cements, heat seal coatings, barrier coatings, inks, and specialty adhesives and coatings. The reactive Versamid polyamides may be used to modify the solid versamid resins or converted to thermoset resins by reaction with epoxy resins, heat-reactive phenolic resins, and other substances. The Versamid resins are frequently used as adhesives and include Versamid resins 930, 940, 950, and 100. The adhesives are used for a wide range of different purposes such as bookbinding adhesives, heat seal adhesives for bread wrappers, cigarette packages, packaged soups and packaged foods in paperboard boxes, and the manufacture of corrugated fiber boxes. Generally, they are used with flexible packaging materials including paper, glassine, cellophane, aluminum foil, and cellulose acetate films.^[35]

Versamid polyamide resins are useful in the field of printing inks, particularly for flexographic and roto-gravure printing and for clear overprint varnishes. Their use is closely tied to the needs of the flexible packaging industry because inks based on Versamid polyamides are largely used for printing on treated polyethylene and polypropylene, cellophane, coated cellophanes, saran, cellulose acetate, Mylar[®], and other plastic films as well as glassine, paper, and aluminium foil. Packages designed from printed stock are used for food products such as apples, carrots, and potatoes, for small articles of clothing, for household goods such as cellulose sponges, and for many other products.^[35]

Amino-containing polyamide resins of the fluid series, Versamid 115 and Versamid 125, find widespread use in casting and laminating applications. When blended with liquid epoxy resins, they harden into tough thermoset products, which are especially

well suited for use in plastic tools and dies, glass-fiber laminates, electrical potting and encapsulating, and general casting and molding. When the fluid Versamid resins are blended with liquid epoxy resins, a chemical reaction occurs between the amino groups of the polyamides and the epoxy groups of the epoxy resins. A cross-linked or 3-D polymer is formed. When the longer-chain reactive polyamides are cross-linked with the epoxy resins, a more flexible, resilient structure is obtained than that of the epoxy cross-linked with the shorter, more rigid molecules of the amine hardeners.

Versamids may be used alone or with plasticizers or other modifiers as surface coatings. In this form they are used most frequently as coatings for flexible substrates, including paper, cellophane, and aluminum foil. They are valued for their heat-seal properties and for their grease and water barrier properties. The soluble polyamides are applied over printed matter on packages as gloss overprint varnishes to protect the printing against abrasion and effects of oil or water, as well as to give an improvement in appearance, gloss, and depth of color.^[35]

Sodium Polyaspartate

Sodium polyaspartate (Fig. 5) is a condensation polymer based on aspartic acid. When aspartic acid is simply heated to 180°C, many condensation reactions occur and the equivalent of water is eliminated with each condensation. The product formed is water-insoluble polysuccinimide. In the subsequent step the polymer is reacted with sodium hydroxide in water, which results in partial cleavage of the amide bonds. Hydrolysis can occur from either of the two sites of the

Fig. 5 Structure of sodium polyaspartate.

succinimide ring. Two different bonds (α and β) are hydrolyzed, resulting in a sodium polyaspartate copolymer with 30% α -linkages and 70% β -linkages.^[40] As a polymer of amino acid, it is an example of a polypeptide.

Sodium polyaspartate is used as a chelating agent. It can be applied to remove calcium phosphate deposits consisting of hydroxyapatite and brushite or dicalcium phosphate dihydrate from stainless-steel surfaces.^[41] Sodium polyaspartate is also present in mascara, shampoo, facial moisturizer, facial cleanser, and moisturizer.^[42] Sodium polyaspartate (PASP) acts as a stabilizer for indocyanine green (ICG), which is a widely used dye in cardiovascular, hepatic, and ophthalmological studies. The stock solution of ICG-PASP is stable and demonstrated fluorescence over a wide range of concentration for 2 weeks when stored in the dark.^[43] Recently, some bioinorganic nanocomposites have been synthesized in which the layered double hydroxides are intercalated with poly(α,β -aspartate). They have good interlayer spacing and modified textures. The bioinorganic hybrid material formed can be used as organic clays with bioactive, biocompatible, and biodegradable properties.^[44]

Pyrrole–Imidazole Polyamides

DNA acts as the storehouse of the biological information for all living organisms. Any chemical substance that can interfere with the four bases present in the DNA severely affects the cellular function of all organisms. Chemical substances that can recognize and bind DNA in a sequence-specific manner have enormous importance in modern biology and medicine. Dervan et al. developed the minor groove-binding hairpin polyamides that contain *N*-methylimidazole (Im)–*N*-methylpyrrole (Py)–hydroxypyrrrole (Hp), which uniquely recognize each of the four Watson-Crick base pairs.^[45,46] Hairpin polyamides are derived from distamycin A, which binds to A:T-rich sequences of DNA. Composed of Py and Im compounds, hairpin polyamides are synthetic ligands that have an affinity and specificity for DNA similar to that of many naturally occurring DNA binding proteins. An Im–Py recognizes G:C, whereas a Py–Im recognizes C:G. In contrast, a Py–Py pair degenerately recognizes A:T or T:A base pairs. An Hp and Py pair (Hp–Py) distinguishes T:A from A:T base pairs. The structure of pyrrole–imidazole polyamides is illustrated in Fig. 6.

The hairpin polyamides are cell permeable and bind to DNA at nanomolar concentrations, with binding coefficients similar to that of transcription factors. The solid phase synthesis of Py–Im polyamides was achieved in 1996 by *t*-Boc chemistry using a

Fig. 6 Structure of pyrrole-imidazole polyamides.

combination of building blocks, Boc-Py-OBt ester and Boc-Im acid and Boc- β -alanine-Pam resin. Cleavage with *N,N*-dimethylaminopropylamine (Dp) affords a β -alanine-Dp tail at the C terminus of Py-Im polyamides. These polyamides can be used for regulation of gene expression and inhibition of gene expression and as gene activators. The cell permeability of polyamides is useful in cell culture experiments.^[47] Wang et al.^[48] recently reported the alkylation of DNA using a combination of the anticancer drug chlorambucil with a sequence-selective hairpin pyrrole-imidazole polyamide ImPy- β -ImPy- γ -ImPy- β -Dp. The alkylation occurs predominantly at the 5'-AGCTGCA-3' sequence, which represents the polyamide binding site. The alkylation inhibits the *in vitro* DNA replication, but not protein or RNA synthesis. Flow cytometric analysis demonstrated that the hybrid arrested cells in the G₂/M phase.^[48] Similarly, Wurtz et al. reported that hairpin polyamide-chlorambucil conjugate binds and selectively alkylates predetermined sites in the HIV-1 promoter at subnanomolar concentrations.^[49]

Aromatic Polyamides/Aramidics

According to the definition of the U.S. Federal Trade Commission, aromatic polyamides or aramid fibers are manufactured fibers that contain a long polyamide chain, with at least 85% of the amide linkages directly attached to the two aromatic rings.^[34] The aromatic rings impart rigidity to the polymer, and in the production of the fibers the stiff chains are generally aligned parallel to the fiber axis, thus leading to a modulus of elasticity, which can be as high as 130 GPa.

Although they are resistant to heat compared with other fibers, at temperatures higher than 300°C the fiber may lose most of its strength.^[50]

These aromatic polyamides cannot be synthesized by the direct condensation of amines and acids because the aromatic amines are less reactive and do not provide polymeric materials. The other hurdle is discoloration and decomposition in the molten state, making the bulk polycondensation technique impractical. Therefore, the aromatic polyamides are synthesized by a more costly solution and interfacial polycondensation technique. The diacid chlorides and diamines serve as starting materials.^[34]

The first aramidic fiber, poly-*m*-phenylene isophthalamide, was prepared in the 1960s by the polycondensation of isophthaloyl chloride with *m*-phenylenediamine (Fig. 7). It is commercialized as Nomex[®].

This fiber has been used in applications where high heat resistance is required, such as heat-protective clothing. At normal temperatures their chemical, mechanical, and electrical insulation properties are comparable with that of nylon 6 and nylon 6,6. The aramidic fibers are directly obtained by the polymerization process and not from fusion, because they degrade before fusion takes place.^[51]

Poly-*p*-phenylene terephthalamide is another aromatic polyamide fiber introduced to the market in 1972. It is prepared by the low-temperature polycondensation of terephthaloyl chloride with *p*-phenylenediamine in a solvent mixture of hexamethylphosphoramide and *N*-methylpyrrolidone in 2:1 ratio at -10°C. The fiber has the highest strength and density among commercially available fibers and is highly competitive with glass, carbon, and steel fibers. It is used as a filler in

Fig. 7 Structure and synthesis of Nomex.

composite materials because of its lighter weight, greater stiffness, and high tensile strength. Other uses for poly-*p*-phenylene terephthalamide include reinforced composites for boat hulls, military protection helmets, lightweight bullet-proof jackets, and filament-wound rocket motors. The fiber is also used as reinforcement in radial tires.^[34]

Peptide Nucleic Acids

Peptide nucleic acids were originally designed as a ligand for the recognition of double-stranded DNA. The concept was to mimic an oligonucleotide binding to double-stranded DNA via Hoogsteen base pairing in the major groove. Peptide nucleic acid is a nucleic acid analog in which the sugar phosphate backbone of natural nucleic acid has been replaced by a synthetic peptide backbone, usually formed from *N*-(2-aminoethyl)-glycine units, resulting in an achiral and uncharged mimic. They do not exist in nature but are synthesized chemically (Fig. 8). The PNAs are chemically and enzymatically (proteases and nucleases) stable and thus are not prone to be degraded inside the living cell. Peptide nucleic acid is an excellent structural mimic of DNA (or RNA), and PNA oligomers are able to form very stable duplex structures with Watson–Crick complementary DNA, RNA (or PNA) oligomers and they can also bind to targets in duplex DNA by helix invasion. The hybrid complexes exhibit extraordinary thermal stability and unique ionic strength effects. Therefore, these molecules are of interest in many areas of chemistry, biology, and medicine including drug discovery, genetic diagnostics, molecular recognition, and the origin of life.

The first experiments conducted with homothymine PNAs clearly demonstrated that PNAs bound to double-stranded DNA in a sequence-specific manner. Two homothymine PNAs had formed a triplex with

Fig. 8 Structure of PNA and DNA. A, adenine; T, thymine; G, guanine; C, cytosine.

the homoadenine target in the double-stranded DNA, while displacing the homothymine strand in the DNA target. Later it was revealed that PNAs with both purine and pyrimidine bases form stable duplexes with DNA and RNA, although not with the extremely high stability of the homopyrimidine 2PNA/DNA triplexes, but still more stable than the corresponding DNA/DNA and DNA/RNA duplexes.^[52]

In vitro studies indicate that PNA could inhibit both transcription and translation of genes to which it has been targeted, which holds promise for its use for antigene and antisense therapy. However, as with other high-molecular-weight drugs, the delivery of PNA, involving passage through the cell membrane, appears to be a general problem.^[53] The PNA oligomers can also be used to selectively suppress the growth of specific types of bacteria.^[54]

The unique physicochemical characteristics of PNAs led to the development of PNA probes for various molecular, genetics, and cytogenetics applications. Also, PNA-based hybridization technology is developing rapidly within the field of in situ fluorescence hybridization, indicating the great potential of PNA probes for chromosomal investigations.^[55]

Peptidomimetics

Peptides and proteins are important constituents of the human body and microorganisms such as bacteria and viruses, but their use in medicinal purposes suffers from many problems. They are poorly absorbed in the gastrointestinal tract and have a short plasma half-life when given in the form of injection. Therefore, attempts were made to design and synthesize molecular fragments that could replace parts of peptides. A peptidomimetic is a small protein-like chain designed to mimic a peptide. They typically arise from modification of an existing peptide to alter the molecule's properties. For example, they may arise from modifications to change the molecule's stability or biological activity. This can play a role in the development of drug-like compounds from existing peptides. These modifications involve changes to the peptide that will not occur naturally (such as altered backbones and the incorporation of non-natural amino acids). Alternatively, they could be large molecules that are completely unrelated to peptides but look like peptides. The peptidomimetics have some important features in their use as drugs or in biological application. They have conformationally restrained structures that can minimize binding to non-target receptors and enhance activity at the desired receptor. The addition of hydrophobic groups or replacement of amide bonds results in better transport properties through cellular membranes. Isosteres, cyclic peptides, and more

modification in the peptidomimetics reduce the rate of degradation by peptidases and other enzymes.^[56] In the future, these peptidomimetics would be designed to easily pass through cell membranes and to survive in the human body long enough to reach the biological target. Peptidomimetics will be useful for infectious diseases like malaria, tuberculosis, hepatitis C, and HIV and for non-infectious diseases like Alzheimer's and high blood pressure.^[57]

An example of peptidomimetics is an anticancer agent designed and synthesized to induce programmed cell death (apoptosis) of cancer cells. Walensky et al. synthesized a peptidomimetic called stabilized α -helix of BCL-2 domains, which was effective in inhibiting the growth of human leukemia cells xenografted in mice.^[58]

CONCLUSION

We summarized the polyamides into two broad categories—natural and synthetic. These polyamides play an important role in every aspect of life. They are crucial for the biological processes as enzymes and are important for the outer skeleton of humans and animals. Polyamides find strong applications in modern industries as nylons, Kevlar, sodium polyaspartate, Versamids, etc. They are also used in the biotechnological and pharmaceutical industries. The emerging fields of science such as tissue engineering, protein engineering, and biomaterial engineering are using these polyamides as scaffolds for various applications.

P. Christian

School of Chemistry, University of Manchester, Manchester, Greater Manchester, U.K.

INTRODUCTION

Polycaprolactone (PCL) is an aliphatic polyester and was initially investigated for use as a biodegradable packaging material after the realization of its degradability by microorganisms. PCL is also degraded by hydrolysis in physiological conditions and has therefore received a great deal of attention for use as an implantable material.

PCL is now one of several degradable polymers approved for use in the human body as drug delivery devices, adhesion barriers, sutures, and staples and is being extensively investigated as a biomaterial for tissue repair and regeneration. Degradable polymers have different degradation rates and are commonly investigated as blends as a method to tailor the degradation rate. The focus of this article is the recent use of PCL as a biomaterial.

SYNTHESIS AND STRUCTURE

Polymerization

PCL is a biodegradable polyester, which may be prepared by a variety of routes (cationic,^[1] anionic,^[2] and coordination polymerization^[3] as well as by free-radical initiation^[4] and is generally a tough white material, insoluble in water but soluble in a range of organic solvents. Commercially available material is generally a high-molecular-weight straight-chain polymer with a narrow molecular weight distribution. It has a low T_g of -60°C and a T_m of 60°C , the polymer being around 57% crystalline at an M_w of 120 kDa.^[1] Relatively, low-molecular-weight polymer was initially prepared by Carrothers who condensed capronic acid by simply heating it.^[5] The reaction results in the elimination of water. However, the reaction is an equilibrium and the reverse reaction is sufficiently dominant to make a significant impact on the molecular weight of the final material and therefore compromise its mechanical properties.

A more practical approach to its synthesis is via the ring opening polymerization (ROP) of a lactone,

(a cyclic ester). PCL may be prepared by anionic or cationic polymerization of ϵ -caprolactone (Fig. 1A). These reactions produce high-molecular-weight material with very little chain branching and therefore a high degree of crystallinity. High-molecular-weight material may also be prepared by free-radical polymerization of 2-methylene-1,3-dioxepane Fig. 1B.^[4] This method relies on a propagating primary carbon radical, which is very reactive and renders the polymerization reaction very sensitive to contaminants. The final product is a polymer with a significant amount of branching, which results owing to a radical back-biting mechanism. The branching necessarily results in a polymer with lower crystallinity. Generally the tin-catalyzed polymerization of the bulk monomer is used to prepare the materials, and this results in high-molecular-weight polymer (200 kDa) with a T_m of 60°C and 57% crystallinity. The T_g of the polymer is fairly low at -60°C . The combination of high crystallinity and low T_g results in a polymer with a Young's modulus of approximately 200–400 MPa, which may be easily softened upon gentle heating.

ϵ -Caprolactone can be copolymerized with other monomers such as ethylene oxide, chloroprene, tetrahydrofuran, D-valerolactone, 4-vinylanisole, styrene, methylmethacrylate, vinylacetate^[6] (and many others as shown in Table 1^[7–17]), but most relevant to use in the human body are copolymers of caprolactone and lactic acid.^[3,18–21] The mechanical properties of PCL compared to that of polylactic acid (PLA) are shown in Table 2. A recent article by Albertsson and Varma^[22] details ROP of lactones for a variety of biomedical applications.

Enzyme-Catalyzed Polymerization

PCL and copolymers have been successfully polymerized using enzymes.^[23] This is an advantage for biomaterials development, as enzymes are natural molecules and rule out the use of harsh often-toxic catalysts and monomers. He et al.^[10] demonstrated the polymerization of ϵ -caprolactone with monohydroxyl or dihydroxyl poly(ethylene glycol) (PEG) using Novozyme-435 as a catalyst (an immobilized lipase B isolated from *Candida*

P

Fig. 1 (A) ϵ -caprolactone; (B) 2-methylene-1,3-dioxepane; and (C) PCL.

antartica). By altering the caprolactone:ethylene glycol ratio, control over molecular weight was obtained. These polymers were found to be semicrystalline and degradable by *Pseudomonas lipase*. ϵ -Caprolactone has also been copolymerized with D,L-lactide in a variety of ratios using the same enzyme.^[24]

DEGRADATION

Hydrolytic Degradation

Although PCL is biodegradable via hydrolysis of the ester linkages (Fig. 2), its degradation rate is very slow compared to materials such as PLA, as PCL has higher crystallinity and increased hydrophobicity, which reduces the diffusion rate of water through the polymer. PLA degrades rapidly and produces acidic degradation products that can lead to cell death and inflammation around the implant. Although the degradation of PCL is slower and produces less-acidic degradation products, the degradation may be too slow to allow efficient tissue regrowth. Ideally a biodegradable polymer will degrade at a rate similar to the rate of tissue formation. A great deal of research has therefore focused on producing PCL with a variable degradation rate and has aimed at the synthesis of copolymers^[25] or the manufacture of polymer blends.^[26]

The hydrolytic degradation may be catalyzed by either an increase or a decrease in the pH of the system and therefore may also be autocatalyzed by the resulting acidic by-products, eventually forming carbon dioxide and water. Degradation rate and mechanical strength can be altered by changes in molecular weight (lower molecular weight results in faster degradation) and crystallinity (amorphous regions degrade faster

than crystalline regions).^[6,7] Complete degradation of PCL is said to take more than two years *in vivo*^[27] and has a slower degradation rate than other biodegradable polymers.^[8]

When considering the biocompatibility of the polymer, it is very important to consider the catalyst. Many cationic or coordination polymerization reactions use compounds based on metals such as tin, titanium, or zinc. These metals remain in the polymer after processing and can have an adverse effect on cell proliferation. Whilst the use of anionic or free-radical polymerization might be used to circumvent the problem, anionic polymerizations are exceptionally sensitive to trace impurities and the free-radical polymerization relies on an unusual primary carbon radical, which is also very unstable. Furthermore the monomer for the free-radical reaction must be prepared and purified before the polymer may be produced.

There has been some success in using Lewis acids as catalysts for the polymerization. These can be based on catalysts such as BF_3 . The reaction proceeds at 80°C and tends to produce low-molecular-weight polymer ($< 30 \text{ kDa}$) unless a polyalcohol is added.^[28] However, the persistence of the catalyst is of particular use in the preparation of PCL with tuneable degradability. The BF_3 catalyses the hydrolysis reaction and can result in a rapid decrease in pH; treatment of the polymer by soaking in a potassium fluoride in ethanol solution allows the degradation to be retarded by converting the catalytic BF_3 species into an inactive KBF_4 salt. It also appears that the small amounts of fluoride and BF_4K , which remain, have little negative effect on cell proliferation.

While there has much interest in the biocompatibility of PCL in its pure form, it has also been used to prepare composites and, with the aid of rapid prototyping, patient-specific implants.^[29,30] The preparation of a truly biodegradable composite requires not only a biodegradable polymer but also a degradable reinforcing phase. The preparation of the final composite is not trivial. All the polymerization reactions are water sensitive and, owing to the adhesive properties of the polymer, moulds must be made from specialist materials such as polytetrafluoroethylene (PTFE). Furthermore PCL has a very high-melt viscosity ($\sim 50,000$ centipoise at 60°C). This makes simple injection molding of the composite almost impossible and results in poor fiber-polymer binding. To achieve reliable degradation and optimum mechanical properties, the composite must be prepared via a monomer transfer molding process (MTM). Particular success has been reported using the diethyl zinc-catalyzed polymerization of ϵ -caprolactone with vicryl mesh, and with BF_3 -catalyzed polymerization with phosphate glass fibers. During the MTM process, a reactive mixture of monomer and catalyst is prepared and then

Table 1 A review of several copolymer systems that include PCL segments

Polymer type	Notes	References
PCL-PEG multiblock	Prepared by butyltitanate-catalyzed reaction. Increased degradation rate in vitro and in vivo.	[7]
PCL-PEG multiblock	Prepared by tin alkoxide-catalyzed reaction. Increased photodegradation owing to PCL sensitization of the ether linkages.	[8]
PLA-PCL-PLA triblock	Prepared by zinc-catalyzed reaction. The polymers showed increased degradation rates compared to pure PCL but preferential degradation of the PLA segments.	[9]
PCL-PEG multiblock	Prepared by lipase-catalyzed reaction. There is little change in the enzymic degradation compared to PCL.	[10]
PCL-PLLA di- and multiblock	Prepared by macromonomer polymerization with a tin alkoxide catalyst. Tensile properties 1 kPa–20 MPa (strength); 600 kPa–221 MPa (modulus); 510–740 (% elongation at break). Triblock exhibits elastic properties and reasonable degradation over 150 days in phosphate-buffered saline	[11]
PAA-g-PCL graft copolymer	Prepared by radical-initiated macromonomer polymerization. Tensile properties 8–19 MPa (strength); 200–550 MPa (modulus). The polymers showed an increase in both modulus and strength with increasing graft length	[12]
PCL-ethyloxazoline multiblock	Prepared by dimethylaminopyridine-catalyzed macromonomer polymerization. Maximum strength 12 MPa, maximum elongation to break 1000%. The hydrogels exhibit excellent reversible swelling properties	[13]
PCL-hexamethyleneterephthalate multiblock	Prepared by a toluene diisocyanate macromonomer-coupling reaction. Produces a biphasic system with highly crystalline terephthalate regions	[14]
PCL-PLA multiblock	Prepared by high temperature transesterification of homopolymers. CAC dichloride is used to enable photocuring of the material. Modulus 50–270 MPa. Excellent shape memory properties are observed. The polymer shows 90% enzymic degradation over 27 days	[15]
PCL-PLA-PCL triblock	Prepared by anionic polymerization-catalyzed by calcium amide terminated with PEG. Exhibits a biphasic system, which may form micelles	[16]
PEG-PCL-PEG triblock	Prepared by macromonomer coupling and tin alkoxide polymerization and diisocyanate coupling. Maximum modulus 1.4 MPa, maximum viscosity 4.5 KPa. Degrades very slowly, showing only marginal molecular weight loss over 1 yr	[17]

injected into a mold containing the reinforcing fibers. The mould is then heated to the reaction temperature to promote the polymerization reaction. This approach resulted in good fiber mesh penetration and good composite properties.^[30]

Enzymatic Degradation

As discussed above, enzymes can be utilized to polymerize caprolactone and copolymers. Therefore there

exists the possibility of enzymatic degradation. Lipases have been used for such polymerization reactions and have therefore been used to study the degradation of PCLs and various polymer blends^[31] Two lipases have been studied, Novozyme 435 and Candida Rugosa, on PCL and poly (vinyl acetate) (PVAc) blends. Both the homopolymers were found to undergo chain scission, and the rate coefficient for specific chain scission of PCL was a function of the PVAc concentration. Enzyme degradation occurred over a period of 20 days at which time the enzymes became inactive.^[31]

Table 2 Mechanical properties of some common polymers compared to PCL

Polymer	Modulus (MPa)	Strength (MPa)
Polymethyl methacrylate	2500–3500	55–70
Poly(propene)	1100–1500	35
PLA	120–200	45–65
<i>Poly ε-caprolactone</i>	200–400	40–50

Macrophage Responses

Macrophage responses in vitro are vital to biomaterials research to enable prediction of a potential immune or inflammatory response in vivo. After implantation of a material, the macrophage and the neutrophil are the predominant cells in the resulting inflammatory response.

Fig. 2 Hydrolysis of PCL by water, resulting in an acid and an alcohol. (R indicates the rest of the polymer chain).

The murine BALB/c monocyte macrophage cell line J774A.1 has been investigated in response to PCL.^[32] No activation of the macrophages was observed as determined by interleukin 1- β and hydrogen peroxide release. Proliferation rate was slightly decreased, which may be beneficial as it is thought that macrophages arrive at their target site not only by chemotaxis but also by cell division.^[33] It has been demonstrated that macrophage proliferation as well as recruitment occurs in vivo around Dacron and expanded PTFE implants in Sprague Dawley rats,^[34] suggesting that proliferation could be involved in perpetuation of the chronic inflammatory response.

PCL AS A COMPOSITE

Biodegradable composites are a potential replacement of commonly used metallic implants. Such composites often consist of a polymer matrix with ceramic particles or fibers as reinforcing agents to strengthen the mechanical properties, and some of these are summarized in Table 3.^[30,35–40] There is, however, concern over poor adhesion between the fibers and the matrix of such composites.

Giang et al.^[41] have produced a poly(ϵ -caprolactone)/continuous bioglass fiber composite via the monomer transfer molding technique. The bioglass fibers were surface treated with an amine-ended silane to initiate polymerization of ϵ -caprolactone from the

fiber surface. This was found to improve the Young's modulus and flexural strength of the composite as well as increase water resistance.

The advantages of many composites for tissue engineering are that often a bioceramic is used within a degradable polymer matrix. The degradable polymers including PCL often have acidic degradation products, and so the bioceramic components often have a neutralizing effect owing to their dissolution products.

PCL composites have been prepared with phosphate glasses and have been shown to have neutral degradation products. The composition (Na_2O :0.55, CaO :variable, and P_2O_5 :0.45) of these composites was also shown to affect the degradation rate, therefore allowing tailored degradation rate for specific applications.^[42] PCL/hydroxyapatite composites have also been prepared,^[37] as have composites of poly(ϵ -caprolactone-co-DL-lactide) and bioactive glass (S53P4).^[43]

Composites of PCL with natural materials have been a focus of research over the last few years, for example, with collagen,^[44] silk fibroin,^[45] starch,^[46] and dextran.^[47] Inclusion of natural materials has a variety of advantages—the material becomes biomimetic, mimicking natural tissue if materials such as collagen are used and also will increase degradation potential by natural enzymes of the body such as collagenases. Composites with natural materials are therefore a useful addition to the range of tissue-engineering scaffolds.

Table 3 Properties of some composites containing PCL and reinforcing agents

Reinforcement	Notes	References
Silica: Nanofibers	Chemical grafting using a silane. 2.5% gives 330 MPa modulus	[35]
Chitin: 7 μm fibers	Prepared by melt blending. 45% gives 1.8 GPa modulus, 35 MPa flexural strength	[36]
Hydroxyl apatite: aggregated particles	Prepared by solution mixing and grafted by hydrolysis. An overall decrease in strength and modulus were observed	[37]
Hydroxyl apatite: particles	Prepared by solution mixing tensile modulus 500 MPa at 50%	[38]
Clay: nanoplatelets	Prepared by melt mixing. 10% reinforcement gave 400 MPa modulus, 17 MPa tensile strength	[39]
Polypropylene: in situ reinforcement	Prepared by melt flow mixing. Linear relationship between modulus and PP content 350–1000 MPa similarly for tensile strength 18–25 MPa	[40]
Silica: long fibers	Prepared by a material deposition method. Modulus 12 GPa, strength 168 MPa at 45%	[30]

Composites containing PCL have been investigated for many applications and will be discussed in relation to specific applications below.

APPLICATIONS

PCL is used and currently investigated for a number of applications in the body, mainly drug delivery and as a material for tissue repair. The applications are summarized in Table 4.

Drug Delivery

Controlled release devices work in several ways: via diffusion through a semipermeable polymer membrane, via the use of a porous polymer, and via biodegradation.

Some researchers are now working on self-regulated and responsive systems, which release drugs in response to biological need or stimulus, instead of a predetermined, unchangeable rate based on the polymer-release characteristics. These more recent systems differ from traditional devices as they can target specific tissues and regulate the supply of the active agent in proportion to the biological need, often triggered by a biological stimulus.

Owing to its slow degradation rate, PCL is ideally suited to long-term delivery over a period of more than one year. This has led to applications in various drug delivery systems as microspheres and nanospheres. Such micro-/nanospheres can be used as an injectable delivery system. A variety of drugs have been encapsulated in PCL for targeted drug delivery and for controlled drug release either in PCL alone or as copolymers.^[48]

An example: capronor

In 1979, the Research Triangle Institute patented the contraceptive implant, Capronor. It is an inch-long tube composed of PCL, which releases a steady dose of levonorgestrel (a synthetic progestogen) over 12–18 mo. Capronor has become favorable over its rival Norplant (based on poly(dimethylsiloxane), because it requires fewer implants, is biodegradable, is easy to insert, is less obvious under the skin, and can be formed via a variety of polymerization reactions.

Other examples of PCL as a drug delivery polymer

PCL nanoparticles^[49] and microspheres^[50] have been investigated for the delivery of insulin. Both appear to release insulin over prolonged periods of time, a characteristic necessary for the effective control of blood sugar levels.

PCL has also been developed as an anticancer drug delivery system in the form of methoxy PEG/poly(ϵ -caprolactone) amphiphilic block copolymeric nanospheres for tumor-specific folate-mediated targeting,^[51] nanoscopic micelles comprising block copolymers of poly(ϵ -caprolactone) and PEG for doxorubicin delivery,^[52] nanospheres for tamoxifen administration,^[53] and PCL nanospheres loaded with the pure antiestrogen RU 58668, a promising estrogen-dependent anticancer agent.^[54]

Other examples of PCL in drug delivery include the release of 5-fluorouracil-loaded PCL microspheres,^[55] ovalbumin (hydroxyl-functionalized glycerol poly(ϵ -caprolactone)-based microspheres and poly(*N*-isopropylacrylamide) (PNIPAAm) hydrogel),^[56] and

Table 4 Summary of the many applications of PCL and its composites/copolymers

Application	Composition of PCL, e.g., composite and copolymer	Form, e.g., nanospheres and fibrous	References
Drug delivery	PCL homopolymer, block copolymers of PCL and PEG hydroxyl-functionalized glycerol PCL, PNIPAAm hydrogel), PCL/PLGA	Microspheres, nanospheres, nanoscopic micelles, fibers	[48–60]
Skin	Collagen/PCL, PLGA/PCL, PCL homopolymer	Fibrous mat, knitted mesh, films	[61–64]
Nerve	PCL with LIF	Matrix	[65,66]
Cartilage	PCL/polyurethane, PCL/PLA	Porous, fibrous	[67–70]
Bone/bone-cartilage interface	PCL/bioactive glass, PCL/hydroxyapatite, PCL/tricalcium phosphates, PCL/chitosan	Matrix	[71–81]
Liver	Peptide-functionalized PCL/PEG, PCL/PGA	Nanofibers, fibrous mesh	[82–84]
Heart	PCL homopolymer	Nanofibrous mesh	[85]
Gene delivery	PCL/PEG, PCL homopolymer	Micelles, capsules	[87,88]

microspheres of PCL/poly(lactide-co-glycolide) (PLGA) loaded with contraceptive steroid drugs^[57] for the delivery of the lipophilic drugs levonorgestrel and ethinyl-estradiol. The hydrophilic macromolecule ovalbumin and the lipophilic drug progesterone have also been incorporated into PCL in the form of fibers produced by gravity spinning.^[58] The release behavior may be ideal for specific release of growth factors that are influential at specific time points in, for example, a wound-healing process.

PCL has also been studied as nanospheres coated with bioadhesive hyaluronic acid for ocular delivery,^[59] which again requires long-term release.

Sustained ex vivo skin antiseptic activity of chlorhexidine has been reported in PCL nanocapsules against *Staphylococcus epidermidis*.^[60] The capsules were 200–300 nm in diameter, and sustained release was demonstrated for up to 8 hr. The bactericidal activity was more effective compared to a solution of chlorhexidine, and a significant reduction in the number of colony forming units (CFU) (5 to $>1 \log_{10}$) was observed with chlorhexidine nanocapsules for 8 hr.

Tissue Engineering

Tissue engineering is a broad multidisciplinary subject aiming to regenerate damaged or diseased tissues via porous scaffold templates to direct new tissue formation. The production of porous PCL templates has therefore received a great deal of attention from researchers worldwide for a wide variety of tissue engineering applications owing to food and drug administration (FDA) approval and the need for cellular ingrowth into tissue-engineering scaffolds.

Porosity (in the range of $10 \mu\text{m}$) can be achieved by particulate leaching of salts.^[89] The process of electrospinning has gained renewed attention over the last five years and nano-to-microstructured biodegradable poly(L-lactide-co- ϵ -caprolactone) fabrics have been prepared^[90,91] as well as pure PCL electrospun fibers^[92,93] Supercritical CO_2 can also be utilized to produce porous scaffolds.^[94,95]

Freeform fabrication has also become a highly useful technique to produce patient-specific implants for tissue repair.^[96] This allows the production of specific geometries and architectures.

Skin

PCL has shown promise for skin tissue engineering. Skin was the first organ/tissue to be repaired using the tissue-engineering approach. However, many tissue-engineered skin equivalents have not worked well owing to the requirement for an active dermis and epidermis.

Composites of Collagen and PCL for Tissue Engineering of the Skin.^[61] Fibrous collagen mats were impregnated with PCL solutions, and after solvent evaporation were tested for both fibroblast and keratinocyte growth and compatibility. A 1:20 ratio of collagen:PCL was found to be optimal.

Matrices for dermal repair using fibroblasts grown on knitted poly(lactic-co-glycolic acid) (10:90)-poly(ϵ -caprolactone) (PLGA-PCL) mesh have been studied.^[62] PLGA-PCL mesh supported cell attachment, homogenous cell distribution, proliferation, and neo-tissue formation.

Khor et al.^[63] have investigated PCL as an epidermal equivalent. Human keratinocytes were cultured on solvent cast and biaxially stretched PCL films, which were found to promote good keratinocyte responses (proliferation to monolayers of cobblestone appearance) on 5–15 μm thick films, which is thought would make a better epidermal substrate owing to the better flexibility and strength to mass ratio compared to solvent cast films.

In another study,^[64] it was found that 5 μm thickness (via biaxial stretching) films have potential for skin tissue engineering when using dermal fibroblasts. Proliferation on the PCL films was superior to that on the polyurethane (PU) samples, therefore showing potential to be applied in tissue engineering a dermal equivalent or skin graft.

Nerve

Nerve repair via guided tissue regeneration based on fibrous or tubular tissue engineering materials is a relatively new area of research as an alternative to donor nerve graft harvesting.

PCL/ poly-DL-lactic acid (PDLLA) is one of several materials that shows promise for such applications,^[65] in the form of tubular structures with an internal diameter of 1.7 mm. These nerve guides were found to retain their mechanical properties and flexibility over the study period of 8–10 weeks, and mass loss was evident thereafter. Galla et al.^[66] developed a three-dimensional matrix, consisting of fibrin loaded with Schwann cells, with or without the neurotrophic factor leukemia inhibitory factor (LIF), and this matrix was used to fill tubular PCL conduits. This system was found to repair a 10 mm nerve gap in the buccal branch of a rat facial nerve.

Cartilage

Cartilage has a limited capacity for self-repair owing to its avascular nature. Therefore, a tissue-engineering approach may be ideal as a repair and regeneration strategy.

Longitudinal lesions in menisci are one of the most common surgical problems of the knee, in particular, the avascular part of the meniscus. PU with PCL, 1,4-butanediisocyanate, and 1,4-butanediol has been investigated in the form of a porous scaffold produced by liquid–liquid phase separation and salt leaching. Biocompatibility and meniscus-like tissue formation were shown in an animal model, and compression behavior was comparable to normal meniscus tissue.^[67] PCL in the form of fibrous scaffolds has also been investigated for cartilage applications,^[68] and with poly(L-lactide).^[69]

As with many tissue types, addition of growth factors to scaffolds can aid cell recruitment and differentiation. Huang, Hutmacher, and Lee^[70] demonstrated *in vivo* mesenchymal cell recruitment by a PCL scaffold loaded with transforming growth factor- β 1 (TGF- β 1). Chondrogenesis occurred after subperiosteal implantation.

Bone/cartilage interface

Owing to failure of integration of many materials developed for cartilage repair, the bone/cartilage interface may be a more successful way of regenerating cartilage using a tissue-engineering approach. This would also address the repair of osteochondral defects. An injectable bioactive glass (S53P4)/biodegradable polymer composite has been successful in an *in vivo* rabbit model for osteoconductivity and articular cartilage regeneration^[71] via colonization of chondroblasts and mature chondrocytes. The composite was injected as a viscous liquid or a moldable paste. These materials were injected at 47–50°C and then underwent solidification during cooling owing to the crystallization of the polymer matrix. Cao, Ho, and Teoh^[72] have also demonstrated success in engineering a bone/cartilage interface by using a three-dimensional PCL scaffold fabricated by fused deposition modeling. Fibers were oriented at 0, 60, and 120° in layers, resulting in a highly porous structure. Coculture of osteogenic cells in one-half of the scaffold and chondrogenic cells in the other half resulted in proliferation, migration, and integration at the interface.

Bone

Current surgical methods for the treatment of bone defects involve the use of autografts and allografts, which can cause donor-site morbidity and requires more than one operation. Recently tissue-engineered bone using a variety of materials has been generated.

A great deal of interest has focused on the use of PCL in bone defects owing to the search for a degradable bone repair material. To promote bone bonding, many composites of PCL with various bioceramics have been investigated.

PCL composite scaffolds for bone engineering have been developed with hydroxyapatite and tricalcium phosphates,^[73–75] novel hydroxyapatite/PCL composites with fluoridation of the hydroxyapatite,^[76] and tricalcium phosphates with recombinant human bone morphogenetic protein 2 (rhBMP-2) to stimulate bone formation^[77] with organosiloxanes, and^[78,79] PCL–chitosan matrices containing platelet derived growth factor-BB (PDGF-BB) were found to induce bone formation in a rat calvarial defect.^[80] In all studies, inclusion of the bioceramic component enhances bone cell responses and bone formation.

The potential of using PCL synthesized by a novel method, involving boron trifluoride dimethyl etherate polymerization and a potassium fluoride post-treatment, has been investigated for craniofacial bone repair.^[81] The method of production of PCL enabled control of the molecular weight and degradation time. Craniofacial osteoblast responses showed a preference for KF-treated PCL, where greater cell attachment and spreading were observed as well as synthesis of a collagen-I-rich-mineralized extracellular matrix.

Liver

Although liver has a capacity for regeneration, decreased hepatocyte adhesion to polymer materials for tissue engineering limits the function of tissue-engineered hepatic assist devices. To enhance hepatocyte adhesion, Carlisle et al.^[82] grafted RGD and YIGSR adhesion peptides to PCL in an attempt to mimic the extracellular matrix. Peptides were grafted using PEG–peptide links to allylamines coated on the PCL surface using pulsed plasma deposition. Adhesion on PCL surfaces was significantly enhanced by both YIGSR and RGD.

Primary rat hepatocytes were found to self-assemble into multicellular spheroids and maintain differentiated functions (ammonia metabolism, albumin secretion, and cytochrome P450 enzymatic activity) when cultured on PCL-co-ethyl ethylene phosphate nanofiber scaffold conjugated with galactose ligand.^[83]

A number of liver diseases target the biliary tree, and therefore bile duct tissue engineering has been investigated. Human biliary epithelial cells have been cultured on PGA/PCL fiber mesh scaffolds. Cells formed spheroidal aggregates, proliferated, and expressed long-term phenotypic stability for up to six months.^[84]

Heart

Heart tissue is not capable of regeneration after damage because of the terminally differentiated state of cardiomyocytes. Shin et al.^[85] have developed an *in vitro* system for engineered myocardium using electrospun nanofibrous meshes. Cardiac-specific proteins such

as α -myosin heavy chain, connexin43, and cardiac troponin were found to be successfully expressed. The results suggest that cardiac grafts can be matured in vitro to obtain sufficient function to enable implantation.

Gene Delivery/Therapy

The insertion of a functioning gene into the cells of a patient can correct single-gene defects such as errors of metabolism, and this process is known as gene therapy.^[86] Tissue-engineering scaffolds could be used as a source of gene transfer or as a source of genetically engineered cells. Ideally, autologous cells are used for all tissue-engineering applications; however, non-autologous can be used if immunoisolation techniques are performed. Novel biodegradable ternary copolymers hy-poly(ethylene imine) (PEI)-g-PCL-b-PEG have been developed for non-viral gene delivery.^[87]

Depending on their compositions, these polymers were completely soluble in water or form micelles. Complexation of plasmid DNA with various copolymers was investigated, and copolymer composition was found to affect the gene transfection efficiency. The ternary copolymers were found to have potential for gene delivery owing to their biocompatibility, biodegradability, and relatively high gene transfection efficiency, and their neutral surface charge allows potential intravenous delivery.

Chen et al.^[88] developed immunoisolation device based on PCL capsules to encapsulate human atrial natriuretic peptide-producing Chinese hamster ovary cells for implantation into hypertensive rats. These show promise in the study and treatment of renovascular hypertension and cardiovascular diseases.

CONCLUSIONS

PCL is a very versatile material and can also be prepared as a range of copolymers. However, its major role in the human body so far has been in controlled release devices. Over the last few years, extensive research has been performed to investigate the potential of PCL as a tissue-regeneration scaffold. The main tissue targets that have been investigated are bone, cartilage, skin, nerve, and liver.

Poly(carbonate)urethanes

Michael Szycher

CT Biomaterials Division, CardioTech International, Inc., Woburn, Massachusetts, U.S.A.

INTRODUCTION

Polyurethanes have unique mechanical and biologic properties that make them ideal for many implantable devices. Polyurethanes display excellent mechanical properties such as high tensile strength, tear and abrasion resistance, and good blood compatibility. Accordingly, polyurethanes are widely used in medical implants such as cardiac pacemakers, catheters, cardiac assist devices, heart valves, and vascular grafts. The excellent mechanical properties of segmented polyurethanes are attributed to their two-phase morphology derived from microphase separation of soft and hard segments.

The current generation of commercially available polyurethanes is susceptible to certain in-vivo degradation mechanisms. For instance, poly(ester)urethanes are subject to hydrolytic degradation and are no longer used in long-term implanted devices. Poly(ether)urethanes, while hydrolytically stable, are subject to oxidative degradation in several forms, including environmental stress cracking (ESC) and metal ion oxidation (MIO). For these reasons, for long-term implantation, the poly(carbonate)urethanes are recommended.

POLY(URETHANE) POLYCARBONATES

The dictionary defines elastomer as a “material which at room temperature can be stretched repeatedly and upon immediate release will return to its approximate original length.” Since natural rubber was the original elastomer, in polymeric nomenclature, synthetic materials that approximate or exceed cured natural rubber in physical properties are called elastomeric. Because natural rubber exhibits such an excellent combination of physical properties, e.g., tensile strength of 4000 psi and 400 to 600% ultimate elongation, the term elastomeric grade is frequently used to characterize and describe those synthetic materials with the highest physical performance.

Among the highest performing biomedical-grade elastomers are the polyurethanes. Polyurethanes are block copolymers containing blocks of low molecular weight polyesters or polyethers linked together by a urethane group. These have the versatility of being either rigid, semirigid, or flexible. They have also

demonstrated excellent blood compatibility^[1] and outstanding hydrolytic stability,^[2] superior abrasion resistance, excellent physical strength, and high flexure endurance. No wonder the polyurethanes enjoy such great popularity among producers of medical prostheses. They bridge the gap among elastomers and elastoplastics, as shown in Fig. 1.

However, the use of the generic term polyurethane is deceiving in that all useful polyurethane polymers contain a minority of urethane functional groups. Thus, polyurethane is a term of convenience rather than accuracy since these polymers are not derived by polymerizing a monomeric urethane reactant, nor are they polymers containing primarily urethane linkages. In fact, in other groups such as ethers, carbonates are the majority linkages in the molecular chain. Although urethane linkages represent the minority of functional groups, as long as the polymers contain a significant number of urethane linkages, the name polyurethane is correctly ascribed to these polymers. Thus, the polyurethanes are a heterogeneous family of polymers, unlike PVC, polyethylene, and polystyrene. The polyurethanes comprise an array of different products, ranging from rigid foams to soft, millable grains.

Polyurethanes are based on three monomers—an isocyanate source, a macroglycol, and a chain extender or curative. As shown in Fig. 2, the isocyanates can be either aromatic or aliphatic and, as subsequent data will show, there is a profound difference between polymers made from either of these materials.

The macroglycols represent perhaps the single most important choice in the synthesis of medical-grade polyurethanes. The final physical and biological properties we associate with the polyurethanes depend for the most part on what type of macroglycol is used in the synthesis of medical-grade elastomers. Depending on the macroglycol used, the resultant polyurethanes can be either hydrophilic or hydrophobic. We will critically discuss these crucial monomers in greater detail subsequently.

Among chain extenders, there are two choices, either difunctional or multifunctional monomers. For the production of linear elastomers, only difunctional chain extenders are used. Of these, diols and diamines are by far the most important. Linear elastomers produce thermoplastic polyurethanes, whereas the diamines produce, thermosetting polyurethanes.

Bridges the Gap between Rubber and Plastics!

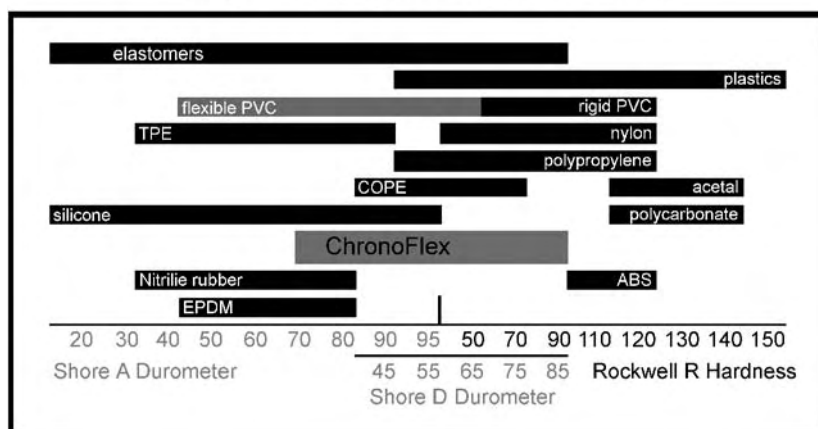

Fig. 1 ChronoFlex polyurethanes bridge the gap between rubber and elastoplastics because they can be synthesized in Durometer hardnesses ranging from a soft 75A to a hard 75D.

We will now discuss the three monomers that constitute the polyurethane elastomers, starting with the isocyanate sources. Table 1 presents the chemical structure of the prototype aromatic isocyanate example, methylene diphenyl diisocyanate, better known in the industry as MDI. MDI is a very quick-reacting isocyanate. In fact, it is so reactive that, in many cases, a catalyst is not required for synthesis if a diamine chain extender is used. On a practical basis, commercially available aromatic polyurethanes reacted with diols contain small amounts of a catalyst.

Thus, polyurethanes are a versatile family of polymers that comprise the widest array of properties, ranging from soft to hard, hydrophilic to hydrophobic, and thermoplastic to thermosets.

BIODURABILITY TESTING

Although poly(ether)urethanes are the materials of choice for a wide variety of medical implants, in

long-term applications, the poly(ether)urethanes degrade and cause malfunction or failure of the device. Degradation is usually apparent in terms of surface cracking, stiffening, erosion, or the deterioration of flexural strength. The mechanisms responsible for such degradation include environmental stress cracking, the generation of cracks and crazes produced by the biological environment acting on the polyurethane surface and metal ion oxidation, which is primarily restricted to pacemaker leads. It is generally accepted that ether linkages in the poly(ether)urethanes are the most vulnerable sites for initiation of degradation. Efforts have been made to overcome this problem by developing polyurethanes that are not exclusively based on polyether macroglycols, such as those disclosed in U.S. Patent 4,875,308 (Coury et al.), U.S. Patent 5,133,742 (Pinchuck), and U.S. Patent 5,109,077 (Wick). Nevertheless, the combination of degradation resistance, mechanical characteristics, processability, and clarity is suboptimal for certain applications.

Poly(carbonate) macrodiols have been used as reactive ingredients in the synthesis of block and segmented copolymer systems in high-performance polyurethane elastomers. Processes for preparing poly(carbonate) macrodiols on a range of bishydroxy alkylene compounds are disclosed in JP 62,241,920 (Toa Gosei Chemical Industry Co., Ltd.), JP 62,187,725

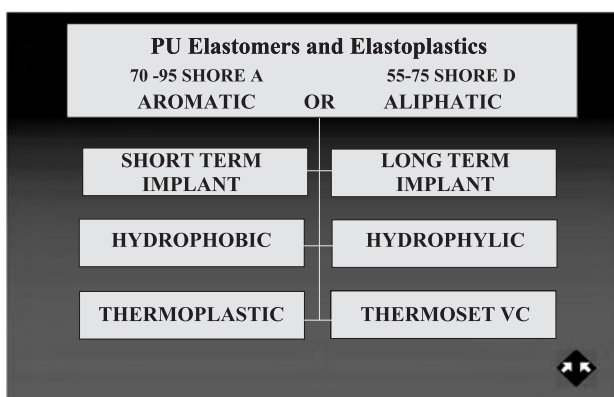

Fig. 2 The universe of polyurethanes, the most versatile polymer in the world.

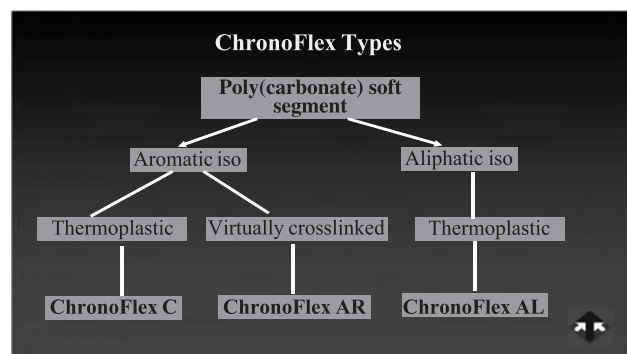

Fig. 3 CT Biomaterials produces three types of ChronoFlex biodurable polymers: 1) ChronoFlex C; 2) ChronoFlex AR; and 3) ChronoFlex AL. This figure shows the chemical constituents of these three types.

(Daicel Chemical Industries, Ltd.), DE 3,717,060 (Bayer AG), U.S. 4,131,731 (Beatrice Foods Company), and U.S. 5,171,830 (Arco Chemical Technology).

In U.S. Patents 5,254,662 and 5,863,627, Szycher disclosed biodurable, i.e., hydrolytically stable and enzymatically (biologically) stable polyurethane elastomers, in combination with a low modulus of elasticity and other desirable mechanical properties. The poly(carbonate)urethanes are prepared from the reaction of cycloaliphatic or aromatic diisocyanates with poly(carbonate) macrodiols extended with diols or diamines. The chemical composition of the ChronoFlex polymers is shown in Fig. 3.

ChronoFlex has been shown to be biodurable^[3] when tested according to the Stokes method.^[4] This method is an accelerated test designed to predict the long-term stability of polyurethanes in the corrosive environment of the human body.

Szycher was the first to discover the connection between polyether-based polyurethanes and biologically induced environmental stress cracking.^[5] This basic discovery led to the development of a poly(carbonate)urethane,^[6] which is not only biodurable but also displays a low modulus of elasticity. A low

Fig. 4 Eight samples are implanted in rabbits for the accelerated test.

modulus of elasticity is an essential characteristic of polymers designed to interface with the cardiovascular system to enable the prostheses to have compliance with the host artery.

In this accelerated test, a polyurethane test tube is placed over a mandrel and stretched to different levels. The assembly of the stretched polymer and the mandrel is then implanted subcutaneously. Eight samples are implanted on either side of the vertebral column, as shown in Fig. 4.

Once an assembly of four test mandrels has been sterilized, they are implanted in experimental animals, e.g., rabbits. The mandrel dimensions are shown in Fig. 5. Each string of four samples is implanted subcutaneously between the natural plane that divides the hypodermis from the superficial muscular layer, as shown in Fig. 6.

After explantation, the mandrels are cleaned in Tergazyme™ solution for several days until all the biological tissue is gently removed. The specimens are then evaluated under scanning electron microscopy conditions to ascertain any surface cracking. Figures 7, 8, and 9 are microscans showing the results of implantation of three polyurethanes, Tecoflex, Pellethane, and ChronoFlex.

As shown, both Tecoflex and Pellethane have experienced catastrophic failure, secondary to surface

Fig. 5 Mandrel used to hold elongated tubing.

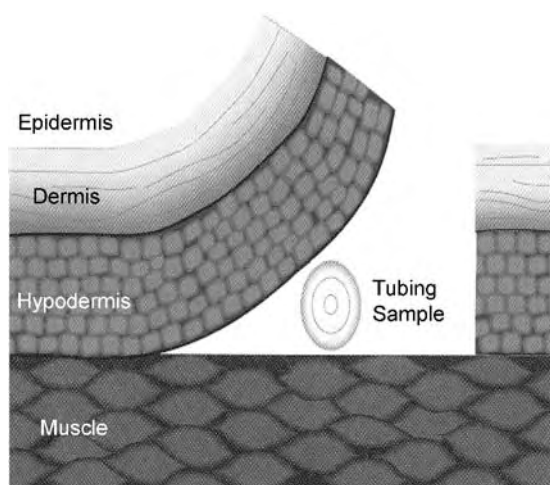

Fig. 6 Implantation of test specimen immediately below the hypodermis and above the muscle layer.

cracking. This is similar to the catastrophic failures experienced clinically when these poly(ether)urethanes are implanted for long periods of time. In contrast, the poly(carbonate)urethane ChronoFlex appears free of microcracks under the conditions of the test.

BIOCOMPATIBILITY TESTING

ChronoFlex polyurethanes have undergone rigorous in-vitro biocompatibility tests. While biocompatibility

Fig. 7 Catastrophic failure: TecoFlex EG-85A, an aliphatic poly(ether)urethane. After three months, the tubing is seen fractured. A small piece of tubing still hangs on the left side of the mandrel, maintained in place by the left suture.

Fig. 8 Pellethane 2363-80A. After three months, this aromatic poly(ether)urethane has undergone complete failure, secondary to microcracking. This is classical environmental-stress cracking (ESC), which is followed by fracture.

of polymers is highly application specific, ChronoFlex polymers have consistently performed well in contact with biological tissue and circulating blood.

Testing of ChronoFlex at independent laboratories has shown this family to be biocompatible when tested under USP Class VI standards, as shown in Table 2, which summarizes the results.

Fig. 9 ChronoFlex AL 80A poly(carbonate)urethane does not display any sign of ESC or failure after three months implantation at 500% elongation. It is our hypothesis that ether-free polyurethanes are biodegradable because no susceptible ether linkages are accessible to degrading enzymes.

Table 2 ChronoFlex biocompatibility testing

Test identification	Results
Agar overlay	Nontoxic
USP class VI	Nontoxic
MEM elution	Nontoxic
Hemolysis	Nonhemolytic
Ames mutagenicity	Nonmutagenic

AROMATIC VERSUS ALIPHATIC POLYURETHANES

As previously discussed, polyurethanes are divided into aromatic or aliphatic types on the basis of the presence or absence of benzene rings in the diisocyanate monomer used in the formulation. ChronoFlex C and AR use methylene bis(diphenyl) diisocyanate and are thus called aromatic. ChronoFlex AL is based on hydrogenated methylene bis(cyclohexyl) diisocyanate and is thus called aliphatic. This represents a major difference in formulation, which produces distinct differences between these two types of polyurethanes, as shown in Table 3.

Softening at Body Temperature

All polyurethanes soften within minutes of insertion into the body. Device manufacturers exploit this feature because it enhances patient comfort and reduces the risk to the vascular endothelium. Aliphatic polyurethanes display a significant lowering in the modulus of elasticity over corresponding aromatic polyurethanes. The actual softening at body temperature needs to be measured empirically since each formulation and hardness varies in its ability to soften.

Yellowing

Most medical-grade polyurethanes are clear to slightly yellow in their original state. However, aromatic-based polyurethanes turn dark yellow to amber as a result of processing, sterilization, or exposure to UV light.

Table 3 Physical differences between aromatic versus aliphatic polyurethanes

	Aromatic	Aliphatic
Softening at body temperature	Slight	Significant
Yellowing	Yes	No
Melt-processing temperature	High	Moderate
Solvent resistance	Good	Poor

While this discoloration, which is caused by the formation of chromophoric groups in the hard segment of the molecular chain, does not affect the physical properties of the product, it nevertheless affects the esthetics of the device. In contrast, aliphatic-based polyurethanes are more resistant to yellowing although they can also yellow slightly.

Melt-Processing Temperatures

Aliphatic polyurethanes melt at temperatures significantly lower than aromatics. For example, ChronoFlex AL elastomers are extruded at temperatures in the range of 350–365°F, whereas ChronoFlex C of equivalent durometer hardness extrudes, at nozzle temperatures in the range of 380–435°F. For medical applications, the lower the processing temperatures, the lower the rate of thermogradation since degradation follows Arrhenius' law, i.e., the rate of degradation doubles for each increment of 10°C. It follows that lower extrusion temperatures are advantageous in minimizing potential degradation that may be detrimental in the delicate biological environment.

Solvent Resistance

Aliphatic polyurethanes exhibit lower resistance to organic solvents and oils than aromatics. This is particularly true of the lower durometer aliphatics in which prolonged contact with solvents may lead to swelling and short-term contact may lead to surface tackiness.

MELT PROCESSING

ChronoFlex thermoplastic elastomers can be processed on conventional extrusion or injection-molding equipment. As with all polyurethanes, certain precautions need to be observed to ensure trouble-free operations.

Drying

ChronoFlex pellets should be dried to a moisture content equal to or less than 0.01% by weight prior to melt processing. Since ChronoFlex elastomers are highly hygroscopic, i.e., they attract and hold chemisorbed water, the pellets must be dried before extrusion. Unless pellets are properly dried, ChronoFlex tubing will exhibit haze and gels, and, under extreme moisture conditions, will appear foamy or hazy.

We recommend a machine-mounted, desiccant-type hopper drier that is capable of reaching and maintaining

a dew point of -40°F . Typically, the pellets must be dried for at least three hours with a drier inlet air temperature of 160°F . Temperatures above 170°F will likely cause pellet bridging due to surface blocking. If the pellets can be predried for extended periods, such as overnight, an inlet temperature of 150°F is generally sufficient.

Extruder

We suggest a single-stage, nonvented, 24/1 L/D extruder with a heavy-duty, DC-variable speed, high-torque drive. For example, a 2.5-inch extruder should have a 40–50 hp drive. The use of screens up to 325 mesh are common with ChronoFlex elastomers.

Screw

A general-purpose screw is recommended with an L/D ratio of 24:1 with a 12-6-6 screw for softer grades and a 6-9-9 screw for the harder grades.

Dies

A maximum drawdown ratio of 2:1 is recommended to reduce residual stresses and help reduce postextrusion shrinkage. All tooling should be streamlined to minimize material hang-up and possible polymer thermal degradation. Screws utilizing 303 or 304 stainless steel have proven acceptable in contact with ChronoFlex elastomers.

Extrusion Conditions

For extrusion, there should be four independently controlled heating sections—feed, transition, metering, and die. See Fig. 10 for recommended conditions for the softer ChronoFlex grades.

REGULATORY STATUS

ChronoFlex is used in catheters, ports, vascular grafts, and so forth. Their most common use is in long-term implants. They are appropriate for a variety of uses in which biodurability, performance, longevity, toughness, and high-stress/-strain properties are desired.

The U.S. Food and Drug Administration's (FDA) Center for Radiological Health regulates medical device applications. Raw materials, including polyurethanes, are not approved per se by the FDA. Raw materials are components of devices reviewed by FDA and are not approved individually. FDA evaluates the safety and effectiveness of a device for its intended use, and

Fig. 10 A typical extruder that shows the four independent heating sections.

approvals are granted to the final product based on these considerations. It is the responsibility of the device manufacturer to determine the suitability of all components and raw materials to be used in the finished device.

The use of a medical-grade polyurethane to make an implant creates a need for toxicological data, which is generally provided by the manufacturer, as USP Class VI biocompatibility. Implant is defined as a device that is placed into a surgically or naturally formed cavity of the human body and is intended to remain implanted continuously for a period of 30 days or more.

CT Biomaterials has tested ChronoFlex in Class VI tests and are thus considered to have a low level of toxicity under the conditions of testing. Historically, this test has served as a standard to have a polyurethane considered viable as a raw material for use in implantable medical devices. Beyond USP Class VI testing, other standard test methods are used such as cytotoxicity, hemolysis, and physicochemical characteristics. The FDA has also adopted International Standards Organization (ISO) 10993: "Biological Evaluation of Medical Devices Part I—Evaluation and Testing," which, for many manufacturers, has replaced USP Class VI as the standard to have a polyurethane considered viable as a suitable raw material for use in medical devices.

CT Biomaterials has collected relevant toxicological data about ChronoFlex and has submitted a series of Device Master Files (MAFs). These files can be reviewed by the FDA in conjunction with a product review submitted by a device manufacturer that has been authorized by CT Biomaterials. CT Biomaterials maintains individual MAFs on ChronoFlex AL, AR, and C.

The MAFs submitted by CT Biomaterials on the ChronoFlex family of polyurethanes contain the following sections: 1) facilities; 2) manufacturing procedures; 3) synthesis details; and 4) QA/QC personnel

involved in the manufacturing and testing of the polymers.

For example, ChronoFlex C displays tensile strengths in the range of 5000 to 7000 psi, depending on durometer hardness. This is one of the strongest polymers available on the market, and, when coupled with ultimate tensile strain (elongation) in the 300–490% range, it is considered among the toughest of the thermoplastic elastomers (Table 4).

INTRODUCTION

The process of self-assembly occurs naturally in living systems to form complex structures out of “random events” in an incredibly accurate way. Order out of disorder is achieved in a fashion that is analogous to a jigsaw puzzle where each piece fits together in a specific configuration by a process that is called molecular recognition. Self-assemblies and template-assisted assemblies have recently become a key approach to nanofabrication for the assembly of nanoarchitectures. In 1992, Decher and coworkers reported on a template-assisted assembly technique based on a process that relies on electrostatic interactions between polycations and polyanions to form ultrathin multilayers of polymers, known as polyelectrolyte multilayers (PEMs).^[1,2] This approach takes advantage of the spontaneous self-assembly of a polyelectrolyte on a substrate when immersed in a polyelectrolyte solution. The polyelectrolytes interact electrostatically with the surface adsorbing a polymer monolayer. The substrate is subsequently rinsed with water and immersed in an oppositely charge polyelectrolyte solution until a second layer is adsorbed. Then, the substrate with the two layers of adsorbed polymers is rinsed again with water. These steps can be repeated as many times as polyelectrolyte layers are required. This method is known as layer-by-layer deposition or electrostatic self-assembly. The approach overcomes the limitations encountered in covalent and coordination chemistries in terms of the required proximity of reactive and neighboring groups for the binding to occur.

A number of chemical interactions and materials have been used since the first report on the fabrication of PEMs appeared in the scientific literature.^[3] Initially, the multilayers were formed using electrostatic interactions, but later other types of chemical interactions (i.e., hydrogen bonding, covalent bonds, stereocomplex formation, etc.) have been used successfully. In a similar way, the number of different

chemical structures and materials used to form PEMs has been growing, and a wealth of new applications have emerged. Polyelectrolytes, macromolecules, biomacromolecules, and biological cells, among others, are some of the materials currently used when assembling PEMs. Also, a variety of new applications such as light emitting diodes, separation membranes, flow control, and cell adhesion and culture have been explored using this assembly technique. In this entry, we intend to cover the fundamental aspects of PEM structure and conditions for multilayer formation based on electrostatic interactions. In addition, the characterization techniques commonly used to analyze the topography and chemical interactions of the layers are described in a general way. Finally, we discuss some interesting applications and describe relevant aspects regarding the relation between the materials and the specific application.

POLYELECTROLYTE MULTILAYER STRUCTURE

The structure of PEMs, in the simplest film arrangement of same repeating pairs of polyanion and polycation, has been described as a three-characteristic zone model.^[4,5] The region closest to the substrate is known as Zone I and consists of one or just a few layers of polyelectrolytes. This zone is shaped by the characteristic properties of the substrate in terms of charge and roughness. The next stratum, Zone II, is considered to be neutral and exhibits bulk film properties. Last, surface Zone III (the outermost) can interact with the solution (or air). Though the structure of PEMs is subdivided into three zones, the transition between them is subtle. Fig. 1 shows an example of the buildup of the three zones and their relative thickness.

The presence of counterions in Zone I depends on the charge and roughness of the substrate, whereas they are believed to be everywhere in Zone III. The counterions

Fig. 1 Polyelectrolyte multilayers zone model.

in Zone III are associated with the excess charge created when charge overcompensation of the previous surface occurs owing to the adsorption of a new polymer layer. At the same time, it is deemed that layers distant from the surface will play a role in the charge excess observed at the surface by interspersing with the adjacent layers.^[6] These distinctive properties between the three zones play an important part in the swelling and deswelling of PEMs. Because Zone II is considered a neutral region, due to overall charge compensation, it could be expected to behave similarly to a polyzwitterion. Such a neutral zone should swell when immersed in an ionic solution and deswell in pure water. This behavior is better observed when the polyelectrolyte complex has been created in the presence of salt. When the PEMs are formed in pure water, the swelling is considerably less.^[7] On the other hand, Zone III is considered to behave as a polyion. Therefore, under pure water conditions Zone III would be expected to swell, and under ionic solution conditions it would be expected to deswell, as polyelectrolytes would do.

The formation of the three zones should be considered only when a minimum number of layers have been assembled. Zones I and III will be the first to form, and Zone II will not form until the other two zones (I and III) have attained their final thickness. After this point, Zones I and III are expected to maintain their thickness even when more layers are added to the multilayer film. Therefore, when a new layer is added to the surface of the film (Zone III), the material in the boundary between Zone II and III will move away from the coercing effect of Zone III and will become part of Zone II. In this way, the thickness of Zone III will remain the same, and that of Zone II will increase further.^[1,8]

CONDITIONS FOR MULTILAYER FORMATION AND MULTILAYER MATERIALS

Conditions for Multilayer Formation

In general, the formation of PEMs is based on the electrostatic attraction of oppositely charged polymers

that are sequentially stacked. Experimental conditions such as temperature, ionic strength, pH, flexibility of the polymers, and polyelectrolyte charge, among others, will affect the final structure of the polymers when shaping the multilayers. There have been several model representations for the formation of PEMs.^[9–12] The more prominent of them presents a mechanism of multilayer formation based on experimental data showing interpenetration of succeeding layers of weak and flexible polyelectrolytes at high ionic strength.^[11] To model the building up of multilayers in a simplified way, a couple of assumptions need to be made. The first of these is the assumption that the process is irreversible, so no desorption should occur due to equilibrium reactions, competition between the polyelectrolyte and salt ions, or detachment of the deposited polyion by interaction with the oppositely charged polyion in solution.^[6,13] Second, there are no strict boundaries between adjacent layers; instead, interpenetration of polymer chains takes place between neighboring films.^[14–16]

We will consider here flexible weak polyelectrolytes at high ionic strength to describe the multilayer formation.^[11] At high ionic strength, ions in solution exert a screening effect on the charged groups of the polyelectrolytes leading to short-range electrostatic interactions with the charged surface. The formation of the first layer starts with the adsorption of a first polymer containing multiple charges. This charge excess produces a reversal of the charge on the substrate surface. Nonelectrostatic interactions, such as van der Waals forces, hydrophobic interactions, etc., between the polyelectrolyte and the surface can contribute to the attraction forces taking part in the anchorage of the polyions to the surface. This can increase the amount of polyion adsorbed on the surface and in turn will produce a higher charge reversal. Because the first layer is the base for the successive adhesion of polyelectrolytes, it is practical to deposit a polyion with good adhesion characteristics first and change to the desired polyelectrolytes in the layers that follow. Once the first layer has been formed, an oppositely charged polyion solution is then placed in contact with the first layer to generate a second layer. Repulsions between the surface and the second polyion (both having the

same charge) will create a depletion layer in the proximity of the substrate surface.^[11] Moving outward from the end of the depletion layer to the outer side of the first polyion, complexation with the second polyelectrolyte occurs. The polyions in the first layer interact with the secondary polyions in a way that all are complexed and no further interaction with the secondary polyion can take place. On the other hand, the second polyelectrolyte interacts with the first polyion on one side and with the bulk solution on the other side. It can form large loops extending toward the solution, producing a formation similar to a double layer. Therefore, the amount of polyions in the first layer is limited by substrate surface constrictions, such as charge area and roughness, whereas the extent of the second layer is not limited because the side of the layer facing the bulk of the solution is in thermal equilibrium with it. Further layer depositions should follow the same interactions just described. Deposition of a larger number of layers will produce collective interactions between the layers in the bottom, middle, and top portions of the PEMs (Zones I, II, and III), creating different grouped characteristics. This has been discussed in the previous section.

This model is based on linear electrostatics and cannot be applied to excessively high local density charges. Therefore, it is valid only for weakly charged polyelectrolytes. An interesting feature of PEMs is that they can also be produced by replacing a polyelectrolyte layer for another charge species such as biological polymers (i.e., proteins, DNA) and non-biological chemicals (i.e., surfactants). The variety of charged species that can be used to create PEMs makes this type of assembly very flexible and broadens the number of applications where PEMs could be used. Examples of charged materials used for PEMs assembly will be discussed in the next section.

Multilayer Materials

Polyelectrolytes and other materials

The first work in what is known today as PEMs utilized negatively and positively charged polyions to produce an assembly of multiple nanosize layers in the Z dimension.^[17] Since then, a variety of charged materials have been used to create structures for specific applications. Even though PEMs buildup is not confined to the electrostatic interactions of oppositely charged species, most of the work carried out in this field relies on these types of interactions. Table 1 shows some of the most common polyion chemical structures reported in the literature. Nevertheless, there have been reports on PEM assemblies based on the interactions between polyelectrolytes with biomolecules and other

biological materials such as lipids, proteins, cells, and viruses.^[18–26]

MULTILAYER DEPOSITION TECHNIQUES

Even though the layer-by-layer deposition process commonly relies on electrostatic attractions, as already mentioned, several different deposition methods have been reported in the literature since the assembly of the first multilayer inorganic colloids by Iler.^[27] Some of these interactions include covalent bonds, hydrogen bonding, donor–acceptor interactions, and stereo-complex formations among others. In the following sections, a number of methods used for the fabrication of PEMs using some of the above-mentioned interactions will be described.

Dipping Technique (Total Surface Immersion)

The first studies on the sequential formation of monolayers of polyions (of up to 100 layers) and their multilayer structural organization were published by Decher and coworkers.^[1,17] This method has been widely used since its introduction and consists of the immersion of a charged substrate in a polyion solution A, of opposite charge. A rinsing step in water or salt solution follows the deposition of the first monolayer to remove unbound polyions. The substrate is again immersed in a polyion solution B, but this time with the polyion having the same charge as the substrate. A rinsing step follows the deposition of polyion B. These steps produce A/B bilayers, and further deposition steps using the same polyions will generate an (A/B)_n structure.

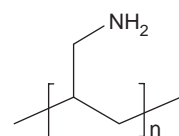

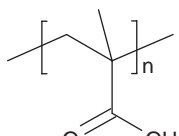

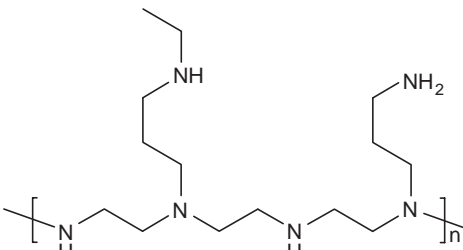

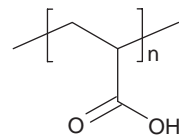

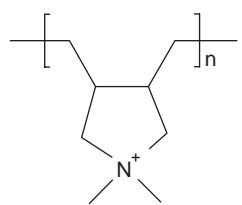

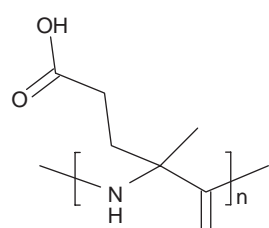

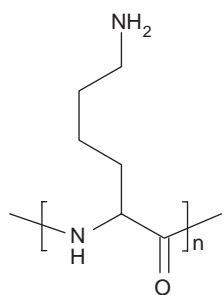

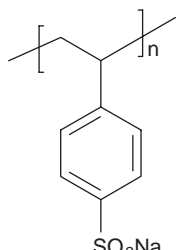

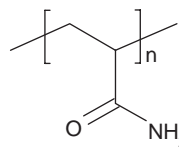

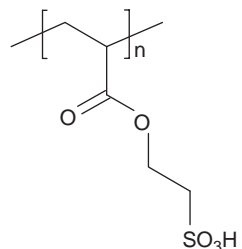

Other methods based on the same sequential deposition principle, but in restricted areas, have emerged. These methods have been developed mainly for the need of producing PEM areas of micrometer size.

Patterning Techniques

Stamping

This technique uses a polymer-on-polymer stamping procedure to pattern regions of weak PEM films on a substrate chemically.^[28–30] In this case, the polyions used were poly(allylamine hydrochloride) (PAH) and poly(acrylic acid) (PAA). A poly(dimethyl siloxane) (PDMS) stamp is immersed in the weak polyion for about 1 h. The stamp is then rinsed with water and dried. To finally obtain the pattern on the substrate, the stamp is brought into contact with the substrate for a short period of time, removed, and then rinsed with water. The thickness of the layers is adjusted by varying the pH of the polyion solution. Thicker layers

Table 1 Chemical structures of some common polyelectrolytes

Polycations	Polyanions

are obtained when the pH of the polyamine solution significantly increases, and, hence, the polyamine is less charged. More recently, a similar type of patterning approach was used to fabricate polymer–colloid templates and to control selective cell attachment.^[31]

Microfluidics

Microfluidic structures have been used as molds for flowing through polyelectrolytes to facilitate their deposition, in a patterned fashion, on different surfaces. Either stagnant or dynamic depositions have been achieved using this platform. The dynamic deposition has been carried out by spinning the polyelectrolytes through microchannels placed on a carboxylic terminated self-assembled monolayer (16-mercaptohexadecanoic acid) previously deposited on a gold surface.^[32] With this system, up to 40 layers were deposited in a very short time. In addition, sub-micrometer width lines can be patterned using this approach. Stagnant deposition of polyelectrolytes using microfluidic networks has been recently presented (D. R. Reyes, S. P. Forry, L. E. Locascio, M. Gaitan, in preparation).^[25] In this case, a microfluidic network is placed on an oxidized PDMS flat surface, and then the microchannels are filled with the polyelectrolyte solution. The polyelectrolytes are allowed to deposit on the PDMS surface and are later removed from the channels following a rinsing step with water. By repeating this cycle, PEM lines are patterned on this elastomer.

Substrate Materials

The motivation when choosing a certain material for PEM formation is primarily based on the feasibility of a strong interaction between the polyelectrolyte and the substrate, and on the purpose for the formation of the multilayers (i.e., detection in characterization studies, surface attachment of chemical or biological material, etc.). Thus, the physico-chemical characteristics play an important role in selecting a substrate. There are a variety of materials that have been used as substrates for multilayer formation, such as glass, silicon, gold, quartz, and polymers.

Electrostatic interactions are commonly used to build up PEMs. For this type of interaction to occur between a substrate and a polyelectrolyte, the substrate should either have an intrinsic charge under the deposition conditions or should be capable of acquiring surface charge by chemical or physical means (i.e., redox reactions with strong acids or bases, or treatment with a gas plasma). These treatments will increase the interaction between the substrate and the first layer

of polyelectrolyte, which is essential for a uniform PEMs assembly.

Glass and quartz are substrate materials suitable for detection methods such as UV–Vis spectroscopy and optical microscopy because they are transparent at these wavelengths. Silicon is compatible with detection techniques such as x-ray reflectivity, IR spectroscopy, and ellipsometry.^[2,6,17,33–39] Gold surfaces are commonly employed for electrochemical, quartz crystal microbalance (QCM), and surface plasmon resonance (SPR) detection techniques.^[40–51]

The functionalization of substrates is an alternative when optimizing the interaction between the substrate surface and a polyelectrolyte. For example, materials such as glass, quartz, and oxidized silicon wafers can be deprotonated by chemical treatment with a strong base to produce a negatively charged surface. On the other hand, the same surfaces could be positively charged by further reactions with silanes such as trialkoxy-3-aminopropylsilane.^[38,52,53] Positive and negative charges can be attained on gold surfaces as well when treated with thiols or disulfides compounds.^[54,55] Polydimethylsiloxane becomes amenable to polyelectrolyte deposition, by means of electrostatic forces, when treated with oxygen plasma and promptly immersed in polyelectrolyte solution. Polymeric surfaces such as poly(propylene), poly(styrene), poly(methyl methacrylate), and poly(ethylene terephthalate) can also be used as the substrate for PEM depositions with good results. Deposition on such uncharged surfaces is also an alternative if the appropriate hydrophobic polyelectrolytes combination is selected and no surface treatment is desired.^[56,57]

CHARACTERIZATION TECHNIQUES

Characterization of the multilayer's thickness, surface topography, and, in some cases, the internal structure interactions can be carried out either by stopping the deposition steps and analyzing multilayer formation as a dried sample or by direct measurement in solution. Analysis techniques such as UV–Vis spectroscopy, ellipsometry, and x-ray reflection have been commonly used to measure the thickness of layers deposited on solid substrates.^[2,6,17,33,34,38,39,51,58] Other techniques have been added to the repertoire of analytical methods to monitor these deposited layers, for example, QCM, SPR, scanning angle reflectometry, atomic force microscopy, Fourier transform infrared (FTIR) spectroscopy, and optical waveguide lightmode spectroscopy (D. R. Reyes, S. P. Forry, L. E. Locascio, M. Gaitan, in preparation).^[25,32,42–44,48,49,59–76] Refer to Table 2 for a brief description of the parameters obtained, workable film thickness range, and important references regarding these techniques.

Table 2 Characterization techniques

Techniques	Parameter measured	Film thickness range ^a	References
Ellipsometry	Change in intensity and state of polarization of a reflected light at a surface	From a few to 6000 nm	[6,33,38,39]
X-ray reflection	Electron density of the material, film thickness, and average roughness	From about 1 nm to 1 μ m	[2,17,34,58]
Quartz crystal microbalance	Changes in resonance frequency of a quartz crystal when a film of a material is adsorbed on the crystal surface	From < 1 nm to a few micrometers	[42,43,59–63]
Surface plasmon spectroscopy	Change in angle of incidence (needed to excite a surface plasmon) when the thickness of a material changes	From < 1 nm to ~200–300 nm ^[77,78]	[44,48,49,64,65]
Scanning angle reflectometry	Interface changes in the reflectivity coefficients of a layer deposited on a surface	From < 1 nm to 100–150 nm ^[79,80]	[66]
Atomic force microscopy	Attractive or repulsive forces occurring between a tip and a sample when the sample surface is being scanned; a topographic image of the surface is produced	From < 1 nm to about 5 or 6 μ m	(D.R. Reyes, S.P. Forry, L.E. Locascio, M. Gaitan, in preparation) ^[25,32,67,68]
Fourier transform infrared spectroscopy	Absorption of infrared wavelengths, due to functional groups, by the sample	N/A ^b	[69–73]
Optical waveguide lightmode spectroscopy	An evanescent field of a laser is coupled to a grating integrated in a planar optical waveguide, the measurement of the incoupling angles permits the monitoring of the adsorbed macromolecules	From < 3 nm to 100–200 nm ^[81] (for up to 400 nm, see Ref. [75].)	[66,74–76]

^aFilm thickness range reported came from commercial instruments unless a reference is cited.

^bFourier transform IR spectroscopy is used for chemical characterization of functional groups on the surface, and it will not provide thickness or morphology information unless it is combined with other techniques. The film thicknesses that could be analyzed with FTIR are in the range of a few to several hundred nanometers.

APPLICATIONS

Light Emitting Diodes (LED)

Organic polymeric materials have received interest for electronic and electrochromic applications because they offer the capability of forming complex circuits on low-cost plastic materials and flexible displays. Semi-conducting and electrochromic polymer devices have been developed, and complex circuits have been demonstrated by ink-jet processes.^[82–85] The ink-jet based processes can typically produce dots of material with a minimum diameter on the order of 10 μ m with 10 μ m spacing.

More recently, the polycation poly(phenylene vinylene) (PPV) has been deposited using layer-by-layer self-assembly processes in combination with the polyanions poly(methacrylic acid) (PMA) and poly(styrene

sulfonate) (PSS).^[86] It has been observed that the number of deposited bilayers contributes linearly to the amount of absorbance and photoluminescence of the device up to about 30 bilayers, although the thickness of each bilayer is reported to be constant up to 50 bilayers. It has also been reported that the type of anion chosen will affect the behavior and performance of the devices and that PMA is the polyanion of choice. Devices assembled with PPV/PMA were observed to perform with luminance levels of 20–60 cd/m^2 and with a rectification ratio of greater than 10^5 . These materials can be patterned on surfaces using selective deposition techniques that are based on using a mold to transfer (or stamp) the polymers on the surface.^[87]

An important advantage of using a layer-by-layer self-assembly process to construct polymer-based light emitting diodes is the molecular level control of film thickness. This degree of control has the potential to produce

devices of high quality and uniformity. However, methods based on PEMs have so far not yielded circuits of equal complexity to the ink-jet based processes.

Separations

The fabrication of membranes suitable for separations using layer-by-layer deposition of polyions has been used for a number of applications. Gas and aqueous samples have been subjected to selective permeability separations using these polyelectrolyte membranes, and evident improvements have been obtained.

With gases, asymmetric membranes combining PAH, PSS, and dimethyl silicone membranes have proven to have an increased permeability for CO₂ than for N₂ when compared with the same polyions on porous poly(propylene) membranes. Permeability values increased from 6.2 to 23.8 when the temperature was increased from 20°C to 50°C.^[88] Another alternative for the separation of the components of a gas sample is the use of a composite gas permeable membrane formed of PAH and PSS to modify poly(4-methyl-L-pentene). This asymmetric membrane was demonstrated to have 18,000 times better barrier capacity for nitrogen than for oxygen and hydrogen. When polyaniline and PSS were alternatively used, the permeability of the membrane did not change compared to the bare surface of poly(4-methyl-L-pentene).^[89]

Control of permeabilization properties for separation purposes in aqueous media can also be achieved with polyelectrolyte layers. For example, multilayer deposition of derivatized PAA/PAH films produces a layer with hydrophobic characteristics that passivates electrodes below this layer. Subsequent cross-linking of the polyions provides wider pH range stability. This allows for base-promoted hydrolysis, which generates a selective, hydrophobic layer. The new layer demonstrated better permeability toward Ru(NH₃)₆³⁺ when compared to Fe(CN)₆³⁻, as a result of newly created carboxylic groups.^[90]

The modification of capillary surfaces using layer-by-layer deposition was tested for the deposition of polybrene (polycation) and dextran sulfate (polyanion). In comparison with the conventional capillary modification, the layer-by-layer deposition technique showed remarkable improvements. Using this technique, the modified capillary surface tolerated 600 replicate analyses and proved to be stable under basic conditions (1 M NaOH) and acid concentrations of about 0.1 M HCl. Electroosmotic flows (EOF) independent of pH were observed at pHs in the range between 2 and 11. Also, the relative standard deviation was less than 1% between runs carried out on different days and different capillaries. Protein separations at

pHs near the proteins' isoelectric point were obtained as well as reproducible separations of samples with complex matrices such as plasma. Separations of cationic, neutral, and anionic amino acids, within the same electrophoretic run, were attained using capillary zone electrophoresis.^[91,92] In another study, commonly used polyelectrolytes such as PDADMAC and PSS showed the use of PEMs as modifying coating materials in conventional capillary separations. Extreme pH and ionic strength as well as dehydration and rehydration experiments were performed, proving these coatings to be stable under such conditions for the separation of a series of proteins.^[93]

Chiral separations have been demonstrated using optically active PEMs as membranes. L- and D-poly(lysine) (PL) and L- and D-poly(glutamic acid) (PGA) were used as the membrane components for the separation of chiral compounds. This approach showed a better chiral separation when a combination of the two optically active polyelectrolytes, L- and D-PL and L- and D-PGA, were used rather than only one. No selectivity for any of the chiral probes was observed when optically inactive polyelectrolytes were used. Control of the selectivity and flux of the optical species was achieved by regulating the salt concentration. Swelling of the PEMs generates reversible doping ion exchange/transport sites, which allows for a small or large flux of ions through the membranes depending on the size of the created sites. For a higher flux, a reduction of selectivity is observed, and the opposite effect is observed for a smaller flux.^[94]

Biomolecules, Cell Adhesion, and Cell Encapsulation

Cell adhesion on the extracellular matrix is mediated by cell surface proteins. These surface proteins include the cadherin, selectin, and integrin families.^[95] In addition to protein-specific interactions, charge interactions seem to have a role in the adherence of cells when growing on artificial surfaces.^[25,96-98] Cells were initially cultured on slightly negative glass surfaces, where they attached and spread out. Later, plastics such as polystyrene were used for cell culture after being treated with an electric ion discharge or high-energy ionizing radiation to promote cell adhesion.^[99] Most of the work done using PEMs as a biomaterial surface to culture cells was inspired and driven by the charge interactions between the surface of the PEMs and the charged surface of the cells. Even though charge interactions are thought to be important as a first mechanism when attaching and growing cells on PEMs, polyelectrolytes have also been modified with the RGD domain that is recognized by integrins.^[29] RGD is a known cell adhesion molecule, which is

composed of the amino acids arginine-glycine-aspartic acid and is found in the extracellular matrix protein fibronectin.^[100] Although not all polyelectrolytes are suitable as surface material for growing cells, there are a number of them that have shown good biocompatibility. In the next paragraphs we will discuss some examples of the polyelectrolytes, cells, and approaches used to culture cells on PEMs in macrocultures as well as in micropatterns.

A number of cells such as osteoblast-like cells, human periodontal ligament cells, chondrosarcoma cells, mammalian fibroblasts, and rat retinal cells have been cultured on a variety of polyelectrolytes. The intrinsic properties of PEMs, primarily their surface charge, the flexibility in using a wide variety of combinations of cations and anions, and the ease of deposition and patterning, have made them very convenient as a biomaterial scaffold for growing cells. PAH, PGA, PSS, and poly(L-lysine) (PLL) have shown good adhesive properties (similar to controls) for growing human osteoblast-like SaOS-2 cells and human periodontal ligament cells.^[101] Cell attachment of these two cell types was observed as fast as 20 min after seeding on PAH, PGA, and PLL. Results of cell viability, osteoblast phenotype expression, and inflammatory responses have indicated that PSS, PGA, and PLL can be considered as biocompatible coatings for bone tissue implants.

The organization of chondrosarcoma cell contacts in a three-dimensional matrix containing titanium beads modified with PLL or PAH and polyanions PGA or PSS was studied. Discrete focal spots of vinculin and actin cables were observed when chondrosarcoma cells adhered to uncoated or negatively charged surfaces. Also, cells plated onto these surfaces showed a twofold increase in phosphorylation of p44/42 MAPK/ERK. On the other hand, no cytoskeletal vinculin and actin organization was observed when cells were plated on a positively charged surface.^[102]

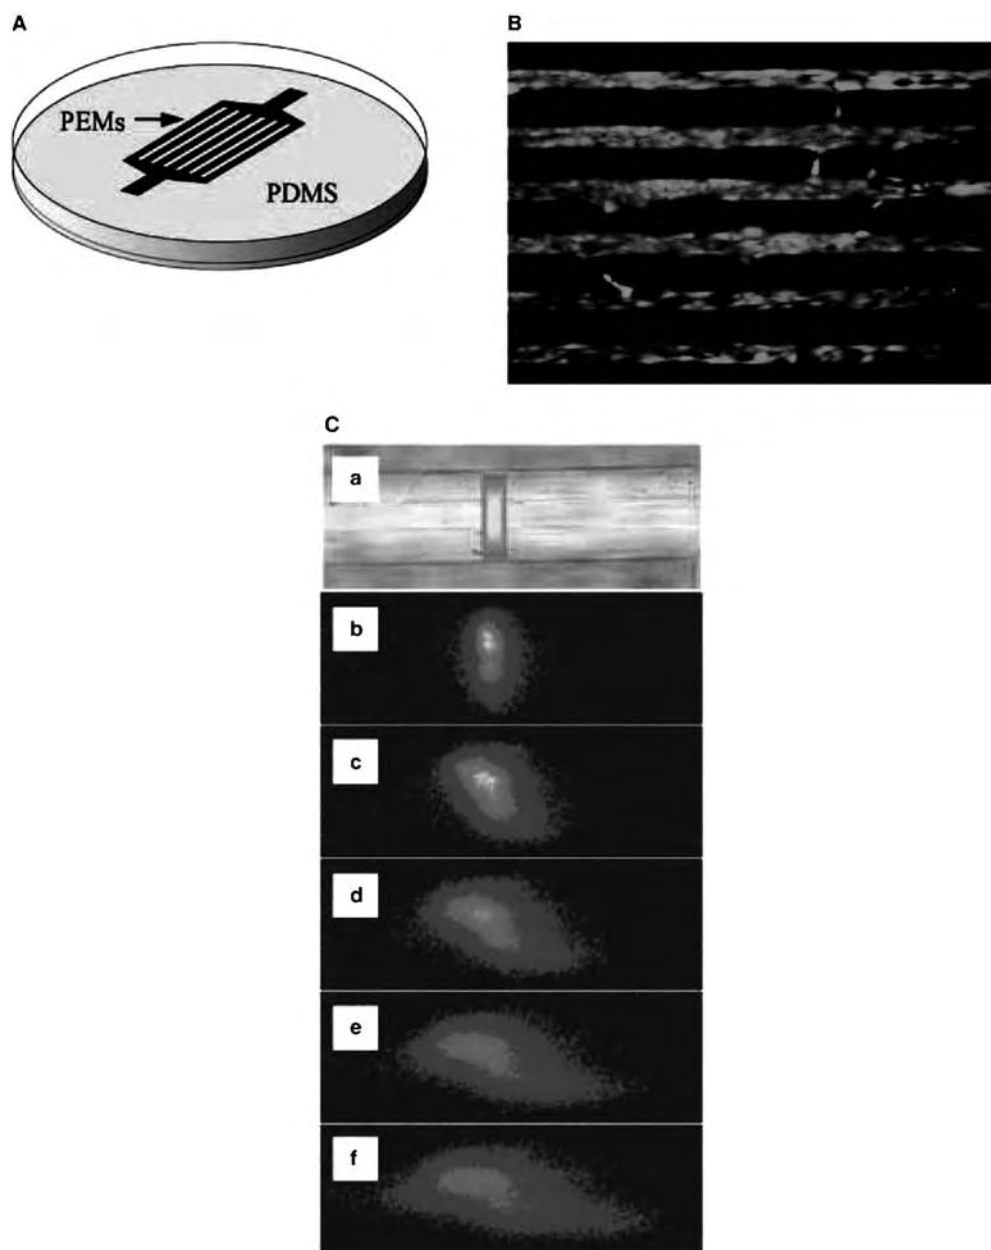

Another approach for using PEMs as adhesive material for cell attachment is the patterning of polyelectrolytes using stamping methods or microfluidic patterning. Polyelectrolytes have been patterned on various substrates to either attach cells or prevent them from attaching to specific areas on the substrate surface. While polyelectrolytes such as PAH, PSS, PLL, PEI, and many others are good materials for cell attachment, others such as PAA/polyacrylamide (PAAm) and PAA/PMA have been shown to be resistant coatings for mammalian fibroblasts.^[24]

Rat retinal (R28) cells have been successfully patterned on PAH and PEI, and the viability and morphology on such coatings have been studied.^[25] These cells attached and grew on patterned lines (approximately 55 μm wide) of these polyelectrolytes

deposited on PDMS surfaces. This approach took advantage of the reversible nature of the PDMS that, in oxidized form, has a highly charged negative surface, but reverts back to its natural uncharged hydrophobic state when stored in air. This characteristic of PDMS was used to create a PDMS substrate with two regions of different cell adhesion characteristics: 1) an oxidized surface onto which PEMs were patterned using microfluidic patterning to direct cellular deposition (the cell adhesion region) and 2) an uncharged region in the areas where PEMs were not deposited that reverted back to its hydrophobic state after exposure to air, (the cell resistant region) (see Fig. 2A). The cells attached and grew onto the areas where PEMs were deposited, whereas the cells were repelled from the uncharged PDMS areas (see Fig. 2B). Cells attached between 5 and 6 hr, the same time they normally attach in control culture dishes. A viability assay 24 h after seeding the cells proved they were viable, and their morphology remained the same on the areas larger than 55 μm when compared with the control experiments.

As previously mentioned, the adhesion of cells can also be directed by modifying the outermost polyelectrolyte on the PEMs with peptide sequences known to bind to protein receptors on the surface of the cells. An example of a well-known peptide sequence that binds surface proteins is the RGD motif. This motif was used to modify the outermost layer of PEMs, which contained PAH as the first layer and PAA (outermost polyelectrolyte) and PAAm.^[24] To control the ligand density (RGD motif), the pH of the PAH solution was changed during the stamping process. It was determined that a PAH solution buffered to a pH of 11 provided the highest functional group densities. The lowest functional group densities were obtained at a solution of pH 3.5. Cells tended to attach in higher numbers as the RGD densities increased. Interestingly, cells with nicely shaped focal adhesions and cell-spanning stress fibers were only found in line patterns of 25 μm or wider, indicating that geometry and surface functionality are both important in determining cell adhesion.

Recently, PEMs have been used to coat cells in suspension to encapsulate single cells, and the characteristics of these nanoencapsulated cells have been studied. Diaspro et al. coated *Saccharomyces cerevisiae* (yeast) cells by sequential incubation in suspension with alternating solutions of negatively charged (PSS) and positively charged (PAH) polyelectrolytes.^[21] In this method, the positively charged polyelectrolyte was incubated with the cells in the first step, taking advantage of the negative charges on the yeast cell surface to induce complete coating. As a result of this work, it was determined that single yeast cells could be effectively encapsulated by the PEMs, forming a

P

Fig. 2 Panel A shows the patterned PEMs (black) lines surrounded by the native hydrophobic PDMS surface (gray). Panel B shows the cell patterning occurring on the PEMs. The green color of the cells indicates that they are viable while attached on the PAH/PSS PEMs (11 layers). The dark areas are where the native PDMS is exposed (not covered by the PEMs). Panel C shows the velocity profile of fluorescent dye that was induced to become fluorescent upon exposure to a focused UV light source. In sequential images, a–f, the profile of the fluorescent dye is imaged as it moves through a microfluidic channel that was negatively charged on one side and positively charged (due to PEM deposition) on the other side. The images demonstrate flow in two directions in a single microfluidic channel. (Panels A and B, from Ref. [25]; Panel C, from Ref. [103].)

porous shell around the cell. Greater than 98% of the cells in suspension were successfully coated, and cells with four to six layers of polyelectrolytes were found to be intact and retained normal metabolic behavior. Encapsulated cells were able to divide, although at a slower rate than the uncoated yeast cells under the same conditions. It was postulated that the

polyelectrolyte shell hindered the first cell division, causing a reduction in cell proliferation.

Other bioapplications of PEMs include the deposition of biomolecules, such as enzymes and antigens, intercalated in multilayers. Preparation of active enzymes in thin films has been shown for horseradish peroxidase with a bipolar quaternary ammonium as

the polycation. In this example, up to 16 bilayers were deposited, and the activity of the enzyme was electrochemically measured using a gold electrode laying on the substrate surface.^[104] Another example of the combination of biomolecules with the multilayers' deposition is the fabrication of an immunosensor based on an antibody linked to a gold particle deposited alternately with cysteamine on a gold electrode. Using cyclic voltammetry and impedance spectroscopy measurements, this sensor showed a linear range from 5 to 400 $\mu\text{g/L}$ for the detection of human IgG and a detection limit of about 0.5 $\mu\text{g/L}$.^[105] The entrapment of proteins in hollow polyelectrolyte microcapsules is another interesting example of a biological application. A polyelectrolyte hollow structure can be obtained by deposition of multilayers on colloidal particles followed by the dissolution of the core particle.^[106] This provides an empty PEM cage or capsule with a thickness in the range of 5–50 nm. Using this approach, proteins like α -chymotrypsin have been encapsulated in microcapsules fabricated from polyions such as PAH and PSS.^[107,108] The encapsulated proteins demonstrated high enzymatic activity, as well as thermal and mechanical stability. This microcapsule serves as protection against high molecular weight inhibitors and also serves as a bioreactor.

Microfluidic Flow Control

One of the earliest uses of PEMs in microfluidics was for flow modulation in electroosmotically pumped systems. Electroosmotic pumping is the most common method for pumping solutions in a microfluidic format because of its unique ability to control very low-volume flow rates. Electroosmotic flow is flow that occurs when an electric field is applied across a microchannel or capillary that is filled with buffer solution. Electroosmotic flow is modulated by several parameters including buffer concentration, electric field strength, wall charge (positive or negative), and wall surface charge density. For instance, a higher field strength or a higher surface charge density results in faster flows, keeping all other conditions constant. Importantly, if the wall charge is positive, the ions that are attracted to the wall forming the double layer are negative, resulting in a flow toward the positive electrode. If the wall charge is negative, the ions attracted to the wall are positive, resulting in a bulk fluid flow toward the negative electrode.

As described previously, PEMs can be adsorbed to a variety of substrate materials that are used to fabricate microfluidic channels including glass, silicon, poly(methyl methacrylate), poly(carbonate), poly(styrene), and PDMS. In a microfluidic device, PEMs can be adsorbed to the surface of the microfluidic channel and

thus may be used to modulate and control EOF. For example, microfluidic devices fabricated in different types of polymer materials exhibit different EOF rates when all factors other than the material are held constant. However, when these polymer microchannels are coated with the same PEMs, the EOF rates in the different materials are altered and become the same.^[109] Laminar flow patterning can also be used to micro pattern one side of a microfluidic channel with PEMs while leaving the other side of the microchannel uncoated in its native state. If the native state of the polymer microchannel is negatively charged and the PEM coated side of the microchannel is positively charged, electroosmotic fluid flow can be propagated in the microchannel in two directions simultaneously (Fig. 2C).^[103] Polyelectrolyte multilayer coatings can be used in microfluidic devices to create unique microflow patterns, increase or decrease EOF, and eliminate differences in flow behavior in microchannels made from different materials.

CONCLUSIONS

Owing to the unique characteristics of PEM films as well as their simple self-assembly deposition processes, these nanoscale structures have found broad application in widely different fields ranging from electronics to analytical chemistry to biomaterials. Although this chapter is not comprehensive in covering all applications of PEMs, it should provide the reader with examples that demonstrate the enormous potential of these films. For other reviews on PEM materials, we refer the reader to Decher and coworkers and Bertrand et al.^[5,15,110]

Polyepoxy Compound Fixation

Yasuharu Noishiki

Department of Surgery, Yokohama City University School of Medicine, Kanazawa-ku, Yokohama, Japan

Teruo Miyata

Koken Bioscience Institute, Koken Co. Ltd., Toshima-ku, Tokyo, Japan

INTRODUCTION

Characteristic advantages of polyepoxy compounds (PCs) as a cross-linker for biological materials are explained in this article. Glutaraldehyde (GA) has been used for fixation of biological materials in the fields of artificial organs, but GA has both advantages and disadvantages. Compared with GA, PCs have various advantages with little disadvantages. With these peculiarities, PCs are anticipated as a new cross-linker for biological materials. In this article, basic chemical reactions and mechanisms of PC cross-linking will be explained in detail as PCs are used in the fields of biological materials. Some examples of artificial organs cross-linked with PCs are also demonstrated.

CROSS-LINKING OF BIOLOGICAL MATERIALS FOR ARTIFICIAL ORGANS

Before the explanation of PCs,^[1,2] biological materials for artificial organs will be discussed. Numerous synthetic polymer materials have been used in the medical field and many artificial organs with sufficient mechanical strength and desirable shapes and sizes have been created. But, implantable materials with very fine mechanical and structural properties for host-cell migration and proliferation in order to create new hybrid artificial organs or tissue-engineered systems cannot be produced from synthetic materials. Biological materials have an extremely fine structure and unique properties that cannot be imitated with synthetic polymer materials. Therefore, some biological materials obtained from animal tissues have been used as raw materials for implantable artificial organs.^[3-6]

Unless they are autologous, biological materials for implantation need some modification such as chemical cross-linking in order to give toughness and durability in vivo, to prevent rapid biodegradability and to reduce antigenicity. Several chemical reagents, such as glutaraldehyde (GA), formaldehyde, hexamethylene diisocyanate, dialdehyde starch, etc. have been used for the fixation of biological materials. Among them, GA is the most frequently used.^[7-11] GA alone has been used

especially for the fixation of materials and products that are used for permanent implants such as biological heart valves.^[12-15] After fixation with GA, materials become mechanically stronger than the original natural tissue. Fixed materials are resistant to collagenase digestion.

Most biological tissues obtained from mammals contain collagen fibers. Because of collagenase digestion, the framework of the implanted tissue is destroyed, resulting in absorption of the tissue in vivo, which is a natural reaction to a foreign body. Collagenase digestion is the most common fate suffered by implanted biological materials. After GA fixation, not only collagen fibers but also most other tissue components become resistant to enzymatic digestion and unexpected reactions such as immunogenicity are reduced. However, GA has also severe side effects such as cytotoxicity, which cannot be ignored in implantable biomedical materials.^[16,17] For this reason, we needed to develop a new system of cross-linking. We introduced PC fixation technology into the medical field in 1986 in order to overcome this problem.^[1]

In this article, we would like to explain the principle of PC cross-linking and to introduce its applications to heart valves, blood vessel prostheses, antiadhesive membranes, and hemostatic materials.

PC AS A CROSS-LINKER FOR BIOLOGICAL MATERIALS

PCs are now widely used as cross-linking agents, adhesion promoters, stabilizers of textile and paper, and for many other industrial purposes.^[18,19] Among them, water soluble PCs are useful for the treatment of biological materials. High-quality water-soluble PCs are commercially available under the trade name Denacol, which is produced by Nagase ChemteX Corporation (Osaka, Japan).^[20] In this article, the water-soluble PCs, i.e., Denacol, will be introduced in detail.

Nagase ChemteX Corporation has developed and characterized PCs that include monofunctional and polyfunctional epoxy compounds, called by the generic name Denacol. Denacol, especially its polyfunctional

epoxy compounds, is not only water soluble but also highly reactive (the epoxy group of Denacol reacts easily with amino, carboxyl, and hydroxyl groups). With this water solubility and reactivity Denacol can be used as a cross-linking agent in water-based systems. Denacol has been applied in such industrial fields as textile finishing, paper finishing, paints, and adhesives. Denacol can be also used as a cross-linking agent and insolubilizing agent for various water dispersible or soluble high polymers, such as acrylic resin, polyvinyl-alcohol, latex, casein, starch, polyester, and polyurethane, which have functional groups containing active hydrogen, such as carboxyl, amino, and hydroxyl groups. Many properties such as water resistance, solvent resistance, adhesiveness, weathering property, and thermal resistance can be improved by cross-linking with Denacol.

The most representative Denacol compounds are sorbitol polyglycidyl ether, diglycerol polyglycidyl ether, glycerol polyglycidyl ether, trimethylolpropane polyglycidyl ether, neopentylglycol diglycidyl ether, 1,6-hexanediol diglycidyl ether, ethylene polyethylene glycol diglycidyl ether, and propylene polypropylene glycol diglycidyl ether. Their chemical structures and properties are shown in Table 1.^[20]

As shown in these structures, they have more than two epoxy groups in their molecular structure. These polyfunctional sites can work to cross-link biological materials in water-based systems, especially under physiological conditions.

These epoxy groups can react effectively under various conditions when certain catalysts are used. Table 2 shows examples of typical reactions with some reactants.^[20] Reaction speed and properties vary substantially according to the compound structure, solvents, catalysts, and reaction conditions such as temperature, pH, concentration, and duration. Details of epoxy group reaction and reactivity with various functional groups are given in a technical data sheet^[20] provided by Nagase ChemteX Corporation.

PC CROSS-LINKING OF COLLAGEN MOLECULES

PCs can cross-link not only collagen molecules, but also many other components of biological materials. We introduced the PC cross-linking technology in the medical field. Detailed information related to the application of PCs in the medical field is described elsewhere.^[21–26] In this article, we will explain the reaction of PCs with collagen fibers as an example, since most biological materials obtained from animals contain a high amount of collagen fibers.

Collagen is produced and released by cells such as fibroblasts and is a triple helical rodlike protein.

Collagen molecules contain three polypeptide chains (called alpha-chains) coiled in a triple helix. The amino acids of these polypeptide chains have characteristic features. Their most characteristic sites are the $-\text{COOH}$ and $\epsilon\text{-NH}_2$ groups. Figure 1 shows schematically a representative cross-linking reaction of PC with two collagen molecules, i.e., cross-linking. As shown in the Fig. 1, epoxy groups can react with both $-\text{COOH}$ and $\epsilon\text{-NH}_2$ groups. Before cross-linking, the total number of $\epsilon\text{-NH}_2$ groups is higher than the number of $-\text{COOH}$ groups. Therefore, collagen molecules have a positive charge under physiological conditions. Although it depends on the reaction conditions, $\epsilon\text{-NH}_2$ groups are more highly reactive than $-\text{COOH}$ groups. Therefore, most $\epsilon\text{-NH}_2$ groups are used up in the reaction. After the reaction, the total number of $\epsilon\text{-NH}_2$ groups is smaller than the number of $-\text{COOH}$ groups, and the collagen molecules have a negative charge under physiological conditions, and become less thrombogenic, because platelets have a negative charge, and repulsion of their negative charge prevents platelet aggregation on treated collagen molecules.

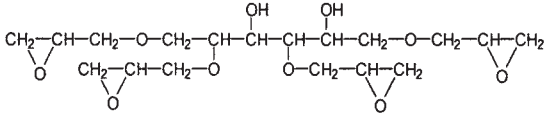

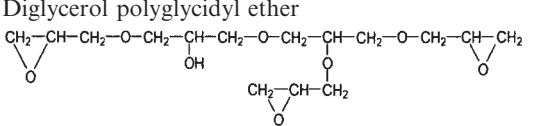

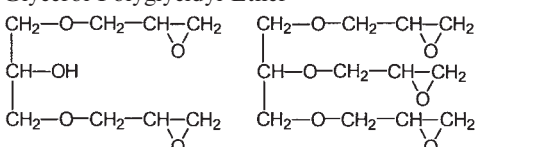

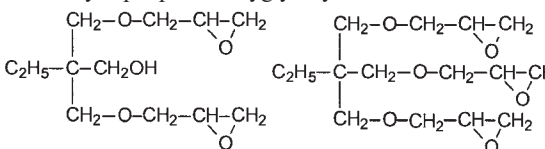

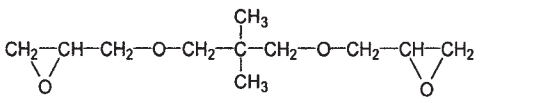

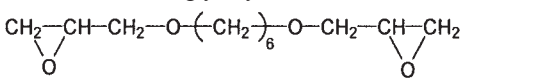

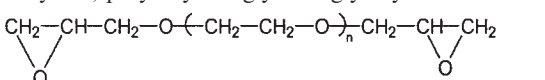

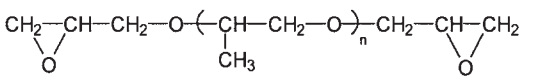

COMPARISON OF GA WITH PCs

Most biological materials for medical use have been cross-linked with GA. As described above, GA treatment has many advantages, but it also has disadvantages. The greatest advantage of the GA treatment is the stability of its reaction.^[7–9] The treatment makes materials stable *in vivo* after implantation. Materials cross-linked with GA show no biodegradability at all for a long period of time after implantation. The reaction can reduce the antigenicity of animal tissues.^[8,9]

As an effect, GA makes materials stiff. Their color becomes yellowish. Materials lose their original elasticity and softness. A major problem is the cytotoxicity of GA. GA is highly cytotoxic and induces various problems.^[16,17] After implantation, nonreactive GA molecules ooze out continuously for a long period of time from the cross-linked materials.^[17] GA molecules tend to polymerize themselves. Polymerized molecules are also the source of leaking nonreactive monomers. These are cytotoxic and damage surrounding cells *in vivo*.^[17]

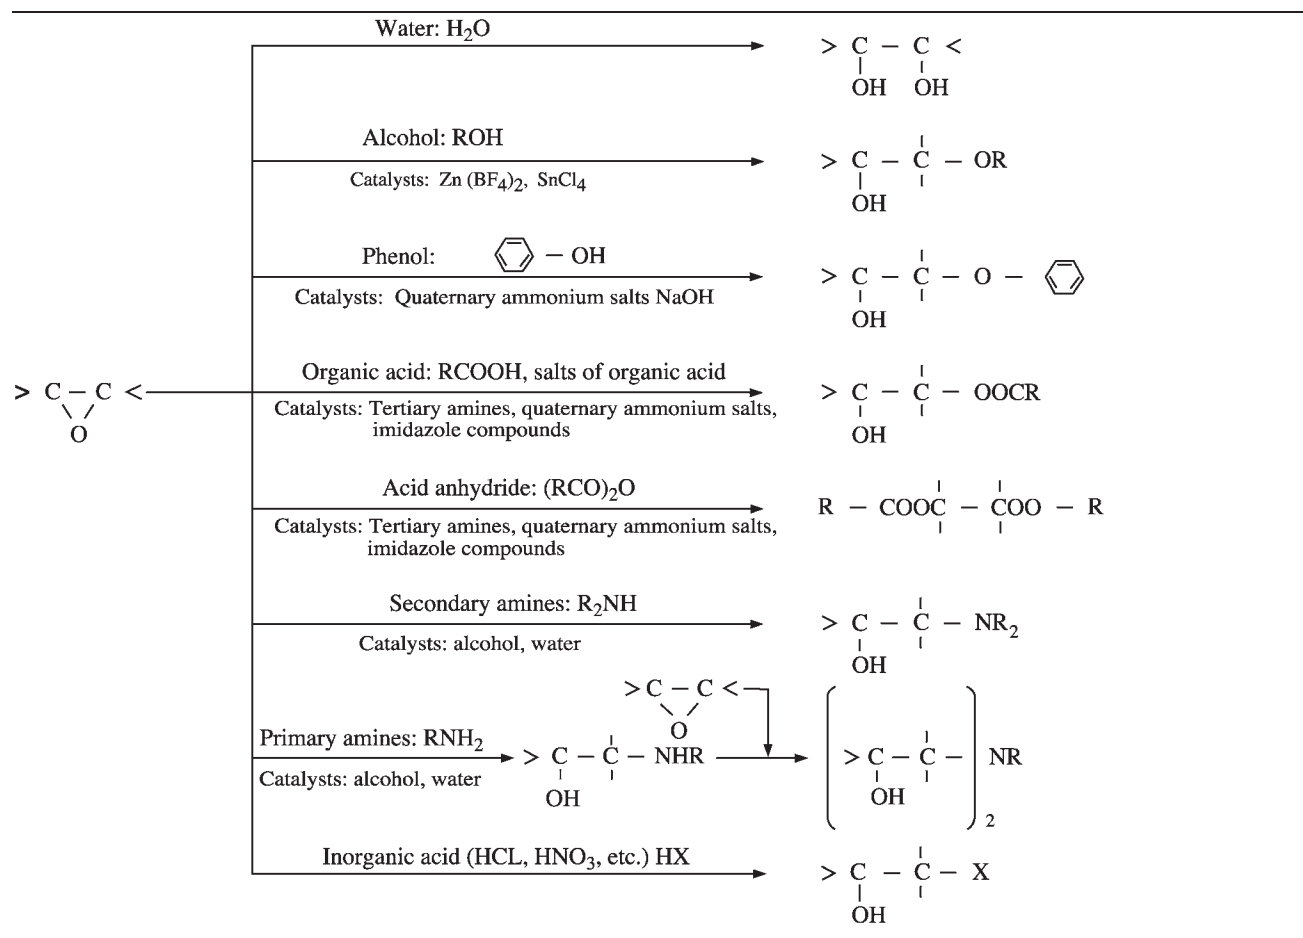

Host cells cannot migrate or proliferate on GA cross-linked materials. The materials cannot obtain cell compatibility. Sometimes, this side effect is desirable. In the case of cross-linked heart valves, host cells cannot adhere to the surface, and this can prevent pannus hyperplasia over the heart valve leaflets. But in the case of artificial blood vessels and pericardium, surrounding host cells cannot migrate into the cross-linked tissues, resulting in poor connection of the graft to the surrounding tissues.

Table 2 Reaction of epoxy group

Usually, biological materials are very soft and elastic except for bone and other hard tissues. Materials cross-linked with GA become strong, but also stiff. This stiffness causes trouble when the materials are used at sites that require elasticity and softness. Some of these disadvantages stem from the molecular structure of GA. As shown in Fig. 2, GA is composed of a chain of five carbons.^[16] It is extremely stiff, and it is also hydrophobic. Usually, most biological materials are hydrophilic. The original properties are changed after cross-linking with GA. The chain of five carbons changes the original soft and hydrophilic properties into stiff and hydrophobic properties. This change is caused by the molecular structure of GA.

The molecular structure of PCs is different from that of GA. Some of the disadvantages mentioned previously can be overcome with the use of PCs. As shown in Fig. 2, PCs have ether bonds in their molecular structure.^[20] A nickname for the ether bond is free joint, and the molecules of PCs are flexible. Materials maintain their original softness and elasticity after cross-linking.^[1,2]

Another advantage of PCs is their hydrophilicity. As shown in Fig. 1, a hydroxyl group is created after reaction of PCs with $\epsilon\text{-NH}_2$ groups and carboxyl

groups.^[20] The epoxy circle is opened at the reaction and takes a -H from the $\epsilon\text{-NH}_2$ group of collagen molecules, resulting in the creation of a new -OH group at each reaction site. This gives the materials hydrophilicity. Usually, with this chemical reaction, PC cross-linking maintains the original hydrophilicity of the materials. Cross-linking with GA makes the materials hydrophobic. This is against nature.

Calcification of materials cross-linked with GA is another large disadvantage.^[27,28] The mechanism of calcification is not yet known, but GA-treated materials easily become calcified, especially when they are implanted in young patients. In the case of heart valves, a very high ratio of calcification has been reported in biological heart valves implanted in child patients.^[27,28] Experimentally, calcification is easily demonstrated in a subcutaneous implantation model in growing animals. Within three weeks, GA-cross-linked materials become calcified, but with PC cross-linking, the calcification ratio is extremely low. Imamura and his colleagues demonstrated a low calcification ratio in a PC cross-linked heart valve experiment, a subcutaneous implantation model with PC cross-linking compared with GA cross-linking.^[29] Okoshi and his colleagues also

Fig. 1 Cross-linking of collagen molecules with a polyepoxy compound.

obtained similar results with the materials cross-linked with PC and GA. Less than 3% of the materials cross-linked with PC showed calcification compared with 100% for GA cross-linking.^[30]

Fine controlability of cross-linking ratio is also one of the advantages of PCs. Compared with GA, control of the reaction rate with PC cross-linking is easy.^[20] The reaction proceeds smoothly and relatively slowly compared with GA. The reaction with PC can be accelerated using catalysts and control of reaction conditions such as pH, temperature, reaction time, and concentration of the cross-linker. Therefore, the reaction ratio and speed of PC cross-linking is controllable.

Related to the cytotoxicity of cross-linking reagent, PC is less cytotoxic than GA. Besides, nonreactive epoxy groups can be easily reduced by heating in water, or adding some small-molecule amine solutions such as glycine. Therefore, the cytotoxicity of materials cross-linked with PCs is extremely low compared with that of materials treated with GA.

Murayama et al. studied the reduction of antigenicity and immunogenicity both quantitatively and

qualitatively in dogs and mice. They reported that treatments with either GA or PC reduced antigenicity and immunogenicity equally.^[31,32]

APPLICATION OF PC CROSS-LINKING TO THE FIELD OF HEART VALVES

Imamura created porcine heart valves cross-linked with PC.^[29,33] Their heart valves were elastic and soft, and there was no calcification during implantation.^[34-36] We also created a right ventricular-to-pulmonary artery conduit having a valve made from the jugular vein of a cow.^[37-39] This has a natural venous valve, but we adapted it for use as a pulmonary valve. The conduit was extremely soft and pliable after cross-linking with PC. It was possible to open and close the valve with less than a 5-mmHg pressure difference.^[39]

We have developed a new heparinization technique that uses protamine sulfate and sodium heparin to make biological materials antithrombogenic.^[40,41] Protamine is composed of positively charged amino acids such as lysine and arginine. Heparin contains many carboxyl groups and sulfonic groups, resulting in a negative charge under physiological conditions. Heparin and protamine can bind ionically. We used this ionic bond for heparinization of biological materials. The heart valve experiment performed by Ichikawa and his colleagues adopted our heparinization technology. The valve was implanted in the right ventricle in the pulmonary artery position. The technique prevented thrombus formation and calcification in animal experiments for more than one year. At the time of the heart valve

	Tensile strength (g/mm ²)	Elongation rate (%)	Compliance at 90 mmHg
Native artery	224	100	1.05
GA cross-linked A.	144	86	0.45
PC cross-linked A.	195	126	1.08

retrieval, the valve was extremely soft and elastic without calcification. Detailed data is available in their papers.^[38,39]

APPLICATION TO BLOOD VESSEL PROSTHESES

We developed a new vascular prosthesis made of an animal artery.^[42-46] The graft was heparinized by our own method described above and cross-linked with PC. The following is a summary of our animal experiments.

Canine carotid arteries were soaked in distilled water and then sonicated and squeezed in order to create an acellular matrix for biological vascular grafting. With this treatment, a tubular framework composed of elastic laminae and collagen fibers was obtained. A protamine sulfate solution was poured into the lumen of the tube. Then the tube was cross-linked with PC from the outer surface of the tube, which made the graft white, hydrophilic, soft, pliable, and biodurable. Table 3 shows the elasticity, tensile strength, and compliance of the PC cross-linked graft compared with the control GA cross-linked graft. The graft was dipped into a heparin solution, which allowed heparin to bind ionically. The cross-linking percentage of the ϵ -NH₂ group of collagen side chains is about 85%. Figure 3 shows a PC cross-linked graft (top) and a control GA cross-linked graft (bottom). The PC cross-linked graft is white, and its wall is thick due to water content. The GA cross-linked graft is yellow and its wall is thin.

Eighty grafts (3 mm internal diameter, 6 cm in length) were implanted in the carotid arteries of 40 dogs

Fig. 3 Canine carotid arteries cross-linked by PC (top) and GA (bottom).

and retrieved from one to 389 days after implantation.^[1] Three grafts were occluded by graft infection and 77 were patent (96% patency). Sixteen control grafts cross-linked with GA were stiff. All of them were found to be occluded at the time of the graft retrieval. Measurement of the heparin content revealed that about 90% of the heparin was released from the graft wall within 1 month. After the release of heparin, the surface of the graft was completely covered with endothelial cells. The antithrombogenicity of the graft was due to the slow release of heparin, permitting the attachment of endothelial cells that have natural antithrombogenicity. The graft wall kept its soft and pliable properties even after long-term implantation.

In specimens examined six months or more after implantation, host cells such as fibroblasts and smooth muscle cells had migrated into the acellular matrix, i.e., the graft wall. Smooth muscle cells near the luminal surface were aligned in parallel to the circumference. Near the adventitia side, they were arranged in a longitudinal direction like a natural arterial wall. These results indicate that the antithrombogenicity produced by the combination of the slow release of heparin and endothelialization, together with the natural vessel compliance in the graft, were the major reason for its success as a small-caliber graft.

We also implanted the grafts in the aorta-coronary bypass position in eight dogs,^[47] and observed the grafts for up to four months. All the grafts were confirmed to be patent by autopsy or graft angiography.

These successful results were possible only with the combined use of the heparinization technique and PC cross-linking. With GA cross-linking, it would be impossible to obtain such good results.

APPLICATION TO A GROWABLE VASCULAR PROSTHESIS

Conventional artificial blood vessels retain their original dimensions, such as thickness, length, and internal diameter, after implantation. Therefore, they cannot be implanted in child or infant patients, because relative stenosis will occur as the child grows. In order to overcome this problem, we developed an expansible vascular

prosthesis that can grow *in vivo* after implantation.^[48,49] Our animal experiments were as follows.

Biological tubes obtained from humans or animals were used as the raw material for an inner graft. The graft was covered with an outer graft made of a polyester fiber mesh. The inner graft was characterized by measuring the rate of reaction of ϵ -NH₂ groups on the side chains in its collagen. The ratio was about 40%. If we used a fast cross-linking rate, the growth of the graft, i.e., inflation of the graft by blood pressure during implantation, could be made slow. If we used a slow cross-linking rate, the graft would grow fast after implantation. The graft growth was controllable with the cross-linking ratio of collagen. We used Denacol EX-861 (a trade name of Nagase ChemteX Corporation).^[20] Denacol EX-861 is a hydrophilic cross-linker with slightly high molecular weight. Therefore, it was easy to control the cross-linking rate. The collagen tube thus obtained (inner diameter 4 mm, length 6 cm) was covered with a polyester mesh (internal diameter 10 mm) and implanted in the descending aorta of four young dogs. The animals weighed from 4.5 to 7.5 kg. The grafts were retrieved from six months to three years after implantation. At the time of graft retrieval, the animals weighed from 8.5 to 10.3 kg. The average inner diameter of the graft was 9 mm. Growth of the graft was limited by the size of the polyester mesh that covered the inner graft. The expansible graft was made possible by the epoxy cross-linking technique, which can control the inflation rate, in conjunction with the outer polyester mesh tube, which can determine the final growth size.

APPLICATION TO A HEMOSTAT

Insoluble collagen of bovine dermis was solubilized by pepsin in acidic solution. Telopeptides, which are nonhelical parts at the terminals of the molecule, were digested by pepsin treatment. This solubilized collagen was named Atelocollagen.^[50] A 3% atelocollagen solution was extruded from a nozzle having 200 70- μ m pores into saturated aqueous sodium-sulfate solution. The resulting fibers were dipped in a PC solution, and washed with water. After freeze-drying the fibers, they were cut into small lengths and entangled with each other to create a cotton-like structure. This cotton-like material was used as a hemostat.^[51,52] Scanning electron microscope observation showed that each collagen fiber had very fine fissures on its surface, which were caused by cross-linking the collagen molecules of soluble collagen fibers. These very fine fissures increased the surface area, so that each fiber could absorb blood easily and could make contact with platelets and fibrinogen, resulting in acceleration of blood coagulation.

As stated above, the absorbing ratio *in vivo* of the collagen fibers can be controlled by varying the degree of PC cross-linking. The ratio of cross-linking, which is measured as the rate of reaction of ϵ -amino groups on the side chains in collagen, is about 30%. A higher amount of cross-linking will slow the absorbing ratio, and a lower amount of cross-linking will increase the absorbing ratio. Accordingly, the *in-vivo* absorbing ratio of the hemostatic material of our experiment can be conveniently adjusted, depending on the condition of the bleeding region where it is to be used. These fine controls of the *in-vivo* absorption are only possible with the use of the atelocollagen spinning technique and the PC cross-linking.

USE IN ANTIADHESIVE MEMBRANES

We also developed an antiadhesive collagen membrane. The membrane was heparinized with our own heparinization technique described previously, and cross-linked with GA. The membrane showed excellent antiadhesive properties on serous membrane peeled off surfaces of the large intestine of dogs. But even two years after operation, the membrane still remained on the colon surface. In order to make the membrane absorbible *in vivo*, we changed the cross-linking method from GA to PC.^[53,54] Thus, we could control the cross-linking rate in order to make the membrane absorbible *in vivo* after its antiadhesive function was finished. The following is a summary of the experiment.

A thin piece of human amnion was obtained aseptically and treated with 0.01% ficin in phosphate buffer, pH 7.4, at room temperature for 24 hours and washed with distilled water repeatedly. The membrane was heparinized with our own method using protamine sulfate impregnation. The membrane was cross-linked with 3% PC Denacol EX-810 (Nagase ChemteX Corporation, Osaka, Japan) for 12 hours. The cross-linking rate was about 30%. Then the membrane was dipped in a 1% heparin solution at pH 6.9 for 24 hours. The membrane was again washed in distilled water repeatedly, and preserved in a 70% solution of ethanol.

Ten mongrel dogs weighing 8–12 kg were used. Six of them were used for the heparinized membrane experiment, and the other four were used as controls. The peritoneal cavity of the animal was entered via a midline incision under general anesthesia. 5 cm² pieces of the colon serous membrane, which consists of a layer of mesothelial cells resting on loose connective tissue, were removed from each of the dogs and pieces of the membranes were sutured onto each site with intermittent sutures at 16 places per site. The animals were killed at from three to 687 days after surgery.

All the heparinized membranes prevented intestinal adhesion. The heparinized membranes were already

absorbed after a period of one month, but after periods of less than one month, the membranes remained on the colon surface. But, no adhesion was observed whether the membranes were absorbed or not. In the control experiment, all the areas covered with the GA-treated membranes had serious omentum adhesion.

The mechanism of the antiadhesion system was as follows. In the early stage of the intestinal adhesion, fibrin deposition on the operation sites always occurs. The fibrin deposit makes a fibrin network, which binds the wound surface to the nearby tissues. This fibrin network can be dissolved by fibrinolysis. But if fibroblasts infiltrate the fibrin network, they will synthesize collagen fibers around them. The collagen network cannot be dissolved by fibrinolysis. Next, capillary blood vessels follow the fibroblast migration. This accelerates fibroblast proliferation and collagen synthesis. In this process, adhesion tissue composed of fibroblasts and collagen fibers is created between the wound and the surrounding tissues.

If we can prevent the creation of a fibrin network, fibroblasts cannot migrate into the network, since they will have no anchoring sites and cannot synthesize collagen fibers between the wound surface and the surrounding tissues. Therefore, no adhesion tissue will be created. In this experiment, the slow release of heparin from the membrane effectively prevented fibrin deposition, thus preventing adhesion. Once adhesion was prevented, the membrane was no longer needed, and therefore it was designed to be dissolved one month after implantation.^[54] The area left after the membrane was dissolved was covered with mesothelial cells that have a natural antiadhesive property. The cross-linking ratio of collagen molecules was easily controlled with the PC cross-linking technique. This experiment showed one successful example of PC cross-linking of biological materials.

CONCLUSION

Compared with GA cross-linking, PC cross-linking proceeds relatively slowly, but it can be accelerated and the reaction rate is controllable. The low cytotoxicity of PC is also a great advantage over GA. This PC cross-linking method is not widely used yet, but in the near future, the method will become a major technique in the field of materials for medical use.

ACKNOWLEDGMENTS

We would like to express our grateful thanks to Dr. S. Shimizu, chief scientist of Nagase ChemteX Corporation, for his invaluable suggestions, and to the company

for supplying all information related to Denacol technology.

INTRODUCTION

Poly(glycolic acid) (PGA) is a synthetic polymer that degrades to natural metabolic waste products. The chemical structure of glycolic acid can be written as HOCH₂COOH. Note that the molecular termination is a hydroxyl group on one end and a carboxyl group on the other. Glycolic acid, also known as hydroxyacetic acid, is found naturally in young plants and green fruits. Glycolate, which is the ester or salt form of the acid, is produced from ribulose 1,5 biphosphate, a Calvin cycle initiator, in chloroplasts and transferred to peroxisomes, where it is oxidized to glyoxylate, which can be transaminated to the amino acid glycine. It is further processed in the mitochondria, passed back to the peroxisome for transamination and reduction, and then finally passed back to the chloroplast as glycerate, where adenosine triphosphate (ATP) phosphorylates it. The 3-phospho-glycerate can then reenter the Calvin cycle for sugar production. This process, which is called photorespiration, is a seemingly wasteful side reaction of photosynthesis that consumes both oxygen and ATP and produces carbon dioxide and hydrogen peroxide. In human metabolism, the specific glycolic acid oxidase is not present, but it may be slowly oxidized and transaminated to glycine in a similar manner. This slow metabolism would lead to localized build up of glycolic acid. The ramifications of which will be discussed later as pertaining to the in-vivo tissue response.

SYNTHESIS OF PGA

After one has sufficient quantity of monomer from either an extraction and purification from plants^[1] or synthesis in the laboratory, the polymer can be synthesized. Two different methods can be employed to produce the polymer. The first is polycondensation. In condensation reactions, the monomer subunits react

and release a small molecule such as water.^[2] Because glycolic acid contains two functional groups that can participate in a condensation reaction, it can self-polymerize.^[2,3] The basic reactions involve creating dimers from two monomers, tetramers from two dimers, and so on to eventually form a polymer (Scheme 1).

The reaction is characterized by the early disappearance of monomers from the solution and the slow increase of high molecular weight species. Due to the random nature of the polymer formation, there is a broad molecular weight distribution throughout the reaction, and significant concentrations of high molecular weight polymers are difficult to achieve.^[2,3] Adding to the difficulty, common commercial esterification catalysts, such as antimony trioxide, also catalyze the reverse reaction, namely depolymerization.^[3] Moreover, glycolic acid has a great tendency to cyclodimerize to glycolide (Scheme 2), which thus ends its reactivity in condensation reactions.

Due to these drawbacks, a second method of preparing PGA is preferred, namely ring-opening polymerization (ROP) of glycolide (Scheme 3).^[3]

Depending on the catalyst used, these polymerization reactions can be anionic, cationic, or involve insertion mechanisms. Of these mechanisms, insertion using metal alkoxides or carboxylates as catalysts is the most commercially viable and therefore will be the only method discussed. The tin (Scheme 2) octoate catalyst is the most commonly used due to its acceptance by the U.S. Food and Drug Administration (FDA) as a food stabilizer.^[3] The polymerization of glycolide is typically carried out in bulk at 220°C for 4 hours. This results in a 96% conversion to polymer with molecular weights ranging from 10⁴ to 10⁶ Daltons.^[3] As is the case with polyesters in general, equilibration reactions such as ester interchange and chain unzipping may take place, the effects of which would be the formation of shorter chains and low molecular weight species such as cyclic dimers, trimers,

Poly(Glycolic Acid)

Scheme 1 Condensation polymerization of glycolic acid to PGA. Note that the number of repeating units (n) in the polymer is an average number.

and, to a lesser extent, cyclic oligomers, and even monomers.^[2,3] These species can drastically affect the mechanical properties of the final products, and their production must be carefully monitored and avoided if possible. This ROP method can also be employed to form copolymers with other α -hydroxy acids of the general form $[-O-CH(R)-CO-]$. Other copolymerization methods include ABA block copolymer formations with a monoester group of poly(ethylene glycol) or fatty acids.^[4] These various copolymers of glycolide also have significant uses in medicine.

PGA CHARACTERIZATION

The regularity of the PGA backbone and its rather compact repeat unit suggests that the polymer will tend to at least partially crystallize. Indeed, early X-ray diffraction work reveals that the unit cell contains two antiparallel polymer chains and these chains have a sheetlike molecular arrangement of planar zig-zag conformations. Also, the C=O groups of adjacent polymers in the unit cell overlap (Fig. 1). The density of the crystal was determined to be rather high at 1.69 grams per cm^3 . It was suggested that the close approach of ester groups, which results in tight molecular packing, produces the abnormally high melting temperature and insolubility of the polymer.^[5]

PGA DEGRADATION

Biodegradation is the destruction of one or more chemicals by biological processes. PGA is not removed

glycolide

Scheme 2 Dimerization of glycolic acid to glycolide.

Scheme 3 Ring-opening polymerization of glycolide to PGA.

by biodegradation alone but also by mechanisms of hydrolytic degradation, erosion, and bioabsorption. Hydrolytic degradation is the breakdown of a material by physical or chemical interactions with water, and bioabsorption is the uptake of material by a cell. Hydrolytic degradation is the predominant mechanism of PGA breakdown resulting in the loss of mechanical strength.^[6]

There have been many theories about the hydrolytic degradation of PGA. All the theories have had two central dogmas. First, the amorphous region of the polymer is quickly degraded, which results in a significant loss of mechanical properties in a matter of days to weeks. Second, the crystalline region of the remaining fragments degrade more slowly yet crystallinity remains measurable until the material is completely degraded. One such theory was formulated from a detailed multitime point analysis described by Hurrell and Cameron,^[6] a group that employed analysis techniques that included small and wide angle X-ray scattering (SAXS and WAXS, respectively), mass measurement, differential scanning calorimetry, pH measurement, and UV-spectrophotometry. One key finding was that, as the degradation proceeded, the intensity of the crystal peaks on the WAXS profiles increased with respect to the amorphous halo.^[6] This confirms earlier findings that the amorphous region degrades first and leaves the crystalline regions intact.^[3] This observation continued over the first 10 days, at which time, the crystallinity leveled off, and the amorphous halo was only faintly visible. Again, this observation is supported by clinical findings that PGA sutures lose most of their strength in the first two

Fig. 1 Crystal structure of polyglycolide.

weeks.^[3] Another valuable observation is the rapid drop in the glass transition temperature over the first 6 hours and then it continues to drop at a much slower rate. This rapid drop may indicate that water had diffused to the center of the sample in the first 6 hours. This corresponds well with the previously reported diffusion constant of $5.0 \pm 1.0 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$ of water into PGA.^[6] A final observation showed a dramatic drop in pH after about 10 days despite being in a buffered solution.^[6] This indicated that glycolic acid is released during the first 10 days, but the rate of release may increase dramatically around the 10-day point. In all the techniques applied to analyzing PGA degradation, a dramatic change in rate or morphology was noted at the 10-day point.

These observations and calculations helped devise the following four-stage degradation profile:

- The first stage of the degradation process is characterized by homogeneous diffusion of the hydrolytic solution into the sample. A sharp drop in the glass transition temperature characterizes this stage. For their model, this stage occurred over the first 6 hours.
- The second stage is that of homogeneous hydrolysis. During this stage, there is solution absorbed and relatively low mass loss. The chain hydrolysis reduces the polymer fractions to a critical molecular weight that is capable of diffusing from the solid. This stage took place over the first 10 days.
- The end of the second stage and beginning of the third stage is marked by a significant drop in the localized pH. This pH drop is a function of oligomer diffusion from the construct. Cameron theorizes that, as oligomers diffuse out and additional fluid diffuses in, a reaction-erosion front forms on the surface.^[6] This would expedite the degradation of the sample and address crystal breakdown. Due to the observation that cracks originate on the surface and proceed inward during hydrolysis, it is believed that these fronts proceed inward via hydrodynamic forces and eventually reach the opposing front at the center.

- The time at which these fronts meet is the onset of stage four. During stage four, only small crystalline fragments remain within the implant site. There is no structural integrity left in the implant, and the stage concludes at the removal of all traces of the PGA.^[6]

With hydrolytic degradation of polyesters, changing the pH of the hydrolytic media can significantly alter the rate of degradation. This would be an interesting aside if one were to assume all bodily tissues and fluids remained at a pH near 7.4. While this may be true for the majority of bulk tissues and fluids, it is certainly not the rule. Localized pH values of 1.0 are common in the stomach, but the pH in the small intestine and bladder often exceeds 10.0. In addition to regional pH differences, one must be aware of the local effects of inflammatory and foreign body responses. Depending on the cells recruited, local effectors can either raise or lower the pH, depending on the proteins involved. To compare pH effects, an experiment was developed to degrade PGA suture material in three different buffered solutions. The three different buffer solutions were maintained as acidic (pH = 5.25), slightly alkaline (pH = 7.44), and strongly alkaline (pH = 10.09). During the degradation process, samples were tested for strength retention, i.e., standard uniaxial fiber testing in a controlled environmental chamber.^[7] Other experimentation added scanning electron microscopy (SEM) to evaluate surface morphology during degradation.^[7,8] Initial results found that the suture material degraded significantly faster in the strong alkaline solution than in either of the less alkaline solutions. In fact, there was no significant difference in the degradation behavior of the acidic or slightly alkaline treated samples prior to 21 days of immersion. Two possible factors could be responsible for differences seen in this study, the so-called cage-effect in the crystalline regions and the pH effect on the ability to form hydrogen bonds.^[7]

The hydrolysis of simple organic esters in acidic media follows the general mechanism in Scheme 4.

It is believed that the reversal process of two fragmentary ends rejoining in the amorphous region is

Scheme 4 Acid-catalyzed ester hydrolysis.

insignificant due to chain mobility, but this cannot be said about the crystalline regions. Two chains held in a crystal lattice that are separated by hydrolytic cleavage have a greater chance to recombine. This is the so-called cage effect. If this does indeed exist, it could slow down the degradation in acidic or near-neutral pH buffer conditions. The cage effect may not even be restricted to the crystalline regions. If sufficiently immobile polymers, either due to high viscosity or high molecular weights, a cage could be created in amorphous regions as well.^[7,8]

The same cannot be said in the presence of a strong alkaline-buffered solution due to the irreversibility of hydrolysis.^[7-9] Alternatively, it has been reported that the capability of adjacent polymer chains to form hydrogen bonds is significantly reduced or even lost at higher pH levels. Since hydrogen bonding was previously identified as a contributing factor to PGA's crystallinity and stability,^[5] it would stand to reason that the elimination of those bonds could accelerate degradation. A relatively looser structure would be more open to attack.^[9]

It is likely that both of these mechanisms contribute to the hydrolytic degradation of PGA. The cage effect would be more pronounced in acidic or neutral attacks, and the reduction of pH-dependent hydrogen bonding would be more pronounced in strong alkaline attacks. The former mechanism preserves the crystalline regions while the latter rapidly degrades the amorphous regions. These mechanisms are closely tied to the experimental observations if we accept a chain scission model. This model states that chain scission during hydrolytic degradation begins at tie-chain segments at the point where the rigid crystals tie into the amorphous chains.^[7,8,17] These ends carry the load in the bulk polymer and are most susceptible to move during hydrolytic cleavage in acidic or neutral attacks. The tie-chains are also theorized to participate in extensive hydrogen bonding with the crystal lattices and are therefore prone to dissociate with strong alkaline attacks. Both outcomes can predict the loss of mechanical strength and elasticity observed experimentally.^[7,9]

Localized pH is not the only effectors that can change degradation rates in vivo. The role of enzymes has also been identified as contributing to the degradation of PGA. As stated earlier, humans do not possess the specific glycolic acid oxidase that can expedite breakdown and removal of PGA, but we do possess a number of nonspecific esterases and proteases that may be expressed by cells recruited in a foreign body response to implanted polymers.^[9] Experiments have demonstrated that certain families of enzymes increased the rate of degradation of PGA in vitro.^[10] Specifically, the presence of bromelain, esterase, or leucine aminopeptidase reduced the complete degradation time of

PGA sutures to less than one week from the previously reported values ranging from two to four weeks.^[3,4,10] This in-vitro work prompted an in-vivo exploration of implant sites. Large quantities of acid phosphatase and leucine aminopeptidase were found at the implant sites of orthopedic PGA fixatives. While the biodegradation properties of leucine aminopeptidase were seen in vitro, acid phosphatase did not enhance in-vitro degradation.^[10] The role of the acid phosphatase is unclear, but it has been speculated to play a role in absorption.^[10]

PGA APPLICATIONS

As previously mentioned, PGA is a semicrystalline material with a high melting temperature and low solubility. In fact, the only known means of solvent processing PGA is in hexafluoroisopropanol or hexafluoroacetone sesquihydrate in carbon tetrachloride.^[6,12] However, both of these solvents, have high toxicity levels appropriate for yarn or fabric production but not for drug delivery since the drug may react with the solvent or trace amounts of the solvent could be incorporated into the end product. Melt processing is the typical commercial method, specifically hot-drawn fibers or melt-pressed molding. With the former technique, fiber diameters as low as 10 μm can be produced, and the latter is capable of larger-sized constructs typically for orthopedic applications.^[3,11] These fibers can then be further processed through winding, weaving, and braiding techniques to produce currently marketed products such as suture and wound dressings.^[3,11,13] Several products have been commercially available since the early 1970s and have paved the way for new advances in PGA processing and products.

Current medical research involving PGA is in four key areas: drug delivery, orthopedic fixation, degradable sutures, and tissue engineering. As previously stated, PGA has many drawbacks as a drug delivery device except for its rapid and predictable degradation. To avoid toxicity of solvents, scientists sought a drug that was thermally stable at temperature compatible with melt-processing PGA.^[12] For this study, their drug of choice was theophylline, a bronchodilator that is used in the treatment of chronic asthma and pulmonary disease. The drug is water-soluble, weakly basic, and sublimates without degradation at temperature above PGA's processing temperature.^[12] Even at low concentrations, its inclusion prevented crystal formation in PGA, which may be evidence of even distribution throughout the polymer, and should give a more even dosage. Both of these theories proved correct and illustrate the strength of PGA as a drug-delivery polymer. A rather steady dispensing of the drug from day 6 to day 15 was observed,^[12] which

provided additional support to their previous theory on the four-stage degradation process of PGA.

The second area of interest is in orthopedic fixation devices, namely rods, plates, and screws. Two different uses are emerging. The first is as a binding agent with other polymers such as calcium phosphate fibers,^[14] and the second is as a self-reinforced polymer.^[15] In the former application, PGA is used to provide initial support that is gradually reduced until the calcium phosphate is carrying the full load. Nevertheless, a material with a two-week degradation time may not be adequate for bone repair. To slow the rate of hydrolytic degradation, researchers chose a novel surface plasma treatment, CH₄ and Parlene[®], to make the surface more hydrophobic.^[14] In doing so, they slowed the rate of media uptake and therefore slowed the first stage of degradation, which appears to be pivotal in the overall degradation rate. These plasma coatings were found to be nontoxic and thus provide a new method to decrease the degradation rate of PGA to counter the many factors that can increase the rate of degradation. Along a similar methodology, a method of coating self-reinforced PGA (sintered suture) with another slower degrading polymer is presented.^[15] The constructs were briefly submerged in chloroform containing polydioxanone, poly(hydroxybutyric acid), or poly(lactic acid). This was done to form a thin, slowly degrading coating that would prevent water uptake by the PGA construct. The idea may have been sound, but the application suffered cracking and delamination and was eventually ruled out since it did not statistically decrease the degradation rate of the constructs *in vivo*. It was concluded by this group that self-reinforced PGA materials degrade too rapidly to be effective internal fixatives for cortical bone fractures.^[15]

The third area of interest returns to sutures. As long as surgeons are cutting into the body, there will be a quest for the perfect suture. One that can be used anywhere, has strong knot retention, retains strength long enough for complete closure, and avoids adverse effects on healing. This has led researchers to reevaluate modifications to PGA that affect its strength and degradation rate. One such approach has been to anneal the suture material for different lengths of times and at different temperatures while subjecting the suture to a slight axial load.^[16] The idea is that the crystalline regions will align along the long axis of the suture, and polymer chains in the amorphous regions will straighten to increase strength and decrease the degradation rate. This was the response elicited from the testing. A very complex relationship emerged that linked annealing temperature and load with hydrolytic degradation and mechanical properties.^[16] Further evaluation will be necessary to test the limits of these relationships.

Fig. 2 Scanning electron micrograph of electrospun PGA fibers (scale bar = 10 microns).

The emerging discipline of tissue engineering is reaching into many aspects of anatomy and physiology—from wound closure to full organ replacement. Electrospinning is the deliberate charging of a polymer, either in solution or melt, by applying a high voltage potential between that solution and a grounded target. The phenomenon of combining electrospinning with tissue fabrication, which occurs when electrical forces at the surface of the polymer solution overcome the surface tension, creates a polymer solution jet. This jet produces fibers with diameters from microns to nanometers, specifically down to 50 nm.^[17] Many factors can affect the morphology of electrospun fibers although these variables have only recently been examined with PGA.

As described earlier, PGA can be tailored into many different scaffold configurations utilizing electrospinning. Electrospinning uses a static electric field to draw the polymer fibers out of solution rather than a mechanical drawing or ejection system previously described for fiber formation. PGA fibers can be produced from $1.2 \pm 0.4 \mu\text{m}$ diameters at a 140-mg/ml concentration in hexafluoroisopropanol to $110 \pm 40 \text{ nm}$ diameters at a 50-mg/ml concentration. Fiber diameter varied linearly with concentration. Fiber alignment, as depicted in the micrograph in Fig. 2, was achieved through rotation and translation of the grounded target. Fibrous mats produced in this manner demonstrated significant mechanical strength and anisotropic properties related to fiber orientation. It is speculated that these relationships can be exploited to develop a wide variety of biomimicking tissue-engineering scaffolds.^[18]

PGA REGULATORY ISSUES

Regulatory pathways have not always been as critical. The United States federal government did not tightly regulate initial PGA products, which were approved

for sale prior to the medical device amendment to the Food, Drug and Cosmetic Act in 1976; however, new devices or drugs will be much more thoroughly scrutinized for compliance to specific parts of the Good Manufacturing Practices as outlined in CFR title 21.^{[19]a} Even with this scrutiny, similar products can still be expedited through the regulatory process. And, as often the case, the first product approved becomes the standard to which all others are measured. Outside the United States, the European Union has established the European Medicines Evaluation Agency (EMA) to regulate the marketing of medical products as either a medical device or medicinal product. Similarly, the Japanese Pharmaceutical and Medical Safety Bureau (PMSB) requires demonstration of safety and efficacy of medical products regulated as either medical devices or pharmaceuticals. Regulation of PGA products are increasingly hard to characterize as devices, drugs, or biologics, and approval for use must be sought on a case-by-case, country-by-country basis. Further information about issues facing tissue-engineered products can be found in a World Technology Evaluation Center (WTEC) report on tissue engineering research.^[20]

One area that is always a concern of the regulatory bodies is the sterilization of products. Gamma irradiation is becoming a popular method to sterilize everything from latex gloves to lunch meats. Care should be taken before applying this technology to PGA constructs. It has been reported that gamma irradiation can significantly affect the degradation properties of PGA. Utilizing the techniques of electron spin resonance (ESR) analysis and scanning electron microscopy, chain scission, and degradation were monitored *in vitro*. Gamma irradiation of ester groups can enhance the susceptibility to form chain scissions even at a normal sterilization dose of 25 kilograys (kGy).^[21] At this dosage, total mechanical strength is lost during the first 10 days in buffered media. Significant decrease in the molecular weight after irradiation was measured, and ESR confirmed many chain scission radicals in the polymer chains. Although initial SEM analysis showed no difference before placing the samples in media, it became quickly apparent that irradiated samples degraded at a much faster rate and appeared to degrade by the same mechanism. This provides confirmation that merely inspecting for cracks cannot accurately predict damage caused by gamma irradiation. It would be advisable to select an alternate means of sterilization.^[21]

^aCurrent Good Manufacturing Practices for Medical Device Manufacturers, Code of Federal Regulations, Title 21 Part 820.

PGA IN-VIVO TISSUE RESPONSE

In addition to regulatory issues, such as sterilization, the greatest hurdle is often tissue compatibility. Work has been done to describe the immune response to PGA implants. In general, they are very acceptable. The principle cell type found in effusion samples around PGA implants was a small lymphocyte although a few monocytes were also found.^[22] This could be interpreted as a slight foreign body response to the implant, but the absence of neutrophils supports a noninfectious response, possibly a lymphocyte-mediated immunological reaction.^[22] These data can be taken to show PGA is relatively inert immunologically; however, inert may not be good enough for the next generation of tissue engineering materials. It would be desirable to create materials that are bioactive, *i.e.*, they cause a biological response. The desired response would be that of natural healing and incorporation—not encapsulation.

Many groups are racing to find the magic material that promotes natural healing, augments native tissues (if desired), or is capable of replacing native tissue with a new tissue construct. One such approach was to take highly porous PGA matrices of nonwoven 12-micron diameter fibers and implant them subcutaneously in a rat model to see if native tissue would grow into the matrix and form a new tissue mass. Initially, the matrices were encapsulated, but, with time, the capsule thinned and cells migrated into the matrix. Histological examination showed the cells migrated from the skeletal muscle rather than from the skin or adipose tissue.^[23] Much to researchers' dismay, the tissue receded as the matrix degraded. Upon complete degradation of the matrix, no trace of the cells that had previously ingrown could be found, and no internal scar was evident even though a fibrous capsule previously existed in that location. When comparing PGA to other matrix material, less neovascularization was noticed. It was postulated that the rapid release of glycolic acid into the local environment dropped the localized pH and down-regulated vascular formation.^[23]

Another approach taken with a PGA based product was pre-hydrolyzing the surface to promote cell adhesion.^[24] The premise of this research is that short-term exposure to an alkaline solution will begin hydrolyzing the surface of the matrix, improve its wetting behavior, and ultimately make it a more suitable cell culture surface. SEM analysis revealed surface erosion without crack formation from this processing. A 50% mass reduction in the fibers of the matrix was targeted (13- μ m diameter fibers reduced to 9 μ m). Wetting behavior was also effected by this treatment by changing the surface composition from 51% carbon and 49% oxygen to 49% carbon and 51% oxygen as measured by XPS.^[24] This increase in oxygen on the

Fig. 3 Transmission electron micrograph of a PGA scaffold (1- μm untreated fibers) implanted for 2 weeks in a rat skeletal muscle model.

surface could account for the increased hydrophilic nature of the surface. Through this experimental technique, they were able to devise a way to improve static, in-vitro cell seeding densities.^[24] They did not expand to animal trials or do long-term seeding studies to see if the trend continued.

The final method to be presented is work being done to enhance the usefulness of PGA as a tissue-engineering polymer. The focus of this work can be surmised as encapsulation versus incorporation. Many researchers have shown that PGA is encapsulated by collagen during the degradation process. This may be acceptable for sutures but not a tissue scaffold. Building on work with electrospun PGA presented earlier, one would want to look at cellular response to the material/matrix construct. Scientists have described a size scale for tissue engineering claiming that cells cannot migrate through pores under 20 to 50 microns. They maintain that small pores promote encapsulation, and large pores promote incorporation.^[25] Nevertheless, unpublished data seems to contradict this dogma. Figures 3 and 4 are two transmission electron micrographs that show cells within an electrospun PGA matrix with pore sizes below 5 microns and below 0.8 μm , respectively.

Observationally, the micrograph in Fig. 3 shows a typical capsule formation by actively secreting fibroblasts while the micrograph in Fig. 4 shows no capsule and high cell densities laying down orderly matrices. The difference between the two is that the first is 1- μm fibers and the second is 0.2- μm fibers that were

Fig. 4 Transmission electron micrograph of a PGA scaffold (0.3- μm fibers that were acid pretreated) implanted for 2 weeks in a rat skeletal muscle model.

pretreated in 11.7-molar hydrochloric acid. While other research presented claimed no difference in degradation with acidic versus neutral pH buffers, the material was not exposed to as strong an acid. These preliminary findings, if supported by additional analytical and animal experimentations, may bring PGA back into the forefront as a bioabsorbable polymer for medicine, specifically tissue engineering.

Poly(lactic acid)s

Michel Vert

CRBA-UMR CNRS 5473, Faculty of Pharmacy, Université Montpellier 1, Montpellier
Cedex 5, France

INTRODUCTION

Poly(α -hydroxy acid)s are aliphatic polyesters that derive from α -hydroxy acids. The main members of the family are poly(glycolic acid) (PGA) and poly(lactic acid) (PLA), also named polyglycolide and polylactide. In the biomedical field, poly(glycolic acid) and lactic acid-rich copolymers were first developed as bioresorbable sutures, thanks to the sensitivity of the corresponding polymer chains to water and in-vivo hydrolysis.^[1] Soon after, it was shown that polymers are more resistant to water than PGA and degrade more slowly in aqueous media.^[2,3] Furthermore, it was rapidly found that not only the degradation rate, but also most of the physical, thermal, and mechanical characteristics of poly(α -hydroxy acids) can be modified and somewhat adjusted via molecular chemical and configurational structures, a feature of great interest in the biomedical and the pharmaceutical fields.^[5,6] Indeed, lactic acid (2-hydroxy propanoic) is the simplest chiral hydroxy acid. It exists in two optically active optical isomers or enantiomers, namely L- (S- according to absolute configuration) and D- (R)-lactic acids. The stereocopolymerization of these two enantiomers can generate polymeric materials with similar chemical compositions, but very different physical properties, depending on the enantiomeric composition and the chiral lactyl unit distribution within the chains. Last but not least, lactic acid, like glycolic acid, is normally present in biochemical pathways of many cells and living organisms. Therefore, poly(lactic acid) (PLA) and lactic acid- and glycolic acid-containing copolymer chains (PLAGA) degrade to natural metabolic compounds. Lactic acid-based polymers were first studied from a scientific viewpoint^[2] until they became of industrial interest for bone surgery in the 1990s^[6] after their known properties had been considerably improved.^[3,7]

This contribution deals primarily with poly(α -hydroxy acid)s based on lactic acid enantiomers. However, many comments and characteristics will be of value for lactic acid-based copolymers involving glycolyl and/or other counits.

SYNTHESIS OF PLA POLYMERS

The prime precursor of lactic acid-based polymers is lactic acid, a compound of interest in the food industry. Lactic acid can be manufactured either by carbohydrate fermentation (L-enantiomer) or by chemical synthesis (racemic mixture of L- and D-enantiomers), although fermentation dominates.^[8] Lactic acid-based polymers were first synthesized at the time other polycondensates like Nylon[®]-type polyamide were investigated.^[9] The resulting poor polymers being rather sensitive to humidity and heat, they were considered useless. Fortunately, advances in polymer chemistry opened another route, namely the ring-opening polymerization of the cyclic dimer of lactic acid.^[10] PLA polymers and stereocopolymers correspond to the following general formula where R = methyl ($-\text{CH}_3$) (Scheme 1).

Formula A is commonly used mostly because it is more symmetrical and emphasizes the ester links. Formula B obeys the IUPAC rules. When it was realized in 1981 that the properties of a given member of the poly(α -hydroxy acid) family were batch-dependent, the use of the acronym PLAX was recommended to name PLA stereocopolymers and reflect the gross composition in repeating units, at least. In PLAX, X is the percentage of L-lactyl units present in the PLA chains.^[11] Since then, more than 20 factors have been identified that can affect the behavior of PLA polymers.^[12] Of course, it is not possible to reflect the contribution of all these factors within a simple acronym, but we strongly believe that everyone ought to use the PLAX acronym to make the comparison of literature data more consistent. The chirality of the lactic acid molecule makes PLA polymers rather special in the field of synthetic polymers. Being aware of the particularities is critical for applications in human therapy. Indeed LA-containing stereocopolymer and copolymer molecules are outstanding because of the presence of chiral centers along the chain. Indeed, chirality generates an extra source of differentiation between polymers having similar gross compositions in L-LA and D-LA units, namely the distribution of chiral centers. This distribution depends on many more or less interrelated factors including the gross composition, the mechanism

Scheme 1 Usual (A) and nomenclature official (B) general formula of PLA polymers.

chain formation, the nature of monomer, and the occurrence of configurational rearrangements caused by intrachain and interchain transesterification reactions.^[13,14]

FORMATION OF LACTIC ACID-BASED POLYMERS

There are two main routes to make lactic acid-based polymers, namely the step-growth polymerization or copolycondensation of lactic acid enantiomers together and with other hydroxyacids, and the chain-growth polymerization or ring-opening polymerization of lactide cyclic dimers together or with other heterocyclic monomers.

Step-Growth Polymerization of Lactic Acids

The step-growth polymerization of lactic acid corresponds to the following equilibrium (Scheme 2).

The resulting PLA homopolymers have low molecular weight (LMW) although high molecular weight polycondensates have been reported as feasible in literature, using particular catalytic and polycondensation conditions.^[15,16] When L- or the D-lactic acid is used, homo-oligomers are obtained that are semicrystalline, and oligo-L and oligo-D lactic acids have similar physical characteristics, provided molecular weights are comparable. When the two enantiomers are mixed in equal proportions (racemic lactic acid), oligomeric chains composed of L- and D-repeating units are obtained where these units are distributed at random. Poly(DL-lactic acid) polycondensates are thus amorphous. If L- and D-lactic acids are mixed in different proportions, stereocopolycondensates are obtained that can be amorphous or crystalline, depending on the proportion of the two enantiomeric repeating units. Under normal conditions, PLAX

Scheme 2 Poly(lactic acid)s obtained by polycondensation (step-growth polymerization) of lactic acids.

Scheme 3 The various lactide-type diastereoisomers.

polycondensate chains are ended by OH and COOH groups in equivalent amounts.

Chain-Growth Polymerization of Lactides, the Cyclic Dimers Derived from Lactic Acids

To obtain high molecular weight chains, the most efficient route is the ring-opening polymerization (ROP) of lactides, the cyclic dimers of lactic acids. Because of their dimeric structure and because of the presence of two chiral centers, there are different lactide diastereoisomers as shown in Scheme 3.

The official IUPAC name of these cyclic dimers is 3,6-dimethyl-1,4-dioxane-2,5-diones, or dilactides. In literature, people generally use lactide for the sake of simplicity.

- D-lactide, L-lactide, and meso-lactide are composed of two D-lactyl, two L-lactyl, and one D- and one L-lactyl unit, respectively, whereas rac-lactide is a 50/50 mixture of L- and D-lactides.
- L-lactide and D-lactide are generated during the thermal degradation of lactic acid oligomers obtained by polycondensation of L-lactic acid and D-lactic acid, respectively. They melt at 97–98°C and are soluble in many organic solvents (acetone, ethyl acetate, and benzene, for instance).
- Rac-lactide (Mp = 126°C) is obtained by the same method starting from rac-lactic acid. This lactide can be readily purified by recrystallization from hot saturated solutions in organic solvents.
- Meso-lactide (Mp = 46°C) is usually extracted by crystallization from the hot solution remaining after recrystallization of rac-lactide and evaporation of

Scheme 4 Polydimeric poly(lactic acid)s obtained by ring opening polymerization.

most of the solvent. It is rather difficult to obtain pure meso-lactide.^[14]

The structure of the cyclic dimers composed of lactic acid enantiomers includes two ester bonds that are chemically equivalent. As soon as one of the ester bonds is broken due to the action of a reagent, the second ester bond is stabilized and can no longer be involved in the polymerization process, although it can be affected by transesterification reactions^[13,14,18] (Scheme 4).

The polymer chains that result from the ROP of lactides are actually polydimer chains according to chain growing by the addition of pairs of repeating units (Scheme 4).^[3,14] This particularity is the source of rather complex structures that are typical of lactic acid polymers obtained by ring-opening polymerization of lactides. The various structures and corresponding structure–properties relationships have been extensively described and discussed in reviews and encyclopedia.^[4,19–22]

The polymerization of lactides can be initiated by a great number of compounds that were identified very early.^[23] However, resulting polymers are not equivalent. Lactide ROP generally leaves an initiator or a catalyst residue at one terminal unit.^[24–26] This particularity is not observed when zinc metal or zinc lactate are used as initiators in bulk polymerization,^[27] all PLAX chain being terminated by OH and COOH end groups. Carboxylic chain ends being involved in the hydrolytic degradation of PLA chains, their presence is one of the major factors that can dramatically affect the degradation of PLA polymers, as discussed later in this article.

The initial list of compounds that are able to polymerize lactides was complemented by more exotic initiators such as alkaline earth derivatives^[28] and other complex catalysts,^[29] polymerizations being conducted either in solution or in bulk. Almost all the possible mechanisms, i.e., anionic, cationic, and coordination–insertion have been proposed, but not always conclusively demonstrated. Despite the number of papers appearing in literature, the mechanisms involved in many polymerization reactions are still a matter of debate, as is the case for stannous or tin octoate (tin(II)

2-ethyl hexanoate). Stannous octoate is largely used in academia and industry. However, fundamental investigations are usually conducted in solution whereas industry prefers bulk polymerizations. Zinc metal was selected in France many years ago.^[30] Nowadays, zinc lactate, which was shown to be the active species, is preferred. Zinc metal and zinc lactate provide polymers with rather different physico-chemical and degradation behaviors as compared with stannous octoate.^[31,32]

Both tin and zinc initiating systems are now approved by the FDA, the former having been the first approved for biomedical applications after being approved as a food additive, the second being a known oligo element. Industrially, the polymerization of lactides is generally carried out at temperatures ranging between 100 and 180°C. It is worth noting that at high temperatures, transesterification reactions can dramatically change the repeating unit distribution of the L and D repeating units of poly(lactic acid) derived from lactides and tend to randomize them although differences remain with respect to bernoullian statistics because transesterification reactions seem to be dependent on the configurations of the units vicinal to reacting ester bonds.^[14] Conversion is generally very high although the resulting polymers often contain residues of monomers and catalysts. For biomedical applications, it is recommended to purify once or twice the crude polymers by the dissolution–precipitation method. Careful purification is a critical factor that determines the behavior and the properties of PLA polymers, in particular, the degradation characteristics. Lactides can be copolymerized with many other heterocyclic monomers such as glycolide,^[33] benzyl malolactonate,^[34] and ϵ -caprolactone.^[35] A particular copolymer composed of largely alternating lactyl and glycolyl units was obtained by ROP of 3-methyl-1,4-dioxane-2,5-dione, a cyclic monomer composed of one lactic acid and one glycolic acid residue.^[36] Such copolymer does not seem to have been tested for biomedical applications yet.

High molar mass PLA polymers have been obtained by postcondensation of oligomeric polycondensates of lactic acids either by using a coupling reagent^[17–37] or a chain extender after appropriated functionalization of chain ends.^[38,39] In the latter case, the resulting polymer chains can contain nonmetabolite residues whose presence must be confronted to requirements of the biomedical applications.

Lactides can lead to diblock and triblock copolymers when polymerization is initiated by tin octanoate in the presence of monoalcohol or diol oligomers. The best example is that of methyl-OH poly(ethylene glycols) and diOH polyethylene glycols.^[39] Particular chain ends can be introduced if low molecular weight monoalcohols are used as cocatalysts in combination with stannous octoate^[23,25] or polymerization is initiated by alkoxides, for instance.^[40]

CHARACTERIZATION OF LACTIC ACID-BASED POLYMERS

PLA stereocopolymers can be characterized by using many techniques and literature is enriching with data issued from solution and solid-state NMR spectroscopies,^[41] ATD, DSC, and TGA,^[42] IRTF and Raman spectroscopies,^[43] MALDI-tof,^[44] and Capillary Zone Electrophoresis.^[45] Stereocopolymers composed of chains enriched in one of the enantiomeric lactyl units can be advantageously characterized by chiroptical properties, namely Optical Rotatory Dispersion and Circular Dichroism.

Because of the pair addition mechanism related to the dimeric structures of lactides that acts in favor of the formation of stereoregular chains, lactide-derived stereocopolymers exhibit higher stereoregularity than polycondensates issued from a bernouillian polycondensation of enantiomeric lactic acids. For instance, in the absence of transesterification reactions, DL-lactide leads to partially isotactic PLA₅₀, whereas meso-lactide leads to partially syndiotactic PLA₅₀.^[14] The use of stereoselective polymers can yield more or less semicrystalline racemic PLA₅₀, depending on the initiating system.^[29] PLA₀ and PLA₁₀₀ can form highly semicrystalline and high melting temperature stereocomplexes.^[17] Therefore, combining the effects of molar mass, molar mass distribution, composition in chiral units, distribution in chiral units, and morphology, PLA_x polymers can be made that cover a very large range of physical, thermal, and mechanical properties. The problem is controlling these properties because they can change dramatically during processing, regardless of the processing method, at the sterilization stage and even on storage.^[11]

Literature is sometimes misleading because authors do not identify the PLA polymer they worked with. The confusion starts at the level of the gross chain composition that can be defined either from the M/M or W/W composition of the monomer feed or from the analysis of chain composition by NMR. In the biomedical field, any scientific contribution dealing with PLA_x polymers should mention the identity of the investigated compounds as accurately as possible, a requirement underlined 20 years ago and still not respected.^[11]

DEGRADATION OF LACTIC ACID-BASED POLYMERS

Basically, the degradation of polymeric materials in an animal or human body can result either from cell-mediated or from chemistry-mediated cleavages of labile bonds or from both. In literature, there is a lot of confusion related to the absence of a standard terminology

and to the misuse of words such as degradable, bioabsorbable, biodegradable, bioresorbable, etc. The term degradation should be reserved to degradations in the absence of living cells or when the mechanism of degradation is unknown. Accordingly, biodegradation ought to be reserved to reflect the degradation due to the biological activity of cells. Bioresorbable should be reserved to qualify polymers that are proved eliminated from the human body after degradation and metabolization to CO₂ and H₂O, or because they can be excreted as small enough oligomers through kidney filtration.

For many years, the degradation in aqueous media, i.e., in vitro as well as in vivo, was regarded as homogeneous (bulk erosion),^[47] although surface erosion was claimed in a few cases.^[1] This was primarily due to the fact that molecular weight changes were monitored by viscometry. Since then, Size Exclusion Chromatography (SEC) has revealed that two populations of macromolecules are often observed when rather large-size devices are allowed to degrade in liquid media and in an animal body as well.^[48,49] Indeed, when a device made of a lactic acid-based polymer is placed in contact with an aqueous medium, water penetrates into the specimen and the hydrolytic cleavage of ester bonds starts and autocatalysis as well. Water absorption is thus a critical factor.^[50] For a time, the partially degraded macromolecules remain insoluble in the surrounding aqueous medium, and the degradation proceeds homogeneously. As soon as the molecular weight of some of the partially degraded macromolecules becomes low enough to allow dissolution of the formed oligomers in the surrounding aqueous medium, the diffusion of these oligomers starts within the whole bulk, with the soluble compounds moving slowly to and off the surface while they continue to degrade. This process, which combines diffusion, chemical reaction, and dissolution phenomena, results in a differentiation between the rates of degradation at surface and interior of the matrix.^[22] In vivo, where the medium is buffered, neutralization of terminal carboxyl groups might also contribute to discriminate the surface degradation rate.

Basically there are four main factors that condition the diffusion–reaction–dissolution phenomena: 1) the hydrolysis rate constant of the ester bond; 2) the diffusion coefficient of water within the matrix; 3) the diffusion coefficient of chain fragments within the polymeric matrix; and 4) the solubility of degradation products, generally oligomers, within the surrounding liquid medium from which penetrating water is issued.^[51]

During degradation, hollow structures can be observed depending on the initial configurational structures of polymer chains and on the existence of initially present or degradation-induced semicrystalline domains.^[48] The formation or not of crystalline residues was mapped and discussed in detail, at least for zinc-derived PLA_x and copolymers with glycolic acid.^[52]

The mechanism of heterogenous degradation contributed very much to the understanding of the effects of many other factors, namely matrix morphology, size and shape, presence of chemically reactive compounds within the matrix, and nature of the degradation medium.^[53] The heterogeneous degradation mechanism provided fruitful information on the behavior that can be expected from lactic acid-based polymers where additives or foreign molecules (oligomers, drug, initiator, and solvent residues) are present or have been introduced. For instance, one can mention the case of an entrapped drug in a PLA-based drug delivery system or when an implanted matrix absorbs compounds by absorption from surrounding body fluids. Indeed, any electrostatic interaction between a PLA matrix and acidic, basic, or amphoteric molecules can dramatically affect the degradation characteristics by changing the natural acid-base equilibrium due to the presence of chain end carboxylic groups. For acidic compounds, one can expect faster hydrolysis of ester bonds. In contrast, in the case of basic compounds, two effects can be observed: base catalysis of ester bond cleavage when the basic compound is in excess with respect to acid chain ends, and decrease of the degradation rate in the contrary.^[51] Examples were reported that deal with oligomers,^[54] residual monomers,^[55] coral,^[56] caffeine,^[57] and gentamycin.^[58] Reviews are available.^[12,59,60]

The heterogeneous degradation mechanism helped also very much in understanding the differences found between the degradation rates observed for films, powder, and microspheres issued from the same batch of PLA₅₀ polymer.^[61] The authors showed conclusively that the smaller the size of a polymer device, the slower the degradation rate. From the same logic, one can understand why porous systems degrade at a slower rate than plain ones, especially if dimensions of the considered device are submillimeter.

Recently, attention was paid to the effects of the initiator on the degradation characteristics of some PLA_x polymers. It has been shown that dramatic differences in repeating unit distribution can be observed in the case of stereocopolymers such as PLA₅₀ polymerized in the presence of stannous octoate or zinc metal.^[62] Later on, it was suggested that, in bulk polymerization of lactides, stannous octoate causes more or less chain end modifications by esterification of alcoholic end groups by octanoic acid and generates hydrophobic residues, which resist purification by precipitation from an organic solution with ethanol or water.^[63,64] Such modifications do not occur in the case of zinc metal or zinc lactate initiations. Whether similar effects can be observed in the case of polymers obtained using other initiating systems, or through solution polymerization, or in the presence of alcohols is still unknown. Indeed, scientists rarely investigated

the effect of resulting structures on degradation characteristics and comparison of literature data is seldom feasible significantly. Nevertheless, the influence of chain end hydrophobization on degradation characteristics of PLA_x polymers is well exemplified by the difference between the so-called H and non H polymers appearing in the catalog of one of the greatest suppliers of PLA_x polymers, namely Boehringer Ingelheim (Germany). At this point, people ought to keep in mind that degradation of lactic acid-based matrices and release of low molecular weight compounds from these matrices depend on experimental conditions and on device's history much more than for any other type of polymeric matrix. It is then strongly recommended again that careful identification of the investigated compounds be included in any paper in the field. Anyhow, this concept of heterogeneous degradation in aqueous media helped very much to understand the in-vivo behaviors of PLA polymers.

CHARACTERISTICS OF THE DEGRADATION OF PLA_x POLYMERS IN VIVO

Most of the basic information regarding biocompatibility, configuration-dependence of degradability and crystallinity, and routes of elimination after ¹⁴C labeling was identified very early.^[2] Until 1981, when it was shown that PLA₁₀₀ and LA-rich stereocopolymers prepared in the presence of zinc metal and carefully purified can last for a year in vivo with less than 10% molecular weight decrease,^[11] literature had reported much shorter half lifetime.^[65-67] Despite these discrepancies, it was conclusively shown that the in-vivo degradability of PLA polymers, copolymers, and stereocopolymers depends on the gross composition and on the content in chiral units.^[68,69] Since then, most of the contributions concluded to excellent biocompatibility of PLA polymers.^[70,71] Year after year, literature was enriched in information on devices made of PLA_x polymers, such as experimental implants for bone surgery^[3,72] or microspheres and nanospheres for drug delivery.^[60] From a general viewpoint, a majority of authors agree to say that poly(α -hydroxy acids) do not degrade enzymatically in an animal body. Discussions were generally based on the comparison of in-vivo and in-vitro degradation characteristics, differences being assigned to the action of enzymes. However the correlation cannot be straightforward. As the particularities of the chemistry-based hydrolytic degradation of PLA polymers showed, one can find many reasons to see different oligomer diffusion and solubilization between a device implanted in vivo and the same device allowed to age in an abiotic medium modeling body fluids. Phenomena like adsorption of proteins, absorption of lipids, and greater solubility of lactic

acid-based oligomers in blood are examples of sources of difference.^[73] Superoxide ions can also contribute if one refers to data reported in the case of sutures.^[74] Anyhow, it has been found that in-vitro and in-vivo degradation characteristics are comparable in the case of small cylinders made of lactic acid-based polymers implanted subcutaneously in rats.^[75] In agreement with these findings, parallel-sided plates implanted intramuscularly in rabbits and similar plates allowed to age in isoosmolar pH = 7.4 phosphate buffer showed similar degradation characteristics except shape modifications that were greater in vivo than in vitro according to the effect of the mechanical stresses generated by muscles.^[76] Nevertheless, the subject is the source of endless debates^[77,78] in the absence of careful characterization of the investigated compounds, including processing and sterilization protocols that are known to affect the initial properties of LA-based polymers. To model body fluids, it is recommended to take into account the physiological environmental pH, ionic strength, and temperature as much as possible. Using 0.13 M pH = 7.4 isosmolar phosphate buffer at 37°C is a current choice although the presence of phosphate ions can be perturbing. The use of any other pH = 7.4 isoosmolar buffered medium is possible.

The glass transition temperature of PLA_x stereocopolymers is in the range of 55–60°C, depending on the composition in chiral units.^[12] It is a critical factor in the case of implanted polymers because absorbed water acts as a plasticizer, thus resulting in a decrease of the glass transition temperature up to below body temperature (37°C). The diffusion of soluble oligomers or drug molecules outside a PLA_x matrix is also very much related to glass transition. Last but not least, raising the temperature to shorten degradation time can be the source of unexpected phenomena that are able to change the regime of degradation from typical of glassy state to typical of degradation in a rubbery state.

All these particularities are of great interest to control the lifetime and the degradation behavior of lactic acid-based polymers in vivo. Nowadays, everybody agrees to conclude that LA-based polymers are remarkably biocompatible. However, secondary and even tertiary inflammatory responses can be observed, respectively, when the release of soluble oligomers becomes critical as in the case of matrices remaining amorphous during the whole degradation process, and later on when crystalline microdomains are released under the form of tiny particles that are very inflammatory and degradation-resistant. Anyhow, once formed during degradation, any tiny lactic acid-based crystalline particulate will be phagocytosed sooner or later to undergo intracellular degradation.^[79] PLA stereocomplexes are normally more resistant to hydrolytic degradation than PLA₁₀₀ polymers, although contradictory data have been published recently.^[80] The best

method to monitor the fate of PLA polymers undergoing degradation within complex living media such as an animal body is radiolabeling. Recently, a method to tritiate lactide and glycolide by catalytic isotopic exchange in the presence of palladium on calcium carbonate was reported that is applicable to any lactic acid-based polymer.^[81,82]

LACTIC ACID-BASED POLYMERS' BIOMEDICAL APPLICATIONS

From a general viewpoint, PLA_x polymers have a high potential as degradable and bioresorbable polymers to make therapeutic devices aimed at helping the body to self repair, i.e., when the prosthetic system is required for a limited period of time.

It is the case of sutures. However, whereas the good fiber-forming, highly crystalline, and rapidly degradable poly(glycolic acid) is well adapted to make sutures, PLA_x semicrystalline polymers are not recommended for this kind of application. Indeed, PLA_x fibers are small-size devices and highly crystalline, two factors that work against the fast degradation requested for the healing of soft tissue. In contrast, rather long lasting PLA_x polymers are of interest to make degradable bone fracture fixation devices such as screws, plates, pins, staples, etc. Nowadays, several devices are on the market for the temporary internal fixation of bone fracture (screws, plates, pins) and anterior cruciate ligament autograft (interference screw) from several companies (Figs. 1 and 2).^[6,83] As early as 1978, a totally bioresorbable composite system composed of PGA fibers reinforcing PLA₁₀₀ matrices, the long-lasting matrix protecting the fastly degraded fibers, was patented.^[84] Later on, other composite systems were proposed such as self-reinforced PGA plates where PGA fibers were embedded in a PGA matrix.^[85] SR-PGA systems went up to clinical and industrial applications. The new generation

of self-reinforced devices is based on PLA polymers.^[86] PLA_x are also worthwhile compounds for bone tissue reconstruction,^[68,70] in particular, they have a potential in maxillar and mandibular reconstruction.^[87] Many potential applications have been proposed such as tiny tubes to help nerve regeneration.^[88]

In drug delivery, the literature is full of examples of PLA_x-based drug formulations and devices such as implants, microparticles, and solid nanoparticles or nanoaggregates made of self-assembling di- and tri-block copolymers.^[89,90] Several reviews have been issued that cover well a very rich field.^[5,60]

Nowadays, one of the most stimulating areas of potential applications is tissue engineering, a technique that consists in culturing cells on a degradable or biodegradable scaffold for the sake of implantation or for cell-growth stimulation and tissue reconstruction. Tissues like skin, bone, and cartilage are the favorite targets of scientists.^[91,92] PLA₅₀ plasticized with oligoPLA₅₀ has been successfully used in periodontal-guided tissue regeneration in animals.^[93] Among the various degradable and biodegradable scaffolds presently under prospect, those made of PLAGA 3D porous devices seem to be the most attractive.^[91,92,94,95] The potential applications have been reviewed.^[96] Another challenge that is considered is the development of bioresorbable stents.

Last but not least, high-scale production of low-cost PLA polymers is becoming a reality, thanks to U.S. and Japanese companies. However, the brands that are commercialized for environmental protection and applications^[97,98] are formulated with additives, and thus, they should be far from being comparable to biomedical grades and they should be considered with great care in case one wants to test their potential in relation to therapeutic applications in humans.

CONCLUSIONS

Lactic acid-based polymers have a great interest in the biomedical and pharmaceutical fields. For several

applications, they have reached the clinical and industrial stages. However, one must keep in mind that PLA is a generic name. Behind this name there are a lot of very different compounds for the reasons we tried to underline in this much-too-short presentation. The future is likely to be oriented toward medicated PLA matrices and devices, thanks to the ability of PLA polymers to accommodate antibiotic and/or antitumoral drugs as well as larger molecules like growth factors and other proteins. Another trend targets the development of functionalized lactic acid-based polymers that should pave the route to more hydrophilic systems, including hydrogels, to cross-linking and to chemical modification.

INTRODUCTION

Poly(lactide-co-glycolide) (PLGA) is a synthetic copolymer of lactic acid (α -hydroxy propanoic acid) and glycolic acid (hydroxy acetic acid). Lactic acid contains an asymmetric carbon atom, and therefore has two optical isomers: L(+) lactic acid and D(-) lactic acid. Lactic acid is present in nature as either an intermediate or an end product in carbohydrate metabolism. It is widely distributed in all living creatures (man, animals, plants, and microorganisms). Glycolic acid occurs in nature to a limited extent. Poly(lactide-co-glycolide) degrades *in vivo* to innocuous products. Its final degradation products are lactate (salt form of lactic acid) and glycolate (salt form of glycolic acid).

Poly(lactide-co-glycolide) can be synthesized by direct polycondensation of lactic acid and glycolic acid. However, the most efficient route to obtain high-molecular weight (MW) copolymers is the ring opening polymerization of lactide and glycolide. Lactide and glycolide are the cyclic diesters of lactic acid and glycolic acid, respectively, and they are prepared by thermal degradation of lactic and glycolic acid oligomers, respectively. Being a biocompatible and biodegradable polymer with adjustable properties and capable of being processed to form a variety of objects, PLGA finds extensive biomedical applications, such as sutures, orthopedic fixation devices, and drug delivery systems. Poly(lactide-co-glycolide) scaffolds are investigated for tissue engineering applications. The synthesis, properties, and biomedical applications of PLGA are discussed in this entry.

SYNTHESIS OF PLGA

Poly(lactide-co-glycolide) can be prepared by the direct polycondensation of lactic and glycolic acid (Scheme 1). The polycondensation reaction can be effected in solution or in the melt/solid state.

As a high degree of dehydration, required for the production of high-MW polymer, is difficult to achieve, polycondensation was considered to be an inadequate method to obtain high polymers.^[1] However, Ajioka et al. prepared high-MW (160 kDa) poly(L-lactic-co-glycolic acid) by azeotropic

dehydration of a solution of L-lactic acid and glycolic acid in diphenylether for 20–40 hr at 130°C using tin powder as catalyst.^[2] The solvents introduce complexity of both process control and purification of the end product. Therefore, polycondensation is preferred to be effected in the melt state. The melt polycondensation system involves two equilibria: the dehydration/hydration for ester formation and the ring/chain equilibrium for cyclic diester formation. In ordinary melt polycondensation, the cyclic diesters lactide and/or glycolide (Scheme 2) are formed by depolymerization because the reaction conditions of high temperature and high vacuum can induce not only dehydration but also formation of the cyclic diesters in equilibrium with the polymer. This prevents further growth of the polymer chain, and a high-MW polymer cannot be obtained.

To overcome this problem, a melt/solid polycondensation method was recently developed (Scheme 3).^[3] In the first step, oligomers are prepared by dehydration of monomers. In the second step, the oligomers are melt-polymerized under vacuum (10 Torr) using, for example, zinc acetate dihydrate or tin chloride dihydrate/*p*-toluenesulfonic acid as catalysts. A third step then follows in which condensation is continued at the solid state for 10 hr under high vacuum (0.5 Torr). It is believed that in the solid state, the polymerization reaction is favored over the depolymerization or other side reactions. With this melt/solid polycondensation method, polymers with MW comparable to the polymers produced by the ring opening polymerization of the cyclic diesters can be produced.

To prepare high-MW PLGA in a relatively short reaction time, it is necessary to proceed by ring-opening polymerization of the cyclic diesters, lactide, and glycolide (Scheme 4). Lactide and glycolide are produced by thermal degradation of lactic and glycolic acid oligomers, respectively, and are commercially available. As the lactide molecule bears two asymmetric carbon atoms, lactide exists in the form of three diastereoisomers (L-, D-, and *meso*-lactide) and a racemate (50/50 mixture of L- and D-lactides commonly referred to as DL-lactide) (Scheme 2). The ring opening polymerization reaction can be conducted at temperatures higher than the melting point of the polymer

Scheme 1 Polycondensation of lactic and glycolic acid.

(melt polymerization), at temperatures lower than the melting point of the polymer (solid-state polymerization), or in solution.

Polymers having high MW can be synthesized using a variety of catalysts, such as powdered zinc, Lewis acids (e.g., zinc chloride and antimony trifluoride), or organometallic compounds (e.g., triethyl aluminum or stannous octoate).^[1,4,5] Stannous octoate is the most commonly used catalyst because of its acceptance by the U.S. Food and Drug Administration as a food stabilizer. When organometallic catalysts, such as diethyl zinc, are employed, the polymerization reaction is considered to follow a coordination mechanism.^[6] The initiation of the reaction is considered to involve a nucleophilic attack of the catalyst species on one of the lactide or glycolide carbonyls leading to the opening of the ring and formation of active species. Lactide/glycolide molecules are then coordinated to the active species to create the polymer chain (Scheme 5).

The situation with the stannous octoate-catalyzed polymerization is more complex. Based on kinetic and spectroscopic data, Kowalski, Duda, and Penczek concluded that stannous octoate is by itself neither an initiator nor a catalyst of lactide polymerization.^[7] Reaction of stannous octoate with hydroxyl containing compounds (e.g., alcohols and water), added in the polymerization feed or present as impurities of stannous octoate, provides the initiating species. Chain growth proceeds by a coordination–insertion mechanism in the $\cdots\text{Sn}-\text{OR}$ bond in a similar way to that shown for $\cdots\text{Zn}-\text{OR}$, as shown in Scheme 5.^[7,8] Transesterification reactions toward the conclusion of polymerization (i.e., at high conversion) may cause a broadening of the MW distribution.^[5,6] The polymerization was found to be first order with regard to the monomer (lactide/glycolide) concentration.^[6,7] The rate of polymerization was initially increased with the concentration of stannous octoate in the polymerization feed, but after reaching a maximum it eventually decreased with further increasing stannous octoate concentration.^[7]

Owing to chain growing by dimer (lactide or glycolide) addition (Scheme 5), the polymer chains that result from the ring opening polymerization of lactide and glycolide are actually polydimer chains. Thus, PLGA formed by ring-opening polymerization of lactide and glycolide is more accurately referred to as poly(lactide-*co*-glycolide). Because of the addition of pairs of repeating units during chain growth, and the existence of different stereoisomers of lactide, poly(lactide) (PLA) homopolymers and PLGA copolymers having different and rather complex configurational structures can be obtained through ring-opening polymerization. Using different mixtures of lactide stereoisomers, stereocopolymers (PLA and PLGA polymers containing L- and D-lactic acid units) having different physical and biological properties can be synthesized.^[4]

Lactide and glycolide of high purity are required to obtain high-MW copolymers. The exclusion of moisture is also essential because it may cause termination of the chain growth or hydrolysis of the monomers to acidic products. Thus, the polymerization is carried out either in high vacuum or in inert atmosphere (e.g., in nitrogen). In practice, the amount and type of the catalyst determine the temperature and the time required to produce high-MW polymer in high yield. As a rule, the higher the amount of catalyst the shorter the time required to produce high-MW polymer. Also, the amount of catalyst required to produce high-MW polymer decreases as the temperature of polymerization increases.^[9] When organometallic catalysts, such as triethyl aluminum and stannous octoate, are employed in lactide/glycolide polymerization, the MW of the polymer initially increases sharply with the catalyst level, and after reaching a maximum it eventually decreases with further increase of the catalyst level.^[1,9,10] The ascending part of the polymer MW vs. catalyst level curve, observed at low catalyst/monomer ratios, may be attributed to the increased rate of polymerization with increasing catalyst levels. The descending part of the polymer MW vs. catalyst-level

Scheme 2 Structures of glycolide and lactide.

Scheme 3 Melt/solid polycondensation of lactic and glycolic (R = H) acid.

curve, observed at high catalyst/monomer ratios, may be attributed to the formation of a higher number of initiating species at high catalyst levels. A higher number of initiating species would initiate a greater number of polymerization reactions, leading to the formation of relatively small chains, i.e., to a decreased MW of the synthesized polymer. In support of the latter consideration, Kricheldorf, Kreiser-Saunders, and Stricker, using relatively high stannous octoate proportions in L-lactide polymerizations at 180°C, found that the MWs of synthesized polymers paralleled the monomer/stannous octoate ratio.^[8] As glycolide is more reactive than lactide, PLGA copolymer chains may contain blocks of glycolide units rather than a random distribution of glycolide and lactide units.^[5] Indeed, PLGA copolymers produced by melt polymerization under vacuum were found to have heterogeneous microstructure, based on ¹³C-NMR spectra.^[9]

The ring-opening polymerization of lactide and glycolide in bulk (melt or solid polymerization) is usually carried out at temperatures ranging between 130°C and 220°C over a period of 2–6 hr. Stannous octoate is added at 0.03–0.1% w/w proportions. Under these conditions, copolymers with molecular weights in the range 10⁴–10⁵ are prepared at high conversions (higher than 90%).^[5] Long reaction periods at high temperatures may cause significant depolymerization (chain unzipping) and should therefore be avoided.^[9,10] It is pertinent to remember here that the cyclic diesters lactide and glycolide are prepared by thermal breakdown of low-MW PLA and PGA, respectively. For PLGA copolymers synthesized under identical conditions, increasing the glycolide content of the feed resulted in copolymer of lower MW, indicating that more severe reaction conditions are required to polymerize glycolide than lactide.^[9] A pilot-scale polymerization process for the preparation of PLGA has been described in detail.^[11]

As previously mentioned, minor reactions, such as ester interchange and chain unzipping, may take place during lactide/glycolide polymerization, which lead to

the formation of low-MW species (e.g., cyclic dimers, trimers, cyclic oligomers, and even monomers). These, together with unreacted monomers and catalyst residues, may adversely affect the properties of the final product, such as mechanical strength and degradation rate, and should therefore be removed by careful purification (once or twice) of the crude polymer. The purification can be effected by first dissolving the polymerization product in dichloromethane or chloroform and then precipitating the polymer in excess methanol or diethyl ether. The purified polymer is collected by filtration and dried. Alternatively, after the polymerization is complete, residual monomers are removed from the polymer melt by applying vacuum.^[11] The purified polymer is stored under vacuum or is packaged under nitrogen in moisture-proof packages.

P

POLY(LACTIDE-CO-GLYCOLIDE) PROPERTIES

A distinct advantage of PLGA copolymers, and the one that characterizes this family of polymers, is that they can be designed so as to acquire specific, desired properties. A broad spectrum of performance characteristics can be obtained by careful manipulation of three key properties of the copolymer: composition (lactide/glycolide ratio), lactide stereoisomeric composition (L- or DL-lactide), and MW. The notation L-PLGA(*X*:*Y*) or DL-PLGA(*X*:*Y*) will be used in this entry to describe PLGA copolymers consisting of *X* mol% L- or DL-lactide, respectively, and *Y* mol% glycolide.

Solubility

Solubility in common organic solvents is important with regard to the ease of polymer characterization, processing, and application. Poly(lactide-co-glycolide) containing less than 50% glycolyl units (glycolic acid units) is soluble in most common organic solvents,

Scheme 4 Ring opening polymerization of lactide and glycolide.

Scheme 5 Coordination mechanism of polymerization of lactide.

such as halogenated hydrocarbons (chloroform and dichloromethane), ethyl acetate, acetone, dioxan, and tetrahydrofuran. Poly(lactide-*co*-glycolide) rich in glycolyl units (50% and higher) is insoluble in most organic solvents, and uncommon solvents, such as hexafluoroisopropanol, have been used in characterization and processing of PLGA with high content of glycolyl units.

Crystallinity

Crystallinity affects the rate of degradation and the mechanical properties of PLGA. Poly(lactide-*co*-glycolide) crystallinity depends on chemical composition (lactide/glycolide ratio) and stereoisomeric composition of lactide units in the copolymer.^[5,12] Poly(DL-lactide-*co*-glycolide) consisting of 0–75% glycolyl units is amorphous. Poly(L-lactide-*co*-glycolide) with 25–75% glycolyl units is also amorphous. The crystallinities, glass transition temperatures, and melting points of poly(L-lactide-*co*-glycolide) copolymers are presented in Fig. 1.

Thermal Stability

Poly(lactide-*co*-glycolide) copolymers are thermoplastic materials exhibiting adequate heat stability in the absence of moisture. Thus, they can be melt processed to produce sutures, orthopedic fixation devices, and drug delivery systems. Poly(lactide-*co*-glycolide) degrades to lactide and glycolide after prolonged heating above 200°C under nitrogen or vacuum.^[5] At lower temperatures, thermal degradation is a function of time and temperature and is considerably accelerated by impurities, residual monomers, and humidity.

Mechanical Properties

The mechanical properties (strength, toughness, and elasticity) of PLGA depend on composition (lactide/glycolide ratio), lactide stereochemistry, MW, and processing.^[12,13] Crystalline polymers, such as poly(L-lactide) and poly(glycolide), exhibit significantly higher mechanical strength than the amorphous poly(DL-lactide) and the amorphous or less crystalline PLGA. Certain mechanical properties of commonly used lactide/glycolide polymers are presented in Table 1.

Degradation

Poly(lactide-*co*-glycolide) degrades *in vitro* through hydrolysis of ester bonds. The final degradation products *in vitro* are lactic acid and glycolic acid. Poly(lactide-*co*-glycolide) degradation has been proposed to be a two-stage process.^[14] During the first stage, random hydrolytic cleavage of ester bonds occurs, leading to MW reduction. The chain scission process appears to follow first-order kinetics. The second stage is characterized by the onset of mass loss from the polymer matrix, accompanied by an increase in the rate of chain scission. Mass loss begins when the polymer has been degraded to a degree where chain fragments small enough to dissolve in the degradation medium and diffuse out from the polymer matrix have been generated. Because esterification of carboxylic acid chain ends (end-capping) to reduce the initial carboxylic end group concentration was shown to retard degradation, chain scission is believed to be autocatalyzed by the generated carboxylic acid end groups.^[14,15]

After the early work on PLGA, hydrolytic degradation was regarded as homogenous (bulk erosion).^[14] However, more recent research has shown that relatively large-sized PLGA devices degrade (both *in vitro* and *in vivo*) through a heterogenous process, with the degradation of the core being faster than that of the surface of the device.^[16] In Fig. 2, the core of poly(DL-lactide-*co*-glycolide) (50:50) matrices (cylindrical tablets) was completely degraded (dissolved away, so that the matrix appeared to be centrally hollow under the electron microscope) after 20 days' incubation in phosphate buffer, pH 7.4.^[17] Vert and coworkers introduced the concept of heterogenous PLGA degradation related to "diffusion–reaction–dissolution" phenomena: the soluble oligomers that eventually form during polymer degradation can escape faster from the surface than from the interior of the matrix, resulting in a smaller autocatalytic effect at the

carboxyl-depleted surface and, consequently, a lower degradation rate at the surface than in the interior of the matrix.^[16] According to the diffusion–reaction–dissolution model, relatively large PLA devices, which degrade via a heterogenous mechanism, were found to degrade faster than relatively small PLA devices that degrade via a homogenous mechanism.^[16]

In vivo degradation of PLGA proceeds through hydrolysis of ester bonds, as the *in vitro* degradation. No involvement of the living tissues (cells and enzymes) is considered to take place during the early stages of degradation, apart from that resulting from the foreign body response. During foreign body reaction, cells accumulating around the polymer implant may produce free radicals and acidic products that could accelerate polymer hydrolysis. Enzyme-catalyzed PLGA degradation *in vivo* has been claimed by some investigators based on differences between the *in vitro* and the *in vivo* degradation characteristics. Although degradation has been shown to be accelerated by enzymes *in vitro*, no convincing data have been presented for enzymatic hydrolysis of PLGA *in vivo*.^[18] Enzymes are not the only body constituent that could affect PLGA degradation. Phenomena like adsorption of proteins, absorption of lipids, and greater solubility of PLGA oligomers in blood may be the sources of differences between the *in vitro* and *in vivo* degradation.^[19] However, when degradation has advanced to the stage that implant coherence is lost and the matrix begins to fragment, living tissues participate actively in further polymer degradation; small enough fragments (less than 10 μm) are assimilated by phagocytes and are further hydrolyzed intracellularly to monomeric anions (lactate and glycolate).^[11,20] Lactate and glycolate are also the final products of PLGA extracellular hydrolysis. The final stage of *in vivo* degradation is elimination. During this stage, L-lactate is converted into carbon dioxide and pyruvate. Pyruvate then enters the Krebs cycle. D-Lactate is not metabolized and has only been detected in excreta.^[1,21] Glycolate is excreted

Fig. 2 Scanning electron microscope picture of a DL-PLGA (50:50) tablet after 20 days of incubation in phosphate buffer, pH 7.4 at 37°C. (From Ref. [17].)

directly in the urine or may be oxidized to glyoxylate, which is then converted to glycine, serine, and pyruvate. Pyruvate then can enter Krebs cycle, as before, with lactate.^[11] Several studies reported that PLGA degrades at similar rates in vitro (in media modeling body fluids) and in vivo. Other studies, however, found faster PLGA degradation in vivo than in vitro. This discrepancy is probably due to differences in the experimental conditions, degradation parameters measured, and types of polymers involved in these studies. From a PLGA device development perspective, an in vivo degradation rate higher to that measured in vitro in simulated body fluids should be taken into account.

The factors affecting the rate of PLGA degradation are well documented in the literature and are those related to the following.^[20,22,23]

1. Polymer characteristics, such as chemical composition (lactide/glycolide ratio) monomer distribution pattern, chain-ends chemical composition, MW, MW distribution, and polymer purity (e.g., residual monomers).^[24]
2. Device characteristics, such as size, shape, porosity, and presence of additives (e.g., acidic or basic compounds, plasticizers, or drugs).
3. Melt-processing, annealing, and sterilization.
4. Environment in which degradation takes place, such as site of in vivo implantation, and the pH and temperature of the degradation medium.

Chemical composition and lactide stereoisomeric composition are the most influencing factors for PLGA degradation as they determine, among other properties, the hydrophilicity and the crystallinity of the polymer. Among the first to evaluate the effect of composition on PLGA degradation rate in vivo were Miller, Brady, and Cutright.^[25] They found that PLGA (50:50) was the fastest degrading composition, with the

degradation rate being decreased when either lactide or glycolide content of the copolymer was increased (Fig. 3). Although the degradation rates reported may be a little higher than those obtained in recent years, probably due to better standardization of the experimental conditions and better characterization of polymers in more recent degradation studies, the trends shown in Fig 3 have been confirmed by studies conducted after the work of Miller, Brady, and Cutright.^[25]

The effect of composition on PLGA degradation (Fig. 3) can be explained based on the combined effects that the changes of composition have on copolymer hydrophilicity and crystallinity. An increase in hydrophilicity increases the rate of PLGA degradation, whereas an increase in crystallinity has the opposite effect. Hydrophilicity increases as the proportion of the more hydrophilic glycolide in the copolymer increases and crystallinity increases as the proportion of

Fig. 3 Half-life in months of lactide/glycolide polymers implanted in rat tissue. (From Ref. [25].)

glycolide or L-lactide units exceeds 75% (Fig. 1). Increased hydrophilicity and decreased crystallinity account for the increased PLGA degradation rate as the lactide content decreases from 100 mol% to 50 mol% (Fig. 3). In addition, glycolic linkages are hydrolyzed faster than the lactic linkages and this may also contribute to the observed increase in degradation rate with increasing glycolide content of PLGA copolymers from 0 to 50 mol% glycolide (Fig 3).^[22] However, with a further increase of the glycolide content, crystallinity of the copolymer increases and outweighs the effect of increased copolymer hydrophilicity on degradation. The net result is a decrease in degradation rate as the glycolide content of PLGA increases from 50 to 100 mol% (Fig 3). By changing the lactide/glycolide ratio and lactide stereoisomeric composition, polymers having *in vivo* degradation times from a few weeks to more than 2yr can be produced (Table 2).

Not only the monomer proportion, but also the distribution pattern of the two monomers in the copolymer chains (copolymer “microstructure”) may affect the degradation of PLGA copolymers that are rich in glycolide. As glycolide is more reactive than lactide, these copolymers may contain blocks of glycolide rather than a random sequence of glycolide and lactide.^[5] At the same monomer ratio, the copolymers having a homogenous microstructure (random monomer sequence) are expected to degrade faster than the copolymers having a heterogenous microstructure.^[26]

Poly(lactide-*co*-glycolide) degradation time increases with the average MW of the copolymer.^[15,27] Apart from the average MW, the MW distribution may also affect PLGA degradation. A wide MW distribution would indicate the presence of relatively large numbers of carboxylic end groups, which can facilitate the autocatalytic degradation of the polymer chains.^[20]

The chemical composition of chain ends could significantly affect PLGA degradation. The chemical

composition of the chain terminus depends on the type of catalyst/initiator used in polymerization, but it can be modified after PLGA preparation. It has been reported, for example, that stannous octoate causes chain-end modification by esterification of alcoholic end groups by octanoic acid and generates hydrophobic residues.^[28] Such modifications do not occur with zinc metal or zinc lactate initiators, and, as a result, these initiators provide PLGA polymers with different physicochemical and degradation properties as compared with stannous octoate. The influence of the chain-end composition on PLGA degradation has been exploited by PLGA suppliers (e.g., Boehringer Ingelheim in Germany and Alkermes in the United States), which have commercialized copolymers with free carboxyl end groups exhibiting faster degradation than normal copolymers of the same composition but with ester end groups (Table 2).

Sterilization by ionizing γ - or β -rays has been shown to cause radiation dose-dependent degradation of PLGA.^[5,29] On the contrary, sterilization by ethylene oxide does not appear to adversely affect PLGA properties. Both γ irradiation and ethylene oxide have been applied to sterilize commercial PLGA devices. Recently, plasma sterilization was introduced as a sterilizing method for polyester devices. A low-temperature radiofrequency plasma treatment was applied to sterilize PLA pins. Treatment with oxygen or carbon dioxide plasmas at a power of 100 W for 15 min sterilized the pins efficiently. The method caused a slight increase of the MW of the polymer, whereas it did not adversely affect the crystallinity and the mechanical properties of the polymer.^[30]

Biocompatibility and Tissue Reactions

The biocompatibility and nontoxicity of PLGA polymers were first demonstrated with the application of these polymers in the production of biodegradable sutures. Dexon (PGA) and Vicryl L-PLGA (8:92) sutures have successfully been used in the clinic for more than 30 yr.

In general, host responses to a polymeric implant are affected by polymer physical and chemical properties and implant properties (volume, shape, and surface characteristics) and are considered to be tissue-dependent, organ-dependent, and species-dependent.^[20] Several studies have shown that PLGA implantation in bone or soft tissues of animals causes none or only a mild inflammatory response, which diminishes with time.^[31–33] No toxicity or allergic responses were observed.

Soft tissue responses to PLGA occur in three phases.^[20] The first phase includes the initiation, resolution, and organization of the acute and chronic

^aCopolymer with free carboxyl end groups.

inflammatory response. A minimal inflammatory reaction with the presence of polymorphonuclear leukocytes, lymphocytes, plasma cells, and monocytes is observed. The second phase is characterized by the presence of foreign body reactions with the accumulation of monocytes, which differentiate to macrophages, which in turn may fuse or join together to form giant cells, and fibroblast infiltration, which leads to implant encapsulation (and progressive invasion) by connective tissue. Formation of blood capillaries (neovascularization), which surround and invade the implant, is also observed. The third phase is characterized by implant fragmentation and phagocytosis of small fragments by macrophages and foreign body giant cells. Also, fiber formation and neovascularization are enhanced and connective tissue replaces the resorbed polymer. The duration of the second and third phases depends on the rate of polymer degradation. The implants are finally totally resorbed and replaced by connective tissue. Similar responses are observed when PLGA is implanted intraosteally.^[31,33]

A mild foreign body reaction is elicited on PLGA implantation with accumulation of histiocytes and mast cells in close vicinity to the implant. A bony capsule builds around the implant with a fibrous interface separating the osteoid line from the polymer. Polymer degradation is accompanied by a fibrous and vascular invasion of the cracks that develop. The implant is progressively replaced by bone, and polymer fragments resulting from polymer degradation are surrounded by giant and mononucleated cells. Polymer debris is observed intracellularly. The implant is finally replaced by woven bone.

Clinical trials of PLGA application in man as sutures and fracture fixation devices (rods, pins, screws, and plates) have confirmed the biocompatibility of PLGA polymers.^[34-36] Late-stage severe foreign body reactions in about 5-8% of patients with PGA rod implants have been reported.^[11] The factors that may contribute to late-stage body reactions are numerous and complex. Polymer purity appears to be important. This is because a much lower incidence of late-stage

foreign body reactions has been observed with purified melt processed PLA than with bulk PLA, which may have contained a relatively high level of residual lactide.^[11] It has also been suggested that the occurrence of inflammatory reactions may depend on the anatomical region, the capacity of the tissue to clear the degradation products, and the volume of polymer implanted.^[37] Tiainen et al. noted that the complications in the use of resorbable polymeric devices reported in the literature mainly concerned homopolymers (L-PLA and PGA) and not PLGA copolymers.^[33]

BIOMEDICAL APPLICATIONS

Lactide/glycolide homopolymers and copolymers have been applied in the clinic as sutures, fixation devices in bone surgery (plates, screws, and pins), and drug delivery systems. Commercially available PLGA products are presented in Table 3. Poly(glycolide) and glycolide-rich poly(L-lactide-*co*-glycolide) have good fiber-forming properties and suitable (relatively fast) degradation rate to be applied as sutures.^[34]

The use of PLGA in bone surgery offers significant advantages. First, implant degradation obviates the need for a second surgical event for removal. Second, the implant can be engineered to degrade at a rate that will slowly transfer load to the healing bone, resulting in a healed bone, which is strong and has no tendency to refracture on implant removal. The latter is a serious problem with metal implants, where the load is exclusively carried by the rigid implant during bone healing. Crystalline PLA and L-lactide-rich poly(L-lactide-*co*-glycolide) have appropriate mechanical properties (high strength and tensile/flexural modulus), especially when reinforced, and the degradation rate is slow enough to be applied for orthopedic fixation.^[38,39] Self-reinforced, amorphous PLGA copolymers of adequate mechanical strength and appropriate rate of *in vivo* degradation have recently been developed as osteofixation materials in craniofacial surgery.^[33]

Amorphous PLGA polymers have received wide attention as excipients in controlled drug delivery systems and as antigen carriers in the development of novel vaccines.^[40-42] Apart from their established biocompatibility, the main reason behind the extensive investigation of PLGA polymers for drug delivery applications is their controlled degradation. By controlling the rate of *in vivo* degradation, the rate of drug release can be controlled and delivery systems with tailor-made drug release properties can be developed. For example, in the area of cancer treatment, a single once-a-month injection of a PLGA depot of goserelin provides a continuous supply of the required amount of drug for 1 mo and has replaced 30 daily injections

of the drug. Currently, a number of approved drug products in the market utilize PLGA polymers (Table 3).

Tissue engineering can be used to restore, maintain, or enhance tissues and organs. Poly(lactide-*co*-glycolide) porous scaffolds have been proposed as three-dimensional templates to guide tissue regeneration.^[43]

CONCLUSIONS

Poly(lactide-*co*-glycolide) copolymers represent an important family of polymers for medicine. They are biocompatible and biodegradable, degrading *in vivo* to innocuous products. In some cases, foreign body reactions on *in vivo* implantation can be minimized by careful control of polymer properties (e.g., purity or degradation rate). Poly(lactide-*co*-glycolide) properties can be tailored for the specific application by simply changing the lactide/glycolide ratio and/or lactide diastereoisomeric structure. Poly(lactide-*co*-glycolide) application in controlled drug delivery and orthopedics has grown in the last two decades and is expected to grow further in the years to come. Owing to the progress in molecular biology and genetics, an ever-increasing number of novel types of drugs (recombinant proteins and genes) will become available. Efficient *in vivo* administration of these drugs will require the development of novel delivery technologies involving, among others, PLGA carriers. Poly(lactide-*co*-glycolide)-based vaccines, reducing or even eliminating the need for booster immunizations or capable of inducing the appropriate type of immune responses (e.g., cytotoxic T cell responses against viral infections or cancer), will be clinically tested. Tissue engineering is the new field where PLGA copolymers are expected to make a major impact in the near future. Clinical application of PLGA scaffolds in tissue engineering is expected to be realized, when the progress in fabrication techniques and scaffolds properties will allow the PLGA scaffolds to meet important clinical design criteria, such as the ability to be fabricated during surgery and being tailored for specific applications. The scaffolds can be designed to release, at a controlled rate, growth factors that induce cellular differentiation and tissue growth *in vitro* or cell migration into the wound site *in vivo*.^[44] Copolymers of PLGA with other polymers may also find significant biomedical applications in the years to come. For example, block copolymers of PLGA with poly(ethylene glycol) have been applied for the preparation of surface engineered nanoparticulate drug carriers. These carriers exhibit long-circulation properties in blood following intravenous administration and are currently being investigated for drug-targeting applications.^[45]

INTRODUCTION

In this article, the fabrication of polymeric foams (cellular solids) will be discussed in general terms while providing examples of processes that are suitable for the processing of biodegradable polymers in the context of TE. Parameters that are used to describe foam properties will also be briefly discussed.

OVERVIEW

Polymer foams or polymeric cellular solids can be best described as a dispersion of gas in a solid. Polymer foams may also be described as an emulsion of air in a polymeric phase. The density of the foam dictates the major and minor phases of this air-polymer emulsion, which is a function of its porosity. The extent of porosity and the nature of the pores (gaseous voids) and their relationship to one another governs and dictates the changes in mechanical properties as a solid (dense) polymer evolves into a foam. This process of transitioning from a solid to a less dense gas-filled structure is generally referred to as foaming. Porosity can be introduced in a polymer matrix by a variety of means. The structural and mechanical characteristics of the foamed material are influenced to a significant extent by the foaming process. Because the uses of polymer foams extend from applications as mundane as wall insulations, chair cushions, vibrational dampeners, and shock absorbers to the more esoteric such as bioreactors for separations and scaffolds for tissue engineering (TE), the requirements with respect to the extent and nature of porosity vary over a wide range. Different polymers can be used to generate tailored foams for some of the aforementioned applications. The book on cellular solids by Gibson and Ashby is highly recommended for those seeking a more in-depth analysis and mathematical treatment of foam structure and properties.^[1]

CELLULAR SOLIDS

An important characteristic of a porous material is its relative density (ρ_{rel}). Relative density for a foam is defined as the ratio of the foam density to the density of the virgin material:

$$\rho_{rel} = \frac{\rho_{foam}}{\rho_{polymer}} \quad (1)$$

Foams can be characterized into distinct groups based on their ρ_{rel} . As the ρ_{rel} of a foam increases, the void (cell) walls thicken, the pores become less connected, and the porosity diminishes. Conversely, as the ρ_{rel} decreases, the void walls get thinner, voids (cells) become interconnected, and the porosity increases. As the cells become interconnected and cell walls coalesce, the architecture of the porous solid will evolve from one that is dominated by closed cells to one with an open-cell architecture, eventually resulting in a bicontinuous structure of polymer phase and gaseous phase. The evolution and morphology of the cells (pores) is dictated to a significant extent by the nature of the foaming process and the pore-forming agent, i.e., the porogen. Cellular solids by definition are porous materials with a ρ_{rel} less than 0.3. Above this density the morphology of a porous solid evolves from one of interconnected pores to isolated pores. The porosity of the porous polymer is defined as follows:

$$P = (1 - \rho_{rel}) \quad (2)$$

Cellular solids can possess both closed-cell and open-cell architecture. The transition from a closed-cell to an open-cell architecture occurs when adjacent cells fuse via a process called reticulation. This process is typically accompanied by an increase in porosity and can occur under certain foaming conditions as discussed later.

STRUCTURAL, MORPHOLOGICAL, AND MECHANICAL REQUIREMENTS OF POLYMER FOAMS FOR TE APPLICATIONS

The structural, morphological, and mechanical requirements for polymer foams when used as scaffolds for TE are quite different from those required for more traditional applications.

1. Polymer foam scaffolds must be derived from bicompatible degradable polymers to ensure cytocompatibility, correct evolution of tissue, and *in vivo* biocompatibility. In some instances, a nondegradable bicompatible polymer might be adequate. Applications for a nondegradable porous scaffold material may include cartilage, bone, and certain muscular regenerative applications. On the whole, a degradable polymer is preferred. As a consequence, the choice of synthetic polymers is significantly diminished; usable polymers include poly(esters) derived from α -hydroxyacids, α,ω -hydroxyacids such as caprolactones, orthoesters, and *p*-dioxanone; poly(anhydrides); poly(ethyleneglycol); and other polyols.
2. The pores in polymeric scaffolds for TE have to be highly interconnected to allow for easy diffusion of cells and nutrients during the tissue cultivation process.
3. The polymer content in a scaffold has to be minimal, *i.e.*, the porosity has to be relatively high to ensure rapid resorption of the scaffold so as to maximize the growth of the tissue.
4. The foam scaffold has to be mechanically robust enough to withstand both handling during and after association with mammalian cells and fluid-induced shear stress during cultivation in a bioreactor or after implantation in a tissue site of interest. The mechanical robustness of the scaffold becomes even more critical when mechanical stimulation is used as a means to stimulate tissue development.

FABRICATION OF POLYMER FOAMS

Gas Foaming

Polyurethane, polystyrene, and polyethylene foams are typically manufactured by a gas foaming process. In this process, gas bubbles are introduced within a polymer melt or monomer solution either by blowing an inert gas such as nitrogen into the melt (solution) or by the use of a chemical blowing agent.^[2] Chemical blowing agents are inorganic or organic compounds that liberate gaseous molecules such as carbon dioxide and nitrogen upon heating. In a variation of this

approach, gas bubbles can be generated *in situ* by reaction of one of the monomer components such as isocyanate with water to liberate carbon dioxide. Furthermore, volatile solvents such as halogenated hydrocarbons can be utilized to generate bubbles primarily composed of solvent vapors. The gas is then dispersed using mechanical means such as stirring, and the bubbles are allowed to nucleate and grow. Once the gas bubbles have stabilized, the polymer phase is either rapidly solidified or physically cross-linked, as in the case of polyurethane foams, to impart structural stability. The rate of nucleation and growth of gas bubbles and bubble size is a function of solution viscosity and surface tension. Due to the dynamics of bubble growth and fusion, gas foaming yields voids that have a polyhedral structure.

Porosity can also be introduced in a solid by first saturating the solid with an inert gas under high pressure and then relieving the pressure causing rapid expansion of the gaseous phase. Heating the polymer to its glass transition temperature, where it begins to exhibit viscoelastic flow, further enhances the segregation of the gaseous phase into stable bubbles. This process can yield microcellular plastics with isolated closed-pore and reticulated open-pore morphology. Mooney and coworkers have adapted this approach to produce poly(DL-lactic-co-glycolic acid) (PLGA) foams with partially open-cell architecture for TE applications.^[3] The advantage of this process with regard to the fabrication of scaffolds for TE is that it can be carried out in the absence of solvents. Residual solvents in polymer foams can pose biocompatibility problems *in vivo*.

Removal of a Fugitive Phase

Removal of a fugitive phase is one of the oldest techniques to create porosity in a matrix. It is the preferred method for the production of porous ceramics and metals. In this process, an organic component such as a polymer or wax serves as the fugitive phase and hence the porogen. The desired inorganic phase is dispersed with the organic fugitive phase and then heated above the pyrolysis temperature of the fugitive phase to generate the voids, with concurrent sintering of the inorganic phase. The advantage of this approach is that the porosity and pore morphology can be controlled *a priori*. Yet another advantage is that foams with both isolated closed-pore and open-pore morphology may be obtained. However, because synthetic polymers are not capable of surviving the pyrolysis step, other mechanisms to remove the fugitive phase have been explored.

Pore formation using a water-soluble fugitive phase
