Contents

Volume 1

<i>Preface</i>	xxix
Adhesives <i>J. Brock Thomas, Nicholas A. Peppas</i>	1
Allografts <i>Kirby S. Black, Patti E. Dawson</i>	8
Alumina <i>Jae Sung Lee</i>	17
Angiogenesis Inhibitors <i>Shaker A. Mousa, Ahmed S. Mousa</i>	26
Animal Models for Bone Tissue Engineering <i>Mark P. Mooney, Michael I. Siegel</i>	33
Animal Surrogate Systems for Toxicity Testing <i>Michael L. Shuler, Gretchen J. McAuliffe, Daniel A. Tatosian</i>	51
Antimicrobial/Antibiotic (Infection Resistance) Materials <i>Franck Furno, Roger Bayston</i>	61
Antimineralization Treatment <i>Bart Meuris, Willem Flameng</i>	71
Articular Cartilage Biomechanics <i>Jennifer S. Wayne</i>	85
Artificial Heart Fluid Dynamics: Positive Displacement Pumps <i>Steven Deutsch, John M. Tarbell, Keefe B. Manning, Gerson Rosenberg, Arnold A. Fontaine</i>	95
Artificial Muscles <i>Mohsen Shahinpoor</i>	108
Artificial Neural Networks: An Overview <i>Evangelia Micheli-Tzanakou</i>	119
Bioactive Glass <i>Marivalda M. Pereira, Larry L. Hench</i>	133
Bioactive Materials and Scaffolds for Tissue Engineering <i>Qi-Zhi Chen, Aldo R. Boccaccini</i>	142
Bioadhesion <i>John D. Smart</i>	152
Biocatalysis <i>Claire F. Komives, Ruizhen Rachel Chen</i>	162
Biocompatibility Testing <i>Joel D. Bumgardner, Marcia Vasquez-Lee, Keertik S. Fulzele, Daniel H. Smith, Kellye D. Branch, Seth I. Christian, David L. Williams</i>	169
Biocomposites <i>Huinan Liu, Grace E. Park, Thomas J. Webster</i>	179
Biodegradable Polymers: An Overview <i>Chih-Chang Chu</i>	195
Biofilms <i>Clive Edwards</i>	207
Biofunctional Polymers <i>Jennifer L. West</i>	218
Biologic and Synthetic Apatites <i>Besim Ben-Nissan, Racquel LeGeros</i>	225
Biological Adhesives from Nature <i>Lloyd D. Graham</i>	236
Biological Effects of Radiofrequency Electromagnetic Field <i>Henry Lai</i>	254
Biomaterials Immune Response <i>Sandra C. P. Cachinho, John A. Hunt</i>	262
Biomaterials: Protein–Surface Interactions <i>Robert A. Latour, Jr.</i>	270
Biomedical Ethics <i>Daniel E. Wueste</i>	285
Biomimetic Materials <i>Jun-ichi Kikuchi, Atsushi Ikeda, Mineo Hashizume</i>	294
Biopotential Amplifiers <i>Albert Lozano-Nieto</i>	301
Bioreactors <i>Lito C. Mejia, Kent S. Vilendrer</i>	310
Biorubber/Poly(Glycerol Sebacate) <i>Yadong Wang</i>	327
Biosensors <i>Jerome S. Schultz</i>	335
Biosynthesis and Applications of Alginates <i>Bernd H. A. Rehm</i>	350
Biphasic Calcium Phosphate (BCP) Bioceramics: Chemical, Physical, and Biological Properties <i>Guy Daculsi, Racquel LeGeros</i>	359
Blood-Material Interactions <i>Stephen R. Hanson</i>	367
Blood Purification <i>Yukihiko Nosé, Hisashi Okubo</i>	378

Blood Vessel Mechanics <i>Ruth J. Okamoto</i>	392
Bone Cement <i>Julie Hasenwinkel</i>	403
Bone Fracture Fixation <i>Eleftherios Tsiridis, Constantin Schizas</i>	413
Bone-Implant Interface <i>D. A. Puleo</i>	423
Bone Plates and Screws, Bioabsorbable <i>Riitta Suuronen, Christian Lindqvist</i>	432
Bone Remodeling <i>Elisabeth H. Burger, Jenneke Klein-Nulend, Theo H. Smit</i>	439
Burn Dressing <i>Andrew Burd</i>	448
Calcium Phosphate Ceramics: New Generation Produced in Japan <i>Atsuo Ito, Hajime Ohgushi</i>	461
Cardiac Assist Devices <i>Keefe B. Manning, Conrad M. Zapanta, John M. Tarbell</i>	470
Cardiac Bioelectricity <i>Clive M. Baumgarten</i>	480
Cardiac Catheters <i>Tommy L. Miller, Juana Maria Alfaro, Deepak Banerjee, Benjamin Lee, Anthony J. Minisi</i>	491
Cardiac Elastography, Full-Field Development <i>Tomy Varghese, Q. Chen, P. Rahko, James A. Zagzebski</i>	506
Cardiac Output, Basic Measurement Principles <i>Leslie A. Geddes</i>	514
Cardiac Pacemaker <i>Rakesh K. Pai, Fred M. Kusumoto</i>	532
Cardiac Patch Engineering <i>Michael J. Yost, Robert L. Price, David G. Simpson, Wentao Yan, Louis Terracio</i>	542
Cartilage Regeneration <i>Nic D. Leipzig, Kyriacos A. Athanasiou</i>	552
Cell Culture Assays <i>P. J. Doherty</i>	561
Cell-Material Interaction <i>Aditya Chaubey, Karen J. L. Burg</i>	568
Centrifugal Blood Pumps <i>Gerald E. Miller</i>	574
Ceramics <i>Robert H. Doremus</i>	585
Ceramics in Dentistry <i>Nicolas M. Jedyndakiewicz</i>	593
Chitosan <i>M. N. V. Ravi Kumar, S. M. Hudson</i>	604
Chondroitin Sulfates <i>Nicola Volpi</i>	618
Collagen <i>Matthew J. Beckman, Kelly J. Shields, Robert F. Diegelmann</i>	628
Collagen Fixation <i>Thomas J. Koob</i>	639
Collagen Processing <i>Michael J. Yost, Louis Terracio, Robert L. Price</i>	652
Composites <i>Chia-Wei Wang, Ann Marie Sastry</i>	659
Compression of Digital Biomedical Signals <i>Tapio Grönfors, Martti Juhola</i>	677
Computer-Assisted Surgery <i>Thomas L. Husted, Timothy J. Broderick</i>	687
Conductive Polymers <i>Gordon Wallace, Leon Kane-Maguire</i>	695
Confocal Microscopy <i>Denis Semwogerere, Eric R. Weeks</i>	705
Contact Lenses: Silicone Hydrogels <i>Paul C. Nicolson, Jürgen Vogt</i>	715
Control of Movement <i>Dejan B. Popović</i>	729
Controlled Release <i>Brent Vernon, Michael Wegner</i>	739
Corneal Implants <i>Traian V. Chirila, Celia R. Hicks</i>	747
Corrosion <i>Rachel L. Williams</i>	754
Cryopreservation of Living Cells <i>Dayong Gao, J. K. Critser</i>	762
Defibrillators <i>Paul Wang</i>	772

Volume 2

Degradable Polymer Composites <i>Debra D. Wright</i>	779
Dendrimers for Drug Delivery <i>Hu Yang, W. John Kao</i>	789
Dental Biomechanics <i>A. N. Natali, P. G. Pavan, E. L. Carniel</i>	799
Dental Implants <i>Nirit Tagger-Green, Eli E. Machtei</i>	808
Diamond and Diamond-Like Carbons <i>James H. Arps, Geoff Dearnaley</i>	822

Dielectric Properties of Tissues / <i>Kenneth R. Foster</i>	832
Digital Biomedical Signal Acquisition and Processing: Basic Topics / <i>Martin Oswaldo Mendez Garcia, Luca T. Mainardi</i>	843
Digital Biomedical Signal Processing: Advanced Topics / <i>Luca T. Mainardi</i>	854
Distal Protection Devices / <i>Thomas Tu, Roger Laham</i>	870
Drug Delivery, Controlled / <i>M. N. V. Ravi Kumar, A. J. Domb</i>	880
Elastin / <i>William T. Brinkman, Karthik Nagapudi, Elliot L. Chaikof</i>	891
Elastomers, Biodegradable / <i>John J. Stankus, Jianjun Guan, William R. Wagner</i>	897
Electric Cell-Substrate Impedance Sensing / <i>Philippe Lam</i>	908
Electrical Impedance Imaging / <i>Keith D. Paulsen, Alex Hartov</i>	915
Electroactive Polymeric Materials / <i>V. Prasad Shastri</i>	926
Electrocardiography / <i>Soumyadipta Acharya, Bruce Taylor</i>	936
Electrogastrography / <i>Robert M. Stern, Kenneth L. Koch</i>	947
Electromyography / <i>Didier Gamet, Odette Fokapu</i>	956
Electron Microscopy / <i>Robert L. Price, Jeff Davis, Michael J. Yost, Richard L. Goodwin, Louis Terracio</i>	968
Electrospinning / <i>Darrell H. Reneker, Haoqing Hou</i>	978
Endoscopy / <i>Jonathan T. C. Liu, Tonya Kaltenbach, Thomas D. Wang, Roy M. Soetikno</i>	986
Ergonomics / <i>Brian N. Craig</i>	999
Excitable Tissue, Electrical Stimulation Of / <i>Dominique M. Durand</i>	1009
Extracellular Matrix Scaffolds / <i>Stephen F. Badylak</i>	1021
Eye Tracking: Characteristics and Methods / <i>Daniel C. Richardson, Michael J. Spivey</i>	1028
Eye Tracking: Research Areas and Applications / <i>Daniel C. Richardson, Michael J. Spivey</i>	1033
Fabrics / <i>Frank K. Ko</i>	1043
Fiber Optic Biosensors / <i>Ilko K. Ilev, Israel Gannot</i>	1062
Fibrin / <i>Sam L. Helgerson, Thomas Seelich, James P. DiOrio, Bill Tawil, Katharina Bittner, Reiner Spaethe</i>	1072
Fibrin Sealants / <i>Marcus E. Carr, Jr., Erika J. Martin, Heather Ambrose</i>	1080
Finite Element Analysis / <i>Jennifer S. Wayne</i>	1091
Flow Cytometry / <i>J. Paul Robinson</i>	1100
Foreign Body Response / <i>John Hunt</i>	1111
Functional MRI: Applications / <i>Hui Mao</i>	1119
Gait Analysis / <i>Richard Baker</i>	1129
Gene-Activated Matrix / <i>Neil Davies</i>	1142
Gene Therapy / <i>Viraj P. Mane, William McCormack, Brendan Lee</i>	1150
Glucose-Responsive Hydrogels / <i>Nicholas A. Peppas, Christie D. Bures</i>	1163
Glucose Sensors / <i>Jeffrey I. Joseph, Marc J. Torjman</i>	1174
Glues / <i>Shojiro Matsuda, Yoshito Ikada</i>	1185
Glycosaminoglycans and Proteoglycans / <i>Jan C. Schagemann, Hsi-Wei Chung, Eike H. Mrosek, Shawn W. O'Driscoll, Gregory G. Reinholz</i>	1195
Gradient Surfaces: Preparation, Characterization, and Interactions with Biological Species / <i>Hai Bang Lee, Moon Suk Kim, Gilson Khang, Jin Ho Lee</i>	1210
Hard Tissue: Biomaterial Interactions / <i>Feza Korkusuz, Petek Korkusuz</i>	1229
Hard Tissue Elastic Properties / <i>J. Lawrence Katz</i>	1236
Healing of Bone and Connective Tissues / <i>William L. Murphy, Kelley Grorud, Ray Vanderby, Jr.</i>	1249
Hearing Aids / <i>Ian C. Bruce</i>	1263
Hearing Mechanisms / <i>Martin L. Lenhardt</i>	1271
Heart Biomechanics / <i>Jeffrey W. Holmes</i>	1280

Heart Valve, Bioprosthetic	Peter Zilla, Paul Human, Deon Bezuidenhout	1291
Heart Valve Failure, Bioprosthetic	Peter Zilla, Paul Human, Deon Bezuidenhout	1306
Heart Valve Mechanics	Ajit Yoganathan, Anna M. Fallon, Jorge H. Jimenez	1317
Heart Valves, Mechanical	Ajit P. Yoganathan, Zhaoming He, Hwa-Liang Leo, Anna Fallon	1329
Hematopoietic Stem Cells and Assays	Athanassios Mantalaris, Nicki Panoskaltzis, J. H. David Wu	1338
Hemocompatible Materials	Agnese Magnani, Federica M. Piras	1345
Hemodynamics, Macrocirculatory	Baruch B. Lieber, Chander Sadasivan	1356
Heparin-Binding to Improve Biocompatibility	Rolf Larsson	1368
Hip Biomechanics	Farid Amirouche, Mark Gonzalez, Luke Aram	1377
Hip Joint: Overuse Injuries	Marko Pećina, Ivan Bojanić Alan Ivković	1393
Histogenesis	Julie Glowacki	1403
Host Reactions	Kristin J. Pawlowski	1411
Hyaluronan	Jennie Baier Leach, Christine E. Schmidt	1421
Hybrid Vascular Prostheses	Jerome A. Werkmeister, Glenn A. Edwards, John A. M. Ramshaw	1432
Hydrogels	Junji Watanabe, Yoshihiro Kiritoshi, Kwang Woo Nam, Kazuhiko Ishihara	1439
Hydroxyapatite	Alexandra Elizabeth Porter, Nelesh Patel, Serena Best	1451
Hydroxyapatite Coatings	Yunzhi Yang, Kazuhisa Bessho, Kyo-Han Kim, Sang-won Park, Joo L. Ong	1464
Implant, Total Hip	Nadim James Hallab, Joshua Jacobs	1470
Implanted Medical Devices, Power Sources For	Erik R. Scott, Craig L. Schmidt, Paul M. Skarstad	1484
Infection of Medical Devices	Lori L. Burrows, Antoine E. Houry	1497
Inner Ear Implants	Graeme M. Clark	1507
Insulin Delivery	Robert S. Parker	1514
Integrins	David G. Simpson	1524
Intellectual Property Management	Michael Blakeney	1540
Interpenetrating Polymeric Networks	Nicholas A. Peppas, Jing Zhang	1549

Volume 3

Intravascular Ultrasound	Charles D. Choi, Yao Wang, Javier de Ana, Matthew O'Donnell	1559
In Vivo Cardiovascular Models	B. H. Walpoth, O. M. Hess	1566
Kidneys, Artificial	Churn K. Poh, Junfeng Lu, William R. Clark, Dayong Gao	1576
Knee Joint: Overuse Injuries	Ivan Bojanić, Alan Ivković, Marko Pećina	1597
Knee Joint Replacement	M. J. Cross, E. N. Parish, S. Machan	1607
Laboratory Animals: Ethics and Regulations for Care and Use	Kathy E. Laber, M. Michael Swindle	1616
Laser-Tissue Interaction	E. Duco Jansen	1623
Laser Transmyocardial Revascularization	James W. Jones, Nancy A. Crigger, Bruce W. Richman	1632
Ligament Repair: Animal Models	Robert C. Bray, Catherine A. Leonard, Kevin R. Forrester, Paul T. Salo	1640
Liver, Bio-Artificial	François Berthiaume, Christina Chan, Martin L. Yarmush	1649
Lung, Artificial: Basic Principles and Current Applications	William J. Federspiel, Kristie A. Henschir	1661
Lung, Artificial: Current Research and Future Directions	William J. Federspiel, Robert G. Svitek	1673
Lung Surfactants	Robert H. Notter, Zhengdong Wang	1683

Magnetic and Electrophoretic Cell Separation / <i>S. Chethana, Ganapathi Patil, K. S. M. S. Raghavarao</i>	1695
Magnetic Nanoparticles: Structure and Bioapplications / <i>Yudhisthira Sahoo, Edward P. Furlani, Earl J. Bergey</i>	1705
Magnetic Resonance Imaging (MRI) / <i>Simon J. Doran</i>	1713
Magnetic Resonance Imaging in Temperature Measurement / <i>Nadine Barrie Smith</i>	1728
Magnetic Resonance Microscopy / <i>Egidijus Uzgiris</i>	1738
Mass Transfer in Tissue Function: Roles / <i>E. N. Lightfoot, Karen A. Duca,</i>	1749
Matrix Metalloproteinases / <i>Todd A. Telemeco, James R. Bowman, III, David G. Simpson</i>	1763
Mechanical Circulatory Support / <i>Eric J. Okum, Vigneshwar Kasirajan, Robert S. D. Higgins</i>	1775
Mechano-Regulation of Fibroblast Function / <i>James H.-C. Wang, Bhavani P. Thampatty</i>	1783
Medical Imaging, 3-D / <i>Oskar Skrinjar, Paul J. Benkeser</i>	1794
Medical Robotics / <i>John E. Speich, Jacob Rosen</i>	1804
Melt Spinning / <i>Eija Marjut Pirhonen, Ville Ellä</i>	1816
Metallic Orthopedic Devices: Failure Analysis / <i>Lyle D. Zardiackas</i>	1824
Microcirculatory Oxygen Transport / <i>Roland N. Pittman</i>	1842
Microcomputed Tomography and Its Applications / <i>Thomas Dufresne, Paula Chmielewski, Babul Borah, Andres Laib</i>	1850
Microelectromechanical Systems (MEMS) Manufacturing / <i>Marc Madou</i>	1860
Micro-Particle Image Velocimetry in Biomedical Applications / <i>Jinhua Cao, Steve T. Wereley</i>	1873
Microporous Materials / <i>Julian R. Jones, Larry L. Hench</i>	1885
Modeling, Biomedical / <i>Andrew J. Pullan, Nicolas P. Smith</i>	1894
Nanoscale Neurosurgery / <i>William C. Broaddus, Peter J. Haar, George T. Gillies</i>	1903
Nerve Guides / <i>Burkhard Schlosshauer, Martin Lietz</i>	1911
Neuroprostheses / <i>Milos R. Popovic, T. Adam Thrasher</i>	1924
Neutrophil-Biomaterial Interactions / <i>Vibeke Videm</i>	1934
Nickel and Nickel Alloys / <i>Rachel L. Williams</i>	1942
Nitric Oxide / <i>Matthew J. Bizzarro, Vineet Bhandari</i>	1951
Nuclear Magnetic Resonance Spectroscopy / <i>Mari A. Smith, Peter B. Barker</i>	1960
Ocular Implants / <i>Andrew W. Lloyd, Susan Sandeman, Richard G. A. Faragher, Stephen P. Denyer</i>	1974
Ocular Implants for Drug Delivery / <i>Susan S. Lee, Peng Yuan, Michael R. Robinson</i>	1981
Optical Coherence Tomography / <i>Xingde Li, James G. Fujimoto</i>	1996
Optical Detection of Cancers / <i>Xin-Hua Hu, Jun Qing Lu</i>	2009
Optical Mapping / <i>Igor R. Efimov, Vladimir P. Nikolski, Gil Bub</i>	2019
Optics, Biomedical / <i>Sergio Fantini</i>	2029
Organic and Inorganic Matrices / <i>Adele L. Boskey</i>	2039
Orthodontic Wires / <i>Eser Tüfekçi, Steven J. Lindauer</i>	2054
Orthopedic Biomaterials / <i>J. Lawrence Katz, Catherine G. Ambrose, Carl McMillin, Paulette Spencer</i>	2061
Orthopedic Fixation Devices / <i>Jill S. Kawalec</i>	2073
Osteoclastic Bone Resorption / <i>Samuel C. Ramage, Mengnai Li, Matthew J. Beckman</i>	2081
Osteogenic Progenitor Cells of Bone / <i>Richard O. C. Oreffo</i>	2091
Osteoinductive Substances and Materials / <i>Toshimasa Uemura, Hiroko Kojima, Takashi Saito</i>	2102
Particulate Matter and Host Reactions / <i>Edward M. Greenfield</i>	2110
Peripheral Nerve Repair and Regeneration: Historical Perspective / <i>E. E. Sabelman, W. Chang, S. Nguyen, J. M. Rosen</i>	2118
Phosphorylcholine (PC) Technology / <i>Andrew L. Lewis</i>	2136
Photopolymerization / <i>Dong-an Wang, Jennifer H. Elisseeff</i>	2150

Piezoelectric Materials Zoubeida Ounaies	2163
Plasma Modification of Materials Ricky K. Y. Fu, Paul Kim Ho Chu	2174
Polyamides (Synthetic and Natural) Naveen C. Srivastav, Babita Agrawal, Rakesh Kumar	2186
Polycaprolactone J. E. Gough, P. Christian	2197
Poly(carbonate)urethanes Michael Szycher	2208
Polyelectrolyte Multilayers Darwin R. Reyes, Laurie E. Locascio, Michael Gaitan	2217
Polyepoxy Compound Fixation Yasuharu Noishiki, Teruo Miyata	2231
Poly(Glycolic Acid) Eugene D. Boland, Gary E. Wnek, Gary L. Bowlin	2241
Poly(lactic acid)s Michel Vert	2249
Poly(lactic-Co-Glycolic Acid (PLGA)) Konstantinos Avgoustakis	2259
Polymer Foams V. Prasad Shastri, Molly M. Stevens	2270
Polymers Gary E. Wnek	2275
Polymers Used in Tissue Engineering Vasif Hasirci, Deniz Yucel	2282
Polytetrafluoroethylene Robert R. Pavlis	2300
Polyurethane Biomaterials Joanna D. Fromstein, Kimberly A. Woodhouse	2304
Positron Emission Tomography (PET) Anna-Liisa Brownell	2314
Protein Adsorption Modeling Alan H. Goldstein, Alastair N. Cormack	2326

Volume 4

Protein and Cell Signaling with Biomaterials: Influence of Surfactants Solomon W. Leung, James C. K. Lai	2337
Protein and Cell Signaling with Biomaterials: Interfacial Transport James C. K. Lai, Solomon W. Leung	2346
Protein Delivery Systems Nicholas A. Peppas, Cristina Donini	2357
Pyrolytic Carbon Robert B. More, George Sines, Ling Ma, Jack C. Bokros	2370
Rapid Prototyping Shaochen Chen, Carlos A. Aguilar, Yi Lu	2382
Real Time Tomographic Reflection Vikram S. Chib, George D. Stetten	2391
Reconstructive Biomaterials Mutaz B. Habal	2395
Rotary Cell Culture Systems Stephen S. Navran	2402
Self-Assembled Monolayers Koichi Kato	2409
Shape Memory Metals Marie Haidopoulos, Fatiha El Feninat, Diego Mantovani	2418
Silicones Kenneth J. Wynne, James M. Lambert	2427
Silks Juming Yao, Tetsuo Asakura	2442
Small-Angle Light Scattering Methods for Soft Connective Tissue Structural Analysis Michael S. Sacks	2450
Spine Biomechanics Clayton Adam	2464
Stem Cells Andrea Liebmman-Vinson, Sharon C. Presnell	2473
Stent Grafts, Endovascular Timothy A. M. Chuter	2480
Stents Benjamin Thierry, Luc Bilodeau, Maryam Tabrizian	2492
Sterilization of Biomedical Materials Francesco Tessarolo, Giandomenico Nollo	2501
Stress Fractures Marko Pećina, Ivan Bojanić, Alan Ivković	2511
Supercritical Fluid Processing Ihtesham U. Rehman, Jawwad A. Darr, Alireza Moshaverinia	2522
Surface Coatings Shih-Horng Su, Suzanne Conroy, Tung-Liang Lin, Min-Shyan Sheu, Ih-Houng Loh	2531
Surface Modification Sally L. McArthur, Keith M. McLean	2540
Surface Topography and Cell Behavior Douglas W. Hamilton, Salem Ghrebi, Hugh Kim, Babak Chehroudi, Donald M. Brunette	2551
Sutures C. C. Chu	2562

Telemedicine Brett M. Harnett, Charles R. Doarn, Ronald C. Merrell	2579
Tendons and Ligaments, Mechanical Testing Of Richard E. Debski, Susan M. Moore, Eric J. Rainis	2588
Thrombosis Mukul S. Goel, Scott L. Diamond	2601
Tinnitus Devices Martin L. Lenhardt	2610
Tissue Engineering François A. Auger, Lucie Germain	2620
Tissue Engineering: AC Electrokinetics Gerard H. Markx, Anne-Marie Buckle	2628
Tissue Engineering of Bladder Anthony Atala	2636
Tissue Engineering of Blood Vessel Douglas Hamilton, David Vorp	2643
Tissue Engineering of Bone L. Di-Silvio, N. Gurav, Eleftherios Tsiridis	2652
Tissue Engineering of Bone Marrow Athanassios Mantalaris, Nicki Panoskaltzis, J. H. David Wu	2660
Tissue Engineering of Bone Marrow, Culture Systems Athanassios Mantalaris, Nicki Panoskaltzis, J. H. David Wu	2670
Tissue Engineering of Breast Cheryl T. Gomillion, Cheryl A. Parzel, Richard L. White, Jr., Karen J.L. Burg	2678
Tissue Engineering of Cardiac Muscle Wolfram-Hubertus Zimmermann, Thomas Eschenhagen	2686
Tissue Engineering of Cartilage J. N. Amritha De Croos, Rita A. Kandel	2694
Tissue Engineering of Cornea Lucie Germain, Claude J. Giasson, Patrick Carrier, Sylvain L. Guérin, Christian Salesse, François A. Auger	2707
Tissue Engineering of the Esophagus Stephen F. Badylak, Thomas W. Gilbert, Alejandro Nieponice	2719
Tissue Engineering, Fat Barbara Weiser, Markus Neubauer, Achim Göpferich, Torsten Blunk	2725
Tissue Engineering of Heart Valves Ivan Vesely	2737
Tissue Engineering of the Intestine James C. Y. Dunn, Benjamin M. Wu	2751
Tissue Engineering of Ligament E. Gentleman, G. A. Livesay, K. C. Dee, E. A. Nauman	2758
Tissue Engineering of Liver Alexander B. G. Sevy, Katherine M. Kulig, Joseph P. Vacanti	2769
Tissue Engineering, Microscale Wei Tan, Tejal Desai	2779
Tissue Engineering of Microvascular Networks J. T. Borenstein, E. J. Weinberg, M. R. Kaazempur-Mofrad, Joseph P. Vacanti	2792
Tissue Engineering of Pancreas Hiroo Iwata	2802
Tissue Engineering of Peripheral Nerve Archit B. Sanghvi, Joy L. Murray, Christine E. Schmidt	2811
Tissue Engineering of Rotator Cuff Tendons Jonathan P. Van Kleunen, Louis J. Soslowsky, David L. Glaser	2820
Tissue Engineering Scaffolds Eugene D. Boland, Paul G. Espy, Gary L. Bowlin	2828
Tissue Engineering of Skeletal Muscle Christopher Keen, Daniel Newton, Todd A. Telemeco, Gary L. Bowlin, Gary E. Wnek, Clive M. Baumgarten, David G. Simpson	2838
Tissue Engineering of Skin Ricardo R. Brau, Ioannis V. Yannas	2851
Tissue Engineering of the Small Intestine Simon M. Gabe, Richard M. Day, Aldo Boccaccini	2860
Tissue Engineering of Tendons Dominique P. Pioletti, Olivier Siegrist, Pierre-Yves Zambelli	2871
Titanium and Its Alloys Mitsuo Niinomi, Tomokazu Hattori, Toshihiro Kasuga, Hisao Fukui	2876
Transdermal Drug Delivery Brad Phipps, Michel Cormier, Bob Gale, Bill van Osdol, Jay Audett, Rama Padmanabhan, Peter Daddona	2893
Transgenic and Gene-Targeted Organs Brenda M. Ogle, Jeffrey L. Platt	2906
Transparent Ceramics: Bioactive Materials and Tissue Engineering Motohiro Hirose, Koji Ioku, Noriko Kotobuki, Daisuke Kawagoe, Hajime Ohgushi	2916
Ultra-High Molecular Weight Polyethylene (UHMWPE) Kwideok Park, Gladius Lewis, Joon B. Park	2925
Ultrasound and Tissue Interaction K. Kirk Shung	2933

Ultrasound Doppler / <i>Ding-Yu Fei, James A. Arrowood</i>	2942
Ultrasound Therapy, Bone Healing / <i>Özgür Erdoğan</i>	2951
Urinary Prostheses / <i>Daniel Eberli, Anthony Atala</i>	2961
Vascular Fluid Dynamics / <i>Stanley A. Berger</i>	2971
Vascular Grafts / <i>Deon Bezuidenhout, Peter Zilla</i>	2985
Vascular Grafts: Development Strategies / <i>James Laredo, Lian Xue, Howard P. Greisler</i>	2997
Vascular Grafts: Host Interactions / <i>James Laredo, Lian Xue, Howard P. Greisler</i>	3006
Vascular Imaging / <i>Tobias Saam, William S. Kerwin, Chun Yuan</i>	3012
Vascularization of Engineered Constructs / <i>Zerina Lokmic, Rejhan Idrizi, Aurora Messina, Kenneth R. Knight, Wayne Morrison, Geraldine Mitchell</i>	3022
Vascular Tissue Engineering / <i>Alejandro Nieponice, Timothy M. Maul, Lorenzo Soletti, David A. Vorp</i>	3033
Vitrification / <i>Kelvin G. M. Brockbank, John R. Walsh, Ying C. Song, Michael J. Taylor</i>	3046
Wear Debris / <i>John Fisher, Eileen Ingham</i>	3058
Wear Debris, Bone Resorption Animal / <i>Xiaochao Wei, Regis J. O'Keefe, Edward M. Schwarz</i>	3067
Wear Debris from Joint Arthroplasties, Biological Effects Of / <i>Ting Ma, Stuart B. Goodman</i>	3076
Wheeled Mobility: Wheelchairs and Personal Transportation / <i>Jon L. Pearlman, Rory A. Cooper</i>	3083
Xenografts / <i>Brenda M. Ogle, Jeffrey L. Platt</i>	3093
Zirconia Ceramics / <i>Mariano A. Polack</i>	3104

Preface

The field of biomedical engineering continues to apply engineering principles to analyze and solve problems in life sciences and medicine, leading to improvements in the quality of life. Biomaterials represent a central theme in a majority of the problems encountered. These fields have evolved into a very interdisciplinary arena building on traditional engineering principles that bridge advances in the areas of materials science, life sciences, nanotechnology, and cell biology, to name a few. This trend of interdisciplinary research to solve the most challenging yet compelling medical problems has been embraced in the field and is leading to the betterment of human health. It is evident that the fields of biomaterials and biomedical engineering are continually changing due to the rapid creation and advancement in technology in more traditional areas as well as rapidly developing areas (e.g., tissue engineering).

Because the scope of these medical problems is both vast and dynamic, there is a clear need for a source of technical information that has broad coverage, is current, is written at a level accessible to nonexperts, and has the ability to be updated on a regular basis. The *Encyclopedia of Biomaterials and Biomedical Engineering* (EBBE) was born with these considerations in mind in 2001, and its first edition appeared in 2004. Due to the success of that endeavor and the privilege of working with experts worldwide in preparing the second edition of the EBBE, it has blossomed into an expansive array of 298 entries. It is our hope that we have continued to present the material in such a fashion that it conveys a balanced overview to help stimulate further advancements in all areas of biomaterials and biomedical engineering.

We also believe that many thanks are in order for the efforts that led to the successful first edition and the generation of the second edition of the EBBE. We thank all the authors who have enthusiastically provided their time and expertise, and we also thank the editorial board for all of their various contributions during the development of the EBBE. Finally, we are grateful to Informa Healthcare for acquiring the EBBE, making it a priority, and providing the excellent staff needed to ensure its continued success.

It is our continued hope that the EBBE will serve as an important and continual resource for the many individuals whose work touches, and is touched by, biomaterials and biomedical engineering in order to further stimulate, create, and deliver improvements in quality of life.

INTRODUCTION

An adhesive broadly refers to any substance that possesses the ability to hold two other entities together. Historically, adhesives and bioadhesives have referred to distinctly different areas of thought with very little overlap and continuity. The term *adhesive* has been used to describe the particular biomaterial or system used that is responsible for adherence. Bioadhesion has largely remained well entrained in the field of biology referring to cellular interactions (cytoadhesion) or to mucosal adhesion (mucoadhesion). Whether it is cell-to-cell, soft or hard tissue, or mucosal adhesion, the phenomenon of bioadhesion involves the formation of a bond between two biological surfaces or a biological surface and a synthetic surface. Therefore, bioadhesion can be extended to include any type of adhesion process in contact with or within the biological milieu. The term *bioadhesive* refers to the particular substance, natural or synthetic, responsible for this adhesion. Mucoadhesion is often used to describe bioadhesion involving mucus, whereas cytoadhesion refers to cell-to-cell bioadhesion.

Common examples of bioadhesives include dental restoration fixatives, skin adhesives, and bacterial colonization. Much success has been achieved in hard-tissue adhesives with the availability of many commercially available bioadhesive systems. Mucoadhesive materials have been the focus of much research over the last couple of decades in pharmaceutical science research as a novel drug-delivery approach. With mucoadhesive drug-delivery systems, the therapeutic agent can be localized at the desired site of delivery. Peptides, proteins, or actively facilitated compounds can be targeted to the upper small intestine where achieving greater absorption is possible. Similar obstacles can be overcome in other locations of the body, ophthalmic, pulmonary, and vaginal cavities, where mucus is present.

The desire to create biomimetic materials has created interest in further understanding the mechanisms involved with cellular adhesion to aid in engineering effective tissue-engineering scaffolds and biomaterials resistant to biofilm formation. The ability to create

synthetic materials exhibiting molecular structures recognized by specific cellular components has the ability to afford better cell attachment. Increased cell attachment would lead to a more favorable biological response effectively creating more biocompatible scaffolds. On the other hand, with a complete understanding of the biofilm formation process, biomaterials can be designed so as to decrease the propensity of microbial attachment and colonization. Here we provide a broad overview of the molecular and physico-chemical characteristics involved during the formation of bioadhesive bonds along with a short critical review of the progress achieved in each of the distinct thrusts of current research—hard-tissue adhesives, soft-tissue adhesives, and cytoadhesives.

MECHANISMS OF BIOADHESION

Bioadhesion is truly an interfacial phenomenon and only differs from conventional adhesion in the special properties and characteristics of the substrate(s) being adhered. The mechanistic and structural analyses of the phenomenon of bioadhesion have been carefully outlined in several comprehensive reviews.^[1–5] The mechanisms of bioadhesion are often classified into chemical and physical mechanisms with the electronic theory and adsorption theory falling under the former mechanism, and wetting, interpenetration or diffusion, and fracture theory falling under the latter.

Electronic theory describes adhesion between two different electronic structures such as a polymer and a glycoprotein network. Upon contact of these two systems, electron transfer occurs leading to a double layer of electrical charge at the interface. Adsorption theory describes adhesion that occurs owing to secondary forces such as van der Waals, hydrogen bonding, etc. Several occurrences of these types of forces are sufficient to create a substantial adhesive bond.

The wetting theory uses a surface energy analysis to determine to what extent an adhesive or biological surface is capable of spreading over its corresponding substrate to develop intimate contact. Interpenetration theory, or diffusion theory, (Fig. 1) relies on the

Fig. 1 Upon contact, the interface between two polymer systems disappears and chain interpenetration or diffusion occurs. This polymer interpenetration and depth is responsible for the bioadhesion that occurs.

penetration depth of the polymer chains into the biological substrate to be sufficient enough to create a semipermanent adhesive bond. Finally, fracture theory describes adhesion as the difficulty of separation of the two surfaces. In most systems, one theory alone is not sufficient to describe the process of adhesion. Usually, two or more theories more accurately portray the phenomenon that is occurring. In designing a superior bioadhesive, one must successfully employ key attributes of these theories to develop effective bioadhesion.

Hard-Tissue Adhesives

Smith^[6] offers a comprehensive review on the advances, recent trends, and future direction of hard-tissue adhesives. A great deal of interest in finding alternatives to mechanical fixatives such as screws and pins has prompted the development of efficient adhesives for skeletal and hard-tissue bonding. This area of research has had tremendous success in developing and employing bioadhesives. Dental adhesives and sealants, bone cements, and bone graft substitutes are areas where significant progress has been achieved. One key reason to achieving clinical success has been the environment and tissue involved in these particular bioadhesive processes. Great advances have been achieved in bone cements, dental cements, and enamel and dentin adhesives—thanks in great deal to the engineering of polycarboxylate and ionomer materials capable of achieving adhesion in these applications.^[7,8]

Zinc phosphate cements containing Zn and Al (Caulk Tenacin, Mizzy, Inc. Fleck's Cement) possess a high compressive strength and have been widely used since the mid-20th century in dental restoration. Addition of polycarboxylates to zinc oxide (3MTM

ESPETM DurelonTM, Caulk Tylok Plus) provided advances in adhesion owing to the presence of calcium–carboxylate ion interactions. However, a major drawback to the polycarboxylate adhesives is their poor mechanical properties. To overcome this negative attribute and achieve better optical properties, glass ionomer cements (GIC, GC Fuji PlusTM, and ESPE Ketac-Cem[®]) containing polycarboxylic acid and aluminosilicate glass were developed.^[9] These systems were further modified to include chemical polymerizable (Caulk Advance, 3MTM ESPETM VitremerTM Luting), light-cured (Fuji II LC), or dual-cured (Bisco Resinomer, Dentsply Enforce) resins, which overcome issues of drying and limited fracture resistance with the original GIC. Resins used alone (Panavia 21, J. Morita Clearfil DC Cement) have been used as adhesives that are less brittle and more fracture resistant than the originally employed zinc phosphate cements. Mechanical interlocking and electrostatic interactions are responsible for adhesion and rigidity of the material. Zinc-containing materials do not possess the desired optical properties, therefore necessitating glass ionomer systems (Fuji[®]), which are translucent.

Methyl methacrylate–styrene copolymer-based bone cements (SimplexTM P) have been widely used for securing orthopedic implants to bone since the early 1970s. Cement blends containing antibiotics such as tobramycin have recently been approved for use. Fast-setting carbonated apatite (hydroxyapatite) cements (Norian[®] SRS[®]) have recently been introduced to serve as a more biocompatible material for restoration or augmentation of the skeletal system. These materials harden to form dahllite, a complex of naturally occurring apatite found in bones, which resembles the mineral phase of new bone growth. This further remodels to bone through osteoclastic resorption and new bone formation. Owing to the inorganic composition similarities between bone and enamel and dentin, similar types of materials for dental restoration have also been applied as bone graft substitutes. Effective bioadhesives have found success in the areas of hard-tissue adhesives as evident by the large number of commercially available products in this area.

Soft-Tissue Adhesives

Skin adhesives and tissue sealants have been the traditional application of soft-tissue adhesives. Pressure sensitive adhesives (PSA) have found use in the attachment of medical appliances and to aid in the healing process of abrasions (Band-Aid[®]). These bandages typically have a high tack layer composed of an adhesive derived from polyisobutylenes, acrylates, or silicone polymers. Recent advances have led to the

development of bandage systems that are more flexible with greater adhesive capacity and able to resist water, bacteria, and exogenous material. Semipermeable membranes have been utilized in conjunction with biological fluid absorbent materials in hydrocolloid moisture-retentive wound dressings to promote the wound healing process (ConvaTec). Cyanoacrylates have been used as tissue adhesives owing to their ability to polymerize upon contact with fluids present at biological surfaces. Longer alkyl chain cyanoacrylates (2-octyl cyanoacrylate, Dermabond[®]) have become acceptable bioadhesives owing to their slower degradation, which provides a lower concentration of potentially toxic degradation by-products that could elicit an inflammatory response. Fibrin sealants have been used in wound healing, hemostasis, and tissue sealing and receive a biologically favorable response because of their biomimesis of the last stages of thrombosis (Baxter Tisseel[®], Ethicon Crosseal[™]). The fibrin-sealant systems consist of two separate containers of fibrinogen and thrombin and, when combined and applied to the treatment area, are capable of thrombus formation. The elastic clot formed adheres firmly to the bleeding site and is transparent for visual inspection. Albumin glues (Cryolife[®] Bio-Glue[®] Surgical Adhesive) have been applied at sites of surgery to control bleeding. This two-component adhesive system is composed of bovine serum albumin (BSA) and glutaraldehyde, and when mixed the glutaraldehyde cross-links the BSA molecules.

A shift in focus of soft-tissue adhesives has occurred over the last several decades to evaluate their potential use in bioadhesive controlled drug-delivery devices. Having the ability to prolong a therapeutic's residence time at a specific site of delivery will greatly enhance the drug absorption process. These mucoadhesive devices can protect the drug during the absorption process in addition to protecting it on its route to the delivery site.^[10,11] Three major categories of polymers have been used with some success as bioadhesives: hydroxyl-containing, carboxyl-containing, and charged polymers. Proposed mucoadhesives have been applied in the form of viscous liquids or pastes when used to adhere a polymer to a tissue, or as films or microparticles when used in the form of controlled-release systems adhering to the mucus. The two basic macromolecular structures that have received considerable attention are polyacrylic acid (Noveon[®] Carbopol[®]) and chitosan (Novamatrix[™] Protasan[™]).

Carbopols (Fig. 2) are cross-linked polyacrylic acid microparticles that are capable of swelling upon neutralization. Five specific grades, 934P, 971P, 974P, 71G, and Polycarbophil AA-1, have found wide application in the scientific literature. Carbopol 934P is not widely accepted owing to its polymerization in

Fig. 2 Chemical structure of commonly employed poly(acrylic acid) (PAA)-based materials in mucoadhesive drug-delivery systems. 934P is cross-linked with allyl sucrose, 974P with allyl pentaerythritol, and AA-1 with divinyl glycol. A small amount of the acrylic acids are neutralized to potassium acrylate prior to polymerization.

benzene. Carbopol 971P, 974P, and 71G all possess the same basic molecular structure, with the cross-linking density being the only difference between 971P and 974P. Carbopol 71G is simply compressed granules of 971P. Polycarbophil AA-1 differs in that the polymer is cross-linked with divinyl glycol. All the later microparticles are polymerized in ethyl acetate, a benign solvent as compared to benzene. Chitosan is a linear

cationic polymer composed of D-glucosamine and N-acetyl-D-glucosamine units, with the amount of either depending on the percent deacetylation. Chitosan is derived from chitin, which originates from shellfish. These polymers along with sodium alginate and cellulose derivatives compose the first generation of bioadhesives owing to their ability to interact non-specifically with tissue surfaces.

Studies show that upon application of a polymer to a tissue, a process of swelling may occur.^[12] Shortly after the beginning of swelling, adhesion does occur but the adhesive strength is not very high. The effect of the swelling time on bioadhesion can be readily calculated by examining the time required for interpenetration (diffusion) of bioadhesive chains into the tissue in a layer of 150–200 Å. The major emphasis of recent research on mucoadhesive biomaterials is on the use of adhesion promoters, which would enhance the adhesion between synthetic polymers and mucus through additional polymer–biopolymer interpenetration (Fig. 3). The use of adhesion promoters such as linear or tethered polymer chains is a natural result of the diffusional characteristics of adhesion.^[13] We have focused our attention on the enhancement of mucoadhesion by tethered chains of poly(ethylene glycol) (PEG), grafted on a polymer backbone. Mucoadhesion depends largely on the structure of the synthetic polymer gels used in controlled release applications. Therefore, on the macroscopic level, we focus on examining the effects of various preparation conditions on the structure and morphology of PAA and related hydrogels.

The fields of biomaterials and drug delivery have evoked considerable interest and research activity in the past 25 yr. Only in the last decade have modulated release systems been considered for their potential commercial application. Prominent among these systems are ionic networks and gels used as carriers for

Fig. 3 The free polymer chains across the hydrogel–mucus interface act as adhesion promoters. The free chains are initially in the hydrogels. When placed in contact, the chemical potential gradient causes mutual diffusion of chains across the interface.

drug delivery. Hydrogels are hydrophilic polymer networks capable of imbibing large amounts of water. However, they are insoluble because of the presence of physical or chemical cross-links, entanglements, or crystalline regions. Hydrogels can be used in biomedical applications such as drug-delivery systems, biosensors, contact lenses, catheters, and wound dressings.^[14] Because of the presence of certain functional groups along the polymer chains, hydrogels are often sensitive to the conditions of the surrounding environment.^[15] For example, the swelling ratio of these materials may be sensitive to the temperature, pH, or ionic strength of the swelling agent or even to the presence of a magnetic field or ultraviolet light (Fig. 4).

Numerous experimental studies have been done to test the mucoadhesive ability of various polymers.^[16,17] Among the general rules for mucin-attractive polymers are the requirements of hydrogen-bond formation ability. This is reasonable based on the chemical structure of mucin components,^[18,19] including hydroxyl groups in the branched sugar chains, carboxylic, acid and sulfate groups in the terminal segments of branched chains. Consequently, polymers such as PAA are mucoadhesive; their interactions with mucus have been tested and the data have been widely cited.^[20,21]

The very interaction between polymers and mucins in the physiological environment requires more careful investigation, both theoretically and experimentally. The excess amount of water in the physiological environment (the concentration of water in the bulk phase is around 55 M) has important implications on the hydrogen-binding interaction between polymer chains. For example, in aqueous solutions of PEG, the polymer chains are surrounded by a hydration layer, with two to three water molecules/monomer unit.^[22] Thus, the hydrogen-bond formation between PEG and another polymer leads to the breakage of PEG–water

Fig. 4 Network structural changes owing to variations on environmental pH. Higher pHs disrupt the interpolymer complexes and ionic moieties deprotonize leading to extensive swelling (*left*). As pH is decreased, interactions between the tethered grafts with the protonized ionic moieties increase leading to the formation of interpolymer complexes.

hydrogen bond, and this can only occur if there is a net energy decrease. For example, the interaction between PEG and poly(vinyl alcohol) (PVA) is repulsive in water, though such polymers can form hydrogen-bond complex in the dry state.^[23,24] Recent studies of the interaction between PEG and poly(methacrylic acid) (PMAA) in water^[25] showed that the PEG–PMAA complexation diminished even when only 10% of the acid groups in PMAA were dissociated. Therefore, more careful analysis beyond simple consideration of the chemical structure is needed to determine whether there is attraction between polymers and mucins. From an experimental point of view, the current methods for mucoadhesion measurements do not provide direct evidence of the nature of polymer–mucin interactions. These methods mostly exploit homemade or modified equipment, and there is no universally accepted test method.^[26,27] This is the reason that so few comparisons of intergroup data have been made, and, except for a small number of cases, there is no consensus about which polymers are good mucoadhesives.^[26,27] Moreover, different test methods involve various macroscopic phenomena, which are not directly related to polymer–mucin interactions but are method- or sample-dependent.

Determination of adhesive polymer properties can be evaluated by using a range of experimental techniques, leading to the determination of the bond strength. In vitro techniques include mostly tests by which one can follow the destruction of the adhesive bond between a polymer and the mucus or tissue predominantly via application of shear or peeling forces. Often, the same tests are performed under application of tensile forces.

For certain controlled-release systems, there are simple experimental procedures, which can be used to determine the adhesive force, using thin disks. The experiment is carried out in a modified tensile tester using appropriate cells attached to the vertical bars of the tester. The disks or paste are placed between the two plates of the cells and a tensile force is applied at constant extension ratio and until the material breaks by molecular slippage (Figs. 5 and 6). The maximum elastic modulus is usually proportional to the adhesive strength.

The Wilhelmy plate method has been used to test the mucoadhesion of water-soluble polymers.^[20] In this method, the polymer-coated glass plate was tested against mucus. However, the contact time (the hydration time) turned out to be the essential parameter for the result analysis: too short time would cause insufficient interaction between polymers and mucus.^[16] These disadvantages are expected to cause poor correlation with the in vivo interaction.^[28] More importantly, it is barely possible to get an insight into molecular-level interactions between various polymers

Fig. 5 Bioadhesion measurements using a tensiometric device such as an Instron. The adhesive is placed in contact with the substrate to be adhered. The adhesive is removed while measuring the force vs. elongation.

and mucin from the current macroscopic test methods.^[29] Therefore, despite the existence of numerous experimental data, we still do not have enough knowledge to molecularly design the next generation of mucoadhesive devices. We have exploited both theoretical modeling and microscopic measurement methods to provide a clearer picture of polymer–mucus interactions.

Cytoadhesives

The adhesion of cells has been described as a four-step process: cell attachment, cell spreading, organization

Fig. 6 Force vs. displacement curve for bioadhesives in contact with a biological substrate. (A) Represents the peak force, where (B) and (C) represent tissue detachment.

of an actin cytoskeleton, and formation of focal adhesions.^[30] Cellular adhesion is generally promoted through the presence of various adhesion proteins,^[31] with fibronectin being one of the more widely recognized proteins. Platelet adhesion is an integral step in blood coagulation and blood-material interactions.^[32] Coagulation arises from interactions of platelet glycoprotein Ib and exposed connective tissues such as collagen, with plasma von Willebrand factor (vWF) as a cofactor. Material platelet adhesion involves other platelet glycoproteins (IIb/IIIa) along with the coagulation mechanism. This material-platelet adhesion arises from IIb-IIIa interactions with plasma proteins such as fibrinogen, vWF, fibronectin, and vitronectin. Integrins, the family of cell-surface matrix receptors, serve as the mediators for cell adhesion. Arg-Gly-Asp (RGD) has often been employed on synthetic surfaces to stimulate adhesion in tissue-engineering applications so that further processes such as proliferation and migration will occur. This peptide attachment simulates the components of the extra cellular matrix (ECM), thereby imparting biomimetic properties on the biomaterial. Aside from integrin-surface receptors, proteoglycans are also responsible for cell adhesion. Carbohydrate-rich domains located at the cell's surface have the ability to interact with carbohydrate-binding lectin macromolecules.^[33]

Adhesion of bacteria (biofilm formation or biofouling) involves the interaction of bacterial fibers with fibers adsorbed to the surface being colonized.^[34] Bacteria have often been overly simplified and described as a smooth colloidal particle so that DLVO theory could be used, at least partially, to explain the adhesion process.^[35,36] Biofouling of biomaterials occurs owing to non-specific interactions of the bacterial surface dependent on polymer conformation and surface energy whereas certain bacteria (e.g., *Helicobacter pylori*) possess a surface layer of biopolymers capable of specific interactions with a biological host.^[37] This specific interaction is typically mediated by carbohydrate-binding moieties present on the bacterium's surface. Bacterial colonization of the gastrointestinal tract is a result of the ability of certain bacteria's surface binding to mucin molecules present in the mucus gel layer.

CONCLUSIONS

Bioadhesive polymers can be used in a wide range of medical applications including cytoadhesive, mucoadhesive, and tissue adhesive uses. Advances in nanostructure development and nanotechnology allow us to utilize a wide range of materials for such applications. While PAA-based, hydrophilic polymers are excellent bioadhesive candidates, addition of tethered structures,

ionizable groups, and interpenetrating structures seems to promote interdiffusion and therefore adhesion.

INTRODUCTION

Explorations under way for centuries have sought ideal replacement materials capable of restoring our damaged or diseased functional parts to their natural state. Early historical accounts indicate that a number of materials were fashioned to resemble what they would replace, including wood (for teeth), ivory, and animal bone and tissue. These early efforts at grafting were concerned primarily with replicating the form of the part they would replace, but did not succeed at replacing functional elements.

OVERVIEW

More recently, materials used for tissue replacement have included a much more sophisticated array of materials including stainless steels, plastics, and ceramics. In a previous work on biomaterials, homage has been paid “To those unknown and unsung researchers and clinicians who pioneered in adapting commercial metals and polymers in human needs. They replaced worn-out and injured living tissue with man-made substitutes and so took the first steps to perpetuate human life.”^[1] With this focus on man-made substitutes, engineering seems to have dominated the realm of biomaterials. The concept of biomaterials has generally been associated with synthetic materials designed to look, feel, and act like tissue. Such synthetic substitutes have been designed to better mimic the tissues they are intended to replace. Some are extremely durable; however, due to their nonbiologic nature, they do not fully integrate into the biologic systems into which they are placed. These materials either lack an important metabolic function or are actually bioincompatible. These materials, although very durable, are therefore limited in their utility by issues of bioincompatibility and by the nonrenewable nature of these replacements. The nonintegrative nature of these implants can result in short implant durability or patient incompatibility. Mechanical heart valves present one example of incompatibility between patient and graft. Even though the grafts are structurally very durable, their surface properties are thrombogenic. No available material has yet attenuated this characteristic; the

need for patients to take anticoagulants while implants are in place limits mechanical valve utility in many patient populations.

Tissue is used as an alternative to synthetic materials. Initially (and continuing today), tissues of animal origin were used as graft material. Tissue-processing methodologies such as chemical fixation have resulted in improvements in biocompatibility (by allowing cross-species implantation without rejection) and physiologic functionality (due to the intrinsic functionality of the original tissue). However, the chemical fixation of these grafts prevents recipients' cells from interacting with and routinely rebuilding and regenerating the device. Application of chemical fixation techniques to human tissue grafts (especially heart valves) has actually caused an unanticipated decrease in these grafts' functional utility.

As a consequence of the failure of wholly synthetic materials and fixation-treated animal tissues to integrate with the biological environment, newer biomaterials development has begun to incorporate the raw elements of the tissues they have been created to replace. These new generation biomaterials (many of which are currently in development) routinely incorporate the basic structural elements of human tissues—proteins, glycosaminoglycans (GAGs), minerals, and even cells. Current biomaterials development seeks to make the biomaterial more interactive with the cells and surrounding tissues. These design elements, which are becoming more common in biomaterials development, are all elemental to an allograft.

No material has yet been created that is as suitable as an allograft to replace diseased or damaged tissues when seamless integration and function are required. The particular utility of allograft tissue-based replacements is best understood in terms of the body's durability (such durability being primarily a function of normal cellular replication and cellular/matrix interactions that continuously renew and repair tissue matrices). Without reestablishment of this cell/matrix interaction, durability of tissue replacements could be greatly reduced (as has been found with chemically fixed animal tissue grafts). Therefore, the goal of a medical device for tissue replacement should include the ability of the device to interact with the patient's own cells and the potential to allow cells to rebuild and

regenerate tissue. The inclusion of cells in biomaterials created for graft construction (preseeding) is currently an area of great interest and activity. This construct could provide the same long-term durability that our natural tissues provide. The use of allograft tissue for transplantation is based on the ability of graft and host cells to interact and renew.

The term allograft (also known as homograft) indicates tissue from one species transplanted to another animal of the same species (e.g., dog to dog or human to human). A xenograft indicates tissue transplanted from one species to another (e.g., pig to monkey or pig to human). An autograft is tissue reimplanted into the donor. The most common clinical example of an autograft is the use of a patient's own veins or arteries in heart bypass grafting (Fig. 1).

Allografts can be classified into three broad categories—organs, tissues, and cells. There are several ways to make distinctions between organs and tissues, but one of the more clearly defining parameters is whether the tissue requires immediate revascularization (vascular anastomoses), or can be implanted without immediate revascularization. Organ allografts (kidneys, liver, lung, heart, etc.) all require immediate surgical revascularization for their metabolic requirements, thereby requiring reattachment by surgical anastomosis of the major arteries and veins. On the other hand, tissues and cells do not require revascularization and can be implanted without immediately establishing a direct blood supply (heart valves, blood vessels, orthopedic tissues, skin, cornea, etc.). Another distinction can be made regarding whole organs' requirement for an immediate blood supply because of their size and because they are sites of important and

continued metabolic activity (e.g., liver, kidney, pancreas). Allograft tissues are generally much smaller in dimension than whole organ allografts (and can therefore be revascularized in a short time from indirect capillary revascularization), and do not have the metabolic requirements of a whole organ. Examples of cellular allografts include blood, bone marrow, neurological cells, chondrocytes, and pancreatic islets. These do not require immediate revascularization; however, they do require implantation into a highly vascular area.

The history of the use of allografts dates back many years, if not centuries. Skin grafts were first reported in 1881.^[2] The legend of Saints Cosmas and Damien, however, dates back much further. The Roman legend tells of an old servant and admirer of these two saints. The servant fell ill from a cancer in his leg and prayed to Cosmas and Damien and fell asleep in church. The saints appeared with surgical instruments and medicines. After amputating his limb one asked, "What are we going to use to replace the diseased flesh?" Saint Damian answered, "The body of a Moor was buried today at the cemetery of St. Peter. It is still fresh and we can use it for this poor man." The limb was a different color but appeared to work well.^[2-4] Another amazing component of this story is that the saints had been martyred for their faith two centuries before the transplant.

During early experimental use of allografts it was found that if administered in large enough quantities, they could have unfortunate effects on the recipient. These effects were later understood to be one of two responses. One response is rejection, resulting in loss of tissue due to an immunological reaction to antigens in the graft tissue. The second is a sensitization that can result in a massive immune response directed back at the patient through anaphylaxis or graft versus host disease. These effects have prompted wide-ranging research efforts in development and use of various drugs that allow allograft transplantation with reduced concerns for rejection or other negative effects on the recipient.

Immunosuppressive drugs have been used since the late 1950s, starting with azothiaprine.^[4,5] These were known to have an impact on the cells of the immune system, preventing them from recognizing or responding to the allograft tissues. The field of immunosuppressives has grown rapidly and has brought many new drugs (such as cyclosporine and FK-506) to the forefront of transplantation use. These drugs are primarily associated with whole organ and cellular implants. Immunosuppressive drugs are not commonly utilized with tissue allograft implants.

Research efforts directed at preservation of allografts is another topic of interest. Whole organ grafts must still be implanted into the host within a very short

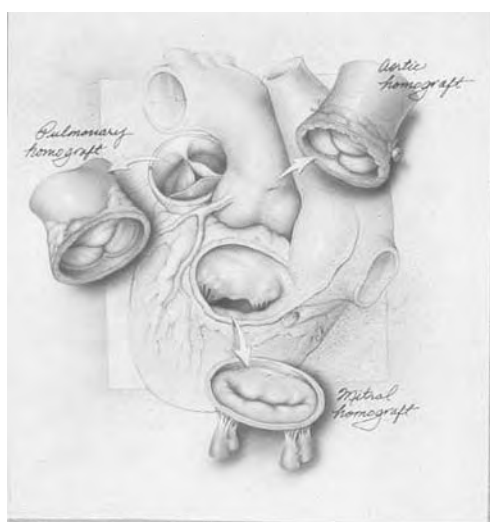

Fig. 1 Depiction of human aortic, pulmonary and mitral valves and their positions in the heart. (Figure by CryoLife, Inc.)

period of time, or the resulting ischemia will affect the organ and result in markedly reduced metabolic function. The major focus of research on whole organ transplantation revolves around development of harvest solutions and transport conditions that allow better survival of the fresh organ for longer time periods. To date, there has been little reported success in development of methods for preserving whole organs for more than 2–3 days. This short time frame does not allow for accumulation or banking of whole organs for better management of these scarce resources. Allograft tissues, on the other hand (due to their smaller size and less complex functional requirements), have been found to be less affected by longer ischemic times. They can be cryopreserved and stored for long times at liquid nitrogen temperatures, thus providing access to these allografts for a wider variety of reconstructions and offering more convenient and widespread use in surgery.

There are many parameters to examine when considering an allograft for replacement of lost or diseased tissue, including patient suitability, graft availability, functional requirements, mechanical requirements, and size. The allograft implantation can often be a challenging implant surgery, requiring the surgeon to undergo specialized training in surgical techniques and postoperative requirements. Nonetheless, the demand for allograft tissue continues to be greater than the supply.

ALLOGRAFT PROPERTIES

The wide variety of medical conditions that are currently treated with allografts demonstrates the diversity of the biomaterial properties possessed by these grafts. Consider that allografts can be optical (cornea), mechanical (bone, cartilage), physiological (organ replacement kidney, liver, lung), hydrodynamic (heart valves, vascular), electrical (nerve), barrier (skin), defense (bone marrow, lymphocytes), or chemical (oxygen carrying blood cells). The diversity of properties is achieved with a wide array of proteins, carbohydrates, lipids, and minerals. This mixture of materials makes a composite implant that can not only function immediately in the new host environment, but can also continue to integrate into the biology of the host through cellular interactions. In many cases the host takes over control of the new implant and makes adjustments to accommodate the graft into its new environment.

How this is accomplished is a question of biology and all its complexities. One of the advantages of allografts is that their complexity and diversity are already inherent in the tissue when harvested. The key is to select tissues that are free of disease and are of correct anatomical characteristics, and to maintain

them in a state that limits changes to their natural structure and capabilities. It is not required to recreate all of the intricacies of the biology of an allograft, but the donor and recipient must be carefully matched to allow the allograft maximum opportunity for its normal biological function. To further understand these diverse properties let us examine three different tissues: skin, heart valves, and orthopedic soft tissues.

Skin

Skin allografts have played a significant role in replacing skin lost in injuries such as burns. The use of skin allografts dates back to 500 B.C. in India.^[2] Gibson and Medawar studied the immunologic nature of skin allografts after using them to treat burned Royal Air Force pilots during World War II. Their work helped to lay the foundation for modern transplantation immunology.

The skin can be thought of from several different perspectives: biochemically, as an assembly of enzymes; cytologically, as a collection of cell types; anatomically, as a formed structure; and physiologically, as a functional aspect of the formed skin. Studies have been conducted that define the permeability mechanics of the skin, absorption of radiation by the skin, and heat loss through the skin.^[6] Skin is described as a membrane, a transport system, and a barrier. Many of these functions are attributable to the properties of the proteins and structural elements.

The two main structures of human skin are the epidermis and dermis. The epidermis is the outermost layer and consists of stratum corneum and differentiating keratinocytes. The epidermis is attached to the dermis through a basement membrane. The stratum corneum is the primary barrier to pathogens, toxins, gas, and fluid and is made up of flat, cornified cells. The primary components of the stratum corneum are the membranes of the dead keratinocytes. The skin is in a continual state of renewal. The keratinocytes of the lower epidermis continue to differentiate and divide, pushing up the next layer.

The underlying dermis is made of collagen fibrils and glycosaminoglycans. The viscoelastic properties of the skin are based on the unique cross-links of these two components. The vascular supply of the dermis supports the nonvascular epidermis layer. The hair follicles and sweat glands originate in the dermis and penetrate through the epidermis. These specialized cells provide sensation and evaporative heat loss capabilities. The skin is highly innervated. The skin of the fingers has unusual structures called rete ridges that allow for determination of the smoothness of a surface. These structures, known as fingerprints, allow for individual identification.

The skin also plays an important role as a first line of defense against biological pathogens like bacteria, fungi, and viruses. There is both a physical barrier (discussed previously) and an active cellular component. The immune cells of the skin include resident monocytes (T cells and macrophages). These cells may play a role as extrathymus educational centers, providing a first look at new antigens as they pass through the skin.

Skin allografts are commonly used and are well accepted clinically, and are generally provided for implant in either a fresh or cryopreserved format.

Heart Valves

The heart valve is a remarkable device. It starts to function before birth, and must continue to function within very narrow tolerances until death. In fact, the function of the heart valve is so essential that any defect can be fatal. Over a 70-year life span the aortic valve can undergo as many as 2.2 billion cycles. The valve is subjected to pressures in the order of 120–150 mmHg and must function in an environment where components of the blood could clot within seconds of a malfunction. The valve itself is a combination of at least five tissue types ranging in function from structural to blood interface barrier. The structure of the heart valve is especially interesting because it is one of the most mechanically active tissues in the body (Figs. 2 and 3).

The main function of the heart valve is to ensure that blood flows in one direction. This is essential to providing blood flow to the tissues for delivery of oxygen and nutrients and removal of CO₂ and wastes and metabolites. The leaflets of the valve provide the

Fig. 2 Depiction of human aortic valve after completion of removal and dissection. (Figure by CryoLife, Inc.)

Fig. 3 Depiction of human pulmonary valve after completion of removal and dissection. (Figure by CryoLife, Inc.)

mechanism for one-way flow. There are four valves in the heart—aortic, pulmonary, mitral, and tricuspid valves.

Heart valves are a fibrous network of structural glycoprotein, collagen, elastin, glycosaminoglycans (GAGs), soluble proteins, and cells. In humans the glycosaminoglycans are made up of 65% hyaluronic acid and 35% chondroitin sulfate. The two basic structural elements of the valve are the conduit and the leaflets. The leaflet structure reflects its structural loading conditions. The aortic leaflet is made up of a three major layers—ventricularis (primarily elastin), fibrosa (primarily collagen), and spongiosa (enriched in GAGs). The leaflet motion in flow has been described as aerodynamic in nature. The ease of motion of the leaflets allows minimal opening pressures and volumes, thus maximizing cardiac output. The aortic valve conduit includes the sinus of Valsalva. These unique structures play an important role in leaflet opening and closing and in laminar flow through the valve. The flow dynamics of these structures were described by Leonardo da Vinci, among others.^[7]

The cellular makeup of the heart valve includes fibroblasts, smooth muscle cells, endothelial cells, and myofibroblasts in the leaflet. The major function of these cells has been speculated to involve repair, although they may provide for some contractile component in leaflet motion. Studies conducted at the CryoLife institution have documented the essential factors for preservation of these multicellular tissues. The maintenance of both the structural elements of the tissue matrix and retention of the cell types in significant numbers can indeed result in valvular replacements that can achieve very high long-term success rates.^[8–11] These cryopreserved valves have proven long-term durability, excellent hemodynamics with low

pressure gradients, a large effective orifice area, and low complication rates with low incidence of endocarditis or thromboembolic events.

Heart valve replacement is a procedure that can make a dramatic difference in a patient's life. Over the last four decades, heart valve replacement has become a safe and routine surgical procedure. Advances in operative procedures have dramatically reduced mortality rates associated with this procedure. The patient's quality of life is dramatically increased following replacement (Fig. 4).

The gold standard of treatment that currently provides the best chance for improved quality of life for patients requiring heart valve replacement is an allograft heart valve. Successful clinical application of long-term storage conditions to allograft heart valves was first reported in 1975 by O'Brien and coworkers, in their original series of cryopreserved heart valve implants.^[10] In this pioneering work, Dr. O'Brien compared the clinical outcomes of the viable cryopreserved valves to an earlier series of nonviable, antibiotic treated, 4°C-stored valves. The viable cryopreserved valve series demonstrated clearly superior durability, which in this series continued to be demonstrated in long-term patient follow-up. Dr. O'Brien's group in Brisbane, Australia has the longest experience with cryopreserved allograft heart valves. The reported freedom from structural valve deterioration in this series using cryopreserved aortic valves for aortic valve replacement at the 10- and 15-year time points was 93% and 80%, respectively. More recently, the same group followed this implant series out to 20 years and reported 60% freedom from structural valve deterioration.^[11]

It is now generally understood that the original donor cells do not persist even in viable allograft heart valve grafts. The preservation of the cellular content in

Fig. 4 Human aortic valve allograft prepared for implant. (Figure by CryoLife, Inc.)

these tissues has come to be accepted as a relevant measure of the ability of cryopreservation to also conserve and preserve the vital structural elements of the allograft. A cryopreserved valve at implant therefore has all the structural parts required for replacement of the patient's own heart valve, and is able to be integrated into the new host environment.

Antibiotic treatment followed by cryogenic processing and storage is presently considered the only clinically accepted method for long-term preservation of human heart valve and vascular allograft tissues.^[12-14] Studies in the CryoLife laboratory show that retention of human valve leaflet viability is clearly achievable using optimized cryopreservation methods. Table 1 shows percent viability (live cells/total cells) and cell density (total cells/mm²) in a comparison between fresh valves and cryopreserved valves. These data demonstrate that cryopreservation does not significantly affect valve cellular content or viability. Cryopreservation of allograft valves thus allows retention of the vital structural and biological elements necessary for valve replacement.

These viability studies were performed using a live/dead viability assay method that simultaneously utilizes two fluorescent nucleic acid stains, ethidium homodimer and Hoechst 33342 dye.^[15] Hoechst 33342 is a membrane-permeant blue fluorescent dye that crosses the cell wall and labels the nucleus of all cells, both viable and nonviable. The ethidium homodimer is membrane-impermeant red fluorescent dye and will label only nuclei of dead cells with permeabilized cell membranes; intact cell membranes will prevent this component from entering the nucleus. Under fluorescent light, the nuclei of cells with permeabilized, compromised cellular membranes appear red; the nuclei of live cells with intact cell membranes appear blue. Intact valve leaflets or sections of conduit wall can be incubated in this solution, mounted to microscope slides, and assessed using a fluorescent microscope for relative cell viability and cell density.

The allograft heart valve continues to demonstrate excellent long-term function in both neonate, young adult, and elderly populations.^[8,16] However, worldwide

Table 1 Human heart valve leaflet cellular viability and density assessment performed on fresh and cryopreserved valves

	Percent viable cells	Cell density cells/mm ²
Fresh	70.69	2434
Cryopreserved	75.19	1880
P value	P=0.13	P=0.08

(Data supplied by CryoLife, Inc.)

these tissues are in relatively small supply. Consequently, only a fraction of those who could benefit from these tissue valves actually receive one. Some of the most common clinical indications for allograft heart valve use are patients with active endocarditis, women of childbearing age, patients contraindicated for anticoagulation, patients with an active lifestyle or small aortic root, pulmonary valve replacement in the Ross procedure, and repair of congenital heart defects.

Since its inception in 1984, CryoLife has specialized in the ultra-low temperature preservation of human tissues for transplantation. During 18 years of tissue processing, CryoLife has documented the implant of over 76,149 cardiovascular allografts. Based on published clinical data and an in-house clinical registry, CryoLife allograft heart valves have been demonstrated to have excellent long-term durability. CryoLife's in-house registry consists of data collected at seven primary centers where a series of 2605 patients have been enrolled to date. This registry consists of 8726 patient-years of data (mean follow-up: 3.3 years). Evaluating the performance of the aortic and pulmonary allograft in the adult population, the durability of these CryoLife cryopreserved allografts (defined as freedom from explant due to structural valve deterioration) at 10 years is 88% and 94%, respectively.^[8]

Orthopedic Soft Tissues

Musculoskeletal tissues compose a large portion of the human body. The structures range from ropelike ligament to smooth bearing surfaces (like articular cartilage). Many of these tissues form the structural elements through which the human body ambulates and articulates. These soft tissues include tendons, ligaments, muscle, fascia, and articular cartilage (Fig. 5).

The tissues' structures are as diverse as their functions. The human ligament is a very specialized dense connective tissue that serves as a connection between bones, attaching at either end through structures known as insertions. Ligaments are composed of collagens, glycosaminoglycans, elastins, actins, and fibronectins. The tendon attaches a muscle to bone, and is similar in structural composition to the ligament. Tendons can be long, narrow structures (such as the flexor digitorum found in the hand), which are commonly contained in synovial sheaths. These sheaths provide a smooth surface for gliding and thicken in some areas to form pulleylike structures. These pulley systems are necessary when the tendon turns a corner, as over the knuckles of the fingers. Biomechanically, the pulleys maintain an appropriate moment arm to allow efficient use of muscle force in the movement of a digit or limb.

Fig. 5 Depiction of the human knee including placement of meniscal and articular cartilage allografts. (Figure by CryoLife, Inc.)

Articular cartilage provides a smooth lubricated surface for joint motion, allows for distribution of loads, and acts as a shock absorber. There are two main forms of articular cartilage—load-bearing and non-load-bearing. The structure of the articular cartilage includes cellular and extracellular constituents and 60–80% extracellular water. The cells are mainly chondrocytes and the extracellular matrix hyaline cartilage. The hyaline cartilage is made up of collagens, proteoglycans, and noncollagenous proteins. The articular cartilage is a unique bearing surface that is both porous and permeable and can absorb and exude fluid. The primary mechanism for smooth joint function depends on lubrication by both boundary lubrication and fluid film lubrication. This combination depends on the adsorption of the lubricating glycoprotein at the surface of the cartilage and the viscoelastic nature of the cartilage allowing a deformable bearing surface, thus allowing lubrication during both high-load/low-relative speed and low-load/high-relative speeds.

No biomaterials have yet been created that have been successful in replacing isolated tendons, cartilage, or menisci. The reliance on allografts for connective tissue grafts is therefore very strong. Although whole knee replacements are remarkably successful for whole joint surgeries in older patients, younger individuals

A

needing isolated tendon or cartilaginous grafts must rely on allografts. Orthopedic allografts are currently processed and implanted in many formats. Bone allografts are available in a wide range of configurations, from morselized freeze-dried chips to large intact bone segments. Orthopedic soft tissue allografts, which include meniscus and tendons, are currently processed using methods that yield nonviable grafts such as lyophilization and uncontrolled freezing (fresh/freezing) or by cryopreservation, which yields viable grafts^[17,18] (Fig. 6).

The first reported clinical implantation of cryopreserved meniscal allografts dates to 1989.^[19] At present, tendons, ligaments, and the fibrocartilaginous meniscus have all been successfully cryopreserved and implanted. Successful cryopreservation results in maintenance of both the collagen and proteoglycan-rich matrix and retention of viability of the cells inhabiting the matrix. Because the cellular components of these tissues are without question the most sensitive to the effects of freeze-induced injury, they represent a convenient marker for judging the success of a cryogenic system. Maintenance of intact cellular membranes resulting in viable cells after processing serves as a relevant measure to verify that ice damage and solution effects during the freezing/storage/thawing process have been sufficiently controlled, and further indicates that the other structural components of the tissue are unlikely to be damaged. Because retention of the structural components of orthopedic grafts is vital to their clinical usefulness, limiting damage to them during processing is clearly important (Fig. 7).

Studies in the CryoLife laboratory demonstrate the retention of cellular viability in orthopedic allografts following a carefully designed cryopreservation regimen.^[20,21] Using a method to measure cellular protein synthesis by labeling with tritiated glycine,^[20] human

Fig. 6 Human Achilles tendon allograft prepared for implant. (Figure by CryoLife, Inc.)

Fig. 7 Human knee meniscus allograft prepared for implant. (Figure by CryoLife, Inc.)

tendon and meniscal grafts have been assessed before and after cryopreservation. Results show that cryopreserved patellar tendons retained 86% viability and cryopreserved meniscus retained 50% viability compared to fresh. Studies utilizing the previously described live/dead viability assay^[15,22] confirmed these earlier findings, cryopreserved menisci demonstrated an average of $54\% \pm 16$ viable cells (range 35 to 81%) post cryopreservation, with storage times ranging as long as 7 years. This group of menisci was compared to a set of menisci prepared using a fresh/frozen method and showed the fresh/frozen grafts to be nonviable (average viability $3\% \pm 8$, range 0–19%) even with only short-term storage (2 weeks to 4 months).^[21] Fresh/frozen graft processing methods can vary depending on the processor. In general, all fresh/frozen processing is conducted without cryoprotectants or control of freezing temperatures, and storage is generally at temperatures above -80°C . All grafts processed by fresh/frozen methods are considered to be nonviable. As suggested earlier, the assessment of cellular viability is a relevant measure to detect damage to the tissue during processing. If cells remain viable, there is more confidence that the critical structural components of the tissue matrix are undamaged during processing and storage.

ALLOGRAFT: APPRECIATION OF THE SOURCE

This article would not be complete without a discussion of the source of organs and tissues. The loss of a loved one—leading to the donation of organs and tissues—is nothing less than tragic. The unselfish gift from the donor and donor family, however, can save

or enhance the lives of up to 50 critically ill individuals. It is the most generous gift a family can give.

The process of organ and tissue donation is complex and depends on a national network of professionals dedicated to the procurement, processing, and distribution of tissue. The national system for whole organ distribution, United Network for Organ Sharing (UNOS), is well known, with some 75,000 to 80,000 people waiting to receive the gift of life.

Approximately 5400 heart valve implants are performed each year, 60% of which are received by children under 15 years of age.^[8] The need is estimated to be twice the existing supply. The same need applies to all other allografts: Cornea, skin, vascular,^[23] and orthopedic allograft needs are all greater than their supply. This is why organ and tissue donation is a vital national need, and why thanks and support should go to all donors and donor families for the special gifts they give. The special charge to participants in the allograft processing system is to continue to advance the technology of tissue processing and preservation in order to increase the opportunity for maximum good to come from tissue donation.

CONCLUSION

Many tissues (like heart valves, blood vessels, and orthopedic tissue) undergo significant mechanical activity over their lifetimes. This requires durability, obtained through the unique blend of natural collagens, elastins, and other matrix proteins and their cellular constituents, which play a mechanical/structural role and a care/maintenance role.

As we continue to understand more about the complex biological and physiological factors from which we are formed, it becomes clear that the most appropriate way to replace diseased or damaged tissues is by developing substitutes that are as close as possible to the original tissue.

Pohang, Korea

INTRODUCTION

Aluminum oxide (Al_2O_3), or alumina, has been used since 1970 as a bulk material in the manufacture of components of prosthesis, and is the inert ceramic most commonly used for surgical implants. It is found in nature as corundum in emery, topaz, amethyst, and emerald, and as the precious gemstones ruby and sapphire. However, it is from the more abundant ores such as bauxite and cryolite and from clays that the material is commercially extracted and purified.

PROCESSING ALUMINA FOR MODERN APPLICATION

The most common process for the extraction and purification of alumina is the Bayer process. The first step in the process is to mix ground bauxite into a solution of sodium hydroxide (digestion). Sodium oxide is thus a common impurity in alumina. By applying steam and pressure in tanks containing the mixture, the bauxite slowly dissolves. The released alumina reacts with sodium hydroxide to form sodium aluminate. After the contents of the tank have passed through other vessels where pressure and temperature are reduced and impurities removed, the solution of sodium aluminate is placed in a special tank where the alumina is precipitated out. The precipitate is removed from the tank, washed, and heated in a kiln to evaporate any water present. The residue is a commercially pure alumina.

For advanced ceramics uses, the alumina manufactured by these processes requires further purification. This is often achieved by recrystallization from ammonium alum. Alumina exists in many crystal phases— α , δ , γ , η , θ , ρ , and χ —depending on the heat-treatment conditions of aluminum hydroxide or aluminum oxyhydroxide. As a biomaterial, α -alumina—or its natural form, corundum—is used, which is the most thermodynamically stable form. Most alumina devices are very fine-grained polycrystalline α - Al_2O_3 produced by pressing and sintering at 1600–1800°C. A very small amount of other oxides (SiO_2 , MgO , or CaO) is used to aid sintering and limit grain growth during sintering. The single-crystal form of alumina has been successfully used to make implants;

this material may be made by feeding fine alumina powders onto the surface of a seed crystal that is slowly withdrawn from the electric arc or oxygen-hydrogen flame as the fused powders build up.

Polycrystalline α - Al_2O_3 has a rhombohedral structure ($a = 4.758 \text{ \AA}$ and $c = 12.991 \text{ \AA}$). The close packing of the aluminum and oxygen atoms within this structure leads to its good mechanical and thermal properties.

Alumina is a highly inert material and resistant to most corrosive environments, including the highly dynamic environment of the human body. Under physiological conditions, alumina is also extremely unreactive and is classed as nearly inert, eliciting little if any response from surrounding tissues and remaining essentially unchanged after many years of service. However, the body does recognize it as a foreign material and attempts to isolate it by forming a layer of nonadherent fibrous tissue around the implant where possible. Properties making alumina suited to biomaterial applications include its high degree of chemical inertness under physiological conditions, excellent wear resistance, ability to be polished to a high surface finish, and excellent hardness. These properties are exploited for implant purposes, where alumina is used as an articulating surface in hip and knee joints.^[1–5] Its ability to be polished to a high surface finish makes it an ideal candidate for this wear application, where alumina operates against materials such as ultrahigh-molecular-weight polyethylene (UHMWPE) and alumina itself. In addition, the bioinertness of alumina has led to improved devices in nearly load-free applications in ear, nose, and throat (ENT) surgery and in some soft tissue replacement. Porous alumina has also been used as a bone spacer, where sections of bone have been removed due to disease. In this application, it acts as a scaffold for bone ingrowth. Single-crystal alumina or sapphire has also been used in dental applications, although alumina's use in this application is declining with the advent of more advanced materials such as resin-based composites.

PHYSICAL PROPERTIES

The polycrystalline and single-crystal aluminas are dense, nonporous, and nearly inert. They are attached

Table 1 Physical properties of alumina bioceramics

	Commercial alumina bioceramics	Standards: ISO 6474 (2nd ed., 1994) ASTM F603-83 DIN 58 8353
Alumina content (% by weight)	>99.7	>99.5
Impurities, SiO ₂ + CaO+Na ₂ O (%)	<0.05	<0.1
Additives (%)	0.25	<0.3
Density (g/cm ³)	>3.98	>3.94
Average grain size (μm)	2.2	<4.5
Surface roughness value (μm)	0.02	–
Vickers hardness number (VHN)	2300	>2000
Compressive strength (MPa)	4500	4000
Flexural strength (MPa)	580 ^a	>250 ^b
Young's modulus (GPa)	380	–
Fracture toughness (Mpa m ^{1/2})	4	–
Impact strength (cm MPa)	>40	>40
Wear resistance ^c (mm ³ h ⁻¹)	0.001	0.01
Corrosion resistance ^c (mgm ⁻² day ⁻¹)	<0.1	<0.1

^aFour-point bending test.

^bBiaxial test.

^cWear and corrosion resistance values refer to particular test arrangements.

to surface irregularities by bone growth, by cementing the implant into the tissues, or by press-fitting into a defect (termed morphological fixation). Alumina is extremely hard and scratch-resistant, second only to diamond. It has excellent corrosion resistance in body fluids. Physical properties of alumina such as strength, fatigue resistance, and the fracture toughness of polycrystalline α -Al₂O₃ are a function of grain size, porosity, and purity.^[1] Alumina, with an average grain size of <4 μm and >99.7% purity, exhibits good flexural strength and excellent compressive strength. These and other physical properties are summarized in Table 1, for a commercially available implant material. Table 1 also lists International Standards Organization (ISO) requirements for alumina implants. Essentially the same requirements are stipulated in American Society for Testing and Materials (ASTM) F603-83 and Deutsches Institut für Normung (DIN) 58 8353. The first alumina standard for medical applications (ISO 6474) was defined in 1979; the 2nd edition, issued in 1994, addresses properties required for high-load applications.^[6] In addition to imposing more stringent requirements in density and grain size, the 1994 standard strengthens impurity requirements for SiO₂ and alkali metal oxides (mainly Na₂O). A small amount of MgO (<0.5%) is used as a grain growth inhibitor and is essential in order to achieve a fully dense sintered body with fine-grain microstructure. CaO impurities favor alumina ceramic fatigue and aging effects; SiO₂ and alkali metals impede densification and promote grain growth. Hence these

oxides must carefully be kept at very low concentration (<0.05%) for medical use. Since 1989, the main commercial products of alumina—ceramic heads and hip sockets—have exceeded the requirements of the standard. It has been shown that alumina implants that meet or exceed ISO standards have excellent resistance to dynamic and impact fatigue, and also resist subcritical crack growth.^[7] However, an increase in average grain size to >7 μm can decrease mechanical properties by about 20%.^[1] In general, the smaller the grains and the lower the porosity, the higher the strength that results.^[8] Although alumina has the highest mechanical properties among biomedical ceramics, its tensile properties are still lower than those of metallic biomaterials. Results from aging and fatigue studies show that it is essential that alumina implants be produced at the highest possible standards of quality assurance, especially if they are to be used as orthopedic prostheses in younger patients.^[9] In some cases, alumina can experience a time-dependent decrease in strength during immersion in saline in vitro and after implantation, probably due to a preferential dissolution of impurities that results in crack propagation.

WEAR

High-density alumina exhibits a high surface wettability, leading to a very low coefficient of friction when sliding against itself or polyethylene. These

excellent wetting characteristics are due to an outer surface of alumina nonsaturated with oxygen ions, which adsorbs a monomolecular film of water and biological molecules.^[2] This adsorbed layer limits the direct contact of the articulating solid surfaces. The high surface energy of alumina—a value measured at 2.64 J/m² for α -form^[10]—is demonstrated through contact angle measurements.

The low coefficient of friction and wear rates of alumina occur only when the grains are very small (<4 μm) and have a very narrow size distribution. These conditions lead to very low surface roughness values (<0.02 μm). If large grains are present, they can pull out and lead to very rapid wear of bearing surfaces, owing to local dry friction. Any roughness on alumina is inverse (due to pullout of grains), in contrast to the protruding asperities encountered with metal carbides. The concave surface roughness is an important factor contributing to the outstanding wear properties of alumina ceramics.^[2]

For alumina on load-bearing, wearing surfaces (as in hip prostheses), macrogeometry, represented by sphericity and circularity, is also important. Alumina balls must have a very high degree of sphericity (<1 μm), produced by polishing and grinding the two mating surfaces together. For example, the alumina ball and socket in a hip prosthesis are polished together and used as a matched pair. The long-term coefficient of friction of an alumina/alumina joint decreases with time and approaches the values of a normal joint (ca. 0.01 m³/h). This leads to wear on alumina-articulating surfaces being nearly 10 times less than wear on metal-polyethylene surfaces.^[1]

BIOCOMPATIBILITY

Because all materials elicit some response from living tissues, no materials implanted in a living host are inert. Alumina is classified as nearly inert because it is nontoxic and biologically inactive.^[11] Nothing goes into solution that would biochemically disturb the normal proliferation of adjacent cells. Because the surfaces of alumina implants are covered in or coated by biomolecules, within about a minute after immersion into body fluid, the implants become camouflaged against the host's immune system.^[3,5] The interface between ceramic and bone is not chemically or biologically bonded, and there is relative movement. Progressive development of a fibrous capsule occurs in soft and hard tissues with variable thickness depending on relative motion. This contact osteogenesis leads to secondary stabilization by bony ingrowth. The sequence of events in interface remodeling is essentially the same as occurs in fracture healing. Although alumina is the most biocompatible material in bulk form,

alumina particles can induce a considerable foreign-body reaction when produced in massive quantity. However, among all the wear particles derived from prosthetic components, alumina particles of very small size (0.0005–0.002 mm) exhibit the highest biocompatibility and lowest fibrogenic potential.

When alumina is used as a ceramic coating by the air-plasma-spray application, the coating is also inert and entirely compatible with bone. Ionic diffusion from alumina is considered negligible.^[12]

Biocompatibility testing of implantation materials is regulated by ISO 10993 and other standards ordained by bodies such as the European EN30993, the U.S. Food and Drug Administration (FDA), and the Japanese Ministry of Health and Welfare (MHW). These agencies share a common approach to testing for biological effects such as cytotoxicity, sensitization, genotoxicity, implantation, chronic toxicity, and carcinogenicity.^[13]

APPLICATIONS

Articulating Surfaces in Joint Replacements

Due to its ability to be polished to a high surface finish and its excellent wear resistance, alumina is often used for wear surfaces in joint replacement prostheses. Such applications include femoral heads for hip replacements and wear plates in knee replacements. More than 100,000 hip prostheses with alumina balls for the femoral head components are implanted annually.^[14] Figure 1 shows a schematic of total hip replacement (THR) surgery.^[15] In hip replacements, the alumina femoral head is used in conjunction with a metallic femoral stem and an acetabular cup made from ultrahigh-molecular-weight polyethylene (UHMWPE) or alumina itself for the opposing articulating surface. Figure 2 shows a modern ball-and-socket system for an artificial hip joint.^[16]

In joint replacements, success depends on two aspects: 1) the frictional and wear behavior of the materials; and 2) the reliability of the anchorage of the components in their bony environment. As shown in Table 2, wear rates for alumina on UHMWPE are as much as 20 times lower than those for metal on UHMWPE, producing less tribological debris and making this combination far superior.^[2] Wear debris leads to complications such as osteolysis in surrounding tissues; keeping it to a minimum is advantageous. The production of particulate wear debris from implant materials (polyethylene in particular) and subsequent osteolysis have been recognized as the major cause of long-term failure in total hip replacement. Due to their low wear rate, noncemented alumina cups press-fitted into the acetabulum of the hip

Fig. 1 Schematic of total hip replacement (THR) surgery. In general, the femoral implant stem is anchored to the bone by either a thin layer (a few mm thick) of polymethylmethacrylate (PMMA) cement or a cementless system involving a snug fit of the stem in the femoral shaft. In typical cementless fixation, the upper third of the stem is covered with a porous coating of sintered metal alloy beads or ceramics. Bone growth into the porous surface provides mechanical anchoring. (From Ref. [15].)

are widely used. The cups are stabilized by the growth of bone into grooves or around pegs.^[1] The mating femoral ball surface, bonded to a titanium alloy or cobalt-chrome alloy stem, can also be made of alumina. Typical diameters for femoral heads are 32 mm and 28 mm and lower. Well-designed tapers are used for their fixation.

An alumina/alumina ceramic bearing couple is theoretically superior to alumina/UHMWPE or metal/UHMWPE as an articulating surface for a total joint system. Use of alumina not only eliminates polyethylene from the device system, but its extremely low coefficient of friction and potential for far superior wear resistance are very advantageous. Polyethylene debris is known to be particularly responsible for the inflammatory response that leads to bone resorption and loosening of implants over time.^[17] In the case of

alumina, however, the usual biologic event is a fibrocytic reaction with very few macrophages and no giant cells^[16,18] unless there is metallic debris or a very large amount of ceramic debris generated by abnormal contact, or following a long period of component loosening.^[19] Experience with retrievals from ceramic implants indicates that ceramic debris is less reactive than polyethylene or metal debris.

However, alumina/alumina bearings have experienced early design failures due mostly to inferior material properties. Since 1985, manufacturers have introduced alumina with small grain sizes that eliminate mechanical failure under physiological loads. Improvements such as hot isotactic pressing (HIP) have led to alumina ceramics of nearly theoretical density (3.97 g/cm^3) that have much reduced grain size, fewer inclusions, and limited grain boundaries, all of which have led to a great increase in the toughness and burst strength of the material.^[12]

By the late 1960s, the Charnley hip implant system with metallic femoral stem and UHMWPE acetabular component had become the primary design for successful total hip arthroplasty (THA). Dense alumina ceramic was introduced in the 1970s in Europe as a potentially improved bearing surface for THA. Figure 3 compares long-term clinical test results in terms of the

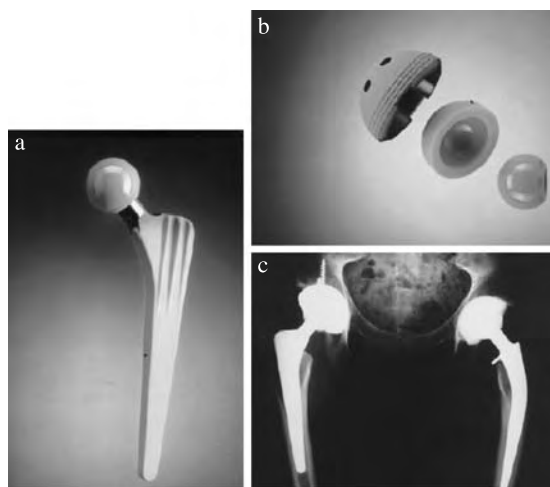

Fig. 2 Modern design of ball-and-socket bearing system for artificial hip joint. (a) Fully hydroxyapatite (HA)-coated cementless stem and alumina ball; (b) cementless titanium shell fully coated with HA, with an alumina liner; (c) one-year follow-up. (From Ref. [16].)

Table 2 Average annual wear rates of articulating surfaces in total hip prostheses

Materials	Wear rates ($\mu\text{m}/\text{year}$)
Co-Cr-Mo alloy/UHMWPE	200
Alumina/UHMWPE	20–130 ^a
Alumina/alumina	2

^a20 ($\mu\text{m}/\text{year}$) refers to observations of explanted components and includes only wear measurements. 130 ($\mu\text{m}/\text{year}$) refers to penetration measurements between head and acetabular components observed by means of radiographic analysis, and includes plastic flow in addition to wear.

Fig. 3 Survivability curves for total hip arthroplasty. Numbers in parentheses indicate the references containing data on which the curves are based.

Kaplan-Meier survivability curves.^[20] For Charnley THAs with metal/PE bearing, a summary of the 42 published clinical studies^[21] is shown as a single curve together with a curve derived from a recent report on 25-year follow-up evaluations for 2000 consecutive primary THAs performed at one institution from 1966–1971.^[22] Such long-term data for alumina/alumina THAs are rare, and their reliability is hampered by the poor quality of early alumina ceramic materials (previously discussed). In any case, the curve in Fig. 3 for alumina/alumina bearings was constructed from a recent report on 20-year follow-up evaluations for 118 consecutive THAs between 1979 and 1980.^[23] The prostheses combined a 32-mm alumina head and an all-alumina socket. Both cemented and uncemented acetabular femoral components were used.

It is notable that the rate of alumina/alumina implant survivorship is satisfactory, yet significantly lower than that of Charnley THAs with similar duration of follow-up. However, a very low rate of acetabular surface wear (<0.025 mm/yr) was identified and little osteolysis was seen. This demonstrates that the limited amount of ceramic debris is generated by the bearing surface. Thus the failures observed in this series do not seem to be directly attributable to the alumina-on-alumina design, but rather to implant fixation (component loosening). The problem may be improved by newer implant designs such as modular, metal-backed, porous-coated, uncemented acetabular components combined with improved femoral designs. Alumina/UHMWPE prostheses are reported to have slightly higher survivability than alumina/alumina bearings, but the number of implants tested was too small (<100 implants) to have statistical significance.^[21]

In total knee replacements, alumina is used in portions coming into contact with bone, and a combination of alumina and UHMWPE is used in sliding

Fig. 4 Cementless total knee prosthesis made by a combination of alumina with UHMWPE. (From Ref. [24].)

portions. The stem is positioned at the center of the tibial plate and the load is transmitted through the stem to the cortical bone in the posterior portion of the tibia (Fig. 4). To improve the anchoring property, the tibial plate is metal-backed and both femoral and tibial components are cemented.^[24] In total knee arthroplasty, problems caused by polyethylene debris are more severe than in hip surgery because of the different curvatures of the femoral condyle and the top of the tibial plateau. The search for further improvement in materials and design therefore continues.

The cementless alumina ceramic total ankle prosthesis employs alumina ceramics for the interface with the bone and a combination of UHMWPE with alumina ceramics for the sliding part.^[25] The tibial component is designed to be loaded on the cortical bone at the anterior part of the tibia and on the cancellous and cortical bones at the posterior part.

Medical-grade alumina has a Young's modulus of 380–420 GPa, which is much higher than that of cancellous bone (0.05–0.5 GPa depending on location and age) or cortical bone (7–25 GPa). There is thus a great mismatch in elastic modulus between a bone and an implant, and the alumina implant consequently shields the bone from mechanical loading, allowing nearly all the mechanical load to be carried by the implant. Living bone must be under a certain amount of tensile load in order to remain healthy. If it is unloaded or is loaded in compression, the resulting stress shielding will cause biological changes, leading to resorption and weakening of the bone and to deterioration of the implant-bone interface.^[9] This limits the effectiveness of alumina as a bone interface material.

Bone Spacers

Porous alumina may also be used in bone spacers to replace large sections of bone that have been removed for a reason such as cancer. Bone spacers may take the

shape of concentric rings around a metallic pin, inserted up the center of the remaining native bone. The porous nature of these implants allows new bone to grow into the pores, effectively using the alumina as a scaffold for new bone formation. Here, load bearing is not the primary concern. When pore size exceeds $100\ \mu\text{m}$, bone will grow within the interconnecting pore channels near the surface and maintain its vascularity and long-term viability (termed biological fixation). In this manner, the implant serves as a structural bridge or scaffold for bone formation.^[1]

Porous ceramics for bone implants—including alumina, calcium phosphates, and hydroxyapatite—are produced by a replamineform (or hydrothermal exchange) process in which the microstructures of certain corals (*Porities* or *Goniopora*) are used to cast the porous ceramic.^[26] Porous alumina may also be made from a suitable foaming agent that evolves gases upon heating. A mixture of powdered calcium carbonate and fine alumina powder can thus be fired at $1450\text{--}1500^\circ\text{C}$ for 20 hours to obtain a foamed material whose pore size and volume fraction (33–48% of porosity) are determined by the size and concentration of the original calcium carbonate particles.

Porous alumina is weaker than the bulk form, with the material rapidly weakening as porosity increases.^[1] Because much surface area is exposed, the environment becomes much more important for porous than for nonporous, dense material. The aging of porous alumina, with subsequent decrease in strength, requires bone ingrowth to stabilize the structure of the implant.

Dental Applications

Dense alumina has been used in dental applications,^[3–5] specifically for replacement teeth. They are used immediately or shortly after extraction (and after a reshaping of the alveoli to achieve the press-fit necessary for an undisturbed period of bone healing), and later as implants in edentulous regions of the jaw. Polycrystalline alumina can be fractured when inserted as an artificial small-diameter dental root. Therefore, in many cases single-crystal alumina or sapphire is used, with bending strength ($13,000\ \text{kg}/\text{cm}^2$) three times higher than polycrystalline alumina ($3,500\ \text{kg}/\text{cm}^2$). Compressive strength ($30,000$ vs. $10,000\ \text{kg}/\text{cm}^2$) and elastic modulus (385 vs. $371 \times 10^4\ \text{kg}/\text{cm}^2$) are also better for single-crystal alumina. It has demonstrated compatibility suitable with alveolar bone and gingival epithelium.

Designs of single-crystal alumina implants have improved since 1975, and their clinical applications have widened.^[27] They have been manufactured as endodontic endosteal implants, endosteal implants, and intramucosal inserts. Porous alumina implants are

Fig. 5 Basic design for porous alumina dental implant. (A) Cervical portion; (B, C,) porous alumina layer and apex portion, made of polycrystalline alumina; (D) screw designed for self-tapping. Root core is made of single crystal alumina. (From Ref. [28].)

made of single-crystal alumina cylindrical core, around which porous polycrystalline alumina is fused at high temperatures. A basic design is shown in Fig. 5. The single-crystal core makes alumina dental implants strong enough to bear occlusal forces.

There are some disadvantages to basing the design of dental implants on alumina: It cannot be customized easily and cannot be bent like metal; it has a high modulus of elasticity compared to bone, and a wide radiolucent zone thus develops around the implants, owing to bone resorption and increased connective tissue at the implant-bone interface. However, if the implant has suitable loading of functional stress, it can maintain functional fixation with biodynamic responses of resorption and remodeling. Alumina dental implants are currently declining in popularity, being replaced by material such as dental porcelain.

Other Applications

Alumina ceramics have been clinically tested in prostheses for elbows, shoulders, wrists, and fingers with success equal to or better than other material systems.^[2,3,5] Alumina ceramics have been used in ENT applications and in maxillofacial surgery.^[28] Extended animal experiments have shown that middle ear mucosa proliferates normally on the surface of dense, pure, alumina ceramic. Since the early 1980s, total and partial ossicular replacements made of alumina ceramic have stood the test of clinical experience, showing improved success compared to plastic components. One advantage of alumina ceramic implants is the possibility of achieving a highly precise fit by careful

grinding. (The procedure requires adjustment of the implants' length and shape for each individual case.) In treating throat cancer patients, the cartilage that prevents the collapse of the trachea may need to be removed, necessitating the insertion of some support structure to keep the trachea open. Trachea-supporting rings made of alumina have shown better results than previously used polymeric rings due to alumina's higher degree of inertness.^[29] Alumina implants have been used for neurosurgical operations such as cranioplasty to repair bone defects in both the cortical convex and suboccipital regions, and to reconstruct the cellar floor and orbital wall.^[30] Orbital support plates have also proven clinically successful and are in routine use.

A soft-tissue application of dense, pure alumina ceramics is in keratoprotheses (corneal replacement). This routinely used eye prosthesis consists of a corundum single crystal as the optical part and an alumina ceramic holding ring.^[31] Small porous collars of alumina or aluminum-calcium phosphate serve as controlled drug-delivery systems to deliver hormones, vaccines, and drugs in a controlled, sustained manner over long periods of time in amounts that are effective, yet not toxic to the host.^[32]

A NEW ALUMINA MATRIX COMPOSITE

Alumina has been successfully used in orthopedic implants for the last 30 years because it is a biocompatible, inert structural material suitable for use in load-bearing joints. Because alumina has limited strength, the application remains limited to designs with sufficient wall thickness. It is relatively brittle, so can fracture; its application is therefore restricted to designs involving compressive loading or limited tensile loads. It is susceptible to slow crack growth and undergoes slight reductions in fracture strength with time, depending on the physiological environment.

Zirconia has higher strength than alumina, with excellent biocompatibility and wear resistance. However, it shows poor hydrothermal stability during sterilization and *in vivo*. Zirconia-toughened alumina (ZTA) has been used in mechanical and engineering applications for more than 20 years. New materials based on mixed zirconia and alumina have recently been proposed as biomaterials that may combine the positive effects of alumina and zirconia ceramics, while avoiding the drawbacks of zirconia. A new material—transformation-toughened and platelet-reinforced alumina (TTPA)—promises zirconia's excellent mechanical performance, but not the problems of hydrothermally-induced degradation that attend the use of alumina matrix material.^[33] The material consists of approximately 75% alumina and 25% zirconia,

combined with small amounts of additives. Chromium oxide forms a solid solution with alumina, and increases hardness and wear resistance. Controlled introduction of strontium oxide can achieve the *in situ* generation of platelet strontiumaluminate particles in the matrix during the sintering process, affording these particles excellent fixation in the alumina matrix.

The new material combines the properties of ceramic and metal, and surpasses the properties of alumina and zirconia in many aspects. It is extremely hard, wear-resistant, and well-tolerated by the body, while demonstrating good fracture toughness and flexural strength. These improved properties could redefine the design limits of implants' diameter and wall thickness. Applications like knee components and finger joints are now technically feasible. The excellent clinical performance of alumina ceramics in hip arthroplasty can thus now be transferred to applications whose existing components fall short of surgeons' expectations.

CONCLUSION

Highly pure, dense alumina is the main bioinert ceramic material used in medical prostheses and has withstood long-term applications in hip surgery and dental implantology. Although some dental implants are single-crystal sapphire, most alumina devices are very fine-grained α - Al_2O_3 produced by pressing and sintering at temperatures ranging from 1600 to 1800°C, depending on the properties of the raw materials. Its wide use in load-bearing applications is based on the combination of excellent corrosion resistance, good biocompatibility, high wear resistance, and high compressive strength. Advances in technology that have produced high-quality alumina enabled alumina/UHMWPE and alumina/alumina couplings to become viable alternatives to conventional metal/UHMWPE designs, especially for young and more active patients. Alumina for articulating surfaces in total joint replacement has the tribological properties most capable of being capitalized into the best clinical results.

However, the phenomena of slow crack growth, static and cyclic fracture, low toughness, deterioration over time in the physiological environment, and sensitivity to tensile strength are serious concerns in high-load-bearing applications. The high modulus of alumina also limits its effectiveness as bone interface material. The recent development of a new alumina matrix composite may extend the useful lifetime of artificial joints from the current 10 years to a much longer period, and may open the door for new applications. It is anticipated that the use of alumina ceramics in total joint prostheses and otologic,

maxillofacial, and dental applications will continue to grow.

INTRODUCTION

Traditional cytotoxic therapies (chemotherapy and radiation therapy) used in the management of solid tumors are associated with significant therapeutic and safety limitations that impact effective disease control and patient survival. The successful administration of cytotoxic therapy can be limited by non-specific toxicity in normal tissues, with poor tolerance resulting in subtherapeutic dosing or treatment discontinuation. Furthermore, overlapping toxicities may affect the successful administration of concurrent chemotherapy and radiation therapy. Tumor resistance is a further obstacle to effective treatment with cytotoxics. These limitations have focused attention on treatment approaches that target tumor cells while limiting damage to healthy cells. Increasing evidence suggests that agents specifically targeting cellular receptors or other elements of the tumor microenvironment may be synergistic with cytotoxics.

The field of angiogenesis modulation is at a major crossroads. A tremendous advancement in basic science in this field is providing excellent support, though there is a lack of strong clinical support at this point with the exception of the recent data on anti-vascular endothelial growth factor (VEGF) as an adjunct to chemotherapy in solid tumor. Clinical outcome should include benefit/risk ratio, cost effectiveness, and hard end points including mortality, quality of life as opposed to tumor size reduction or decrease, and microvascular density with antiangiogenesis agents.

Experimental models should be used to provide guidance, placebo effect, comparative data, and mechanistic understanding but not for expected clinical efficacy.

BACKGROUND

In normal tissue, new blood vessels are formed during tissue growth and repair and during the development of the fetus during pregnancy. In cancerous tissue, tumors cannot grow or spread (metastasize) without the development of new blood vessels. Blood vessels

supply tissues with oxygen and nutrients necessary for survival and growth.^[1]

Endothelial cells, the cells that form the walls of blood vessels, are the source of new blood vessels and have a remarkable ability to divide and migrate. The creation of new blood vessels occurs by a series of sequential steps. An endothelial cell forming the wall of an existing small blood vessel (capillary) becomes activated, secretes enzymes that degrade the extracellular matrix (the surrounding tissue), invades the matrix, and begins dividing. Eventually, strings of new endothelial cells organize into hollow tubes, creating new networks of blood vessels that make tissue growth and repair possible.^[1-3]

Most of the time, endothelial cells lie dormant, but when needed, short bursts of blood vessel growth occur in localized parts of tissues. New capillary growth is tightly controlled by a finely tuned balance between factors that activate endothelial cell growth and those that inhibit it.^[1,2]

The production of new vasculature is a key requirement for tumor growth. Several oncogenes, including growth factors and their receptors, have a role in angiogenesis. Basic fibroblast growth factor (bFGF) and VEGF are key examples.

There is evidence that epidermal growth factor receptor (EGFR) and its ligands are involved in angiogenesis. Both epidermal growth factor (EGF) and transforming growth factor (TGF)-alpha have been shown to be attractants for a rat heart vascular endothelial cell line and to induce angiogenesis *in vivo* in a hamster model. In addition, it has been demonstrated that growth factor coexpression correlates with microvessel density in invasive breast cancer. These angiogenic factors can also interact in a regulatory fashion. For example, TGF-alpha promotes expression of VEGF, and inhibition of EGFR appears to decrease the angiogenic factors VEGF, bFGF, and interleukin (IL)-8, as well as microvessel density.

About 15 proteins are known to activate endothelial cell growth and movement, including angiogenin, epidermal growth factor, estrogen, fibroblast growth factors (acidic and basic), IL-8, prostaglandin E1 and E2, tumor necrosis factor-alpha, VEGF, and granulocyte colony-stimulating factor. Some of the

known inhibitors of angiogenesis include angiostatin, endostatin, interferons, IL-1, IL-12, retinoic acid, and tissue inhibitor of metalloproteinases.^[1,2,4]

At a critical point in the growth of a tumor, the tumor sends out signals to the nearby endothelial cells to activate new blood vessel growth. Two endothelial growth factors, VEGF and bFGF, are expressed by many tumors and seem to be important in sustaining tumor growth.^[1,2]

Angiogenesis is also related to metastasis. It is generally true that tumors with higher densities of blood vessels are more likely to metastasize and are correlated with poorer clinical outcomes. Also, the shedding of cells from the primary tumor begins only after the tumor has a full network of blood vessels. In addition, both angiogenesis and metastasis require matrix metalloproteinases (MMPs), enzymes that break down the surrounding tissue (the extracellular matrix), during blood vessel and tumor invasion.^[1,3]

Strategies

Of the antiangiogenesis drugs now in clinical trial, some are designed to target specific molecules involved in new blood vessel formation. The exact mechanism of other drugs is not known, but they have been shown to be antiangiogenic by specific laboratory tests (in the test tube or in animals).

In general, four strategies are being used by investigators to design antiangiogenesis agents:

1. Block the factors that stimulate the formation of blood vessels.
2. Use natural inhibitors of angiogenesis.
3. Block molecules that allow newly forming blood vessels to invade surrounding tissue.
4. Incapacitate newly dividing endothelial cells.

Angiogenesis and Angiogenesis Inhibitors: A New Potential Anticancer Therapeutic Strategy

Tumor cells cannot grow as a mass above 2 to 3 mm³ because diffusion is insufficient for oxygen and glucose requirements, unless the tumor induces a blood supply. This mechanism of induction of a new blood supply from pre-existing vascular bed is called angiogenesis. Furthermore, tumor invasiveness and metastasis require neovascularization. In fact, recent published studies suggest that acquisition of the angiogenic phenotype is a common pathway for tumor progression, and neovascularization is linked with other molecular steps leading to tumor progression. The angiogenic process is a complex multistep cascade under the control of positive and negative soluble factors. A paracrine interaction occurs between tumor

and endothelial cells. Angiogenesis involves endothelial cell proliferation, migration, and tubule formation with associated changes in the extracellular matrix, allowing subsequent new vessel growth toward the tumor. Each of the above steps may represent a target for antiangiogenic therapy. Antiangiogenesis is to be distinguished from direct targeting and destruction of tumor vasculature.^[1,3]

BIOTECHNOLOGY-DRIVEN STRATEGIES

Kininostatin

Domain5 (D5) of high molecular weight kininogen has been shown to inhibit endothelial cell migration toward vitronectin, endothelial cell proliferation, and angiogenesis in the chicken chorioallantoic membrane assay. Structure-function studies demonstrate that D5 contains a peptide that inhibits only migration and another peptide that inhibits only proliferation. Data on a related inhibitory monoclonal antibody confirmed the role of kininogen in angiogenesis modulation.^[5]

The $\alpha 3$ Chain of Type IV Collagen Inhibits Tumor Growth

Studies from our laboratory have shown that type IV collagen (COL IV), specifically a peptide comprising residues 185–203 of the noncollagenous domain (NCI) of the $\alpha 3$ (IV) chain, has several biological activities, including inhibition of neutrophil activation, promotion of tumor cell adhesion and chemotaxis, and inhibition of tumor cell proliferation.^[6]

Anti-VEGF

VEGF is an endothelial cell-specific mitogen and an angiogenic inducer. VEGF is essential for developmental angiogenesis and is also required for female reproductive functions and bone formation. Substantial evidence also implicates VEGF in tumors and intraocular neovascular syndromes. A humanized anti-VEGF monoclonal antibody (rhuMab VEGF) Avastin demonstrated improved survival in patients with colorectal cancer when combined with chemotherapy versus chemotherapy alone.^[7] It was also shown to have clinical efficacy against lung and renal cancer.^[8,9]

Role of MMP in Cancer Metastasis

MMPs are zinc-dependent endopeptidases that degrade extracellular matrix proteins (collagens, laminin,

and fibronectin) during the process of cancer invasion and metastasis. Contrary to expectations, MMPs are produced primarily by reactive stromal and inflammatory cells surrounding tumors rather than cancer cells. Potent, orally available, hydroxamic acid-derived inhibitors of MMPs are currently in clinical trials for the treatment of lung, prostate, pancreatic, gastric, and breast cancer. These drugs have demonstrated efficacy alone and in combination with chemotherapy in preclinical trials in mice. In contrast, clinical trials in advanced stage cancer demonstrated lack of efficacy. Further trials in early stages of cancer in conjunction with chemotherapeutic agents are in progress.

2-Methoxyestradiol

2-Methoxyestradiol (2ME) is now being recognized as a potent orally active antiangiogenic and antitumor agent that has minimal if any toxicity. Despite being an endogenous estradiol metabolite, 2ME does not show any estrogenic activity in vitro or in vivo at doses at which estradiol and other metabolites are clearly estrogenic. 2ME is presently in phase I study for metastatic and recurrent breast cancer.

Small Molecule Integrin Antagonists

The role of various integrins in angiogenesis-mediated disorders was demonstrated.^[7] In addition to the well-described role of $\alpha v \beta 3$ and $\alpha v \beta 5$ integrins,^[8] a role for $\alpha 5 \beta 1$ integrin in the modulation of angiogenesis was defined.^[9] The role of $\alpha 5 \beta 1$ integrin in angiogenesis was established through the use of monoclonal antibody, cyclic peptide, and nonpeptide $\alpha 5 \beta 1$ integrin antagonists.^[9]

Ocular Angiogenesis

Age-related macular degeneration (ARMD) is the leading cause of blindness in people over the age of 55, affecting more than 10 million Americans. It is a condition in which the central portion of the retina (the macula) deteriorates. It is equally common in men and women and more common in whites than blacks. The cause is unknown, but the condition tends to run in some families. Macular degeneration affects more Americans than cataracts and glaucoma combined. In the most severe form of age-related macular degeneration (known as wet ARMD), abnormal angiogenesis occurs under the retina, resulting in irreversible loss of vision. The loss of vision is due to scarring of the retina secondary to the bleeding from the new blood vessels. Current treatments for wet ARMD utilize laser-based

therapy to destroy offending blood vessels. However, this treatment is not optimal since the laser can permanently scar the overlying retina, and the offending blood vessels often regrow. Advancing novel angiogenesis inhibitors that effectively and safely inhibit the growth of new vessels in diabetic retinopathy and ARMD, and hence restore lost vision, is the main focus of the field now.

Several antiangiogenesis compounds are currently undergoing clinical trials for treatment of these devastating eye diseases. Relevant models of ocular angiogenesis have been essential in the preclinical validation of viable drug candidates for clinical development. A variety of systems are used to test angiostatic agents; however, specific animal models may be more indicative of certain human disease targets. Rationale for and utility and limitations of these animal systems of ocular angiogenesis were discussed with regard to the preclinical pathway of a novel angiostatic steroid, anecortave acetate. Preclinical models have many limitations with regard to an expected clinical outcome, but they can be valuable in providing guidelines for clinical development.^[10]

Ocular Angiogenesis: The Key Contributions of MMP and VEGF

The inappropriate growth of blood vessels in the cornea, iris, trabecular meshwork, and retina is a leading cause of blindness in developed countries. Both MMP and VEGF are involved in the early stages of disease-related angiogenesis (neovascularization). The strategies and compounds under development for inhibiting MMPs and VEGF for preventing neovascularization and improving the outlook for patients at risk for blindness are under investigation.^[10] The role of hypoxia, extracellular matrix, growth factors, and integrins in pigmented epithelial cell biology might contribute to ocular disorders.^[10,11]

Antiangiogenic Therapy in Multiple Myeloma

In recent years, several pieces of evidence have pointed out that disease progression in multiple myeloma (MM) is characterized by increased bone marrow neovascularization. Targeting the mechanisms that control angiogenesis could thus represent an innovative therapeutic approach to MM. Thalidomide, a glutamic acid derivative with sedative properties, is able to inhibit angiogenesis in murine models; this compound has recently been demonstrated to be effective in relapsed/refractory MM, leading to a 30–40% response, coupled with mild systemic toxicity. Inhibition of angiogenesis is probably just one of the mechanisms by which thalidomide exerts

its action in MM, as immunomodulation and inhibition of cytokine production by bone marrow stroma could also be involved. At present, several studies are ongoing, aiming at testing thalidomide-based drug combinations, mainly with dexamethasone, but also with conventional chemotherapy; the results that have been obtained so far show a synergistic effect of the drug combinations, with a response rate ranging from 50 to 70% in pretreated patients. There is now growing interest in novel compounds with potential antiangiogenic effects. Among them, a promising activity both *in vitro* and in animal models has been displayed by thalidomide analogs, inhibitors of VEGF-2, and endostatin.^[12] However, those angiogenesis inhibitors such as thalidomide and anti-VEGF SU015 demonstrated increased incidence of thrombosis when used in combination with chemotherapeutic agents.^[13,14]

Anticoagulants and Angiogenesis

Many cancer patients reportedly have a hypercoagulable state, with recurrent thrombosis due to the impact of cancer cells and chemotherapy on the coagulation cascade.^[15] Analysis of biomarkers of the coagulation cascade and of vessel wall activation was performed and showed significant increases in thrombin generation and endothelial cell perturbation in a treatment cycle-dependent manner when combining angiogenesis inhibitors and chemotherapeutic agents.^[13,14] The incidence of thromboembolic events, possibly related to the particular regimen tested in this study (SU015 and chemotherapeutic agents), discourages further investigation of this regimen.^[14] This investigation, along with the increased incidences of deep vein thrombosis (DVT) in MM patients receiving thalidomide and chemotherapeutic agents,^[13] suggest the potential advantages of using an anticoagulant such as heparin or low-molecular-weight heparin (LMWH). Additionally, studies have demonstrated that unfractionated heparin (UFH) or LMWH interfere with various processes involved in tumor growth and metastasis. Clinical trials have indicated a clinically relevant effect of LMWH, compared to UFH, on the survival of cancer patients with DVT. Mechanism and efficacy of LMWH and its *in vivo* releasable tissue factor pathway inhibitor on the regulation of angiogenesis and tumor growth was documented.^[15,16] Heparin, steroids, and heparin/steroid combinations have been used in a variety of *in vitro* models and *in vivo* in animal models as effective inhibitors of angiogenesis.^[16,17] Additionally, platelet-tumor cell interactions could play a significant role in tumor metastasis.^[18]

About 20 angiogenesis inhibitors are currently being tested in human trials. Most are in early phase I

or II clinical (human) studies. [See list of angiogenesis inhibitors in clinical trials (Table 1)]. Phase I/II trials include a limited number of people to determine the safety, dosage, effectiveness, and side effects of a drug. In phase III trials, hundreds of people around the country are assigned at random to receive either the new treatment or the standard treatment (Table 1).

CRITICAL ISSUES

Antiangiogenesis is likely to develop into a novel therapeutic approach for patients with solid malignancies. Most current clinical trials evaluate antiangiogenic drugs aimed primarily against single angiogenesis stimulators. A single solid malignancy is shown to produce at least three biologically active angiogenesis stimulators (VEGF, bFGF, and IL-8). This suggests that tumor angiogenesis results from the activity of multiple rather than single angiogenesis stimulators. It was shown that a combination of antiangiogenic drugs is more effective in inhibiting tumor-induced endothelial cell growth than a single agent. These results imply that clinical antiangiogenic strategies for the treatment of solid malignancies may be most effective when multiple rather than single antiangiogenesis drugs are used.

Possible Mechanisms of Acquired Resistance to Antiangiogenic Drugs

The ultimate target of antiangiogenic drugs is the genetically stable, activated endothelial cell of a newly forming tumor blood vessel, rather than the genetically unstable tumor cell population *per se*. This led to the notion that acquired resistance to such drugs may not develop as readily, if at all. While there is some evidence that this lack of resistance development may be the case for some direct-acting angiogenesis inhibitors, it is becoming apparent that resistance can develop over time to many types of angiogenesis inhibitors including, possibly, some direct inhibitors, especially when used as monotherapies.^[19] Possible mechanisms for such acquired or induced resistance include 1) redundancy of proangiogenic growth factors when the drug used targets a single such growth factor or its cognate endothelial cell-associated receptor tyrosine kinase; 2) the antiapoptotic/prosurvival function of growth factors such as VEGF, which, in high local concentrations, can antagonize the proapoptotic effects of various angiogenesis inhibitors; 3) epigenetic, transient upregulation, or induction, of various antiapoptotic effector molecules in host endothelial cells; and 4) heterogeneous vascular

Table 1 Angiogenesis inhibitors that have reached clinical trials

Drug	Sponsor	Trial	Mechanism
<i>Drugs that prevent new blood vessels from invading surrounding tissue</i>			
Marimastat	British Biotech—Annapolis, Md.	Phase III	Synthetic inhibitor of matrixmetalloproteinases (MMPs).
Bay 12-9566	Bayer—West Haven, Conn.	Phase III	Synthetic MMP inhibitor.
AG3340	Agouron—LaJolla, Calif.	Phase III	Synthetic MMP inhibitor.
CGS27023A	Novartis—East Hanover, N.J.	Phase I	Synthetic MMP inhibitor.
COL-3	Collagenex Pharmaceuticals—Newtown, PA.	Phase I	Antibiotic derivative that inhibits MMPs.
Vitaxin	Ixsys, Inc.—LaJolla, Calif.	Phase I	Antibody to integrin, present on endothelial cell surface.
<i>Natural inhibitors of angiogenesis</i>			
Platelet factor-4	Repligen—Cambridge, Mass.	Phase II	Inhibits endothelial cell growth.
Interleukin-12	Genetics Institute—Cambridge, Mass.	Phase I/II	Inhibits endothelial cell growth.
<i>Drugs that block factors that stimulate the formation of blood vessels</i>			
RhuMabVEGF	Genentech—South San Francisco, Calif.	Phase II/III	Monoclonal antibody to vascular endothelial growth factor (VEGF).
SU5416	Sugen, Inc.—Redwood City, Calif.	Phase I	Molecule that blocks VEGF receptor signaling.
Interferon- α	Commercially available	Phase II/III	Inhibits release of endothelial growth factor.
<i>Targeted antivascular therapy</i>			
ZD0101	Zeneca Pharmaceuticals—Wilmington, Del.	Phase I/II	Bacterial toxin that binds to new blood vessels and induces inflammatory response.
<i>Interrupts function of dividing endothelial cells</i>			
TNP-40	TAP Pharmaceuticals, Inc.—Deerfield, Ill.	Phase II	Synthetic analogue of fungal protein;inhibits endothelial cell growth.
<i>Unknown mechanism; inhibits angiogenesis in laboratory and animal assays</i>			
Thalidomide	Entremed, Inc.—Rockville, MD.	Phase II	Synthetic sedative: unknown mechanism.
CAI	National Cancer Institute—Bethesda, MD.	Phase I/II	Nonspecific inhibitor cell invasion and motility.
Squalamine	Magainin Pharmaceuticals, Inc.—Plymouth Meeting, PA.	Phase I	Extract from dogfish shark liver; inhibits sodium-hydrogen exchanger, NHE3.
Suramin	Parke-Davis—Morris Plains, N.J.	Phase II/III	Nonspecific multisite effects.
IM862	Cytran—Kirkland, WA.	Phase II	Unknown mechanism.

dependence of tumor cell populations. It is suggested that long-term disease control with antiangiogenic drugs can be best achieved by judicious combination therapy. In this regard, the great molecular diversity of antiangiogenic drug targets, in contrast to chemotherapy, makes this a particularly attractive therapeutic option, especially when used in combinations.^[1,19]

Standard Chemotherapy Versus Angiogenesis Inhibitors

Several differences between standard chemotherapy and antiangiogenesis therapy result from the fact that angiogenesis inhibitors target dividing endothelial cells rather than tumor cells. Antiangiogenic drugs are not likely to cause bone marrow suppression,

gastrointestinal symptoms, or hair loss. Also, since antiangiogenic drugs may not necessarily kill tumors, but rather hold them in check indefinitely, the end point of early clinical trials may be different than for standard therapies. Rather than looking only for tumor response, it may be appropriate to evaluate increases in survival and/or time to disease progression.

Drug resistance is a major problem with chemotherapy agents. This is because most cancer cells are genetically unstable, are more prone to mutations, and are therefore likely to produce drug-resistant cells. Since angiogenic drugs target normal endothelial cells, which are not genetically unstable, drug resistance may not develop. So far, resistance has not been a major problem in long-term animal studies or in clinical trials.

Finally, antiangiogenic therapy may prove useful in combination with therapy directly aimed at tumor cells. Because each therapy is aimed at a different cellular target, the hope is that the combination will prove more effective.

Antiangiogenesis Agents and Thrombosis

Antiangiogenesis agents might mediate endothelial cell dysfunction, which could be associated with increased incidence of thrombosis.^[12–14,20]

Diagnostic Imaging of Angiogenesis

Angiogenesis is a novel field that promises to provide new venues for blood flow in patients with severe ischemic heart disease and severe peripheral vascular disease, and promises to control malignancies by controlling blood supply. However, it became clear early on that a novel field necessitates novel outcome measures that follow its beneficial effects. There is a growing need for non-invasive methods to serially assess the status of the coronary, peripheral, and tumor vasculature. Biomarkers might reflect the prognosis of the diseases as well as the effectiveness of the treatment.^[21]

These might include the following: magnetic resonance imaging and monitoring of angiogenesis, nuclear perfusion imaging of angiogenesis, and other modalities.

INTRODUCTION

Animal models of bone pathologies and wound healing have contributed significantly to the preclinical evaluation of the functional efficacy and biocompatibility of new bone tissue engineering methodologies.^[1–7] However, choosing an appropriate animal model for such evaluations is a critical first step in the experimental design process and in the extrapolation of results to the clinical setting.^[1,8–19] The scientific and ethical implications of choosing an appropriate animal model is a complicated procedure and often a heated topic of debate, and should continue to be guided in part by the three “R”s—replacement, reduction, and refinement.^[9,16–27]

In this entry we will: 1) discuss a number of practical criteria to facilitate the animal model choice for bone tissue engineering studies; 2) review the advantages and disadvantages of various animal models for basic bone biology and the testing of bone replacement materials (BRMs) in critical-sized defects (CSDs); and 3) identify animal models with clinically relevant pathologies that may be used to develop specific bone tissue engineering paradigms and strategies.^[1,10,11,15] This discussion is intended as an aid to less experienced researchers and students designing experimental studies, and to tissue engineers and clinicians who must critically evaluate the results obtained from published animal studies for validity and potential extrapolation to the human clinical condition.

WHAT MAKES AN ANIMAL MODEL “APPROPRIATE”?

When choosing an animal model for bone tissue engineering studies a number of factors should be taken into consideration.^[1,10–12,27,28] These include: 1) animal model appropriateness; 2) potential and expected extrapolation to the clinical setting; 3) genetic homogeneity of the specific animal model; 4) available data concerning skeletal anatomy, bone physiology and

biomechanical properties, and osseous wound healing; 5) cost and availability of the model; 6) generalizability of the results across species; 7) ease and adaptability of the model to experimental and laboratory manipulations; 8) ecological considerations; and 9) ethical and societal implications.

Nonhuman primates are phylogenetically closer to humans than other mammalian groups, which may fulfill many of the considerations listed above and make extrapolation of findings to humans theoretically “better.” However, not all bone tissue engineering experimental manipulations require nonhuman primate models. As we have suggested previously, the choice of an appropriate animal model for bone tissue engineering should be based, in part, on the criteria initially suggested by Smith and Reynolds for determining appropriate animal models in toxicological studies.^[3,10,15,29–32] Smith, on the basis of comparative studies of drug disposition across a large number of mammalian taxa, reported great variation in drug metabolism within the various primate groups.^[31] He suggested that choosing the best animal model should be based on similar physiologic pathways between the model and the human condition, and not necessarily on phyletic affinity. Smith also suggested that the level of hypothesis testing and the expected extrapolation of the results to humans be of major concern in choosing the best animal model.^[31] Based on these practical criteria, we propose that the choice of an appropriate model for bone tissue engineering studies also be linked to the level of hypothesis testing, the expected extrapolation to the specific human clinical condition under study, and the expected commercial market of the tissue-engineered construct.^[1]

The three main strategies taken to engineer bony tissue involve: 1) osteoconduction, which utilizes a scaffold as a mechanical barrier to exclude osteoinhibitory tissues and protect osteogenic tissues in a bony defect; 2) osteoinduction, which utilizes the release of bioactive molecules that bind only to specific host cells with receptors for the molecules and stimulate cell migration and osteogenesis to repair a bony defect;

Table 1 Levels of hypothesis testing in bone tissue engineering paradigms

Level of hypothesis testing	Bone tissue engineering paradigms		
	Osteoconduction	Osteoinduction	Osteogenic cell transplantation
Basic bone cell biology models	In vitro or in vivo manipulation of cell or tissue response to trauma using mechanical or environmental factors	In vitro or in vivo manipulation of cell or tissue response to trauma using growth factors, cytokines, or genes	In vitro or in vivo manipulation of autologous or isohistogenic donor osteogenic cell response to host bone trauma
General clinical models	Repair of CSDs using a passive mechanical scaffold	Repair of CSDs using resorbable scaffolds seeded with growth factors, cytokines, or genes	Repair of CSDs using resorbable scaffolds seeded with osteoblasts or stem cells
Specific clinical models	Repair of bony defects in specific clinical conditions (e.g., periodontitis, diabetes, cleft palate, osteoporosis) using a passive mechanical scaffold	Repair of bony defects in specific clinical conditions (e.g., periodontitis, diabetes, cleft palate, osteoporosis) using resorbable scaffolds seeded with growth factors, cytokines, or genes	Repair of bony defects in specific clinical conditions (e.g., periodontitis, diabetes, cleft palate, osteoporosis) using resorbable scaffolds seeded with osteoblasts or stem cells

(From Ref. [3].)

and 3) osteogenic cell transplantation, which involves the seeding of osteogenic cells from a donor source on a synthetic bone construct that is subsequently implanted into the defect (Table 1).^[33–35] Animal model appropriateness and “goodness-of-fit” will vary across these paradigms as the need for extrapolation to the human condition increases and can be divided into three levels of hypothesis testing: 1) “generic” animal models of basic bone cell biology; 2) phylogenetically “closer” models with comparable anatomy and bony wound healing sequelae; and 3) “fitting” the appropriate animal model to various clinical conditions.

Generic Animal Models and Basic Bone Cell Biology

Studies involving in vitro manipulations of genes, molecules, cells, and tissue are viewed as the most basic. Humans share primitive developmental and regulatory genetic mechanisms that produce homologous cortical and trabecular bony structures, similar bone physiology and wound healing sequelae, and even comparable bone pathophysiology and disease pathogenesis and progression with many other taxonomic orders.^[2,4,13,34,36–48] In general, osteogenic cells from normal and genetically engineered rodents and lagomorphs have been used extensively to elucidate a basic understanding of cell–gene, cell–factor, and cell–cell interactions (see other entries in this volume) as an aid to designing bone tissue engineering strategies (Table 1).^[1,2,35,42,49–52] The data derived from studies using

these generic animal models are as valid as those derived from carnivore or primate models, given that no attempt is made to grossly extrapolate beyond this level of hypothesis testing.

Phylogenetically “Closer” Animal Models and General Clinical Issues

In vivo bone tissue engineering studies at this level of hypothesis testing typically attempt to model clinical problems and complications associated with general skeletal trauma and postoperative bony wound healing. These studies typically involve manipulations of general clinical skeletal models (e.g., long bone, vertebral body, and craniofacial fractures, oncologic resections, elective craniofacial and maxillofacial procedures) and present more difficult problems for choosing an appropriate animal model. Depending on the level of extrapolation to the human condition, not all animal models may be appropriate at this level of hypothesis testing. The commonly used generic animal models (such as rodents and rabbits) differ somewhat in their basic bone microarchitecture and biomechanics, functional gross skeletal anatomy, and healing of CSDs compared to phylogenetically closer models (such as some carnivores and nonhuman primates).^[5,10–13,15,28,36,37,48,53–56] Such interspecific differences should be taken into account before choosing an appropriate model at this level of hypothesis testing.

Basic bone microarchitecture and biomechanics

Appropriate animal models at this level of hypothesis testing should have similar normal human bone microanatomy and systemic physiological processes. The human skeleton shows significant osteoporotic changes during immobilization, normal aging, and/or menopause as a consequence of systemic and environmental factors.^[13,37] In young individuals, the central cancellous bone network is a highly connected, very strong, plate–strut network. In older individuals, osteoclastic activity changes this network to a more fragile, disconnected, strut–strut network that is relatively weak.^[37] Because of these endocrine-mediated, age-related changes, 40–45% of the cancellous bone is lost in the vertebral bodies, long bones, and femoral neck with a concomitant loss of approximately 80–90% strength and a reduced vertebral cortical shell thickness of approximately 200–400 μm . Peak cortical bone mass, connectivity, and thickness are also reduced owing to both cortico-endosteal and intracortical (Haversian) bone remodeling.^[13,37] These changes are accelerated and more pronounced during the development of osteoporosis (age related, menopausal, or immobilization related) and result in strength changes of the human femur during compression and tension, which ranges from 90 to 143 MPa and from 90 to 167 MPa, respectively. Age-related changes in Young's modulus are also seen, which ranges from approximately 5 to 15.5 GPa during compression and from 4 to 17 GPa during tension.^[53] Such age- or disease-related changes in cancellous bone loss, cortical bone thinning, and decreased bone strength and Young's modulus are responsible, in part, for the clinical problems associated with long bone, femoral neck, and vertebral body fractures. Such clinical complications have stimulated an impressive bone tissue engineering initiative to address these issues.^[1,2]

Rodents and rabbits are probably the most commonly used animal models at this level of hypothesis testing.^[10,13,28,37,53] The advantages of these models include: 1) standardization of experimental conditions; 2) genetically specific or mutant strains can be acquired; 3) relatively inexpensive to house and maintain; 4) relatively shorter life spans and fast bone turnover rates; 5) extensive documentation of bone metabolism and skeletal effect of diet; 6) similar lamellar bone architecture; 7) similar cancellous bone thinning and fragility, as well as remodeling rates and sites; and 8) ovariectomy mimics human skeletal aging and menopause.^[12,13,28,34,37] However, there are also a number of disadvantages of the rodent and rabbit models, which should be taken into account before designing bone tissue engineering studies utilizing these models. These include: 1) different skeletal loading patterns; 2) open epiphyses at various growth plates to the age of

12–24 mo; 3) minimal intracortical remodeling; 4) rodents lack Haversian canal systems; 5) rodents also have hemopoietic bone marrow at most skeletal sites, which increases bone turnover rates compared to primates; 6) they have a smaller proportion of cancellous bone to total bone mass; 7) they do not experience a natural menopause and do not show impaired osteoblast function during late stages of estrogen deficiency; and 8) their relatively small size for the testing of prosthetic devices, repeated bone biopsies, or blood testing.^[12,13,28,37] The rodent model also shows age-related changes in femoral head strength, which ranges from approximately 1 to 5 MPa, and in Young's modulus, which ranges from approximately 12 to 405 GPa, during compression.^[53] If one can keep the disadvantages of the small animal models in mind during data interpretation, the rodent and rabbit models are excellent for the initial testing of novel bone tissue engineering paradigms (Table 1).

In contrast, larger animal models (nonhuman primates, dogs, cats, sheep, goats, and swine) show more similar microarchitecture, bone physiology, and biomechanical properties to humans than do the rodent and rabbit models, especially with regard to intracortical bone remodeling.^[12,13,28,37,57] While each large animal model has its own advantages and disadvantages, nonhuman primates are thought to be the model of choice at this level of hypothesis testing, based on very similar, anatomical, gastrointestinal/dietary, endocrine, bone metabolism, and circadian rhythm factors.^[10,12,13,28,37,57–59] However, cost, availability, and genetic heterogeneity of nonhuman primates can be problematic, which necessitates the utilization of other large animal models. In general, the advantages of large animal models over small animal models include: 1) well developed Haversian and trabecular bone remodeling; 2) greater skeletal surface areas and volumes; 3) similar skeletal disuse atrophy results; 4) highly localized bone fragility associated with stress shielding by orthopedic implants; and 5) similar postmenopausal-related osteopenia (with the exception of the dog model). Depending on the large animal model, there are also a number of disadvantages, which include: 1) relative high cost and maintenance expense; 2) USDA housing and space requirements; 3) relatively long life spans; 4) varying gastrointestinal and dietary (trace mineral) requirements, which can affect skeletal calcium:phosphorus ratios; 5) problems with generating large, homogenous samples for statistical testing; 6) potential reservoirs for a host of zoonotic diseases; 7) emotional attachment; and 8) varying ethical concerns.^[12,13,28,37] It is also difficult to create the disproportionate loss of bone strength (characteristic in humans) in many of the large animal models, with some large animal models having a vertebral cortical shell of 1500–3000 μm thickness.^[37] The large animal

models also show age-related changes in femur strength during compression and tension, which ranges from approximately 136 to 195 MPa and 93 to 172 MPa, respectively. They also showed age-related changes in Young's modulus during compression and tension, which ranges from approximately 19 to 27 GPa and 5 to 25 GPa, respectively.^[53]

Gross anatomical, functional, and growth considerations

There are also a number of gross anatomical differences in the long bones, vertebrae, and craniofacial complex of different animal models that need to be considered before determining animal model appropriateness (Figs. 1–4). Such gross skeletal differences are due, in part, to differing endocrine, biomechanical, functional (i.e., locomotor, postural, and masticatory), and dietary influences.^[12,13,28,37,53,57–59] These factors can govern the regulation of bone mass and three-dimensional structure, as well as modulate the “set point” for bone adaptation and bony wound healing.^[28]

While only humans and some birds (emus) are habitually bipedal, most nonhuman primates and rodents maintain upright postures during feeding and grooming.^[41,54,60] Such comparable functional loading produces similarly elongated femoral necks and heads (compare Figs. 1A and 1D), similarly shaped vertebral bodies, vertebral laminar thicknesses, and oriented spinous and mammillary processes of the lumbar vertebrae (compare Figs. 2A and 2B with Figs. 2G and 2H). In contrast, more habitually quadrupedal species (rabbits and dogs in this case) show more robust femoral shafts, thicker and shorter femoral necks (Figs. 1B and 1C), vertically compressed vertebral bodies, relatively thinner vertebral laminae,

and differently oriented bony vertebral processes (Figs. 2C–2F) compared to monkeys and rats. Thus, rats may be an appropriate, less expensive model compared to nonprimates for modeling human femoral or vertebral body morphology if postural loading on tissue engineered constructs is the main concern.

Craniofacial skeletal tissue loss due to congenital defects, disease, and injury is a major clinical problem.^[35] The human craniofacial skeleton is a complex region to model and postural, masticatory, dental, visceral, and neural factors all contribute to its unique adult shape.^[10,15,61] The more common generic animal models (mice and rats) are monophyodonts, exhibiting only a single set of the molar and incisor classes, while other generic models (rabbits and guinea pigs, for instance) have succedaneous dentition but maintain continually erupting incisors.^[8,54,60,62,63] These generic animal models also have large maxillary and mandibular diastema between incisors and premolars/molars with limited alveolar bone in this area (Fig. 3). They are also dolichocephalic (i.e., long, narrow headed) from limited brain cerebralization, with relatively long, narrow, and flat cranial vault bones (Figs. 3 and 4) compared to the human condition.^[54,64] Rats and mice are omnivorous while rabbits and guinea pigs are herbivorous. These functional differences are reflected in the enlarged attachments sites of the masseter m. on the ascending ramus and the reduced coronoid processes seen in the mandibles of rabbits and guinea pigs (Fig. 3). These models are also relatively small, which may affect the design and feasibility of testing synthetic constructs and orthopedic devices for implantation and osteointegration.

Larger, generic animal models have been utilized to overcome some of the disadvantages of the smaller models discussed above. These models include sheep, goats, and swine (both large and miniature versions)

Fig. 1 Cleaned and dried left femora from various animal models. Note the relatively longer femoral necks in the rat and monkey compared to the rabbit and dog, which reflect more habitual upright posture. (H, femoral head; N, femoral neck; S, femoral shaft.)

A

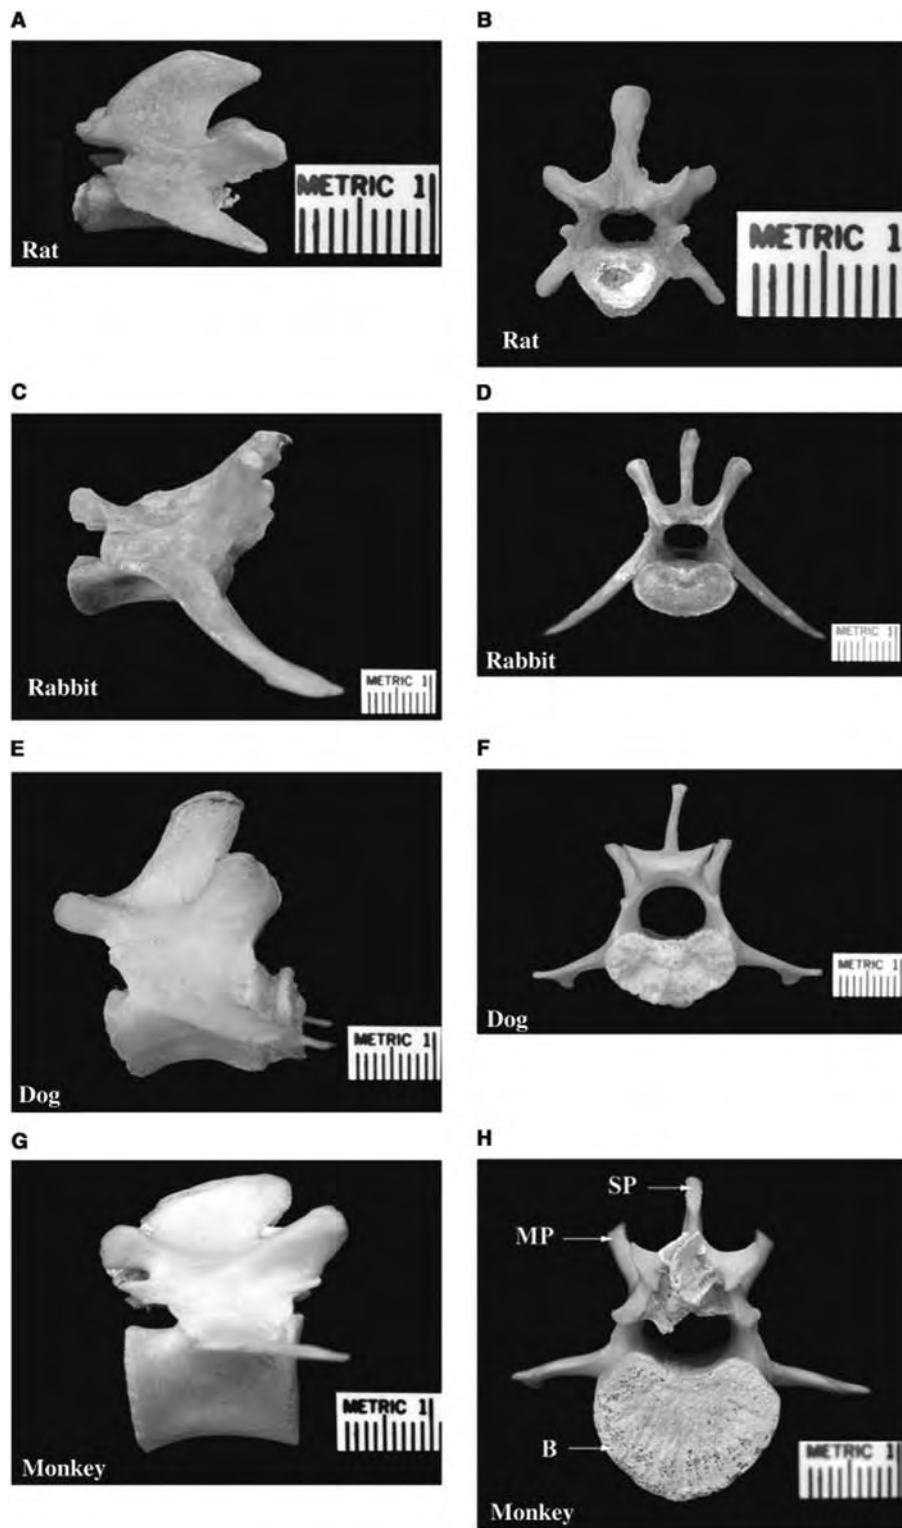

Fig. 2 Cleaned and dried second lumbar (L2) vertebrae from various animal models. Note the more oval-shaped vertebral bodies and broader spinous processes in the rat and monkey compared to the rabbit and dog, which reflect more habitual upright posture and vertebral loading. (B, vertebral body; MP, mammillary process; SP, spinous process.)

and have been well described as models for osteoporosis.^[12-14,28,36,37,53] All three models have varying dental formulas and the goat and sheep have maxillary and mandibular diastemas (Fig. 3).^[65] They are also dolichocephalic (i.e., long, narrow headed) from anteroposterior brain growth and limited superior

cerebralization.^[54,64] Their cranial bones are relatively long, narrow, and flat, but they are still much larger than those of rodents and lagomorphs (Fig. 3). The goat also has horns, which limits the accessibility and surface area of the cranial vault bones for surgical manipulations.^[66,67] Sheep and goats are herbivorous

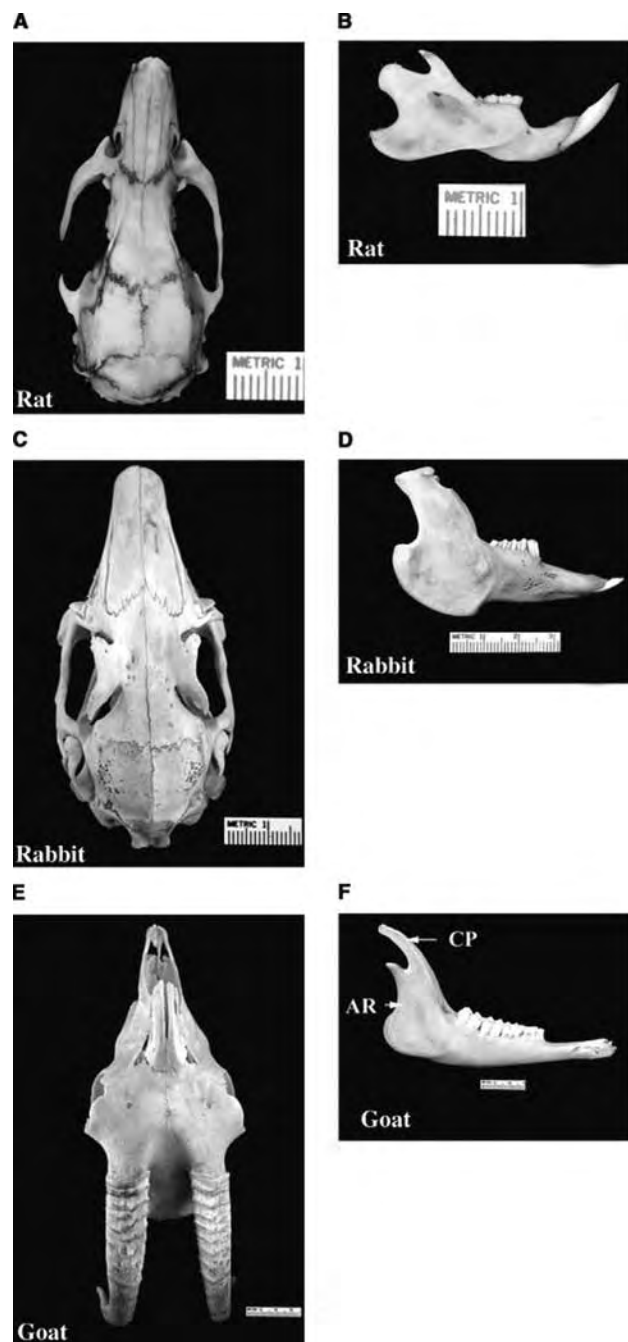

Fig. 3 Cleaned and dried skulls and mandibles from the generic animal models. Note the reduced coronoid processes in the rabbit and goat compared to the rat, which reflects differing masticatory function. (AR, ascending ramus; CP, coronoid process.)

and ruminants while pigs are omnivorous. These functional differences are reflected in the enlarged attachment sites of the masseter m. on the ascending mandibular ramus and zygomatic arch, the reduced temporal fossae for the attachment site of the temporalis m. seen in the skulls and jaws of sheep and goats compared to swine (Figs. 3 and 4). Although

omnivorous, the pig also has a very strong masticatory apparatus with an enlarged ascending mandibular ramus for masseter m. attachment. These larger, generic animal models are more suitable to studies that need greater bony surface area, more alveolar bone, or increased jaw basal bone for testing compared to the smaller, generic animal models. However, these models are much more expensive to purchase and house, bone turnover rate and osseous healing are relatively slow, and they are less genetically homogenous compared to the smaller, generic animal models, although the minpig model overcomes some of these disadvantages.

In contrast, the phylogenetically “closer” models (carnivores and nonhuman primates) exhibit more similar craniofacial structures to humans than do the generic models (Figs. 3 and 4). They possess succedaneous dentition with varying eruption times of both the deciduous and permanent teeth, some with very large canine teeth.^[8,10,54,65,68–70] They are relatively more brachycephalic (i.e., short, wide headed) from increased brain corticalization and gyrification.^[15,54,61,64,71–74] Their cranial bones are relatively shorter, wider, and more curved (Fig. 3 and 4) compared to the generic animal models, which makes them more similar to the human condition. While, cats and dogs are carnivores, laboratory-reared species usually have a much softer, standardized diet than their wild-reared counterparts. Cats and dogs have enlarged coronoid processes for temporalis m. attachment and more inferiorly located mandibular condyles compared to primates, which affords them strong lever arms, reduced horizontal excursion, and increased vertical power. In contrast, some nonhuman primates are omnivorous, while others are herbivorous, although laboratory-reared nonhuman primates also have a standardized, relatively soft diet. Their dental formulae and masticatory apparatus are also closest to those of humans (Figs. 3 and 4). Based on these striking similarities in systemic and oral skeletal physiology and anatomy, nonhuman primates have often become the model of choice of many investigators.^[10,12,28,37,57–59] However, the decreasing availability of wild-caught and laboratory-reared primates, their increased cost, and the social and ethical concerns of using nonhuman primates, necessitate the development and utilization of alternative models.^[9–11,16–25,27,75]

Early surgical intervention of craniofacial and dentofacial deformities have also recently entailed the development of strategies to engineer bone and soft tissue constructs that grow along with the individual.^[35,52] The testing of these growing constructs requires animal models that show similar human craniofacial growth patterns.^[3,10,15,29,30] Appropriate animal models at this level of hypothesis testing would be

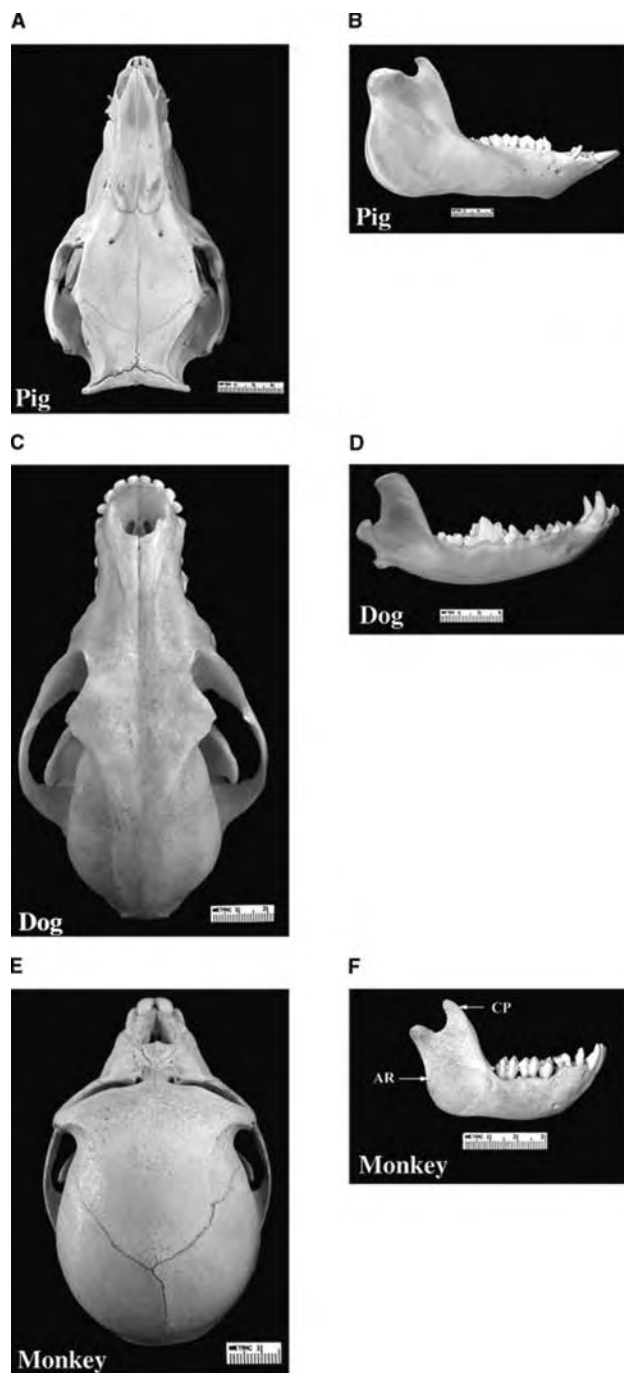

Fig. 4 Cleaned and dried skulls and mandibles from the phylogenetically “closer” animal models. Note the overall differences in the shape of the skull, dentition, and mandibles compared to the generic animal models, which reflect further changes in brain morphology and differing masticatory function.

those that exhibit similar regional growth patterns to humans. In general, human regional craniofacial growth patterns are characterized by a high degree of cranial base flexion (kyphosis), nasomaxillary reduction, anteroinferior displacement of the midface,

and significant vertical and transverse increases in both the neurocranium and the upper face.^[54,61,76] The human craniofacial growth pattern differs from the primitive adult mammalian condition of a long, slender dolichocephalic craniofacial skeleton to a broad, vertically flattened brachycephalic cranium without a prominent snout (Figs. 3 and 4) (for an excellent review see Enlow).^[61] Thus, experimental studies designed to manipulate regional craniofacial growth patterns should choose an animal model based on similar regional growth vectors and patterns, and not necessarily only on phyletic affinity.

In general, under conditions of modeling specific human craniofacial growth patterns, a single animal model may not be appropriate for all regions. For example, short-faced animals (felids and short-faced nonhuman primates) show similar midfacial and nasal capsule growth patterns to humans, while juvenile canids show similar mandibular growth patterns to humans.^[7,29,30] Thus, if the objectives of the study are to improve the human condition, the use of a primate model simply on the basis of phyletic affinity is not justified and an understanding of the relationship between the growth patterns in humans and those in the animal under consideration is a prerequisite to appropriate animal model choice.^[10,15,29,30]

Critical-sized defects and bony wound healing

The most common replacement therapy for bony tissue loss, especially in the craniofacial complex, is autologous bone grafting. However, limited supply and donor site morbidity have stimulated the search for BRMs.^[47,48,55,56,77–84] Bone tissue engineering aims to restore function and/or replace the damaged or diseased bony tissue through the principles of osteogenesis, osteoinduction, and osteoconduction (Table 1). As new BRMs are designed and developed, a consistent, standardized testing paradigm using CSDs was proposed.^[11,85]

A CSD is defined as a defect that heals by less than 10% bony regeneration during the lifetime of the individual.^[11] In contrast, fibrous nonunions can form through a combination of fibrous and bony healing that does not return bony continuity and function, but may eventually heal. Critical-sized defects are thought to result from a number of factors, including: 1) an uneven gradient of soluble osseous growth factors in the wound, which fail to reach the center of the defect and uniformly promote osteogenesis; 2) uneven biomechanical stress and loading, especially toward the center of the defect, which reduces uniform bone cell migration, adhesion, and subsequent osteoid and bone matrix formation; and/or 3) the differential and more rapid migration of fibroblasts (compared to

A

osteoblasts) into the wound site during healing, which results in a higher prevalence of fibrous tissue in the center of the defect.^[11,43,85-88] Thus, the CSD model fails to heal only because it exceeds the body's ability to regenerate adequate amounts of bone, fast enough.

Critical sized-defects make an excellent model to test bone tissue engineering paradigms.^[11,43,85] However, there are a number of confounding variables that can influence the bony wound healing of CSDs and should be taken into account before choosing an appropriate animal model. These include: 1) species-specific differences in bony wound healing; 2) skeletal age of the individual; and 3) anatomic location of the CSD.^[11,85,89]

Species-specific differences in bony wound healing have been reported.^[11,85,89] Spontaneous osseous wound healing was seen to decrease in higher-order species.^[11,89] As noted by Hollinger and Kleinschmidt, "The defect size to volume ratio in the rat is 1.96, while in the human the ratio is 0.12. If the human could regenerate as much bone as the rat it could regenerate bone to fill a defect 23 cm in diameter" (Ref. [11], p. 61). This nonallometric relationship is also seen in Table 2. The size of the CSD in the rodent calvaria ranges from 5 to 8 mm in diameter while in larger animal models the CSD size ranges from 15 to 25 mm in diameter.

There are also significant age-related changes in the healing of CSDs, which also vary across taxonomic levels. Bony defects in skeletally immature animals of most species heal at a faster rate than in skeletally mature individuals. If BRMs are tested in immature animals, falsely high expectations of the osteoconductive properties of the material could be generated.^[11,90] Hollinger and Kleinschmidt suggest that biological age, as determined by radiographic confirmation of epiphyseal closure, be used in conjunction with chronological age and body weight to ascertain skeletal maturity, prior to CSD creation.^[11] Rats are the exception to this rule because they grow constantly throughout their life cycle.^[11,60] While in most animals, the initial size of the CSD decreases with age, the initial size of the CSD in rats stays constant, regardless of age.^[11] However, there has recently been a push to engineer bone and soft tissue constructs that grow along with the individual.^[35,52] The testing of these growing constructs may require the use of CSDs in growing animal models, information on which is currently sparse in the literature.

Anatomic location of the CSD can also affect healing rate and interpretation. The craniofacial complex is much more vascular and more richly innervated than the long bones and vertebral column. Even within species, CSD size varies across these anatomic

locations and CSD sizes in the skull and mandible are relatively smaller than those produced elsewhere (Table 2). Thus, anatomic location and CSD size need to be taken into consideration before choosing an appropriate animal model.

Table 2 reviews studies of selected CSD sizes by anatomic location and species. As can be seen in the table, the majority of the CSD studies have been performed on the calvaria, mandible, and femur across a wide variety of animal species (Figs. 3 and 4). These regions are easily accessible for surgery and represent biomechanically loaded (mandible and femur) or unloaded (calvaria) regions to simulate varying clinical conditions. Animal model choice will vary depending on the paradigm being tested (i.e., size of scaffold, duration of healing, length of construct bioactivity, and so on).

Fitting the Appropriate Animal Model to Specific Human Clinical Conditions

As tissue engineering paradigms become more reproducible and sophisticated, we see bone tissue engineers trying to tackle osseous wound healing problems in specific, clinically compromised, subpopulations of patients (i.e., diabetic, osteoporotic, arthritic, geriatric, congenital anomalies, etc.). Addressing osseous wound healing problems in these clinical situations will require specific animal models of the pathology or disease state. Table 3 presents a selected list of animal models of specific bone pathologies and bone metabolic disease states. A number of these models have been developed for specific purposes (i.e., to study the onset and treatment of postmenopausal osteoporosis, inflammatory arthritis, periodontitis induced bone loss, etc.), but these models can also be adapted to study the various bone tissue engineering paradigms. Osteoconduction, osteoinduction, or cell transplant may be significantly altered in these human clinical groups and animals that model these specific clinical conditions will be instrumental in developing new treatment strategies to regenerate new bone and improve their quality of life.

Animal model choice at this level of hypothesis testing should not necessarily be based only on phyletic affinity but should also take into account the etiology of the particular bone pathology or disease state. Although the expectation is that phyletic affinity and similarity of etiology, disease progression, and pathophysiology are reasonably related, phyletic affinity should not be the exclusive criterion, but should be used in conjunction with similar biomechanical, anatomical, and wound healing factors.^[3,13,17-19,36,39,58,59,139]

Table 2 Selected CSD studies by animal model and anatomic region

Anatomic region	Animal model (Refs.)									
	Mouse	Rat	Rabbit	Cat	Dog	Sheep	Pig	Horse	Nonhuman primates	Goat

Table 3 Selected animal model studies of bone pathologies and bone metabolic disease states

Condition	Technique	Species	Comments	Reference
<i>Inflammatory arthritis models</i>				
Osteoarthritis	Naturally occurring	Various species	Good comparative review of pathogenesis and models	[140]
Type II collagen arthritis	Immune response to injection of type II bovine collagen	DBA/LACJ mouse	Acute inflammatory response in extremity joints and loss of bone mineral density	[141,142]
Spondyloarthropathies	Immune response to injection of bacterial flora	HLA-B27 Transgenic rat	Arthritis, loss of bone mineral density, and tarsal joint ankylosis	[143]
Rheumatoid arthritis	Autoimmune diseases	Rat, mouse	Inflammatory response and loss of bone mineral density	[144]
<i>Osteonecrotic and iatrogenic models</i>				
Femoral head osteonecrosis	Surgically created via ischemic and/or cryogenic insults	Emu, dog, sheep	Developed early and late stage human pathology. Emu is a good bipedal loading model	[41,145]
Osteomyelitis	Injections with various pathogens <i>Staphylococcus aureus</i> , <i>Bacteroides fragilis</i> , <i>Escherichia coli</i>	Rat, rabbit, dog, guinea pig, chicken	Decreased bone mineral density, increased risk of fracture, and increased cortical and trabecular bone loss	[38,146–148]
Disuse atrophy and underloading-induced osteopenia	Limb immobilization, denervation, microgravity	Rat, dog, monkey	Trabecular and cortical bone loss, decreases in bone formation, increases in bone resorption	[36,149]
Age-induced osteopenia	Natural aging	Mouse, rat, monkey	Reduction in skeletal mass and osteopenia	[36]
Seasonal-induced osteopenia	Natural aging postmenopausal	Monkey	Age-related decline and skeletal bone mineral content in males and females	[57,150]
Reproductive cycle-induced osteopenia	Orchidectomy	Rat	Cancellous bone osteopenia and reduced bone turnover	[36]
Diet-induced osteopenia	Antler formation, diet, changes, hibernation	Reindeer, deer caribou, bats	Experience transient mineral deficit and reduced bone turnover	[36]
	Pregnancy, lactation, egg laying	Sheep, rat, dog, chicken, turtle	Altered calcium storage and release with subsequent osteopenia	[36]
	Calcium and phosphorus dietary manipulations	Cat	Develop bone disease and decreases, bone mineral density	[12,151]
	Vitamins C and D deficiency	Rat, rabbit	Osteomalacia, rickets, osteopenia	[36]

Alcohol-induced osteopenia	Pre- and postnatal alcohol exposure	Rat	Osteopenia and reduced skeletal growth	[152,153]
Glucocorticoid-induced osteopenia	Glucocorticoid exposure	Rat, rabbit, dog, sheep	Varies from species to species but decreases bone mass	[36]
Bone metastasis-induced osteopenia	Injection of a breast cancer cell line	Mouse	Causes osteolytic bone metastasis and osteoclasia	[154]
	Spontaneous mammary tumor model	Mouse	Causes osteolytic bone metastasis and osteoclasia	[154]
<i>Oral bone loss models</i>				
Periodontitis	Naturally occurring in laboratory-reared models	Baboon, dog, monkey, marmoset	Isolated vertical bone loss in maxillary and mandibular alveolar and basal bone	[58,59,155–160]
	Oral infection by <i>Porphyromonas gingivalis</i>	Mouse, rat, rhesus monkey, baboon, dog, sheep	Reliably produced maxillary and mandibular alveolar and basal bone loss	[161]
<i>Experimentally induced, estrogen-deficient bone loss models</i>				
Post-menopausal osteoporosis and osteopenia	Various procedures	Various models	Good discussions and critiques of various techniques and models	[36,37,139,149,162]
	Ovariectomy	Sheep	Bone loss in mandible, proximal femur and vertebral body	[12,14,163]
	Ovariectomy	Nonhuman primates	Decreased bone mineral density and reduced vertebral cancellous bone volume	[12,28,164]
	Ovariectomy	Ferret	Increased skeletal bone loss	[165]
	Ovariectomy	Dog	Similar bone microarchitecture but does not develop osteoporosis	[12,166,167]
	Ovariectomy	Rat	Developed cortical thinning and significant bone loss	[12,168–170]
	Ovariectomy	Guinea pig	Showed no effect on bone	[12,171]
	Ovariectomy and calcium-restricted diet	Sinclair S-1 minipig	Showed bone removal and loss comparable to humans	[12,172]
Perturbed bone metabolism models				
Genetic models of various metabolic bone diseases	Knockout and over expression models	Transgenic mice	Skeletal phenotypes range from osteopetrosis to osteopenia	[13,39]

(Continued)

Table 3 Selected animal model studies of bone pathologies and bone metabolic disease states (*Continued*)

Condition	Technique	Species	Comments	Reference
Diabetic osteopenia	Various experimental and transgenic insulin deficiency models	Mouse, rat	Decreased bone mass and increased prevalence of skeletal fractures	[173–175]
Growth hormone resistant dwarfism (Laron syndrome)	Congenital models of GH receptor mutation and GH resistance	Sex-linked dwarf chicken, guinea pig, miniature poodle, cattle, and pigs	Severe skeletal growth retardation and dysmorphic facial features	[176,177]
Calvarial hyperostosis and craniosynostosis	Various congenital experimental, and transgenic models	Various species	Features clinical manifestations ranging from microcephaly to craniofacial dysostoses with digital involvement	[15]
Facial clefting	Various congenital, experimental, and transgenic models	Various species	Features clinical manifestations ranging from minimal alveolar and palatal clefts to median and oblique and facial clefts	[178]

(From Ref. [3].)

CONCLUSIONS

Animal models of bone pathologies and wound healing have contributed significantly to the preclinical evaluation of the functional efficacy and biocompatibility of new bone tissue engineering methodologies. Each animal model has its own utility as well as its own limitations for the study of human bone tissue engineering. We have proposed a number of practical criteria for choosing and evaluating various animal models and suggested that appropriate animal model choice should also be linked to levels of hypothesis testing and/or expected extrapolation to the human clinical condition. The continued intelligent and conservative use of animal models should be based on such objective criteria and not necessarily on phyletic affinity alone.

INTRODUCTION

The chance of a new drug candidate gaining approval fell to 8% in 2004, with the majority of failures happening in phase III clinical trials.^[1] Clinical trials make up the majority of the costs in drug development; a 10% improvement in predicting clinical trial failure could save as much as \$100 million per drug.^[1] Both the expense of testing new drugs and chemicals and the large number of new compounds available to be tested makes a rapid, inexpensive method for accurately assessing efficacy and toxicity in humans essential in the pharmaceutical and chemical industries. An understanding of a drug's absorption, distribution, metabolism, elimination, and toxicity (ADMET) in the human body is important in determining minimum dosages and effective delivery schemes. A non-pharmaceutical chemical's action on the body must be characterized to establish safe exposure levels and first aid procedures.

Animal studies are the primary method used to determine toxicological and pharmacological profiles, but animal experiments can take months to complete, and the cost of testing a single substance can be millions of dollars.^[2,3] Recent estimates have placed the preclinical cost of new drug development between \$335M^[2] and \$620M^[4] with approximately \$90M of that expense in preclinical safety.^[4,5] Furthermore, animal cells do not always react with chemicals and drugs in the same way as human cells do.^[3] Alternatives to animal studies include computational (in silico) models and in vitro methods using one or more living cell type.

The goal of this article is to give a brief overview of many of the animal surrogate systems used for toxicity testing, including mathematical models, single cell type models, barrier models, cocultures, three-dimensional models, and multicell type devices. The reader will see how toxicity can be predicted prior to animal or human studies. Although the use of subcellular components (DNA microarrays, antigen binding, etc.) as animal surrogates in toxicity testing is an important

emerging technology, it will not be covered in this article.

COMPUTATIONAL MODELS

The utilization of computational methods for toxicity studies involves several different length scales, ranging from molecular interactions to whole organism models. At the most local scale, molecular models are used to determine ligand–receptor binding, such as the so-called docking method. Models of larger scope include networks or pathways of interactions, such as gene network systems. Approximations of physiological behavior allow the construction of bulk drug distribution models, such as pharmacokinetic (PK) models or the more detailed, organ-based, physiologically based pharmacokinetic (PBPK) models. Additionally, responses of organisms to different doses of a chemical can be captured with pharmacodynamic (PD) equations. All of these tools are used in research labs in academia and industry to increase throughput of toxicity screens and drug candidate studies.

Chemical Structure-Related Models

Most modeling for toxicity in animals requires experimental knowledge of many parameters for a given substance. Predicting these parameters a priori from molecular structures enables researchers to perform computer simulations of toxicity experiments. The ability to make toxicity predictions without actually synthesizing a chemical is of particular interest in drug discovery, where drug candidates may be screened without requiring laboratory work. Quantitative structure–activity relationships (QSARs) methods and molecular docking techniques are two of the more popular molecular structure-based prediction approaches in the literature.

The concept of QSARs is simple: Compounds that could be considered similar in their action in vivo can

be modeled as variations in a set of descriptors. Descriptors are properties of a chemical that range from molecular weight and octanol/water partition coefficient to more complex properties such as hydrogen bonding donor/acceptor density.^[6] Quantitative structure–activity relationships have been used for the last 40 years to model various ADMET properties, and have already been proven useful in toxicity screening of new chemicals.^[7] Frequently QSARs are used to directly model toxicity for one or more related activity mechanisms, such as the risk of toxicity owing to endocrine disrupting chemicals.^[8] They can also be used to model other chemical properties such as permeability through the skin.^[7]

The use of a QSAR model requires initial training with an experimental data set. Methods for this model generation and training vary from regression techniques to the use of neural networks and self-organizing maps.^[6] Once a model is generated, it is then validated by attempting to predict the remainder of the data set. Following validation, test predictions of additional compounds are made and compared against a new data set. Accuracy of these models varies, but it is not uncommon to have close to 90% accuracy in predicting certain conditions such as carcinogenicity.^[9] This accuracy typically decreases when additional modes of chemical interaction are included.

The interaction between a protein and a chemical can be estimated using molecular simulations. Often these quantum mechanical “docking” studies are combined with mathematical models such as QSARs to help predict which chemicals should be accurately modeled by a data set. These studies require 3-D models of the test chemicals and the protein being studied, which can either be obtained by x-ray crystallography or by building a model of the protein from homologous fragments found in known structures. An example of the use of molecular modeling is a study of the active site in liver cytochrome P450 (CYP) enzymes and the derivation of complementary substrate binding templates.^[10]

Whole Organism Models

Whether data for test compounds are determined from *in vitro* experiments or estimated using computational methods such as QSARs, this information can be used to construct predictive models of organisms PK and PD. These prediction methods range in degrees of complexity from simple PK and PD models to more structured PBPK and PD–PK models.

Pharmacokinetics is the study of drug absorption, distribution, metabolism, and elimination in the body, also known as ADME.^[6] In their simplest forms, PK models fit the concentration profile over time of a

chemical in the blood to one or more exponential functions. These models allow the prediction of the maximal systemic exposure (termed C_{max}), as well as the total accumulated exposure (termed Area Under the Curve, AUC) for a given dose. As it is the amount of drug that tissues “see,” and not the amount swallowed or inhaled that produces an effect, these PK models produce a clear picture of the amount of a chemical that interacts with a tissue. However, the parameters in this basic PK model, the elimination constant and the volume of distribution, are purely mathematical in nature and have no relation to any physiological dimensions. The PK model is an adequate method for predicting plasma concentration levels in very similar animals (i.e., male rats of similar sizes), but is not useful for extrapolating to other species or routes of entry. Additionally, it does not contain explanations for the interindividual variations that cause drastic differences in drug or toxin concentration in the blood.

Pharmacodynamics is the study of the time- and concentration-dependent response of the body to a drug or toxin.^[11] Pharmacodynamics models fit a response-over-time vs. concentration profile to some function, typically using a sigmoidal or hill equation.^[12] As PD models require knowledge of the local compound concentration at the receptor or enzyme site, they greatly benefit from the incorporation of PK models. Although often treated separately, the PK and PD models are functionally linked. Examples of this include the induction of a metabolic enzyme upon exposure to a chemical, which can change the rate of metabolism and hence PKs, or the interactions of drugs that modify protein binding, influencing PDs.^[13] This interaction between PKs and PDs often leads to the use of a coupled PD–PK mathematical model.

Physiologically based pharmacokinetic models are PK models that break the body down into its separate tissues and corresponding blood flows (Fig. 1). Each tissue is treated as a separate entity with parameters describing transport, binding, and reactions. Such an approach requires a wealth of time-dependent data and is a primary reason that these models are not more prevalent. Physiologically based pharmacokinetic models can be used for extrapolation of experimental observations over animals of different body sizes, as well as for PK predictions in different species. Additionally, they allow extrapolation of results from one route of entry to another.^[13] One example of this would be the use of results from a bolus dose study in rats to predict inhalation PKs. These predictions, however, are only valid when the various reactions and distribution terms are accurately known; they cannot predict responses to unanticipated reactions. But if the interindividual differences are understood, for example, the knowledge that one

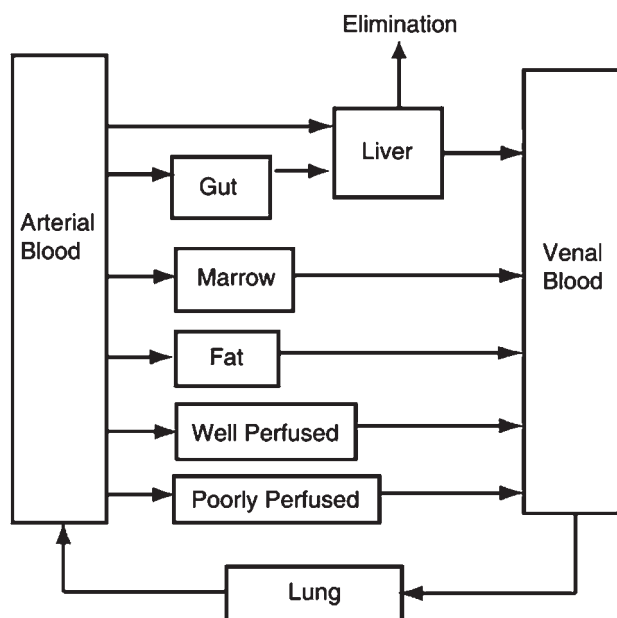

Fig. 1 A schematic representation of a PBPK. Tissues of interest, such as the gut and liver, are explicitly included. Other tissues known to have only minimal interaction can be combined into either well-perfused tissues (e.g., kidney) or slowly perfused tissues (e.g., muscle) to help maintain accurate descriptions of chemical dilution in the body.

individual has severe reduction in a liver CYP isoform activity, then the resultant differences in PKs can be easily described.

SINGLE CELL TYPE IN VITRO MODELS

The use of in vitro cultures for toxicity testing is considered one of the first steps in experimental surrogate trials. There is an enormous literature based on the use of different cells and endpoints for studies, but we will only briefly discuss them here. Two of the formats most frequently utilized for these studies are 96-well plates^[14] and flow cytometry. The 96-well plate assays use cells either attached to the bottom surface of a small well or suspended in culture medium. The cells are challenged with a chemical or treatment and then

assayed using a biomarker that produces either a luminescent (colored) or fluorescent product. This product is measured with a plate reader, and results are typically correlated with a calibration curve. Flow cytometry techniques first require exposure of the cells to a drug or toxicant in culture, and then labeling the cells with fluorescent markers for the respective attributes (i.e., viability, specific protein expression, etc.). These labeled cells are forced single-file past a laser and detector that collects light from the fluorescent tags. Results are expressed as the number of cells that were labeled with a particular condition, for example, number of live cells vs. number of dead and apoptotic cells.^[15] Table 1 lists several different cell conditions with references that have been studied utilizing various in vitro methods.

BARRIER MODELS

Epithelial cells cover most internal and external surfaces of the body and are, therefore, the first tissues that interact with foreign chemicals. Understanding how chemicals interact with and are absorbed through epithelial barriers is crucial for toxicological evaluation. Four epithelial barriers that are critical in toxicology studies are the epidermis, lung epithelium, intestinal epithelium, and blood–brain barrier. These barriers represent entry into the body via chemical contact, inhalation, ingestion, and systemic chemical contact with the brain. The models of epithelial barriers described in this section involve single cell types cultured on porous membrane supports that allow access to the apical (top) chamber and basolateral (bottom) chamber.

Skin penetration is a complex event. The stratum corneum, which is composed of the dead keratinocytes that make up the skin's outermost epidermal layer, is the main barrier to chemicals that come in contact with skin; but partitioning into the stratum corneum, diffusion within the stratum corneum, partitioning into the viable and more hydrophilic deeper epidermal layers, diffusion through the deeper epidermal layers, and metabolism of compounds in the epidermis must

Table 1 Common in vitro toxicity and metabolic assays

Toxic/functional endpoint	Study design	References
Cytotoxicity	Example: propidium iodide/trypan blue exclusion assay	[16,17]
Apoptosis	Mitochondrial H ⁺ potential (with Rhodamine 123)	[18]
Reactive oxygen species	Assays for free radical formation in cells	[19]
Genotoxicity	Micronuclei formation, single cell gel electrophoresis	[20]
Endocrine disruptors	Receptor binding assays	[21]
Metabolism	CYP metabolism	[22,23]

all be taken into consideration in epidermal toxicology testing.^[24] Poumay et al. have reconstructed a fully-differentiated epidermis by culturing normal human-derived epidermal keratinocytes on the air-liquid interface (culture medium in the basolateral chamber, air in the apical chamber) of porous membranes.^[25] The cultured epidermis exhibits basal, spinous, granular, and cornified layers.^[24] The modeled tissue showed progressive cytotoxicity in response to benzalkonium chloride, an irritant, and dinitrochlorobenzene, a sensitizer. Differences in interleukin-1 α and interleukin-8 release allowed the irritant to be distinguished from the sensitizer. Permeation studies with 17- β -estradiol indicate that the model has barrier properties similar to those seen in vivo, and the metabolism of 17- β -estradiol to estrone by the in vitro epidermis shows that the model has metabolizing properties toward hormones.^[25]

The respiratory tract is usually divided into two regions: the central conducting airways (made up of the trachea, bronchi, and bronchioles), and the peripheral alveolar regions.^[26] The airway epithelium filters air before it reaches the alveoli and prevents particulate absorption by means of a mucociliary clearance mechanism, tight junctions (protein connections between epithelial cells that reduce passive diffusion between the cells), metabolic activity, and efflux protein pumps.^[27] Calu-3 immortalized human bronchial epithelial cells grown on the air-liquid interface of porous membranes express apical cilia, mucous production, tight junctions, and several metabolic and transport systems.^[27] Mathias et al. tested the permeability of a wide range of compounds and found that Calu-3 monolayers had permeability characteristics similar to those seen in primary rabbit tracheal epithelial cultures and drug absorption rates similar to those seen in vivo in rat lungs.^[28]

The alveolar epithelium provides an immense surface area for the exchange of CO₂ and O₂.^[26] The alveolar epithelium is composed of two major cell types, Type I and Type II. Type I alveolar cells cover about 95% of the alveolar epithelium and are the main site of gas exchange, but are not able to divide, making them difficult to grow in vitro.^[26] Type II cells are more numerous even though they cover much less surface area and they secrete alveolar fluid, which keeps the surface between the air and cells moist. The Type II cells have well characterized endocytic properties and are the progenitors for Type I alveolar cells. They also express cilia, tight junctions, and CYP enzymes that metabolize foreign materials.^[29] The A549 immortalized cell line, which is derived from a human pulmonary carcinoma, expresses the differentiated biochemical properties of Type II alveolar cells in vivo, making the cell line a good model for studying alveolar metabolism and macromolecule processing.^[29] The

A549 cells do not form tight junctions, however, which make them poor candidates for the study of alveolar permeability.^[29] Currently primary cultures of Type II cells, which form Type I-like monolayers in culture, are the only model available to study absorption through the alveolar epithelium.^[26]

The epithelial lining of the small intestine is composed of several different cell types that display very tight intracellular junctions and are covered with tightly packed projections called microvilli. These microvilli serve to increase the surface area of the intestine available for absorption and contain digestive enzymes. The transport of a drug or chemical across the intestinal epithelium occurs by one or more of four different routes: passive transcellular (through the cell), passive paracellular (between cells), active (energy dependent) carrier-mediated, and transcytosis (transport across the epithelium with uptake into coated vesicles).^[30] When cultured on porous membranes, Caco-2 cells (a human colorectal adenocarcinoma cell line) differentiate into a polarized, highly functional epithelial barrier that is morphologically and biochemically very similar to the small intestinal epithelium.^[30] After a growth period of three weeks, the Caco-2 monolayers express tightly packed microvilli, tight junctions, and are capable of paracellular, transcellular, active, and transcytotic transport. Lennernäs et al.^[31] compared drug transport rates in Caco-2 monolayers with those obtained in the human jejunum (a section of the small intestine) in vivo. The researchers found that the rapidly absorbed, passively transported drugs naproxen, antipyrine, and metoprolol had comparable permeability coefficients in Caco-2 cells and in the human jejunum. The permeability coefficients of the slowly absorbed, passively transported drugs terbutaline and atenolol were 79- and 27-fold lower, respectively, in Caco-2 monolayers when compared with in vivo human jejunum results. The carrier-mediated transport rates of L-dopa, L-leucine, and D-glucose were also found to be lower in Caco-2 monolayers. The researchers concluded that Caco-2 monolayers can be used to successfully predict transport rates in humans for passively diffused drugs, but predictions of transport by carrier-mediated systems may require a scaling factor owing to the low expression of carrier proteins in the cell line.^[31]

The blood-brain barrier (BBB) is formed by the endothelial cells that line the brain capillaries. The function of the BBB is to keep blood and most compounds in blood separated from the brain and from cerebrospinal fluid.^[32] The brain capillary cells exhibit tight junctions that restrict paracellular transport, have a low rate of endocytosis, are highly metabolically active, and contain many enzymes and adenosine triphosphate (ATP)-dependent transporters that regulate the influx and efflux of compounds into the central

nervous system.^[32] Primary bovine brain microvessel endothelial cells (BMECs) grown on a porous membrane retain the characteristics of brain endothelial cells *in vivo* including morphology, BBB enzyme markers, and tight junctions.^[33] Glynn and Yazdanian used this model to study the permeability of anti-retroviral agents through the BBB. The researchers found that nevirapine was the most permeable anti-retroviral agent studied in the BBB model, making this drug a therapeutic candidate for inhibiting HIV viral replication in the brain.^[33]

COCULTURE MODELS

Cocultures of two different cell types are aimed at reproducing the cellular interactions and communication found in a tissue or organ. One example of two cell types that are often cultured together is brain capillary endothelial cells and astrocytes, a type of microglial cell. A major challenge for researchers working to create *in vitro* BBB models is culturing endothelial cells that display the extremely tight junctions seen *in vivo*. Astrocyte foot processes have close interaction with brain capillary endothelial cells in the BBB, and research has shown that *in vitro* cocultures of these cell types enhance the barrier properties of the BBB model.^[34] Ma et al. fabricated a silicon nitride membrane that is an order of magnitude thinner and at least two times as porous as commercially available membranes for coculturing primary bovine brain microvascular endothelial cells and astrocytes on opposite sides; their work was based on the hypothesis that an ultrathin, highly porous membrane would permit a high degree of direct contact between the cells without the astrocytes growing through the endothelial barrier.^[34] Fig. 2 shows astrocytes seeded on the backside of this fabricated membrane with foot processes growing through the pores. The researchers found that the cocultures could be maintained for up to two weeks, but they did not see a synergistic effect of the cocultures in terms of improved barrier properties. The researchers believe, however, that this lack of synergy is most likely because of the commercially available primary bovine brain microvascular endothelial cells losing their ability to respond to astrocyte differentiating signals; the researchers concluded that a different endothelial cell line or different endothelial primary cells may have more physiologically realistic results.^[34]

THREE-DIMENSIONAL MODELS

Three-dimensional (3-D) *in vitro* systems more closely mimic the cell shape and cellular environment found in

Fig. 2 An SEM image of a fabricated BBB membrane, containing 420 nm pores. Rat astrocytes were seeded on the opposite side, and foot processes are shown here growing through several pores.

in vivo.^[35] Cell shape and cellular environment can determine the gene expression and biological behavior of the cells, both of which have important implications in toxicity testing.^[35] Researchers have shown that 3-D cultures, unlike monolayer or suspension cultures, more accurately reproduce specific biochemical and morphological characteristics of the corresponding *in vivo* tissues and may stay in a functionally active, differentiated state for several weeks.^[36] The most commonly used method of 3-D culture is multicellular spheroids, which are aggregates of cells that can reach 1–2 mm in diameter.^[37] Multicellular spheroids form spontaneously in cultures with cells that cannot attach to another substrate. Normally spheroids are cultured in spinner flasks, roller bottles, or roller tubes, all of which limit cell attachment to the substrate by agitating the culture medium and allow rapid harvesting of many spheroids of approximately the same size.^[37] Stationary, nonadherent surfaces like agar or agarose in 96-well culture plates can also be used to cultivate single spheroids.^[37] The spheroids form both an extracellular matrix and a complex network of cell–cell and cell–matrix interactions. The network establishes similar morphological, functional, and mass transport features and differentiation patterns of the corresponding *in vivo* tissue for up to several weeks in culture.^[36] Castaneda and Kinne compared the effects of low concentrations of ethanol on primary rat hepatocyte spheroids and human hepatocellular carcinoma cell line (HepG2) spheroids.^[38] The primary cell spheroids represented normal liver tissue and the HepG2 spheroids represented a hepatocellular carcinoma.^[38] The researchers found that millimolar

concentrations of ethanol increased the inhibition of cell growth and apoptosis in HepG2 spheroids when compared with rat hepatocyte spheroids. This result suggests a possibility that millimolar concentrations of ethanol could be used as a treatment for hepatocellular carcinoma, because the treatment affects mainly tumor cells rather than the surrounding normal tissue.^[38]

Artificial tissues can be assembled *in vitro* by embedding primary or immortalized cells within 3-D scaffolds. Scaffolds are porous, degradable structures engineered for biocompatibility, selective permeability, and mechanical and chemical stability. They are fabricated either from natural materials such as collagen, alginate, and fibrin or synthetic polymers such as polyglycolide, polylactide, and polylactide-co-glycolide.^[39] These artificial organs could greatly accelerate the development of new drugs by creating physiologically accurate *in vitro* models for toxicity testing.^[39] Many different cell types including liver, vascular, bone, lung, intestine, kidney, and cells from mammary, salivary, and thyroid glands have been grown in 3-D matrices and shown positive trends toward regaining *in vivo* tissue function. However, few tests have yet been performed to study drug toxicity in these 3-D models.^[40] Three-dimensional, matrix-embedded cultures are also being integrated into the microcell culture analog (μ CCA), described later in this article under the heading "Microscale Designs."

Bioreactors can be combined with cells grown on 3-D scaffolds to create very high-density cultures that retain some of the metabolizing characteristics of the original tissue.^[41] Beads are often used as scaffolds to create more surface area for cell growth. Dextran-based microcarrier beads allow cells to grow on the bead surface in single or multilayers, and polylysine or alginate beads can be used to microencapsulate cells.^[41] The microcarrier or gel beads can be placed in perfusion reactors where the cells are retained. The culture medium is continuously or semicontinuously added, and spent medium together with its toxic metabolites is removed.^[41]

Choi et al.^[42] used Caco-2 cells seeded on permeable membranes together with HepG2 cells seeded onto cellulose-based microcarrier beads to create a perfusion system that mimics first pass metabolism. The results of this study showed enhanced CYP1A1/2 activity in the coculture perfusion system when compared with pure Caco-2 and HepG2 cultures. CYP1A1/2 is an enzyme responsible for breaking down toxins in the body. The researchers concluded that their *in vitro* system better modeled the *in vivo* metabolic activity of the liver and intestinal epithelium than single cell type cultures.

Hollow-fiber bioreactors are cylinders filled with bundles of hollow fibers meant to simulate the *in vivo* capillary supply.^[43] Cells are immobilized on the

external surface of the hollow fibers, which are composed of semipermeable ultrafiltration membranes. Culture medium flows through the inside of the tubes.^[41] The membrane pore size is small enough to retain cells while allowing gas, nutrients, and metabolic waste products to diffuse freely.^[43] Casciari et al.^[44] used a hollow fiber reactor to create a solid tumor model for testing tumor cell drug metabolism and resistance. The researchers successfully grew six different human tumor cell lines to confluence on 450 μ m internal diameter, polyvinylidene fluoride fibers, and then assessed doxorubicin sensitivity. The results showed that tumor cells in hollow fibers were more resistant to a four-hour doxorubicin exposure than were tumor cells in monolayer cultures.

MULTIPLE CELL DEVICES

Multiple cell or tissue types are used to bridge the gap between single cell or single tissue culture models and whole animal models for toxicity testing. The primary purpose of multiple cell types in the same culture is to investigate interactions between different cell populations, either through direct cell-cell interactions or through soluble proteins or metabolites. Of the approaches taken that combine multiple cell types to explore metabolite exchange, three will be described here.

The simplest method to study soluble protein and metabolite interactions is the use of media that is first incubated in one cell type, and then added to the second cell type. Another approach, termed the integrated discrete multiple organ cell culture (IdMOC) system, combines several cell types into the same culture container, but maintains separate cell populations within that container. The third approach, called a CCA, includes several cell cultures contained in independent culture containers with culture medium recirculating between them. These systems attempt to provide an *in vitro* experimental space that can replicate some of the cell-cell interactions not easily studied *in vivo*.

Conditioned Medium Systems

The goal of this experimental method is to mimic the metabolite exchange that occurs within the circulatory system. Medium conditioning, which is the practice of adding and incubating media in a cell culture then transferring this conditioned media into another cell culture, is a convenient method of exploring metabolic impacts in toxicity testing. An example of this method is the use of liver microsomal fractions to metabolize cyclophosphamide (CP) prior to addition to the target tissue, in this case human fibroblasts.^[45] It was

previously shown that CP is activated in the liver and then acts as a chemotherapeutic agent. Investigators utilized such a system to compare the cytotoxicity of CP when incubated directly with fibroblasts to CP when first conditioned with microsomes. The researchers found that with a dose of 0.3 mg/mL, direct exposure to the fibroblasts required several days to reach the same level of toxicity as was reached after only a few hours of exposure when the CP was pre-conditioned with microsomes. This indicates that the combination of this simple microsome-fibroblast system can begin to replicate the activation of compounds *in vivo*. However, this system is only exploratory in nature and does not include any detail of physiological quantities, such as the actual amount of enzyme or cells present.

Shared Medium Systems

Another method that enables the exchange of metabolites between different cell types is the sharing of culture media by several different cell populations. An example of this approach is the IdMOC system.^[46] This system is built by fabricating small wells, 8 mm diameter and 0.8 mm in height, inside the well of a six-well plate. Within each of the smaller wells, a different cell type is cultured. Medium inside the larger well feeds the different cell cultures. Experiments were conducted utilizing the MCF-7 tumor cell line and six other primary cell types. In response to exposure to tamoxifen, the rank order of cell toxicity as well as a therapeutic index of each primary cell type compared to the cancer cell line was generated. The system has not yet been utilized to directly investigate metabolic exchange, although such a use has been proposed.^[46]

CCA

A CCA combines several cell culture bioreactors representative of different tissues to “mimic” the variety of organs in an animal. This pseudoorgan culture system replicates the circulatory system of animals with a flow of recirculating culture medium. All bioreactor dimensions and the corresponding culture medium flow rates are scaled down from the actual organ sizes and blood flows *in vivo*. The resulting system is an experimental replicate of the corresponding, PBPK, model of the animal. The ability to experimentally study dosing conditions of compounds and the inclusion of metabolite exchange between tissues is an advantage over standard *in vitro* culture techniques. Unlike other *in vitro* systems, a CCA can mimic the dynamics of dose exposure. Because any cell type may be used, these CCA devices can be designed to mimic key target organs from mice, rats, dogs, or even

humans, just by selecting representative cell lines and designing corresponding culture vessels.

Sweeney et al.^[47] developed the first CCA device to study the toxicology of naphthalene. The system was constructed using milk dilution bottles as culture vessels. The bottles were connected with tubing and a peristaltic pump provided recirculating flow. Their device sought to mimic the exposure of naphthalene to a rat. The researchers hypothesized that naphthalene, a chemical that is only moderately toxic in its native form, becomes activated by metabolism in the liver and then can induce damage in lung tissue. To test this hypothesis, the researchers constructed a CCA device that contained the rat hepatoma cell line H4IIE, and a rat lung cell line L2. The remainder of the rat's organs were modeled as a nonmetabolizing body of distribution and included as a culture chamber devoid of cells.

Experiments with this early CCA system were able to show that naphthalene induces toxicity in lung cells after conversion by liver cells. In experiments with no liver cells present, no toxicity was observed in the lung cells. Additionally, the researchers showed that by either increasing liver cell number or increasing CYP1A1 enzyme levels, toxicity to the lung tissue increased—further supporting their original hypothesis. However, parameters in this early system such as the ratio of liquid volume to cell volume and the residence time in each cell container were far from realistic.

A revised system was constructed by Ghanem and Shuler^[48,49] to address several of the concerns from the prototype. The modified system utilized a packed-bed design, with cells cultured on microcarrier beads. This alteration allowed for time-course sampling of cells during experimentation by removal of a portion of the beads with a sterile syringe. The ratio of cells to liquid volume was increased, though the ratio was still much less than the ratio *in vivo*. Experiments with this revised CCA system did not show any toxic response to naphthalene, however, and the decreased residence time in the liver compartment was found to be the cause. The reduced residence time resulted in less conversion of naphthalene to toxic quinines and minimal toxic response.

Microscale Designs

Recently, the CCA concept has been revised by the design of a μ CCA, which is shown in Fig. 3. By creating these systems using microfabrication, the devices now can achieve near *in vivo* residence times and volume ratios. The length scale of capillaries in the body is on the order of 10 μ m. This scale can be easily reached utilizing standard photolithographic

Fig. 3 An example of a microscale cell culture analog. This silicon device includes a liver tissue chamber, a lung tissue chamber, a fat tissue chamber, and an “other tissues” chamber as shown.

technology borrowed from the semiconductor industry. The first system was built to incorporate a liver cell chamber, a lung cell chamber, and an “other tissues” chamber fabricated on a silicon chip.^[50] This device utilized the same H4IIE and L2 cell lines of the previous CCA systems, but the chip was 2.5 cm × 2.5 cm in dimension and enclosed by a Plexiglas casing. Cells were attached to the culture chambers with a combination of poly-D-lysine (Sigma-Aldrich, USA) and either Matrigel (BD Biosciences, USA) for H4IIE cells or fibronectin (Chemicon International, USA) for L2 cells. Additionally, an integrated oxygen sensor was incorporated into the chip. This sensor utilized a ruthenium dye immobilized in a resin as a UV sensitive indicator of dissolved oxygen content.

Another μ CCA was designed that was similar to the first design, but divided the “other tissues” into well-perfused and slowly perfused chambers.^[51] The liver cell line H4IIE was also replaced with a human hepatoma line HepG2/C3A after finding increased CYP expression levels in this new cell model. Naphthalene was used as a study toxicant for this system, and was shown to cause a significant drop in glutathione (GSH) levels in both the liver and the lung cells after 6 hr of exposure. When no liver cells were present, there was no depletion of GSH in the lung cells, indicating that biotransformation in the liver cells produces a recycling product that injures the lung cells. Further experiments in the μ CCA with 1,2-naphthoquinone identified the reactive metabolites to be 1,2-naphthalenediol and 1,2-naphthoquinone. This discovery showed the

utility of the μ CCA system in investigating toxicity mechanisms.

To further clarify naphthalene toxicity, Viravaidya and Shuler investigated the impact of bioaccumulation, or the storage of compounds inside of fat tissue, on the response of the μ CCA system to naphthalene compounds.^[52] The rat preadipocyte cell line 3T3-L1 was used for this study because of its ability to be attached to the silicon surface. Experiments with naphthalene and 1,2-naphthoquinone showed that sequestering of naphtha compounds by the fat cells reduced the loss of GSH in both liver and lung cells when compared to a system with no fat cells. This illustrates the utility of this CCA system to explore the impact of dosing dynamics on toxicity.

CONCLUSIONS

Completing ADMET studies on new pharmaceuticals early enough to direct resources to the best drug candidates and studying the effects of chemical exposure before human illness develops has both economic and ethical value. To this end, basic toxicity predictions with single cell types and mathematical models have been relatively successful in supplementing animal data. In some cases, permeability through and metabolism by epithelial barriers can also be successfully reproduced with in vitro cell cultures. The in vitro representation of more vascularized tissues and organs such as the liver, however, is still challenging to tissue engineers and these tissue-engineering models are often incomplete. As advances in tissue engineering are made on in vitro tissues and organs, pharmaceutical and chemical ADMET studies will continue to improve. In vitro models that interconnect different tissues, particularly when used in conjunction with the corresponding PBPK, offer the possibility of making more realistic models that can act as surrogates for animals and humans in toxicity testing. Developments in μ CCAs, because they combine PBPK models with advances in microfabrication and cell culture, make microscale ADMET studies of pharmaceuticals and chemicals a promising frontier.^[53]

INTRODUCTION

Biomaterials can be defined as substances other than food or drugs comprising therapeutic or diagnostic systems that are in contact with tissue or biological fluids. Examples include partially implanted medical devices (such as contact lenses, central venous catheters, urinary catheters, voice prostheses, etc.) and totally implanted devices (such as pacemakers, mechanical heart valves, prosthetic joints, etc.). To a greater or lesser degree, all of these are prone to infection. The infecting organisms, their sources, and the period in which the devices are at risk vary among devices and their sites of insertion. In order to reduce some of the confusion surrounding biomaterials-related infection (BRI), a categorization system has been proposed to conveniently separate devices according to their method of implantation (Table 1).^[1] Category I devices such as hydrocephalus shunts, vascular grafts, prosthetic hip and knee joints, and prosthetic heart valves are totally implanted and have a very short period of risk at and soon after the time of insertion, and require antimicrobial protection for only a few days after insertion to prevent the majority of infections. By contrast, Category II (central venous access devices), and Category III devices (urinary catheters and voice prostheses) are at risk for the duration of their use.

OVERVIEW

Polymers are the most important class of biomaterials by far. Polymers such as polyethylene, polysiloxanes (silicones), polyurethanes, and poly(vinyl chloride) (PVC) are used extensively for the fabrication of indwelling catheters; however, they provide surfaces to which contaminating microbes can adhere and cause infection. Table 2 describes the incidence of such infections,^[1] which can vary from 1% for hip prostheses to 100% for urinary tract catheters after 3 weeks' use.^[2] Mortality rates following an infection can be as high as 10% in central venous catheter infections^[3] and up to 50% in aortic vascular graft infections.^[4]

Biomaterials-related infections (BRIs) are therefore one of the leading causes of nosocomial infections and primary septicaemia, and result in major consumption of health care resources affecting all clinical disciplines. The continuing development of biomaterials and their increasing use in medicine necessitates greater understanding of the complex nature of BRI. Many of these infections originate from bacterial contamination during surgery by exogenous sources such as the patient's skin or the health care provider's hands, or from hematogenous spread (i.e., infection from another site that is transmitted via the blood stream). Biomaterials-related infections are most commonly caused by coagulase-negative staphylococci (CoNS), with *Staphylococcus epidermidis* the most frequent organisms involved.^[5] Other BRI organisms include *Staphylococcus aureus*, *Propionibacterium acnes*, streptococci, and coliforms.

To understand approaches to prevention of infection in surgical implants, it is important to appreciate the events involved in its establishment. Once inserted, the biomaterials soon become coated with components of the body fluids in which they are bathed. This coating is known as conditioning film. Depending on the body site, the surrounding fluid can be saliva, urine, tear fluid, tissue fluid, blood, etc., and the conditioning film will consist mostly of adsorbed proteins such as fibronectin and fibrinogen, which can act as receptors for bacterial attachment. Plasma proteins are adsorbed in a competitive fashion and can displace each other until stability is reached.^[6] However, the manner in which conditioning films influence microbial attachment remains unclear. Physicochemical surface properties of the biomaterial and bacteria cell surface play a major role in the adhesion process.^[7] It should also be borne in mind that some biomaterials (such as polyvinylpyrrolidone (PVP), used as a catheter coating) have been found to profoundly influence the local macrophage response to infection.^[8]

The course of infections involves three major steps: 1) microbial adhesion; 2) microbial proliferation; and 3) formation of a bacterial biofilm (Fig. 1). Adherence of bacteria to implants and biofilm formation in vivo was first described in 1972.^[9] Most organisms stick

Table 1 Categories of medical implant device and periods of risk of infection

Category and implant	Site	Period of risk ^d
<i>Category I</i> ^a		
Prosthetic hip/knee joint	Hip or knee	A, (B)
Vascular grafts	Thoracic aorta	A, (B)
	Abdominal aorta/groin	A, (B)
Hydrocephalus shunts	Brain to abdomen	A
Prosthetic heart valves	Heart	A, B
<i>Category II</i> ^b		
Central venous catheters (cuffed)	Central venous system	B
CAPD catheters	Abdominal wall/peritoneum	B
<i>Category III</i> ^c		
Urinary catheters	Urethra/bladder	B
Voice prostheses	Trachea/esophagus	B

^aCategory I are totally implanted long-term devices.

^bCategory II are partially implanted, short- to medium-term devices.

^cCategory III are not surgically implanted.

^dPeriods of risk are: A associated with contamination at surgical insertion; B associated with contamination as a consequence of presence or use of device.

avidly to not only a variety of human cells and tissues, but also to the wide range of polymers, glasses, plastics, and metals used to make medical devices. Following the initial attachment phase, the microorganisms adopt a highly characteristic metabolic state in which they begin to produce extracellular enzymes to form long-chain extracellular polymeric substances from glycoside residues, which they synthesise intracellularly. This mucoid substance is variously called extracellular slime matrix, slime, or exopolymer, and consists mainly of high-molecular mass polysaccharide, which appears to determine both the structure and cohesive strength of biofilms by promoting bacterial cell-to-cell associations and the development of thick layers of bacteria.^[10]

Biofilms are phenotypically diverse populations of bacteria, embedded in the extracellular slime matrix. Other components in the biofilm include multivalent

cations, inorganic particles, and colloidal and dissolved compounds. Biofilm development has been explored in increasing detail since the 1980s. Studies have resulted in various models that characterize the complexity of biofilm development as a process of adaptation and changing genetic regulation. The physiology and molecular nature of biofilm formation varies between organisms. Recently, essential biochemical and genetic mechanisms of biofilm formation in *Ss. epidermidis* and *S. aureus*—the main causes of BRI—have been elucidated.^[11] Biofilms play a vital role in both the persistence of infection and the failure of treatment regimens (the two key clinical features of BRI). They can be considered to be stable microenvironments in which bacteria are protected from host-defense mechanisms and most therapeutic agents.^[12,13] Bacteria that can produce defensive enzymes that protect them from antibiotics (e.g., beta-lactamases) can accumulate high

Table 2 Incidence of infection in implantable devices

Implant	Site	Infection rate
Prosthetic hip/knee joint	Hip or knee	1–3%
Vascular grafts	Thoracic aorta	1%
	Abdominal aorta/groin	3–6%
Hydrocephalus shunts	Brain to abdomen	3–20%
Prosthetic heart valves	Heart	1.5%
Central venous catheters (cuffed)	Central venous system	3–10%
		0.5%
CAPD catheters	Abdominal wall/peritoneum	1.3 per patient/yr.
Voice prostheses	Trachea/esophagus	100%

concentrations of these within the microenvironment of the biofilm, whereas others can accumulate catalase or superoxide dismutase locally to protect against oxidizing ions released by phagocytes.^[14]

The concept of the biofilm phenotype explains the persistence of BRI and the need to remove the implant to eradicate infection. The clinical position is further complicated by the increasingly extensive innate resistance to antibiotics in staphylococci, restricting the choice of drugs for treatment. In addition, the bacteria in biofilms are physiologically, metabolically, and morphologically profoundly different from planktonic bacteria.^[15] Ziebuhr et al.^[16] reported that in *S. epidermidis*, such phenotypic changes were accompanied by subtle DNA rearrangements in vivo. It may take

several days to weeks before a thick mature biofilm is achieved, and sometimes detachment events occur.^[14] Active detachment is a physiologically regulated event, but only a few studies^[17] have been performed to demonstrate a biological basis for this process. Unfortunately, it is currently impossible to prevent access of bacteria to implants, even when the highest levels of hygiene are strictly adhered to. In view of the disastrous consequences of BRI, there is clearly a need to develop materials with antimicrobial activity that resist BRI for the lifetime of the device (or at least a significant part of it) and that do not provoke or select microbial resistance. Two main approaches for preventing BRI have been developed: 1) antiadhesive surfaces; and 2) materials coated or impregnated with releasable bioactive substances such as antiseptics, antibiotics, metal (or metal salt), etc.

SURFACE MODIFICATION TO PREVENT OR REDUCE BACTERIAL ADHERENCE

Extensive in-vitro investigation has focused on the search for materials and designs that diminish bacterial attachment and decrease the risk for bacterial infection. Several biomaterials approaches have been proposed, including highly biocompatible substances, biodegradable biomaterials, immobilization of biomolecules, incorporation of grafted hydrophilic outer layers to reduce protein adsorption, creation of low-surface energy (hydrophobicity) and carbon-rich materials, creation of microdomains to regulate cellular and protein adhesion, new copolymers with surface grafting to reduce friction^[18] and bacterial adhesion,^[19] as well as antimicrobial coatings and impregnation. Surface modifications may be engineered by grafting peptides or by using physical or chemical treatments to create charges (e.g., anionic groups, amino acids) on the polymer surfaces or to mimic sequences in natural molecules.^[20] Control of the charge and hydrophobic properties is likewise a pathway to influence biofilm interaction with a substratum surface. Microbial adhesion to biomaterials is mediated by specific interactions between cell surface structures and specific molecular groups on the substratum surface, or when viewed from an overall, physicochemical viewpoint by nonspecific interaction forces, including Lifshitz-van der Waals forces, electrostatic double-layer forces, solvent-dependent interactions, hydrogen bonding, hydrophobic interactions, hydration forces, acid-base interactions, and Brownian motion.^[20] Upon approach of a surface, organisms will be attracted or repelled by the surface, depending on the sum of the different nonspecific interaction forces. Lifshitz-van der Waals forces and Brownian motion usually promote adhesion, whereas electrostatic interactions can be either attractive or repulsive. Because

most organisms are negatively charged, a negatively charged substratum should theoretically exert a repulsive electrostatic force on the organisms, whereas adhesion should be promoted on positively charged surfaces. Bacterial adhesion is reported to be reduced, for example, on extremely hydrophobic surfaces.^[21,22] Gorman et al. have shown a greater adherence of *S. epidermidis* to the more hydrophilic polyurethane catheters than to silicone catheters.^[23] Price et al. were able to show that argon-plasma bombardment and silane treatment created a surface that reduced *Candida* adhesion irrespective of hydrophobicity.^[24] Titanium implants exposed in the oral cavity have been surface-modified by drying processes including ion implantation, ion plating, and oxidizing. The resulting calcium-implanted or alumina-coated surfaces have shown conclusive in vitro evidence of inhibition of adherence of oral bacteria.^[25-27] Such dry process surface modification is also useful in ensuring resistance to wear. Current ideas to prevent surface fouling by protein adsorption also involve tailoring the molecular interactions between the adsorbed proteins and the surface. It is now well established that protein adsorption is the first event following materials-tissue contact, and that the adsorption is generally nonspecific, with multiple binding sites on the proteins interacting with sites on the material surface. Protein adsorption can therefore be minimized by appropriate design of the interface, with modification of macroscopic surface properties such as wettability. Such a nonfouling surface may be obtained by coating with hydrated layers or by grafting with polyethylene oxide, phosphorylcholine (PC), heparin, and glucosamines.^[28-30] More recently, attention has been focused on a protein-based adhesion inhibitor, because proteins in the conditioning film can influence the proliferation of adhering microorganisms. For example, serum albumin reduces staphylococcal adhesion, whereas fibronectin increases it.^[31]

Although many techniques and processes can influence bacterial colonization in vitro, a physicochemical explanation of the mechanisms of inhibition by such materials is still not available. Currently no nontoxic material has been shown to completely inhibit microbial adherence. It is most important that, although some of the studies have given promising in vitro results, clinical in vivo testing has shown uniformly disappointing results. This is largely attributed to the formation of the conditioning film obliterating such surfaces.

BIOMATERIALS COATED OR IMPREGNATED WITH ANTISEPTICS AND ANTIBIOTICS

There is a great deal of confusion in the literature between coating and impregnation, with the terms being

used interchangeably. Because there are considerable implications for the use of these techniques in prevention of BRI, the distinction should be clarified. There are two ways of impregnating biomaterials. One consists of the admixture of the antimicrobial agents with the material during manufacture, and the other involves introduction of the agent into the manufactured material or device. Both should result in the antimicrobial being dispersed throughout the matrix of the material. Coatings can be applied directly to the surface of the manufactured device, or a binding agent can be utilized to fix them to the biomaterial surface. A third situation exists where a biomaterial is coated with a polymer into which an antimicrobial agent is introduced either before or after application of the surface polymer. The real difference between these lies in their efficacy. Factors that affect this are flow of blood or other fluid over the surface at risk (which removes the active agent), deposition of conditioning film on this surface (which obliterates the agent or inactivates it), and any depot effect that may create a durable antimicrobial activity. Leaving aside the issue of the conditioning film, the important site in terms of prevention of infection is the interface between the biomaterial and the fluid flow. Any antimicrobial activity (such as molecules or ions of the active agent) will be washed away from the surface by the flow, but a notional layer a few molecules thick (the Nernst layer^[32]) must remain saturated if protective activity is to be maintained. The source of active agent needed to replace that lost to fluid flow is either the coating or (in the case of impregnation) the biomaterial mass.

Because of their inherent low capacity to act as a depot, coatings are quickly depleted and their activity is short-lived (Fig. 2). If the biomaterial itself is impregnated with antimicrobial agent, the opportunity exists for long-lasting activity in the Nernst layer, and this in turn depends on the rate and mode of diffusion of the agent through the biomaterial.

If the agent is present as large aggregates and is water soluble, then so long as the aggregates are in contact with one another and with the surface, diffusion to the Nernst layer will take place by contiguous

Fig. 2 Biomaterial with antimicrobial coating in fluid flow conditions. (A) Molecules of active agent lost to flow; (B) Nernst layer; (C) coating layer; (D) biomaterial.

dissolution. However, if the agent is present as molecules dispersed throughout the biomaterial (or as aggregates that are not in contact with one another), then any diffusion to replenish the Nernst layer will depend on the ability of the agent to diffuse through the biomaterial itself, and this is dependent on the Hansen parameter.^[33] Thus, unless antimicrobial agents introduced before or after manufacture into biomaterials are able to diffuse toward the surface, they will remain incarcerated and will therefore be useless. Considering the obliterative effect of the conditioning film in addition to the foregoing, it becomes clear why so little progress has been made in clinical efficacy in this field.

An early example of an antimicrobial biomaterial was antibiotic-loaded polymethylmethacrylate (PMMA) bone cement, used in joint replacement. Gentamicin (Refobacin) was added as a powder to the cement-monomer mix during preparation in the operating theater.^[34] The concentration of antibiotic was typically 2.5% by weight. There are now 18 brands of bone cement containing antibiotics, most of which contain gentamicin. Exceptions are a cement containing erythromycin and colistin, and another containing gentamicin and clindamycin. Copolymers are added to some brands but it is unclear whether this is intended to modify antibiotic release characteristics. Many studies have been conducted on the release of gentamicin from bone cement, although standardization of methodology is a major problem when comparing them. Many methods are ill conceived and inappropriate to the scientific question ostensibly being addressed. In a review of the effect of test methods, Bayston and Milner^[35] compared the release characteristics of three antibiotics (gentamicin sulphate, sodium fusidate, and diethanolamine fusidate) from two different cements and concluded that the mechanism of release (using the criteria of Flynn^[36]) depended on the drug particle size and distribution and on the physicochemical relationship between each drug and the cross-linked cement. Gentamicin thus appeared to be released predominantly by a Type I system (contiguous dissolution), whereas the other two drugs were released predominantly by a Type IIb system (diffusion through the PMMA). Each of these may have consequences for not only drug release characteristics but also for long-term mechanical properties of the cement. It is important in addition to be clear about the intended antimicrobial activity: Is it to protect the surface of the cement, or to infuse the surrounding tissues with enough antibiotic to replace levels normally achieved by systemic administration?

Gentamicin loading of PMMA has also been used in the form of beads approximately 0.8 mm in diameter strung on a steel wire. These can be used to pack an infected cavity to provide high local concentrations of

antibiotic for several days. Although these are useful in certain situations, caution should be exercised if they are used for long periods, as they have been found to provoke resistant metabolic variants of staphylococci.^[37] Attempts to produce a vascular graft protected by antibiotics date from the work of Krajicek et al. in 1969, in which antibiotics were added to the collagen used to coat the graft.^[38] A similar approach has been more recently described.^[39] However, the system most used for prevention of vascular graft infection is preinsertion soaking of the gelatin or collagen-sealed graft in a solution of rifampicin. Results of clinical studies remained controversial until the study by Braithwaite et al., who found no clinical benefit from this procedure, apparently because rifampicin is released too rapidly from the sealant.^[40]

In view of the high volume of catheter use and the high infection rates—almost one million infections annually in the United States^[41]—central venous catheters have been the subject of attempts to apply various antimicrobial processes. Elliott recently reviewed the latest use of antimicrobial agents to prevent catheter-related infections.^[42] Although some antibiotics have been found to adhere briefly to catheter biomaterial, many processes involve precoating the catheter with a binding agent. Trooskin et al.^[43] used tridodecylmethylammonium chloride (TDMAC) to bind penicillin to catheters and found that in static *in vitro* soak tests, activity could be extended to two weeks. In flow conditions this period is considerably shortened, however, and there are concerns about TDMAC toxicity. Jansen et al. used a more biocompatible polymer, PVP, to coat poly(urethane) catheters that were then soaked in teicoplanin solution.^[44] Laboratory studies demonstrated retained activity for 3–5 days, but a later clinical study showed no benefit from their use.^[45] Chlorhexidine and silver compounds have also been used, and are discussed in more detail later. A benzalkonium chloride-coated catheter has been the subject of a clinical trial in which it was shown to reduce the incidence of bacterial colonization by 45%.^[46] In order to circumvent the problems of short duration associated with hydromer coatings, Raad and Darouiche developed a catheter coated with minocycline and rifampicin, which showed enhanced *in vitro* activity compared to chlorhexidine/silver-coated catheters. When the two were compared in a clinical trial,^[47] this benefit was confirmed (the rifampicin/minocycline-coated catheters reduced infections by a factor of 12). This could be attributed to the very powerful antistaphylococcal activity of the antibiotics chosen, to their relative lipophilicity, and particularly to the fact that the catheters were coated on both inner and outer surfaces, unlike the chlorhexidine/silver catheters. Protective activity has not been shown beyond approximately 5 days, however,

and there is doubt about the antibiotics' efficacy in longer-term catheter usage. The question of selection or provocation of bacterial resistance^[48] will be answered only with continued clinical use.

The rate of silicone hydrocephalus shunt infections can be as high as 20% in high-risk groups. A process similar to that used to coat central venous catheters with PVP hydromer has been recommended for prevention of shunt infection. A laboratory study has been published^[49] in which catheter segments were soaked in various antibiotics. Results show release of antibiotics for a few days but the system has the significant disadvantage of antibiotic application on the outer surface only, and most shunt infections involve the inner surface. In another paper by the same investigators,^[50] abscess formation was noted in a rabbit model around hydromer-coated catheters, but not around noncoated silicone. This was also found when nonviable bacteria were inoculated, leading the authors to speculate that this may increase susceptibility to persistent infection. A method of true impregnation of silicone shunts has been developed^[51] and has since been explored extensively, partly because of the intimate long-term contact with neural tissue. In addition to intensive safety tests, efficacy has been studied using an *in vitro* model. Almost all infections in hydrocephalus shunts begin as microbial adherence and biofilm development inside the shunt catheters, with no contribution from the patient in terms of inflammatory or immune response. However, the flow of cerebrospinal fluid (CSF) through the catheter as well as the external tissue sink must be included in the simulation. The period of risk is confined to the time of insertion, and although bacteria can persist inside the tubing for long periods, the device is not usually subject to further microbial assault. Any assessment must allow for continuous perfusion of the catheters for several weeks to exclude later regrowth of any microbial survivors. Because many recipients of shunts have a high CSF protein level, there is concern that, unlike the situation with antimicrobial coatings, any antimicrobial protection will transcend the conditioning film. Because attached bacteria are less susceptible to antimicrobial action and are likely to survive longer than any surface protective activity in flow conditions (perhaps especially in the presence of conditioning film), these aspects have received close attention. The assessment systems have satisfied international regulatory scrutiny, especially because animal models suitable for an antimicrobial shunt are not currently available. When the duration of activity of processed shunt catheters was determined against serial staphylococcal challenge, the catheters were protected against colonization for up to 50 days, even in the presence of conditioning film.^[52] Further studies have shown that the process has no effect on bacterial

adhesion to the catheters, but that it kills all adhered bacteria in 48–52 hours (represented by the expression tK_{100}).^[53] In such devices it is essential to kill 100% of adhered bacteria. The time taken to achieve this must relate to the duration of any antimicrobial protective activity in simulated conditions in use. It is doubtful that there are many antimicrobial biomaterials currently available that could achieve tK_{100} under adequate test conditions. Clinical experience with the processed device involving over 12,000 implantations has so far shown a dramatic decrease in infection rates; quantitative results are awaited.

METALS AS ANTIMICROBIALS

Gold, silver, and copper ions are believed to have broad-spectrum antimicrobial activity and are unlikely to provoke resistance.^[20] In view of increasing bacterial resistance to antibiotics, metal coating may therefore be an effective strategy to prevent BRI. In comparison to most heavy metal ions, silver combines high antimicrobial activity with relatively low human toxicity. However, silver ion concentrations higher than 10 mg/L may be toxic to certain human cells.^[54,55] Inorganic silver salts and complexes such as argyrols, silver nitrate, carbonate, silver halides, and the metal itself are used in medicines. Nonetheless, the precise active mechanism remains unknown. A recent review of metal toxicity in yeasts sheds important light on a possible mode of antimicrobial action.^[56] The biocidal activity of silver is related to the biologically active silver ion (Ag^+) which, by binding to bacterial DNA, may inhibit a number of important transport processes (such as phosphate and succinate uptake), and can interact with cellular oxidation processes as well as the respiratory chain.^[57] The silver cation is a highly reactive chemical structure, which binds strongly to electron donor groups containing sulphur, oxygen, or nitrogen. Biological molecules generally contain all these components in the form of thio, amino, imidazole, carboxylate, and phosphate groups. Silver ions are active against a broad spectrum of nosocomial organisms, including multiresistant staphylococci and enterococci, gram-negative enteric bacilli, *Pseudomonas aeruginosa*, and *Candida albicans*, their antibacterial killing rate being directly proportional to Ag^+ concentrations. The desirable properties of such infection-resistant biomaterials have been listed by Guggenbichler et al.^[48] The gold standard should in essence thus possess a broad spectrum of antimicrobial activity and be resistant to microbial colonization. The activity should endure for the lifetime of the device, should not be reduced by contact with body fluids, and should not select drug-resistant organisms. Silver-coated biomaterials should satisfy many of these

requirements, and several methods have been developed for the surface coating of polymers with elemental silver. The techniques include vapor phase/plasma deposition or sputtering of silver coatings and ion beam-assisted deposition/ion implantation techniques using a vacuum process. The antimicrobial activity is short-lived and coatings may not affix permanently (i.e., may peel off), giving only temporary antimicrobial activity.

For the last 30 years, research groups worldwide have studied the microbiocidal activity of new types of medical devices (silver-nylon, silver-coated intramedullary pins, silver-oxide-coated Foley catheters, and silver-coated vascular prostheses) in vitro and in vivo.^[20,58–64] Most of the authors have claimed strong antimicrobial efficacy, and several products have been launched on the market. Despite promising activity in vitro, anti-infective prosthetic devices manufactured from these materials have yet to achieve any conclusive degree of success in clinical trials.^[65] Randomized clinical studies showing statistically significant efficacy of silver-coated medical devices in high-risk populations of patients are rare, deal with small numbers of patients only, or are controversial. A prospective randomized controlled clinical trial of latex urinary catheters coated with hydrogel (consisting primarily of hydrophilic polyurethane) and silver salts has found no significant benefit from their use.^[66] The largest randomized controlled clinical study with 1300 patients revealed no significant differences in infection rates between silver-coated and unmodified urinary catheters.^[60] A further concern revealed by this study was an increase in the incidence of *S. aureus* urinary tract infection (UTI) in the silver group. Another approach to the exploitation of silver in biomaterials is oligodynamic iontophoresis.^[67] This technology uses a biocompatible polymer impregnated with silver, platinum, and carbon particles. When in contact with body fluids, silver and platinum particles act as electrodes and release a steady flow of silver ions. Only in vitro experiments have been performed so far, in which sections of catheters manufactured from the biomaterial were incubated with suspensions of test bacteria. These in vitro results showed antibacterial activity superior to that of metallic silver coatings and were maintained for periods of up to 9 months. Silver-coated devices may be clinically effective only when the concentration of free silver ions can be increased and when contact with plasma proteins, chloride ions, and possible cytotoxic effects are minimized.^[61] However, silver complexed with a sulphonamide and an antiseptic (chlorhexidine) has been used to reduce central venous catheter infections. Although the papers refer to impregnated catheters, they are actually coated. A clinical benefit was shown in one trial^[12] but not in another.^[68] One important difference appeared to be

the duration of catheterization, implying that a benefit would apply only to short-term (i.e., about 5 days) catheters. Hypersensitivity has also been a problem, probably associated with chlorhexidine.^[69]

A

ALTERNATIVE APPROACHES—RECENT ADVANCES

So far, few anti-infective prosthetic devices have achieved any degree of success in clinical trials and practice. It may have been naive to imagine that incorporating antimicrobial agents into biomaterials would totally frustrate the colonization mechanisms that microbes have evolved over millions of years as a basic survival strategy in hostile habitats. Typically, metals cannot be dissolved in organic solvents, and the current methods of impregnation cannot be applied to metals such as silver. A new method has therefore been developed for impregnation of polymers with metal nanoparticles. Antibacterial activity tests are currently underway.

CONCLUSION

A comprehensive comparison of the various antibacterial biomaterials is difficult because a great diversity of methods has been used to demonstrate their activity. Whereas a few materials show promise, a gold standard biomaterial is yet to be developed. Even if we manage to produce such an anti-infective biomaterial, given time, the ingenious, rapidly evolving organisms we face will surely find ways of colonizing it. To maintain control over the problem of device-associated infection, a continuing effort to develop novel materials will be needed.

Antimineralization Treatment

A

Bart Meuris
Willem Flameng

Department of Cardiovascular Diseases, Katholieke Universiteit Leuven, Belgium

INTRODUCTION

Surgical replacement of heart valves with artificial devices revolutionized the care of patients with valvular heart disease. In past decades, countless models of substitute heart valves were developed and investigated, and the technology of their design and manufacture has progressively improved. Nevertheless, an ideal valve replacement device has not been achieved.^[1]

Heart valve substitutes are of two principal types: mechanical prosthetic valves with components manufactured of nonbiologic material (e.g., polymer, metal, carbon) or tissue valves that are constructed, at least in part, of either human or animal tissue. At least 275,000 valves are implanted worldwide each year, of which it is estimated approximately 55% are mechanical and 45% are tissue, with a clear trend toward an increasingly greater usage of tissue valves over the past several years.

Heart valve substitutes are of two principal types: mechanical prosthetic valves with components manufactured of nonbiologic material (e.g., polymer, metal, carbon) or tissue valves that are constructed, at least in part, of either human or animal tissue. At least 275,000 valves are implanted worldwide each year, of which it is estimated approximately 55% are mechanical and 45% are tissue, with a clear trend toward an increasingly greater usage of tissue valves over the past several years.

Tissue valves have been used since the early 1960s, when aortic valves obtained fresh from human cadavers were transplanted to other individuals. Less than a decade later, chemically preserved tissue valves (termed bioprostheses) were first implanted. The term bioprosthesis usually denotes a valve that is chemically treated and mounted on a stent. Today, stented glutaraldehyde-preserved porcine aortic valves and bovine pericardial bioprosthetic valves are used extensively. Although tissue valve substitutes have certain advantages over mechanical valves, their durability is limited.

Mechanical and tissue valves differ in their major causes of failure. Specifically, mechanical prosthetic valves are associated with a substantial risk of systemic thromboemboli and thrombotic occlusion, largely owing to nonphysiologic surfaces and flow abnormalities created by one or more rigid occluders. To minimize this risk, chronic anticoagulation therapy is required in all mechanical valve recipients. However, systemic anticoagulation renders patients vulnerable to potentially serious hemorrhagic complications. Thus, the combined risk of thromboembolic complications and hemorrhage constitutes the principal disadvantage of mechanical prosthetic valves. In contrast with mechanical valves, tissue valves maintain a low rate of thromboembolism without anticoagulation. Their central pattern of flow approximates that of natural heart valves and their cusps are composed of valvular or non-valvular animal tissue, which is typically more thrombo-resistant and biocompatible than synthetic materials.

However, valve failure with structural dysfunction owing to progressive tissue deterioration, including calcification and non-calcific damage, is a serious disadvantage that undermines the attractiveness of tissue valve substitutes and limits their use in younger patients.^[2] Currently, most clinical heart centers use bioprosthetic valves in patients 65–70 years old or older. The life span of current bioprostheses in this age group is around 12–15 years, meaning that these patients will have reached the 8th or 9th decade of life at the moment of bioprosthetic valve failure or have died from other causes. When the cutoff age of 70 years is respected, the percentage of patients presenting for rereplacement of a dysfunctional, degenerated bioprosthesis is extremely low. Implanting bioprosthetic valves in younger patients results in a certain occurrence of valve degeneration within a time frame of several years. Valve calcification in children under the age of 15 can occur within 2 years. Unfortunately, it is precisely the younger patient who would benefit the most from the avoidance of lifelong anticoagulation. Therefore, further research toward the creation of a tissue valve with lifelong durability, even in young patients, is absolutely necessary. In order to accomplish this goal, accurate and reliable insights into the mechanisms and factors that control and influence degeneration and calcification in current bioprostheses must be obtained.

Bioprosthetic heart valves fail as a result of calcification and non-calcific deterioration. Non-calcific damage relates to the occurrence of valve dysfunction in areas not affected by deposition of calcific aggregates. Cuspal tears or perforations in uncalcified parts, pannus overgrowth, leaflet retraction, and dehiscence are examples of non-calcific damage.^[3] Calcification and non-calcific deterioration may occur independently of one another or they may be synergistic. Calcification of bioprosthetic valves has determinants related to 1) host metabolism; 2) implant structure and chemistry; and 3) mechanical factors, with several complex and poorly understood interactions.^[4]

BIOMINERALIZATION OF SOFT TISSUE

The Biomineralization Process

Calcification of biological tissue occurs in two different phases: nucleation and growth. Nucleation is the more

important and critical phase, because calcium and phosphate concentrations in normal body fluids are insufficient to allow spontaneous precipitation. Both in normal bone formation and in pathological calcification, a nucleating site must be present. A nucleating site is a localized microenvironment in which inorganic calcium and phosphate can interact in optimal circumstances and concentrations, allowing spontaneous precipitation and formation of an initial amorphous calcium phosphate crystal. Once nucleation occurs, the concentration of calcium and phosphate in body fluids is sufficient for crystal propagation and growth. Calcium and phosphate in extracellular fluids are in a metastable state: both ions normally do not precipitate, but when certain conditions are met (e.g., higher localized concentrations or the presence of an initial crystal), precipitation can and will take place.

Calcific deposits in mineralized tissue (either physiologic or pathologic) essentially are calcium phosphate salts, presenting in the form of hydroxyapatite. Hydroxyapatite is $\text{Ca}_5(\text{PO}_4)_3(\text{OH})$, but is usually written as $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ to denote that the crystal cell unit comprises two molecules. Although mammalian extracellular fluids are metastable toward hydroxyapatite, the crystal normally does not spontaneously precipitate. Hydroxyapatite requires a substrate that serves as a nucleator for crystal precipitation in bone and teeth as well as in ectopic calcification. Once the initial precipitation occurs, further crystal growth and expansion are just a matter of time. Hydroxyapatite is formed from its preliminary compounds, namely amorphous calcium phosphate and other ions in a different crystalline form such as octa-calcium phosphate, $\text{Ca}_8\text{H}_2(\text{PO}_4)_6$.^[5]

Bone Ossification

In bone formation, mineralization is an energy-requiring process. Living osteogenic cells generate small (100 nm) membranous cell fragments, so-called matrix vesicles, by pinching off vesicles from the outer plasma membrane. This reflects a stage in programmed cell death (apoptosis). These matrix vesicles serve as the initial site of bone calcification in all skeletal tissues. Initial hydroxyapatite mineral crystals are generated at the level of matrix vesicle membranes. This first phase of physiological mineralization is controlled by phosphatases (including alkaline phosphatase) and several Ca^{2+} -binding molecules, which are abundantly present in matrix vesicles. The second phase of biomineralization begins with the breakdown of matrix vesicle membranes, exposing preformed hydroxyapatite to the extracellular fluid, after which crystal proliferation can proceed, governed by extracellular conditions. Both phases of mineralization are under

cellular control: the first phase is initiated by osteogenic cells generating calcifiable matrix vesicles, releasing them into sites of intended calcification. The second phase is controlled by cells regulating extracellular ionic conditions and matrix composition. The whole process implies a variety of cellular elements including mesenchymal cells, osteoblasts, and osteoclasts, and an endless list of mediators such as phosphatases, Ca^{2+} -binding proteins, bone-morphogenetic proteins, and chemoattractants either stimulating or inhibiting crystal growth.

Pathologic Calcification of Living Soft Tissue

Pathological or ectopic mineralization of soft tissues, including articular cartilage and cardiovascular tissues, leads to morbidity and mortality. Recent findings suggest that the mechanisms and factors regulating physiological bone mineralization may be identical or at least similar to those regulating ectopic mineralization.^[6] Pathological mineralization is also initiated by matrix vesicles, membrane-enclosed particles released from the plasma membrane of mineralization-competent cells. In addition, several regulators (activators and inhibitors) of physiological mineralization have been identified and characterized, and evidence indicates that the same factors also contribute to the regulation of ectopic mineralization.

Bioprosthetic Tissue Calcification

In calcification of biological heart valves, the end product—the calcific deposit—is similar to that in bone. Calcific deposits in calcified bioprostheses are calcium phosphate salts, presenting in the form of hydroxyapatite.^[7,8] Unfortunately, the similarity stops there. When considering apatite formation and growth in either physiological mineralization (bone and teeth) or pathological mineralization (arteries, kidneys, muscles), one must deal with energy-requiring mechanisms involving living and functioning tissue cells that perform their functions, excrete mediators, and/or chemoattract other cell types. At the time of implantation, the tissue of a glutaraldehyde-fixed bioprosthesis is not a living physiological environment and energy-requiring processes do not take place. At the time of implantation, a bioprosthetic valve is devoid of living cells. The fixation of tissue with glutaraldehyde does not allow many living cells to enter, stay alive after entering, or perform their functions. The key elements providing physiologic or pathologic soft tissue mineralization are most likely not valid in bioprosthetic tissue calcification.

Terminology

Ectopic calcification is defined as inappropriate biomineralization occurring in soft tissue. In patients with chronic renal failure, a systemic mineral imbalance is associated with widespread ectopic calcification, referred to as metastatic calcification. In the absence of a systemic mineral imbalance, ectopic calcification is typically termed dystrophic calcification. Often, these sites provide evidence of tissue alteration or necrosis. Dystrophic mineralization is commonly observed in soft tissues as a result of injury, disease, and aging. Calcification of bioprosthetic valves in a normocalcemic host can be categorized as dystrophic calcification.

Extrinsic calcification of a tissue valve refers to calcific deposits occurring outside the actual valvular tissue. This may take place in cells adherent to the valve, formed neointima, thrombi, or vegetation. Although all these phenomena are relevant to global valve function and long-term behavior, the main focus of interest is the intrinsic valve calcification, occurring within the substance of the tissue of which the valve is constructed.

TISSUE VALVES: CELLS, FIBERS, AND GROUND SUBSTANCE

Cells and Cell Remnants

Prelevation, subsequent processing and fixation of tissue harvested from an animal, results in irreversible cell death. Cell death leads to the presence of cellular debris such as dead or disrupted cells, membranous cellular degradation products, remnants from the cell nucleus, free cell organelles, and fragments from the endoplasmic reticulum. These cellular remnants demonstrate ultrastructural similarities to matrix vesicles^[9] and have been identified as a potential nucleation site for initial mineralization.^[7,9-11] The mechanisms responsible for this cell-mediated mineralization are uncertain, but a few hypotheses have been formulated.^[7,8,10-12]

1. Intact living connective tissue cells have an intracellular free calcium concentration of around 10^{-7} M, whereas the extracellular free calcium concentration is 10^{-3} M, leading to a 10,000-fold gradient across the plasma membrane. In dead cells and in cells modified by aldehyde cross-linking, Ca^{2+} enters the cell passively, whereas the mechanisms for Ca^{2+} removal (membrane-bound, energy-requiring Ca^{2+} pumps) are no longer active. The intracellularly sequestered Ca^{2+} in mitochondria and endoplasmic reticulum gains free access to the cytoplasm, a mechanism that is certainly important for the abundant smooth muscle cell

portion in the aortic wall portion. The next step is a reaction with intracellular phosphate (PO_4^-). Phosphate is abundantly present throughout the cell, but is highly prevalent within organellar and plasma membranes in the form of phospholipids, proteolipids, and enzymatic systems. The massively released free Ca^{2+} in the cell binds to phosphate and leads to the formation of an early calcium phosphate-based mineral.^[11,12] Hereby, the initial step toward hydroxyapatite formation is set.

2. Phospholipids in membranes not only carry negatively charged phosphates, but also their phosphate groups can be set free through the action of activated phosphatases (triggered through free Ca^{2+} ions). Free inorganic phosphate easily reacts with Ca^{2+} to form an amorphous calcium phosphate precipitate.
3. Not only does calcium have an affinity for phospholipids, but also many membrane-bound proteins and enzymes have a high affinity for Ca^{2+} . These large proteins can attract and bind Ca^{2+} ions.
4. In pathologic cartilage ossification, a non-energy-requiring Ca^{2+} trap has been postulated through the formation of calcium-phospholipidic complexes that can nucleate hydroxyapatite from a metastable calcium phosphate solution.^[13] This non-energy-requiring process may also play a role in bioprosthetic tissue calcification.

Cells, cell remnants, membrane fragments, and organelles are all observed sites of primary nucleation of bioprosthetic valve mineralization.^[7,8] The small, early crystal nuclei will progressively accumulate additional mineral compounds, eventually growing to macroscopic calcific deposits. The role of phospholipids in the initiation of calcification is not to be underestimated. In vivo hydroxyapatite formation induced by phospholipids is demonstrated both in normal physiologic bone formation processes and in pathologic soft tissue mineralization. In commercially available tissue heart valves, a significant correlation exists between cuspal phospholipid levels and calcium content. Consequently, it is not surprising that tissue treatments aimed at removing cells and membrane remnants, thereby reducing phospholipid levels, are successful in reducing calcification, at least in the cusps. However, it is not evident to what extent these treatments effectively also prevent collagen- or elastin-related calcification. Even if cellular remnants are efficiently removed, there is evidence for host cell infiltration in implanted bioprosthetic valves. These cells may become entrapped in a cytotoxic glutaraldehyde-fixed matrix, eventually die, and in that way produce renewed cell debris.

Collagen

Collagen fibers are present in all tissues used for bioprosthetic heart valves. They provide an architectural framework and are important for the mechanical strength required for adequate valve function. The most abundant type of collagen in valvular material is collagen type I.

Collagen fibers have the ability to calcify. There is evidence of calcium deposition in isolated type I collagen samples and in acellular collagen preparations.^[12,14] In both porcine and pericardial cusps, early phases of mineral depositions are described to occur along collagen fibers, whereas calcification along cell debris was minimal in these studies. Calcific crystal nucleation in bioprosthetic tissue seems to be able to occur by different independent mechanisms in cells and in collagen. In porcine aortic wall calcification, the contribution of collagen fiber calcification is probably minimal.^[4]

Collagen fibers are built from consecutive collagen molecules (tropocollagen). In between the 300-nm-long tropocollagen molecules, small 40-nm gaps exist, also known as “hole zones.” Different protective proteoglycans reside in these holes. In bone, this area (the hole zone) is the initial site of crystallization of the collagen fiber at the time the fiber is incorporated in the apatite crystals originating from matrix vesicles. A few possible mechanisms may cause early calcific deposits to occur near the collagen fiber.

1. In bioprosthetic tissue, matrix metalloproteinases (MMPs) and other proteolytic enzymes are able to degrade the protective proteoglycans attached to collagen, thereby exposing sites in collagen prone to calcification.
2. Repetitive mechanical stress can damage the structural integrity of collagen. In damaged collagen fibers, the zones in between consecutive tropocollagen molecules become larger, facilitating calcium deposition.
3. Collagen has a certain affinity for calcium-binding proteins containing γ -carboxyglutamic acid (Gla). These Gla-containing proteins may either originate directly from blood or are secreted locally by infiltrated host lymphocytes and macrophages, infiltrated in the bioprosthesis. Gla proteins are known for their ability to attract and bind calcium.

Elastin

Elastic fibers are abundant structural proteins in the porcine aortic wall and are functionally important components of porcine aortic cusps. Ultrastructurally, elastic fibers consist of a core composed of cross-linked

elastin molecules and an external coating of microfibrils and proteoglycans located at the periphery of the amorphous component. Elastin has particular properties that set it apart from other matrix components. Glutaraldehyde does not chemically react with elastin. Elastin is intermolecularly cross-linked to form desmosine and isodesmosine residues and contains very few lysine groups to react with glutaraldehyde. Radioactive [³H]glutaraldehyde studies confirmed very low reactivity between glutaraldehyde and elastin.^[15]

Calcification of the elastic fiber in humans is well studied. The interest in elastic fiber calcification comes from observations in atherosclerotic arterial wall calcification and in senile aortic wall mineralization that can occur independent of atherosclerosis. Several possible mechanisms and pathways have been described.

1. The external coating of the elastic fiber protects elastin from calcification. Disruption of this protective coating exposes the elastin core to the extracellular environment. Elastin possesses a unique structure that facilitates calcium binding: the elastin core has several binding sites for large cations, such as Ca^{2+} .
2. Matrix metalloproteinases such as MMP-9 and MMP-2 bind and degrade insoluble elastin to soluble peptides. These elastin degradation products can elicit immune responses and trigger unwanted reactions in host cells, such as protease release and apoptosis. The mechanism is well described and occurs through the elastin–laminin receptor, which is present on the surface of most cells.^[16] Vascular smooth muscle cells can assume osteoblastic phenotypes and have osteogenic activity in cell culture experiments.^[17]
3. The elastic fibers in the aortic medium endure several changes with advancing age, including changes in their amino acid composition.^[18] This mechanism is crucial in mineralization of the aging aorta, even in the absence of atheromatous disease. The aged elastic fiber includes a diminished amount of structural proteins, an increasing content of polar amino acids (aspartic and glutamic acid), and introduction of carbonyl groups into amino acid residues. These polar residues are negatively charged and can attract counterions. The fiber thus becomes more susceptible to the activity of elastase; it may totally disintegrate and calcify. These age-related chemical changes in elastin occur independent of the onset and evolution of atheromatous lesions.

The role of elastic fibers in bioprosthetic valve calcification is less clear. Elastin can be damaged during the harvesting and preparation of the tissue.

Disruption of elastic fiber integrity was illustrated in bioprosthetic valves, where ultrastructural studies reported damage to the outer protective elastin coating. The lack of reactivity of glutaraldehyde with elastin leaves the elastic fiber unprotected and susceptible to the activity of degradative enzymes such as MMPs. Local delivery of MMP inhibitors can reduce calcification in subdermally implanted elastin. In porcine aortic valve cusps, degradation of elastic fibers through elastase causes an increase in radial dimensions with a corresponding decrease in radial extensibility and a threefold increase in stiffness. Elastin damage in cusps may be a factor in progressive cusp degeneration.

Ground Substance: Proteoglycans (PGs) and Glycosaminoglycans (GAGs)

Ground substance of tissues is composed largely of PGs carrying GAGs (mucopolysaccharides). Proteoglycans are a major component of the animal extracellular matrix, the “filler” substance existing between cells and fibers. They form large complexes, both to other proteoglycans and also to fibrous matrix proteins (such as collagen). Proteoglycans represent a special class of heavily glycosylated proteins, consisting of a large core protein with one or more covalently attached GAG chains. Solutions of GAGs have a slimy, mucus-like consistency that results from their high viscosity and elasticity. These GAG chains are long, linear carbohydrate polymers that are negatively charged under physiological conditions because of the occurrence of sulfate and uronic acid groups. The highly negative charged side chains of PGs result in an enormous water-binding capacity, which gives these PGs their important mechanical functions: 1) maintaining matrix hydration and volume; and 2) giving tissue the ability to resist and absorb compressive forces.

In a native porcine valve, PGs are mainly located in the spongiosa layer, which is the layer that must absorb the mechanical stress forces during valve closure. The spongiosa also enables shearing stresses between the fibrosa and ventricularis layers. In pericardium, PGs are mainly composed of dermatan and chondroitin sulfate. These highly charged units contribute to tissue hydration and elasticity but also have an important interaction with the abundant collagen fibers. Just like elastin, PGs and GAGs are not effectively stabilized by glutaraldehyde.

In bioprosthetic valves, the role of PGs and GAGs on mineralization is controversial but one thing is clear: losing GAGs is not beneficial to long-term durability of tissue. The presence of GAGs and PGs protects tissues from calcification. In vitro models demonstrated inhibited hydroxyapatite formation after

the addition of high chondroitin sulfate concentrations through a mechanism in which PGs block the active nucleating sites for further apatite crystal growth.^[19] And selective PG extraction from pericardium results in greater accumulation of calcium salts compared with non-extracted tissue, with reduced hydrothermal tissue stability.^[20] Glycosaminoglycan removal from porcine aortic valve cusps results in decreased cuspal thickness, reduced water content, diminished rehydration capacity, and important increases in the flexural rigidity of the cusp.

The mechanisms through which we lose PGs are twofold. First, preparation of bioprosthetic heart valves with the entire process of tissue harvesting, manipulation, fixation, etc., induces GAG loss.^[21] Valve cusps stored under static conditions in 0.2% glutaraldehyde for 6 mo lose over 50% of their original GAG content.^[21] Controlling GAG loss through more elaborate or organ-like preservation techniques could be beneficial. The second factor causing GAG loss is mechanical stress during cyclic functioning of the cusp.^[22] Given this possible importance of maintaining PG and GAG levels in cuspal tissue, alternative tissue fixations that are able to cross-link and fixate both collagen fibers as PGs have been investigated. Methods using products such as acyl azide, carbodiimide with or without the use of diamines, and periodate^[23] have all demonstrated good tissue preservation and reduction of calcification, at least in rat subcutaneous models. In properly cryopreserved porcine tissue, no significant alteration in the content, molecular size, or distribution of PGs occurs.

FACTORS INFLUENCING BIOPROSTHETIC TISSUE CALCIFICATION

Used Material

Amino acid analyses demonstrated that fresh bovine pericardial tissue consists of almost 90% collagen.^[12] Cells and ground substance are scarce in pericardium. Pericardial collagen is almost exclusively type I. Calcified pericardium has a reduced hydroxyproline content, indicating that part of the collagen disappears through absorption or simple breakdown. Several studies attempted to elucidate the origin of pericardial calcification. Unfortunately, the results are controversial: some results stress the appearance of initial deposits along remnants of connective tissue cells,^[12] whereas others claim this initiation occurs at the level of collagen fibrils.

Compared with pericardium, porcine aortic cusps contain more cells. Collagen accounts for approximately 40%, with 1% elastin and 5% GAGs. Collagen is both type I and type III.^[24] This may be of

importance because type III collagen mineralization has never been demonstrated in contrast with type I collagen. A fair comparison between porcine cusps and pericardial tissue regarding its tendency for calcification is difficult. Results will be influenced by the models used (subcutaneous vs circulatory), the exact tissue samples or valves used (influence of tissue handling and design), applied tissue treatments, etc. Clinical evidence points toward longer longevity for pericardial valves. Experimental results are mixed.

The porcine aortic wall portion consists of over 50% elastin and approximately 15% collagen and 2% GAGs. The rest consists of cells, with an abundance of smooth muscle cells. Experimental data indicate an important cell-mediated mechanism for aortic wall calcification,^[25] and a possible role for elastin is not to be excluded.^[15]

Glutaraldehyde

Glutaraldehyde reacts with tissue proteins to form intra- and intermolecular cross-links, resulting in a fixed, stable, non-immunogenic, and sterile tissue. Glutaraldehyde is the reason why bioprosthetic heart valves exist today.

Glutaraldehyde is a bifunctional agent that creates a series of various chemically stable cross-links, mainly between lysine (Lys) and hydroxylysine (Hyl) residues of tissue proteins. At low concentrations, glutaraldehyde produces mainly intramolecular cross-links in collagen, whereas at higher concentrations long polymeric chains of glutaraldehyde form and the reaction is reversible. After implantation of glutaraldehyde cross-linked biomaterial, large polymers of glutaraldehyde are continuously hydrolyzed, which results in the release of free monomeric glutaraldehyde.

Because collagen carries many Lys and Hyl residues, the collagen fiber is extensively cross-linked by glutaraldehyde. The nature and extent of the cross-linked network depends on fixation time, reagent concentration, and fixation temperature.^[26] Studies with radioisotopes of glutaraldehyde (³H]glutaraldehyde) clearly demonstrated a linear relation between glutaraldehyde uptake and tissue stability (resistance to enzymatic digestion).^[27]

Three major problems with glutaraldehyde have never been resolved: 1) tissue permeability: glutaraldehyde penetration in tissue decreases with increasing tissue depth; 2) heterogeneity of glutaraldehyde cross-linking with the formation of highly polymerized glutaraldehyde; and 3) liberation of free glutaraldehyde from the polymeric cross-links.

A few hypotheses have been postulated through which glutaraldehyde as such can be responsible for bioprosthetic tissue mineralization.

1. The pyridinium cross-link produced by glutaraldehyde is a quaternary amine that can cause an influx of PO_4^{3-} into the interfibrillar spaces of collagen, leading to hydroxyapatite formation.
2. Tissue valves contain residual amounts of aldehyde in the tissue after preparation, which can damage blood cells of infiltrating host cells after implantation. The damaged cells can adhere to the surface of the valve and act as a promoter of calcific changes.
3. The released residual glutaraldehyde is harmful to endothelial overgrowth, leaving the biological tissue uncovered for Ca^{2+} -rich plasma insudation.
4. Residual glutaraldehyde as well as unstable glutaraldehyde polymers retained in the interstitium have been implicated in cytotoxicity toward host cells and inflammatory reactions.
5. Glutaraldehyde fixation disables the dynamic interaction between fibrosa and ventricularis, resulting in worsened mechanical properties.

Because early clinical and experimental studies demonstrated that formaldehyde cross-linked valves have grossly inadequate durability, glutaraldehyde is now utilized virtually exclusively. Many different protocols exist concerning exposure time, exact concentrations, applied pressure, and temperature during fixation. The rate of glutaraldehyde incorporation by bovine pericardium is rapid, with nearly half maximal incorporation after only 1 hr and complete reaction occurring in less than 24 hr.^[12] Contrary to a widely held belief, some studies demonstrated beneficial effects of higher concentrations of glutaraldehyde. Several protocols using very early (within 30 min) fixation in a high concentration of glutaraldehyde of over 1% demonstrated lower degrees of tissue mineralization. The mechanisms of this protective effect are purely hypothetical but can be the result of a more efficient tissue fixation, less tissue permeability for diffusing ions, less cell death prior to fixation, or less free glutaraldehyde residuals. Until now, this high-glutaraldehyde strategy has not reached clinical practice.

Blood Contact

The clinical fate of every bioprosthesis is implantation in the blood stream. The interaction of fixed tissue with circulating blood is complex. Evidence exists that the tissue will be confronted with an insudation of lipids, proteins, cholesterol, lipoproteins, lipid-loaded macrophages, etc.^[28,29] Finally, the prosthesis will also be confronted with circulating free plasma calcium that will insudate into the tissue. The effect of blood contact on tissue mineralization is demonstrated in experimental settings.

Host Age

Host age is an undisputed factor in bioprosthetic valve calcification. Calcification is more rapid and aggressive in younger patients. Bioprosthetic valves implanted in children under the age of 15 will calcify to a fully dysfunctional valve within 2–3 years after implantation.^[30] Freedom from structural valve deterioration at 15 years in a population younger than 65 is around 65%, whereas in a population older than 70 it is over 90%. Although the relationship is well established, the mechanisms accounting for the effect of age are uncertain.

One explanation for this dramatic influence of host age is the difference in overall calcium handling and calcium metabolism, including higher levels of blood calcium, phosphate, bone proteins, and enhanced parathyroid hormone and vitamin D metabolism in young patients. Although this phenomenon limits the clinical use of bioprostheses in young patients, it gives the opportunity for preclinical experimental valve testing in young animals, producing high rates of valve calcification within short periods of time.

Mechanical Stress

The role of mechanical stress on bioprosthetic tissue calcification is complex. Implanted valves are subjected to large mechanical stresses during each cardiac cycle, with high transient stresses during valve closure and cyclic flexural and compressive stresses during valve opening. Because of these important repetitive forces, bioprosthetic valves can fail mechanically (cuspal tears) and this can occur in the absence of calcification.^[31] On the other hand, many clinical observations indicate a relation between mechanical stress and cuspal calcification: cusp calcification is more severe in mitral position compared with the aortic position and certainly compared with the tricuspid position. Experimentally, stress and valve calcification have been correlated.^[32]

Within the valve structure, mechanical stresses are the highest near the commissures and lowest at the base of the leaflets.^[33] At a pressure of 100 mm Hg applied to a closed porcine valve, the maximal stress is 160 kPa near the commissures, 70 kPa in the body of the leaflet, 50 kPa at the free edge, and only 40 kPa at the cuspal base. A perfectly similar distribution is obtained for maximal shear stresses in these different regions.^[33] Computer-based mathematical models demonstrated the concentration of stresses in the commissural region.^[34]

When this stress distribution is compared with the distribution of calcific deposits in clinically explanted (degenerated) valves, the regions of high stress coincide

with calcified areas.^[33,35] In over 50% of degenerated tissue valves, regions of calcification coincide with the location of cuspal tears and perforations, indicating that the stress to which the tissue is subjected first leads to calcification and subsequently to mechanical failure.^[35] Because cuspal tears occur mostly in the commissural region, a causative relation between the magnitude of mechanical stress and the site of calcification is more than likely.

The question remains regarding which mechanism is responsible for the relation between stress and mineralization. Three major elements may have a fundamental role: collagen, GAGs, and proteolysis.

1. In a series of *in vitro* accelerated fatigue studies with porcine valves, infrared spectroscopy revealed progressive and severe damage to the molecular structure of type I collagen, with loss of molecular helicity.^[22] Damaged collagen can serve as an initiation site for calcium deposition (*cf.* supra), and it will also lead to structural weakening of the tissue. Experimental animal studies demonstrated that in porcine cusps, calcification occurs earlier in the commissural region than at the base, with the earliest calcific deposits localized within collagen cords.^[32] In pericardial cusps, calcification is observed along the zone of leaflet flexion and initiates at the level of deformed collagen fibers.^[32] Pericardial specimens exposed to collagenase and dynamic stress load fail faster than specimens exposed to collagenase and static load.^[36]
2. Valve fatigue also leads to loss of GAGs from the cuspal extracellular matrix.^[22] The GAG levels dropped from 6.5 $\mu\text{g}/\text{mg}$ in glutaraldehyde-fixed cusps to 0.7 $\mu\text{g}/\text{mg}$ after cyclic fatigue. Loss of GAGs (*cf.* supra) leads to altered biomechanical tissue characteristics, as documented in decreased cuspal bending strength^[22] and altered 3-D cuspal geometry.^[37]
3. Dynamic stress accelerates local proteolytic activity in bovine pericardium.^[36]

In summary, there is evidence for a relation between stress and cuspal tears, between calcification and commissural regions, and between stress distribution and commissural regions. Stress can lead to either ultrastructural damage and initiation of calcification or primary tissue failure and non-calcific tears. In native, normal aortic valve cusps, the damage accumulated by cyclic stress will be repaired and resolved by living fibroblasts. Damaged material will be scavenged, collagen fibers repaired, and tissue GAG levels restored. In a bioprostheses, these processes of scavenging and repair are absent. The keystone for valvular and commissural stress distribution is valve design. Numerical computer models guided valve designers

toward altering stent height and tissue attachment, introducing flexible stents, etc., with the common goal of reducing leaflet (commissural) stress.

Non-collagenous Extracellular Proteins

In physiological bone mineralization, more than 17 different non-collagenous extracellular proteins (NCPs) have a crucial role in the mineralization process. These proteins (osteonectin, osteopontin, osteocalcin, matrix-Gla protein, bone sialoprotein II, bone acidic glycoprotein) are highly anionic proteins, contain high proportions of negatively charged aspartic acid and Gla, and have high affinity for Ca^{2+} and hydroxyapatite. Mainly Gla residues bind strongly to calcium and all of its precipitating salts. The NCPs are critical to the establishment and regulation of mineralization because type I collagen dissociated from NCPs is incapable of supporting hydroxyapatite formation. Together with the whole family of bone-morphogenetic proteins, their role was studied extensively in normal bone formation and in pathological dystrophic vascular calcification related to atherosclerosis. A wide variety of mesenchymal cells and inflammatory cells can synthesize the specific NCPs required to promote and regulate the development of a mineralized matrix. The strong chemotactic properties of NCPs may further promote cell recruitment and continued matrix protein expression. Non-collagenous extracellular proteins have been detected in atherosclerotic plaques and in calcified arteries and native valves.^[38] We are dealing with living tissues, and living fibroblasts, smooth muscle cells, and macrophages respond and interact to biohormonal stimuli. The exact role of this wide array of complex proteins in the calcification of fixed bioprosthetic valve tissue is far from elucidated.

Different NCPs are present in close anatomic proximity with zones of calcification in degenerated bioprosthetic valves. The main cell type expressing these proteins at the surface of the bioprostheses is macrophages, but infiltration with other cell types such as T lymphocytes, monocytes, and mesenchymal cells was also described.^[39] All these cell types are able to synthesize osteopontin, osteonectin, and other NCPs.

Osteocalcin exhibits a high affinity for calcium, phospholipids, and hydroxyapatite. Osteocalcin can be passively absorbed from plasma but it can also be expressed in situ by infiltrating cells. The presence of NCPs such as osteocalcin and osteopontin was demonstrated in clinically explanted calcified bioprostheses and in calcified tissues from rat subdermal models, so the adsorption of these proteins may have a role.

Because many of these NCPs are vitamin-K-dependent proteins, attempts to inhibit bioprosthetic tissue calcification with high-dose warfarin therapy have been performed,^[40,41] although without success.

Enzymes: Phosphatases and Proteinases

Glutaraldehyde-treated tissues have always been regarded as resistant to enzymatic degradation, including enzymes released from dead cells, because all proteins are subject to chemical cross-linking. However, different studies revealed that a variety of enzymes, either originating from the fixed tissue itself or infiltrating from host blood or host cells, can retain their activity. Alkaline phosphatase (ALP) has an important function in the pathogenesis of mineral nucleation in bone and has a role in pathological vascular and non-vascular calcification. Alkaline phosphatase can boost local PO_4^{3-} concentrations by the hydrolysis of organic phosphates. Following standard glutaraldehyde fixation, considerable ALP activity is present in pericardial tissue. Further ultrastructural studies demonstrate enzymatic reaction products along membranes of endothelial cells and interstitial fibroblasts, the sites of early calcific deposits in bioprosthetic valves.^[42,43] The widely held view that glutaraldehyde eliminates all metabolic activities of bioprosthetic tissue might be inaccurate and examination of the role of ALP and other phosphatases may stimulate approaches for inhibiting calcification.

Next to ALP, there are the MMPs, a family of Zn^{2+} -dependent endopeptidases, that contribute to tissue remodeling and repair. The MMPs are produced by several cell types including fibroblasts, macrophages, endothelial cells, and eosinophils. Concerning their possible involvement in tissue degradation (with subsequent calcification), MMPs such as collagenase and elastase were actively present in glutaraldehyde-fixed aortic cusp and wall tissue.^[44] Tissue proteases existed both in soluble form and covalently immobilized to the cross-linked matrix. Both damaged collagen and damaged elastin not only lead to tissue failure, but also enhance collagen- and elastin-mediated calcification. Further research is required to establish whether the removal of these enzymatic activities or their inhibition using specific tissue inhibitors of matrix proteinases can enhance the longevity of biomaterials.

Altered Calcium Metabolism in the Host

The non-normocalcemic host (chronic renal failure, hyperparathyroidism) will reveal early and rapid calcification of an implanted bioprosthesis. Disturbances of mineral metabolism such as hyperphosphatemia and hypercalcemia contribute to tissue calcification. In ectopic calcification, mechanisms include not only passive precipitation of elevated ions but also actively induced changes in vascular smooth muscle cell behavior toward an osteoblast-like phenotype. Specific calcium-regulatory proteins may act locally or systemically. Dysregulations of calcification inhibitors, including fetuin A, matrix Gla

protein, osteoprotegerin, and pyrophosphates, may also be pathophysiologically relevant factors.

Immune Responses

Unlike the situation in cryopreserved homografts, in which the immune response toward the valve is important, the role of immunologic reactions in bioprosthetic tissue calcification is probably limited. Although 1) experimental animals can be sensitized to both fresh and cross-linked bioprosthetic valve tissues;^[45] 2) antibodies to valve components can be detected in some patients following valve dysfunction;^[46] and 3) failed tissue valves often have mononuclear inflammation, no definite role has been demonstrated for circulating macromolecules or immunocompetent cells. In particular, the presence of mononuclear cells in a failed tissue valve does not equate to immunologic rejection. In all papers attempting to demonstrate immune-mediated injury, no evidence indicates that the mononuclear inflammatory cells cause functional valve degeneration. Experiments in congenitally athymic mice (lacking normal T-cell function) demonstrated similar calcification compared with calcium levels in normal mice in subcutaneously implanted fragments.^[47] The morphologic characteristics of the calcification were the same in both groups, with dystrophic mineralization of the spongiosa predominating. Thus, normal T-lymphocyte function is not necessary for porcine bioprosthetic calcification, and immunologic processes do not contribute to this process.^[40,48]

Infection

Clinical experience demonstrated that infection of a bioprosthetic valve leads to rapid calcification. Experimentally, tissue valves affected by endocarditis calcify extensively. Whether this is still intrinsic tissue mineralization or predominantly extrinsic calcific deposits in vegetations is unclear. The mechanisms involved are unclear but the severe inflammatory and infectious processes that take place at the level of an infected valve, with the secretion of several mediators, lytic enzymes, and chemoattractants, must be detrimental for tissue stability and integrity.

ANTICALCIFICATION TREATMENTS

Analogous to any new or modified drug or device, a potential antimineralization treatment must meet rigorous efficacy and safety requirements. Investigations of an anticalcification strategy must demonstrate both the effectiveness of the therapy and the absence of adverse effects. The treatment should not impede valve

performance such as hemodynamics and durability. Adverse effects in this setting could include systemic or local toxicity, tendency toward thrombosis on infection, induction of immunologic effects, or structural degradation, with either immediate loss of mechanical properties or premature deterioration and failure. There are several instances in which an anti-mineralization treatment contributed to unacceptable degradation of the tissue.

Non-Glutaraldehyde-Based Tissue Fixation

Implanting xenogeneic biological tissue requires a chemical process that stabilizes the tissue and protects it from immunologic and enzymatic attack. The processes developed to date were based on cross-linking with chemical agents, of which glutaraldehyde is indisputably the most widely used. The controversial status of glutaraldehyde and possible links with tissue calcification pointed research groups toward new chemical agents capable of inducing cross-linking of the side chains of amino acid residues other than Lys and Hyl. However, the search for an alternative cross-linker is still open.^[49]

Possible alternative cross-linking methodologies include glycerol,^[50] carbodiimide,^[51] acyl azide,^[52,53] epoxy compounds,^[54] genipin,^[55] glutaraldehyde acetals,^[56] poly(ethylene glycol),^[57] and poly(acrylamide) hydrogels,^[58] with numerous modifications and variations. All these tissue treatments aim at achieving a stable, cross-linked, and non-immunogenic tissue through a different type of biochemical bond than that induced by glutaraldehyde. Physical methods such as ultraviolet irradiation and dehydrothermal freeze drying have been investigated.

Despite an abundance of experimental reports claiming tissue stability, anticalcification potential, and possible future clinical application in heart valves, none of these alternative cross-linkers has made a clinical breakthrough. An exception must be made for dye-mediated photooxidation (DMPO). In DMPO, methylene blue and light are used to create cross-links in biological tissue without the use of aldehyde chemistry.^[59] The tissue is placed in a phosphate-buffered saline solution containing the photoactive methylene blue dye. Light of an appropriate wavelength is used to activate the dye catalyst. Oxygen reacts with the dye to form highly reactive oxygen free radicals, which in turn interact with specific amino acid side chains to form new cross-links.^[59,60] Both photooxidized pericardial and porcine tissue has been investigated extensively, with promising results toward biostability, softness, pliability, and calcification resistance.^[59,61] Unfortunately, a negative clinical experience with design-related valve failures in a stented prosthesis with photooxidized

pericardium, blunted further developments in this promising tissue treatment.^[62]

Surfactants (Detergents)

Detergents act by two mechanisms: first by removing acidic phospholipids and second by reducing phospholipid insudation as a result of the hydrophobic barrier preventing their penetration into valve tissue. Possible detergents include sodium dodecyl sulfate (SDS), polysorbate 80 (Tween- 80), Triton X-100, and *N*-lauryl sarcosine. Not all detergents can be used to treat valvular tissue because some (Triton X-100 and *N*-lauryl sarcosine) induce alterations that decrease the durability of the valves,^[63] despite the fact that they are the most efficient detergents. Substances such as SDS and Tween 80 are applied in currently clinically used bioprostheses. Both treatments demonstrated successful antimineralization properties in subcutaneous models,^[64,65] whereas the results with SDS in circulatory models are controversial.^[66] Tween 80 seems to perform better.

Alcohols

Delipidating agents such as methanol/chloroform and ethanol act by removing phospholipids. In pericardial tissue, selective lipid extraction using chloroform/methanol had no effect on tissue stability and demonstrated less calcium accumulation compared with glutaraldehyde-treated controls in rat models.^[67] After accelerated wear testing, however, the delipidated samples calcified in the zones that underwent mechanical stress.^[68] The use of delipidating agents require long-term studies to test the influence of such treatments on tissue properties. Ethanol affects multiple components of valvular tissue.^[69] Ethanol pretreatment induced conformational changes in cuspal collagen (documented through infrared spectroscopy), reduced *in vitro* cholesterol uptake by cusps, increased resistance to collagenase digestion, and reduced water content of cusps.^[69] Cuspal glutaraldehyde content was not changed by ethanol pretreatment. Although these changes can result in significant reductions in calcification potential in rats, the question remains of whether these alterations in ultrastructure will result in deteriorated mechanical properties. Ethanol in sheep circulatory studies prevented cusp calcification.^[66]

Amino-oleic Acid

Although exact mechanisms of action are unknown, 2- α -amino-oleic acid (AOA) is able to mitigate cusp calcification.^[70,71] It is hypothesized that AOA

covalently binds, as a result of a Schiff base reaction, to free aldehyde groups of tissue-bound glutaraldehyde. Next to blocking or reducing the free aldehyde groups, reduced calcium diffusion through AOA-treated leaflets is thought to be part of the AOA mechanism. The AOA inhibition of cusp calcification in rat subdermal implants is exposure time dependent with maximum treatment time (120 hr), resulting in the lowest calcium levels. AOA has poor results as a chemical treatment on the aortic wall portion, certainly in stentless valves.^[66,72] A possible explanation is limited penetration and binding of AOA into the aortic wall tissue, with AOA levels being consistently lower than that of the cusps after the same exposure times.^[72]

Cations

The use of trivalent cations like Al^{3+} and Fe^{3+} originates from the occurrence of osteomalacia in renal dialysis patients. Patients in chronic renal failure accumulate high Al^{3+} levels, with disturbed bone mineralization as a consequence. This observation led to strategies using metallic salts containing Al^{3+} and Fe^{3+} as a tissue treatment to prevent calcification. Tissue incubation in solutions such as AlCl_3 and FeCl_3 demonstrated markedly inhibited calcification in rat models.^[73] The action mechanism is not clear but morphological studies localized both cations at the level of devitalized connective tissue cells, indicating that the mode of action is likely related to the high affinity of these cations for membrane-associated and other intracellular PO_4^{3-} loci.^[73] Al^{3+} and Fe^{3+} can act by forming complexes with phosphate, thereby displacing calcium. This is in the short term, however, because the low solubility product of calcium salts and the calcium concentration in blood could lead to the removal of Al^{3+} and Fe^{3+} in the medium or long term. Pretreatment of tissue with AlCl_3 also inhibited ALP activity, which will result in less mineralization.^[74] Unfortunately, in a circulatory sheep model of mitral valve replacement, Al^{3+} treatment results in higher cusp calcification, necessitating a differential pretreatment of the cusp and aortic wall in order to avoid Al^{3+} -induced calcification in the leaflets.^[75,76]

From successful results in mitigating aortic wall calcification with AlCl_3 pretreatment in rat models, a possible protective effect of Al^{3+} on elastin was hypothesized.^[15] Using isolated elastin preparations, elastic-fiber-oriented calcification is indeed less after Al^{3+} treatment. Aluminum binds to elastin at similar neutral binding sites (peptide carbonyl groups) and causes structural changes in the spatial conformation of elastic fibers, demonstrated by spectroscopy.^[15] Aluminum ion binding can hypothetically block calcium from binding or interacting with elastin. It is,

however, still uncertain whether Al^{3+} will be sufficient to prevent aortic wall calcification when tested in adequate sheep models.

Diphosphonates

Diphosphonates (or biphosphonates or aminodiphosphonates) act by inhibiting calcium phosphate crystal growth and are able to bind covalently to residual glutaraldehyde. Diphosphonates can either be injected systemically^[77] or be used to pretreat the valvular tissue by incubating the tissue in it.^[78] Ethane hydroxydiphosphonate (EHB) and related compounds are drugs used in humans for pathologic calcification disorders like hypercalcemia. These drugs inhibit ALP and interfere with calcium-phosphate crystal formation, but also affect normal bone formation. Injections of EHB or diphosphonates covalently linked to the valve tissue have been investigated experimentally with reduced calcium levels compared with glutaraldehyde-fixed controls. Unfortunately, many problems related to side effects and drug delivery (effect on bone formation, limited durability of the drug, washout effect of blood) limit further clinical use.

Other Strategies and Combination Treatments

When reviewing experimental literature regarding antimineralization treatments, numerous agents and products can be retrieved. Some have demonstrated promising results and have applications in clinical products, whereas others remain experimental. These treatments include No-React[®], glutamic acid, urazole, homocysteine acid, bilinx, toluidine blue, poly (acrylamide), tannic acid, and many others. No-React is a proprietary combination treatment involving heparin applied in some clinically available products. Bilinx is a combination treatment of ethanol and Al^{3+} . The main focus is application in stentless valves to avoid both cusp- and wall-mediated calcification. Tannic acid is a plant polyphenol, known to form multiple bonds with proteins rich in proline, such as elastin.^[79] Treatment of aortic wall samples with tannic acid after standard glutaraldehyde fixation increased resistance to elastase and reduced wall calcification.

Acellularization

Given the importance of the cellular component in bioprosthesis calcification, efforts have been made not only to diminish the total phospholipid content by detergents, but also to accomplish complete acellularization. Removal of cells and cell remnants can be performed through several protocols such as sequential

freeze–thawing of tissue to reach osmotic disruption of cells, extensive rinsing in detergents, or treatment in enzymatic solutions containing, for example, DNase and RNase. One porcine acellular valve construct reached clinical use for right ventricular outflow tract reconstruction, but with the additional tissue protection using cryopreservation as in homografts.^[80] Whether these acellular, unfixed constructs will repopulate with cells is unclear, and their behavior in left-side implantations is uncertain.^[81] Experimental evidence has accumulated that acellularization as such is not the final answer. There is a need for additional tissue fixation or treatment that stimulates rapid recellularization with host cells.^[82,83]

A

Materials Other Than Porcine or Bovine Tissue

Experimental work has been performed using several other tissue sources, such as kangaroo aortic valve tissue,^[84] equine pericardial tissue,^[85] and bovine jugular vein tissue.^[86] Neither experimental results nor preliminary clinical data concerning the bovine jugular vein constructs demonstrate superior characteristics thus far.

Articular Cartilage Biomechanics

A

Jennifer S. Wayne

Department of Biomedical Engineering, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

The word “cartilage” refers to a specialized, soft connective tissue found in numerous sites within the body. There are three main types of cartilages with distinct features and behaviors for their intended function: fibrous, elastic, and hyaline.^[1] Each consists of a firm matrix made up of collagenous and elastic fibers and ground substance with differences among the types dependent on its specific composition and internal arrangement of the components. Fibrous cartilage is located in such structures as the discs between vertebrae in the spinal column (intervertebral discs), symphysis pubis, and the semilunar-shaped discs in the knee that mate the femur to the tibia (menisci). Elastic cartilage, with a predominance of elastic fibers in its matrix, is found in the auricle of the external ear, the auditory tube, the epiglottis, and portions of the larynx.

The third type of cartilage is hyaline, stemming from the Greek word “hyalos” meaning “glass.” The rings of the trachea and larynx contain this cartilage. A major hyaline cartilage is articular cartilage, found covering the ends of bones in diarthrodial (i.e., freely movable) joints such as the hip, knee, and shoulder. Articular cartilage is critical to normal joint function by distributing loads over the joint surfaces, acting as a shock absorber, and aiding in joint lubrication for nearly frictionless articulation. The composition and arrangement of components in the tissue enable it to perform its functions for seven and eight decades with little to no wear. However, in many individuals and for different reasons, the articular cartilage wears away from the joint surface over time in a progressive process called arthritis, leaving a degenerating articular surface with bone exposed. This is a very painful, debilitating condition often necessitating replacement of the joint with metal and plastic parts. Much study of articular cartilage has thus been and continues to be performed to understand its normal function and to develop reparative techniques that can be implemented before the degeneration warrants an artificial replacement.

This article describes the features of articular cartilage that are important to understand how it accomplishes its normal biomechanical function. The

composition of the tissue and the arrangement of its components are first described, followed by general biomechanical behaviors that it exhibits. Then, an overview of recent mathematical models is presented as these models help elucidate how articular cartilage functions.

COMPOSITION AND STRUCTURE

Articular cartilage is a translucent, glistening layer that is white and smooth. In the adult diarthrodial joint, it is avascular, aneural, and lacks lymphatic vessels. In humans, its thickness can range from one millimeter to several millimeters. During normal joint movement, this tissue is subjected to severe loads, often of magnitude several times one’s body weight, as one joint surface rolls and slides over the other, generating complex stresses (tension, compression, and shear) in cartilage.

A strong structure–function relationship exists in all biological tissues. The components of articular cartilage and the structural arrangement of those components enable the tissue to function normally and resist tension, compression, and shear stresses. The major components are the cells, water, collagen fibrils, proteoglycan aggregates (sometimes referred to as ground substance in other tissues), and charged, mobile ions.^[2] In comparison to other tissues, the cells of articular cartilage, the chondrocytes, are sparsely populated within the matrix, accounting for less than 10% of tissue volume. However, they are metabolically active, being responsible for the maintenance of the extracellular matrix. Articular cartilage is highly hydrated. Water, as the most abundant component in the tissue, accounts for 75–85% of its wet weight. Numerous electrolytes are freely mobile within the tissue as is the majority of the water.

The organic extracellular solid matrix is composed of an intertwining mesh of collagen fibrils (predominantly Type II collagen) and proteoglycans. Collagen, the ubiquitous protein responsible for many structural features of biological tissues, makes up 60–65% of cartilage on a dry weight basis. It is biomechanically similar to rope in that it can resist being stretched in tension but does not resist compression. If a

compressive load were applied to a collagen fibril, it would tend to buckle. Thus, the collagen fibril is the prime tensile resisting component of articular cartilage.

Proteoglycans are large, negatively charged, protein-polysaccharide molecules that comprise 10–15% of articular cartilage on a dry weight basis. The immobilized negative charges, the concentration of which is the tissue's fixed charge density (FCD), repel one another and therefore try to distend the proteoglycan molecule, to separate the charges as much as possible. If the negative charges are forced into closer proximity, as occurs in compression, the response is an increased repulsion force. The proteoglycans are thus the prime compression-resisting component of articular cartilage.

The collagen network does not permit the proteoglycan molecule to expand fully but keeps it in a compressed state. Thus, the collagen network in intact articular cartilage is in a state of tension. The inherent state of compression of the proteoglycans leads the tissue to possess a swelling pressure, or propensity to swell. The magnitude of the swelling pressure can be reduced or increased by changing the concentration of ions in the solution bathing the tissue. Physiologic solution is salty, and thus cartilage is bathed in a solution where positive ions can freely move in the tissue. Some of these positive ions shield the negative charges on the proteoglycan molecule. If the solution is made hypertonic (more freely mobile ions), more negative charges are shielded by the positive, and thus the desire to swell decreases. On the contrary, if the solution is made hypotonic (fewer freely mobile ions), greater density of negative charges is left unshielded, and the desire to swell increases.

Together, the collagen and proteoglycans form an interwoven solid matrix that permits the tissue to resist shear stresses as well as tension and compression. Thus, cartilage can be viewed physically akin to a sponge, albeit with pore sizes on the order of nanometers. Water can flow within and out of the interstices of the collagen/proteoglycan matrix when the tissue is subjected to a load.

With knowledge of the components of articular cartilage, the structural organization of those components is important to further understand the tissue's function. While the articular cartilage layer covering

the bone surface is thin, it has a complex organization through its thickness. The layer can be structurally grouped into four zones: superficial tangential zone, middle/transitional zone, deep/radial zone, and calcified zone (Fig. 1). This grouping is based on orientation of the collagen fibrils and cell morphology within the zone. The superficial tangential zone typically comprises 10–20% of the thickness and is the zone that comes in to contact with the cartilage surface on the opposing bone. The collagen fibrils are aligned parallel to the articular surface in this zone and are tightly woven, with interposed chondrocytes oblong in shape. The amount of proteoglycans (content) is the lowest in this zone.

Within the middle zone, the collagen fibrils are transitioning from the parallel arrangement in the superficial tangential zone to the perpendicular orientation in the deep zone. Here, the fibrils can be viewed as having a random orientation but are not as dense as in the superficial tangential zone. The chondrocytes have a more rounded shape and are randomly distributed. The deep zone has collagen fibrils in a perpendicular orientation, crossing the tidemark of uncalcified to calcified cartilage and anchor the tissue to underlying bone. The chondrocytes maintain the rounded shape as in the middle zone but are now arranged in columns. The final zone is that of calcified cartilage where the tissue is transitioning from the uncalcified soft articular cartilage to the calcified hard bone.

BASIC BIOMECHANICAL BEHAVIOR

Stress and strain are two concepts that are important to describe the mechanical behavior of materials and structures. Stress is defined as the force or load on a material divided by the cross-sectional area over which that load is distributed. Strain is a unitless measure of shape changes and can be calculated as deformation divided by the original length of the material. For example, when tension is applied to a rope of a given length (L_0), it will stretch, and the strain it experiences can be calculated by the amount of stretch divided by L_0 . Shear stress induces shear strain, which is a

Fig. 1 Structural organization of collagen Type II fibrils within a cartilage layer. (From Ref. [3].)

measure of how an angle changes within a material, for example from 90° .

In general, biological soft tissues exhibit viscoelastic features.^[4] Viscoelasticity is a phenomenon that is the combination of viscous (dashpot-like) and elastic (spring-like) behaviors. A viscous substance is one that flows (continues to deform with time) under the action of an applied load. An elastic material deforms its shape to a certain extent under the action of an applied load but returns to its original shape once the load is removed. A viscoelastic solid therefore deforms when under load but does so in a time-dependent fashion. Three important characteristics of viscoelasticity are creep, stress relaxation, and hysteresis behaviors (Fig. 2).

In creep, one applies (controls) a specific load (or stress) to the material and monitors how the material changes shape (deforms or strains). If the material is elastic, an immediate jump in strain is exhibited for an applied jump in stress. The strain then remains constant over time as long as the applied stress does not change. Viscoelastic solids also tend to exhibit an immediate jump in strain for an applied jump in stress; however, the strain does not remain constant but exponentially rises until a plateau is reached at some later time, while the applied stress remains at a constant level.

In stress relaxation, one applies (controls) a specific deformation (or strain) to the material and monitors how much load (or stress) the materials responds with. If the material is elastic, an immediate jump in stress is exhibited for an applied jump in strain. The stress then remains constant over time as long as the applied strain does not change. Viscoelastic solids also exhibit an immediate jump in stress for an applied jump in strain; however, the stress does not remain constant but exponentially decreases until a nonzero plateau is reached at some later time, while the applied strain remains at a constant level.

In hysteresis, a stress or strain is applied to a material, most commonly in a linear ramp fashion, and then removed in a similar fashion. The loading and unloading curves are identical for an elastic material (in this case, a linear material). A viscoelastic solid however exhibits a different curve in loading vs. unloading. The loading curve is always above the unloading curve to indicate that there are viscous losses associated with the loading/unloading.

Biological soft tissues also present a nonlinear stress–strain response (Fig. 3). The onset of loading is termed the “toe region,” in which the material begins to resist the load by increasing its modulus. At a subsequent point, the curve becomes linear and remains so until failure commences in the matrix of the tissue. The slope of the curve, at any given strain value, provides a measure of the modulus or stiffness of the

tissue at that strain. The slope in the linear region is typically called the tangent modulus. A collagenous tissue subjected to a tensile test exhibits this nonlinear stress–strain behavior. The three regions of the curve can be explained by what is occurring to the collagen during the tensile loading. At the onset of stretching, the collagen fibrils are crimped or wavy such that the initial resistance (modulus) offered to the stretch results from straightening of this crimp, and a gradual rise in response is seen in the toe region. Once the crimp has been removed from the collagen, further tensile loading stretches the collagen itself, giving the highest modulus the tissue has to offer in the linear region. At a later point, the collagen fibrils begin to fail, as the slope of the stress begins to reduce in the failure region, until the tissue has been torn into two.

Another phenomenon that is important in understanding biological tissue behavior is anisotropy.^[5] The engineering term “anisotropy” depicts how materials respond when a load is applied at a particular point from different coordinate directions, for example in an XYZ rectangular Cartesian coordinate system. A material is said to be “isotropic” if the mechanical behavior, for example modulus, is the same regardless of whether a load is applied in the X, Y, or Z directions. If the behavior is dependent on the direction in which the load is applied, the material is said to be “anisotropic.”

There are different levels of anisotropy, with three commonly implemented in descriptions of biological materials. An isotropic material, as indicated, exhibits the same regardless of which direction the stress is applied. If the response along one direction results in different mechanical behavior than the other two directions, the material is said to be “transversely isotropic.” If the behavior differs along each coordinate direction, the material is called “orthotropic.” Reinforced concrete, i.e., rebar, would be considered transversely isotropic with the greatest tensile resistance (modulus) in the direction of the reinforcing bars. Composite materials can also be isotropic or anisotropic, depending on how the fibers are laid down within the matrix.

Articular cartilage exhibits the phenomena just described, creep, stress-relaxation, nonlinear stress–strain curve, and different degrees of anisotropy in various types of testing conditions. Because articular cartilage endures complex stresses (tension, compression, and shear) during its normal function, numerous experiments have been performed in tension, compression, and shear (Fig. 4) to determine its biomechanical behavior and how this behavior enables the function. Experimental data is often curve fit with a particular mathematical model to determine the properties of the test tissue. Specimens of articular cartilage have been tested either in situ (i.e., an unviolated articular

A

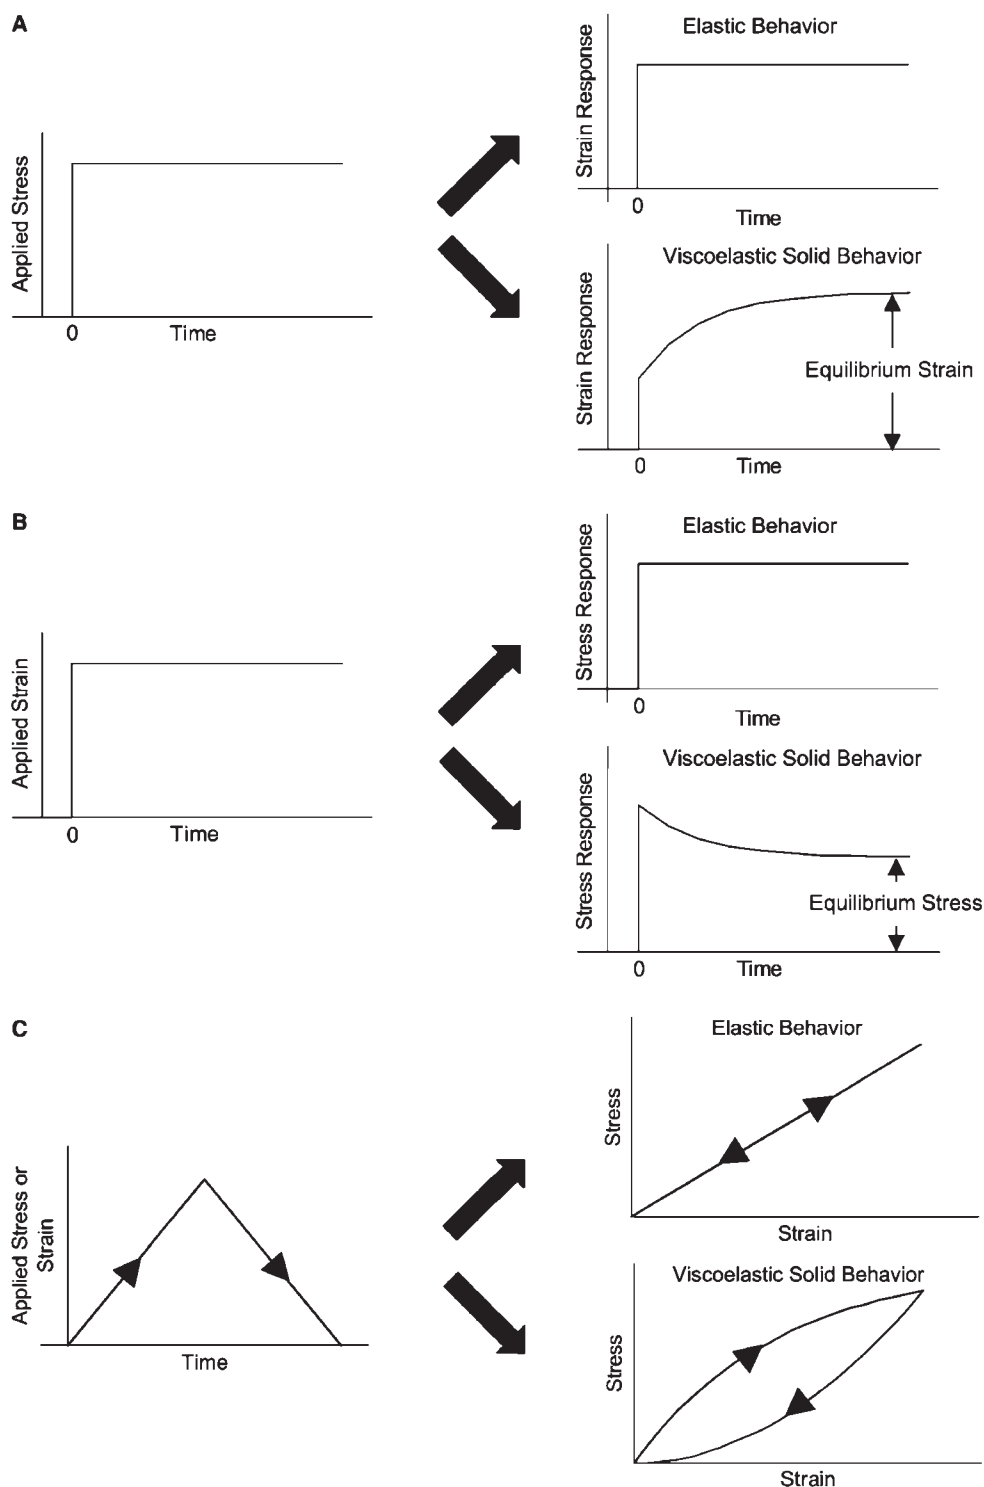

Fig. 2 Depiction of viscoelastic creep, stress relaxation, and hysteresis. In creep (A), the load or stress is controlled (here, applied instantaneously and then held constant) while the response of deformation or strain changes with time until an equilibrium (steady-state) is reached. In stress relaxation (B), the deformation or strain is controlled (here, applied instantaneously and then held constant) while the response of load or stress changes with time until an equilibrium is reached. In contrast, an elastic material does not exhibit a time-dependent response for a constant applied stress or strain. In hysteresis (C), a stress or strain is applied to a material, most commonly in a linear ramp fashion, and then removed. A viscoelastic material exhibits different loading and unloading curves, with the loading curve always residing on top, whereas the curves are identical in an elastic material (in this case, linear).

Fig. 3 Nonlinear stress–strain behavior typical of biological soft tissues.

surface) or as a portion removed from an articular surface (explants). Explants may also be full thickness (all zones) or sectioned into a specific zone to uncover zonal behavior.

As articular cartilage experiences significant compressive stresses, evaluating its response in compression is of great importance. There are three common types of compression tests performed on an articular cartilage—indentation, confined compression, and unconfined compression. Indentation tests are typically carried out on cartilage intact with underlying bone. A stress (or strain) is applied to the articular surface via a small indenter and the resulting response, strain (or stress), is monitored over time. The creep (or stress-relaxation) is then observed. The indenter may be flat-ended or spherical, porous, or impermeable. The stress and strain fields that result in the tissue under indentation loading are quite complex.

Both confined compression and unconfined compression tests require preparation of a cartilage explant, usually in the shape of a cylindrical plug. In confined compression, the tissue may remain intact with the underlying bone or the bone may be removed, whereas in an unconfined compression, the bone is typically removed. For the confined compression test, the cartilage specimen is placed within a confining chamber, with radial dimensions to match that of the cylindrical plug explant such that a snug fit is achieved. A stress (or strain) is then applied to the entire surface area of the explant via a porous, permeable platen and the strain (or stress) response is monitored. In this testing configuration, deformation may only occur in one direction, that of the applied stress, because the confining chamber restricts any radial/lateral expansion. This test and the strains that develop are considered to be one-dimensional, in the direction of the applied stress. Unconfined compression is similar to confined compression in that a stress (or strain) is applied over the entire surface area of the explant. However, the compression platen is made impermeable, and radial/lateral expansion is permitted. Tissue

strain in an unconfined compression test is both axial (along the direction of applied stress) and radial.

Compressive stresses applied to articular surfaces also generate tensile stresses in cartilage owing to the Poisson effect so that tensile tests are performed to determine tissue behavior in this mode of loading. Explants must be cut from the surface to create strips of cartilage to which uniaxial tension may be applied. The nonlinear stress–strain curve depicted in Fig. 3 is exhibited by biological soft tissues subjected to a tensile test. The shear test configuration differs from either the compression or the tension tests just described. In the latter, the stress is applied normal (perpendicular) to the surface area of the specimen, whereas in shear, the stress is applied parallel to the surface. Cartilage explants are removed from the joint, often keeping the bone intact to serve as a way to rigidly hold the specimen during the shear test. Shear stresses are typically induced to the cartilage explant by either a linear or a rotational (torsional) displacement applied to the surface. Creep and stress–relaxation may be exhibited in shear, but the magnitude of the response differs substantially from the axial modes of loading (compression, tension). In general, materials have lower modulus and strength in shear than in axial loading.

The viscoelastic response of articular cartilage found from these different types of experimental tests is important to its function. It helps the tissue absorb rapid loading, like a shock absorber, while controlling the amount of strain experienced. Two primary sources cause the viscoelastic behavior within the cartilage. Fluid movement within cartilage induces a frictional drag on the collagen/proteoglycan solid matrix and thus the flow through cartilage's matrix occurs in a time-dependent fashion.^[6] The collagen/proteoglycan matrix has inherent viscoelastic characteristics as well,^[7] resulting from the internal friction as the components slide relative to one another and each other,^[4] particularly the proteoglycans.

The three uncalcified zones in articular cartilage exhibit different properties. This inhomogeneity (differing from point to point, or zone to zone) results from the different composition and organization found in the zones. Each zone may also yield a different response to applied loads in different directions (at the same point), particularly in tension owing to the organization of the collagen fibrils.^[8] This organization results in the tissue exhibiting transversely isotropic or orthotropic behavior in the superficial tangential zone. The preferred direction, i.e., the direction having the different behavior, is the direction along which the collagen fibrils are oriented. When a tensile stress is applied along the fibril direction, a greater resistance to the stress is exhibited. The tensile tangent modulus in this direction has been estimated to be 5–20 MPa,

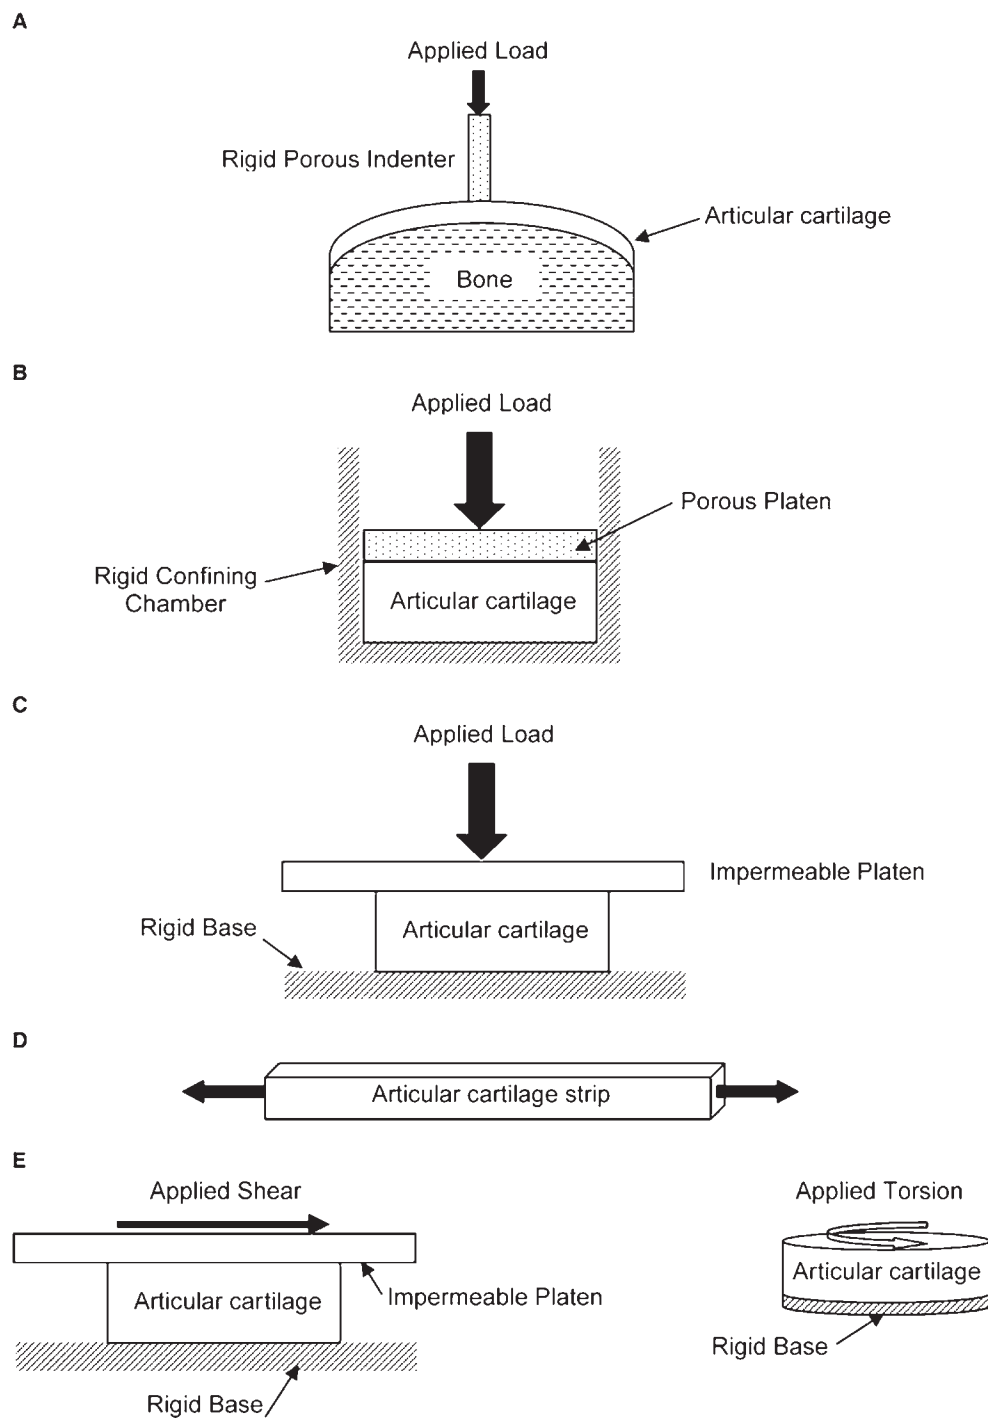

Fig. 4 Common experimental testing configurations to assess cartilage behavior in the laboratory: (A) indentation configuration; (B) confined compression configuration; (C) unconfined compression configuration; (D) tensile test; and (E) shear test, as induced by a linear (left image) or rotational (right image) displacement.

whereas the modulus perpendicular to this direction is significantly lower. In the middle zone, the behavior is more isotropic, with a tensile modulus in the order of 5 MPa. The deep zone could be considered transversely isotropic because of the radially oriented collagen fibrils when subjected to tensile loads, with a modulus in the order of 1 MPa.

In compression, each zone can also exhibit a degree of anisotropy but to a much lesser extent than when subjected to tensile stress.^[9] This results from the proteoglycans acting as the main compression-resisting component, with more isotropic behavior than the collagen acting in tension. There is the possibility that the isotropic middle zone can begin exhibiting more

transversely isotropic behavior as the tissue is compressed from the surface, because the compression redirects the once random orientation of the collagen fibrils to begin aligning more parallel to the articular surface and offering more resistance to further radial expansion. Compressive moduli have been reported in the order of 0.4–0.8 MPa.^[6]

Properties of articular cartilage can vary from joint to joint in a given individual, vary from species to species in a given joint, as well as vary from location to location in a given joint. Some of the differences can be explained by the magnitude of the stresses that the tissue must be capable of resisting, from a structure–function point of view. Certain joints are more highly loaded than others because they bear a great percentage of body weight, for example, the hip and knee in the human. Size/weight of the species also affects the magnitude of stress experienced by the articular cartilage. Finally, joint mechanics dictates that certain locations on an articular surface in a given joint are weight bearing while others are nonweight bearing.

MATHEMATICAL MODELS

A strong structure–function relationship exists in biological tissues where the structure (i.e., types and amounts of components and organization of those components) is best suited for the specific function, and vice-versa, the intended function requires a specific structure. This is akin to an engineer designing a physical structure for a particular application and selects components (I-beams, columns, trusses) made of appropriate materials with appropriate properties (i.e., modulus, strength) to resist the stresses that the structure is expected to experience. The complex stresses (tension, compression, and shear) that articular cartilage endures during its normal function requires that certain components are present and that these components are organized in a particular fashion. For example, articular cartilage is subjected to large magnitude compressive stresses; the biological component for soft tissues that resists compressive stresses is the proteoglycan aggregate. Thus, cartilage has a high proteoglycan content. Additionally, fluid movement is believed critical to normal function, and thus viewing the tissue as porous and permeable aids in understanding function.

Knowledge of articular cartilage behavior and function can come from experimental studies as described previously. More in depth knowledge of how the behavior underlies the function is best realized through implementation of mathematical models. Numerous models have been applied to articular cartilage biomechanics, including solid elasticity (considering the tissue to be one phase, a solid that behaves

elastically), solid viscoelasticity (considering the tissue again to be one phase, a solid that has viscoelastic characteristics), and multiphase models. Multiphase models view the tissue as consisting of distinct phases, typically some combination of water, solid (collagen and proteoglycan), and electrolytes, and mathematically modeling each phase individually as well as the interaction among the phases to describe overall tissue behavior and function.

The biphasic theory^[6] considers articular cartilage to be a mixture of two phases—a porous, permeable solid phase (the collagen/proteoglycan solid matrix acting as an elastic material) and an interstitial fluid phase (water as an ideal fluid). This mixture modeling approach has been extremely helpful in depicting the role that fluid movement plays in cartilage behavior and in understanding the tissue’s function on an articular surface. In this theory, the viscoelastic response of cartilage results from the frictional drag of the fluid on the solid matrix as it flows within the tissue. Both the solid and the fluid phases share the support of stresses experienced by the tissue. The elastic stress in the solid arises from strains induced on the matrix. Fluid stress arises from pressurizing the water in the tissue. A gradient in fluid pressure induces fluid to flow within, into, and out of the tissue.

As a mixture of elastic solid and fluid, the time-dependent, viscoelastic behavior of articular cartilage in compression can be explained in the following manner. Under the applied jump in stress as seen in creep (Fig. 2A), the solid may deform elastically via the Poisson effect (which is a stress applied in one direction to strain a material in the same direction that results in a concomitant strain in the other two directions) to yield the immediate jump in strain, but the majority of the applied stress is initially borne by pressurizing the fluid phase within the tissue. A pressure gradient therefore exists between the high fluid pressure in the tissue and the low fluid pressure outside of the tissue such that fluid flow within and out of the cartilage will occur. As fluid leaves the tissue, the solid matrix compresses (i.e., experiences strain), increasing the solid stress while at the same time reducing the fluid pressure. This increase in solid stress while fluid stress is decreasing can be viewed as stress transfer then between the phases, from fluid to solid. Stress transfer continues until fluid flow ceases (pressure gradient is zero), and all the applied stress is borne by the solid matrix. Equilibrium is then said to have occurred, and the creep curve plateaus.

Similarly, fluid flow is responsible for the observed stress relaxation behavior under the action of an applied compressive strain, as depicted in Fig. 2B. The imposed strain compresses the solid matrix and forces fluid to flow out of the tissue, resulting in an immediate high resistance (large stress response). No more fluid

leaves the tissue after this initial strain because the amount of compression remains constant over time. However, the subsequent stress relaxing (reducing) with time is the result of fluid redistribution within the tissue such that a uniform strain exists throughout the tissue when equilibrium is reached. At equilibrium, fluid pressure is zero, and the nonzero equilibrium stress is supported by the strain generated in the solid matrix.

The coupling of fluid to solid behavior in a mixture model requires an additional property to be specified to govern the interaction between the two phases. The solid matrix is again characterized by a property, elastic modulus, as described previously. The flow of fluid through the permeable solid is governed by a property called permeability. This property captures the resistance of the solid/fluid coupling to fluid flow. A high permeability means that fluid can easily flow in the tissue (low frictional drag), whereas a low permeability indicates that flow is difficult to occur (high frictional drag).

Permeability can be inhomogeneous (differing from point to point) as well as anisotropic (differing in different directions at the same point). It is also strain dependent, that is, it is not a constant but decreases in value as compressive strain occurs in the tissue. This decrease with compaction/compression is straightforward to consider; as the tissue compacts, the pores through which the fluid must flow become smaller. Additionally, the FCD of cartilage increases when the tissue is compacted (same number of negative charges on the proteoglycans now occupying a smaller volume), thus increasingly retarding the movement of the positive ions in the fluid flowing out. Higher friction therefore develops from these two phenomena as fluid flows out of the tissue, leading to the decreased permeability. Normal permeability values for articular cartilage are in the order of $1-5 \times 10^{-15} \text{ m}^4/\text{N sec}$.

Use of the biphasic theory to describe cartilage behavior has led to hypotheses about how cartilage fulfills its functions and resists the demanding stress environment in which it must operate without failing. One of the tissue's main functions is to distribute loads over the joint surface. Distribution of a given applied load over a joint surface is dependent on both area of contact and how stress is transmitted from the articular surface down to the bone. The fact that the tissue deforms under load that increases its area of contact and the congruency between joint surfaces helps distribute the load over the surface. Additionally, the stress of fluid pressurization owing to the applied load, as predicted by theory, can be transmitted through the tissue to an underlying bone over a larger region than that because of contact alone, particularly at early times of loading when tissue deformation is limited.

Consideration of the solid/fluid interaction permits a hypothesis into the longevity of cartilage. The ability of the fluid phase to withstand stresses implies that the solid matrix experiences less stress as the two phases share in supporting the applied stresses. This helps to protect the solid matrix from experiencing excessive stresses and strains that can result in failure. The longer that the fluid remains pressurized, the longer the solid stress and strain remain low. Cartilage's inherent low permeability helps to maintain fluid pressurization. The superficial tangential zone also helps to maintain fluid pressurization longer; the tight weave of collagen fibrils in this anisotropic zone results in an inherently low permeability. The lower proteoglycan content of the zone makes it easier to compress, which can further reduce the low permeability of this zone. Thus, the fluid is hindered from flowing out of the tissue through the superficial tangential zone, thus maintaining a higher fluid pressurization for longer times.

Articular cartilage also helps in lubrication within diarthrodial joints, which increases the tissue's longevity by minimizing wear. Diarthrodial joints are referred to as synovial joints because a capsule, lined with a synovial membrane, encapsulates the joint. The synovial membrane secretes a viscous substance called synovial fluid that consists of a gel of proteins, electrolytes, and water. Sophisticated lubrication mechanisms are at work in these joints,^[10] which do not permit elaboration of them here. However, responses of articular cartilage to applied stresses may enhance joint lubrication. The tissue deforms over time, increasing contact area and congruency between the joint surfaces, which may maintain a layer of the lubricant between opposing articular surfaces to separate the surfaces for longer periods of time. This is referred to as "elastohydrodynamic" ("squeeze-film") lubrication. Fluid flow out of the tissue from interstitial fluid pressurization may increase the amount of lubricant available for articulation; this is often referred to as "weeping" lubrication. Some areas of the joint surface may permit fluid flow into the articular cartilage, creating an ultrafiltration of the synovial fluid. This concentrated layer of the synovial fluid gel with increased viscosity lubricating the surfaces is termed as "boosted" lubrication. A pressurized layer of fluid separating articular surfaces diminishes solid-to-solid contact and thus friction is also reduced. Finally, there is evidence that a specific molecule, "lubricin," is adsorbed onto the articular surface to act as a bound lubricant.

The biphasic theory has been implemented into a computational tool, called finite element analysis, which has permitted more extensive investigations into the functional behavior of articular cartilage.^[11,12] Recently, a similar, poroelastic model has been made available in a commercially available finite element software package.^[13]

Extension of the mixture approach to mathematical modeling has been performed to further define the role of other cartilage features to tissue behavior. In addition to fluid flow as the source of viscoelastic response, the solid matrix has been extended from linearly elastic to viscoelastic to yield a biphasic poroviscoelastic model.^[14] With this, the relative impact of the two main sources of viscoelasticity in cartilage can be observed. The different responses (i.e., modulus) in tension (owing to collagen fibrils) vs. compression (owing to the proteoglycans) have given rise to a modeling of this tension/compression nonlinearity in the solid matrix via a theory called “conewise” linear elasticity.^[15] A different approach to modeling the tension/compression nonlinearity is to consider the collagen fibrils as a distinct solid from the proteoglycans, i.e., two solid phases, rather than the collagen/proteoglycan matrix as one homogeneous solid. This has been implemented in a fibril-network reinforced biphasic model^[16] whereby collagen is simulated as linear springs to resist tension, with a collagen modulus, while the distinct proteoglycans resist the compression, with its own modulus. One of the results is that the stresses experienced by different components (collagen vs. proteoglycan) can be different, even though the strains are the same. A recent modification is to relax the linear assumption of collagen in tension and permit a nonlinear stress–strain relationship to simulate collagen behavior. This is achieved by incorporating a strain dependence on the collagen modulus.^[17] Finally, incorporating a third phase, an ion species, has given rise to the triphasic theory whereby the importance of the FCD, swelling pressure, and flow of ions (resulting in a streaming potential as fluid/ions flow out of cartilage) can be described.^[18] A different approach to depicting the influence of ion flow has yielded an electrokinetic model.^[19]

The mathematical models have grown increasingly complex with the expectation that each modification more appropriately reflects the complex behavior of articular cartilage. With this is the need to accurately reflect the properties used in the models, from inhomogeneities to anisotropy to strain dependence. Additionally, certain features may be more influential in governing behavior in certain modes of loading than in others. It is thus important to fully understand the assumptions inherent in different models so that conclusions can be accurately drawn.

CONCLUSIONS

This article has provided a basis for understanding the biomechanics of articular cartilage and how it functions in a diarthrodial joint. Several book chapters and numerous journal publications have been written with

much details and can be used for further reference (see for example, Ref. [10]). Articular cartilage continues to challenge the scientific community to continue developing new ways to more accurately reflect behavior and discovering more in depth as to how it accomplishes its function. Understanding normal articular cartilage biomechanics then has application to determine the changes that occur when degeneration begins on an articular surface, why it is progressive, and what methods may be used to arrest the progression with repair techniques.

INTRODUCTION

Although the use of mechanical circulatory support was postulated as early as 1812 by Legallois,^[1] it was not until 1961 that the first clinical left heart bypass was performed by Hall et al.^[2] The first artificial heart was implanted by Cooley^[3] in 1969. Thrombus formation and hemolysis are fundamental problems which persist in spite of the use of anticoagulant and platelet-inhibiting agents. In the early 1970s, Phillips et al.^[4] began the use of visualization techniques to study the fluid motion in transparent models of blood pumps. Changes in blood pump geometry and valve type and geometry were shown to influence thrombus formation. Techniques such as hot film anemometry, laser Doppler anemometry, and particle image velocimetry (PIV) are now a routine part of the development of artificial heart pumps. We note that the current review is an abbreviated version of “Experimental Fluid Mechanics of Pulsatile Artificial Blood Pumps,” written by the same authors in the Annual Review of Fluid Mechanics^[5] (Permission granted from Annual Reviews, Deutsch et al. 2006).

General Description

The LionHeart™ Left Ventricular Assist System, shown in Fig. 1, illustrates one end product of experimentation discussed here. In pulsatile pumps, the flow is driven either pneumatically or by a pusher plate against a segmented polyurethane blood sac. Where measurement access to the ventricle is required, the blood sac is

replaced by a diaphragm of the same material so that the interior of the model is exposed. This is a good representation of pusher plate devices, where only the pusher plate side of the sac moves. Generally, the device is cylindrical, with ports for the inlet and outlet artificial heart valves that are joined tangentially to the body. For an adult device under physiologic conditions, the mean aortic (outlet) pressure is 100 mm Hg (120/80), the mean atrial (inlet) pressure is 10 mm Hg (20/0), and the cardiac output is 5 l/min. The beat rate is 72 beats/min (bpm) and the percentage of the cycle in outlet flow (systolic duration) is 30%–50%. Physiological conditions can vary widely and automatic control of the pump cycle is normally through monitoring of the end diastolic volume, diastole being the filling portion of the cycle. Mehta et al.^[6] provides a description of a typical, fully implantable device.

Rosenberg et al.^[7] describe a mock circulatory loop for testing blood pumps. Inlet and outlet compliance chambers simulate the atrial and aortic compliance of the native cardiovascular system while a parallel plate resistor downstream of the aortic compliance simulates the systemic resistance of the circulation. A reservoir between the systemic resistance and atrial compliance controls the preload to the pump. Pressure waveforms are measured in the compliance chambers and flow waveforms at the inlet and outlet ports. The variable compliance and resistance are used to set the fixed flow conditions. Beat rate and systolic duration are also set through an appropriate drive system.

Blood is a shear-thinning, viscoelastic fluid^[8] that is often taken as Newtonian at sufficiently high shear

Fig. 1 The LionHeart™ left ventricular assist system.

rates (above 500 s^{-1}). The hematocrit (relative volume of red blood cells) greatly affects the magnitude and relative importance of the viscous and elastic components of the complex viscosity.^[9] The high shear rate kinematic viscosity asymptote for normal hematocrit blood (40%) is about 3.5 centistokes (cs) and solutions of glycerin and water (40/60) or mineral oils are often taken as blood analogs.^[10] Optical access to the fluid for velocity measurements can be important and Baldwin et al.^[11] among others, used a solution of 79% saturated aqueous sodium iodide, 20% pure glycerol, and 1% water by volume to produce a fluid with a kinematic viscosity of 3.8 cs and an index of refraction (matching Plexiglas) of 1.49 at 25°C . Brookshier and Tarbell^[12] and Long et al.^[13] developed Xanthan gum/glycerin solutions that simulate blood viscoelasticity well; sodium iodide may be added to adjust the index of refraction.

Heart valves, which maintain unidirectional flow, play a major role in the mechanical environment of the artificial heart. They are generally chosen for their durability. With the device shown in Fig. 1, Bjork-Shiley tilting disc valves were used. Mechanical heart valves (MHVs) are not specifically designed for mechanical blood pumps, and their efficiency can be compromised. Yoganathan et al.^[14] gives a survey of MHVs and their fluid mechanics.

Hemolysis—the destruction of red blood cells, and thrombosis—clot formation, must be avoided in artificial blood pumps to achieve long-term clinical success. The relationship of these events to the fluid mechanics, velocity, shear and wall shear rates, and turbulence is the major impetus for flow studies in blood pumps. Neither phenomenon is completely understood. A hemolysis potential curve from the National Heart, Lung, and Blood Institute,^[15] which relates shear stress and exposure time to red cell, white cell, and platelet lysis has been available since 1985. Because blood cells are viscoelastic, they can tolerate high stresses for short exposure times without hemolysis. For example, an exposure time of more than 0.1 ms at a shear stress of $10,000 \text{ dyn/cm}^2$ will

produce red cell lysis, as will 1500 dyn/cm^2 for times over 100 s. Nevaril et al.^[16] concluded that prolonged exposure to laminar shear stress on the order of 1500 dyn/cm^2 could cause lysis of red cells, and Sallam and Hwang^[17] showed that sustained turbulent stresses above 4000 dyn/cm^2 created by a submerged jet would cause hemolysis. Baldwin et al.^[11] concluded on the basis of these and other published studies that stress levels above $1500\text{--}4000 \text{ dyn/cm}^2$ were undesirable. Platelet activation and the initiation of the clotting process may occur at still lower stresses. Thrombosis formation has long been thought to be a function of, among other factors, (low) wall shear stress and blood residence time (see Wootton and Ku,^[18] for example). Hubbell and McIntire^[19] reported that the wall shear rate should be above 500 s^{-1} (18 dyn/cm^2 for a viscosity of 3.5 centipoise [cp]) to prevent clot formation on segmented polyurethane (the blood sac material). Daily et al.^[20] pointed out that “the thrombogenicity of assist devices can be attributed to (1) the coagulability of the blood, (2) the properties of the blood contacting surfaces, and (3) fluid dynamic factors.” It is often not easy to separate these. Early fluid mechanics studies were through flow visualization,^[4,21] single-component laser Doppler anemometry,^[22] hot film anemometry in conjunction with dye washout,^[23] and pulsed Doppler ultrasound.^[24,25] Jarvis et al.^[26] used human blood in a 100 cc artificial ventricle to measure hemolysis directly through quantification of plasma-free hemoglobin and found that the degree of hemolysis was a function of the operating conditions. Baldwin et al.^[27] did extensive measurements of wall shear stress inside a ventricle using flush-mounted hot film anemometry probes. Francischelli et al.^[28] used a fiber optic system to look at residence times for an analog fluid doped with fluorescein dye. Flow visualization continues to be useful for qualitative assessment. More recent flow visualization studies are by Hochareon et al.^[10] Mussivand et al.^[29] and Woodward et al.^[30] for example.

IN VITRO MEASUREMENTS

Baldwin et al.^[11,31–33] published what is still the most thorough study of artificial heart fluid mechanics. They used two-component laser Doppler anemometry (LDA) to make mean and turbulence measurements at some 135 locations within the ventricle and 10 locations at each of the outlet and inlet flow tracts at normal physiologic conditions. A standard four-beam, two-component system was used in backscatter with counter signal processors to perform the measurements. The measurement ellipsoids had a diameter of roughly $65 \mu\text{m}$ and a length of 1.13 mm.

The beat cycle was divided into 8 time windows which varied from 20 to 100 ms, as a function of data rate (as described by Baldwin et al.^[33]), with 40 ms used for most cycle times and locations. Coincident data occurring during any time of interest was placed in the appropriate time window file. Mean and fluctuating velocities and Reynolds stresses were calculated from 250 ensembles at each time window and location. Baldwin et al.^[33] estimated that 95% of the Reynolds stresses would be within 20% of the (converged) values obtained for 4096 ensembles. The Reynolds stresses are not invariant to coordinate rotations, so that data was presented, in principle axes, as the maximum Reynolds normal and shear stress.^[33] A problem inherent to turbulence measurements of this nature is that the beat-to-beat variation of the flow will appear as a “pseudo turbulence” that cannot be separated out. Setting a single “coincidence time” in these unsteady flows may also lead to errors in the stress. In addition, we note, as do the authors, that it is not clear how the Reynolds stresses are related to the damage of red blood cells—roughly $3 \times 8\text{-}\mu\text{m}$, biconcave disks. Perhaps the case can be made, as the authors do, that the turbulent dissipation will increase as the Reynolds stress to the $3/2$, so that the Kolmogorov scale, proportional to the stress to the $-3/8$, will be smaller as the stress increases and therefore more dangerous to the red cells. Some estimates by Baldwin et al.^[11] suggest that the small-scale structure of regurgitant jets through the closed valves is the order of $5\ \mu\text{m}$, as discussed below.

We reproduce the mean velocity map of the chamber flow in Fig. 2. Mean velocities in the chamber are not available at 300 and 400 ms into the cycle (during systole), as the beams are blocked by the pusher plate. The highest velocities in the chamber are in the major orifices of the aortic valve (1.9 m/s) and of the mitral valve (1.2 m/s) in early systole and early diastole, respectively. The inlet jet through the major orifice helps to produce a rotational pattern in the chamber that persists into early systole (0–500 ms). The authors note that this rotational pattern appears to provide good “washing” of the chamber. Other experiments, with sac-type artificial hearts, note quite similar flow patterns (see, for example^[34]). However, Baldwin et al.^[11] demonstrate that the minor orifice of the mitral valve does not show significant inflow during diastole (400–700 ms), and that this may be a result of the rotational motion “clipping” the incoming flow. Of great interest are the large retrograde fluid velocities, through the “closed” valves, in the near wall regions of the aortic valve during diastole and mitral valve during systole.

The major Reynolds normal stresses are shown in Fig. 3. Major Reynolds shear stresses are half these values and are rotated 45° clockwise from the principle stress axis. The authors note that major normal stresses

do not exceed $1000\ \text{dyn/cm}^2$ in the chamber and $2000\ \text{dyn/cm}^2$ in the aortic outflow tract. The outflow values are similar to those observed by Yoganathan et al.^[35] with this valve. Much larger Reynolds stresses were found in the regurgitant (retrograde) jets. The mitral valve regurgitant jet is stronger than that of the aortic valve because of the larger pressure gradient across it during systole than across the aortic valve during diastole. Velocities as high as 4.4 m/s and normal stresses as large as $20,000\ \text{dyn/cm}^2$ were observed.

Baldwin et al.^[11] concludes by asking whether “artificial heart fluid mechanics can be improved.” They base this on the rather innocuous fluid mechanics of the pumping chamber and the relatively minor ways in which the geometry, with respect to the size and shape of the natural heart, may be changed. They find that the near valve flow is of concern. Maymir et al.^[36,37] continued the study of regurgitant jets, in particular, the influence of occluder to housing valve gap width. Meyer et al.^[38,39] extended the work by using a three-component laser Doppler system for three additional MHVs the Medtronic-Hall tilting disc, the Carbomedics, and St. Jude bileaflet designs and report turbulent jets with large sustained Reynolds stress even for the bileaflet valves.

An additional concern with using MHVs is the recognition^[40–42] that they cavitate. Cavitation is the formation of bubbles from gaseous nuclei in the fluid due to a drop in local pressure.^[43] Although Zapanta et al.^[44] showed valve cavitation in vivo in an artificial heart, the problem is not just associated with the use of MHVs in the artificial heart, but with the general use of these valves. There are several serious potential problems associated with cavitation—hemolysis and thrombosis initiation, valve leaflet damage, and the formation of stable gas bubbles that may find their way to the cranial circulation.

Although cavitation-induced pitting of explanted valves has been observed,^[45] significant valve leaflet damage is rare. Lamson et al.^[46] show that the index of hemolysis is a strong function of cavitation intensity and cavitation duration. There have been reports (for example, Dauzat et al.)^[47] of gaseous emboli in the cranial circulation, detected by Doppler ultrasound, for MHV recipients. Bachmann et al.^[48] Biancucci et al.^[49] and Lin et al.^[50] suggest that these emboli might be the aftermath of cavitation growth and collapse. There is no comprehensive current review, but much is described in the work of Graf et al.^[51] Zapanta et al.^[44] Chandran et al.^[52] and Bachmann et al.^[48]

The growing need for long-term pediatric, circulatory assist has resulted in a NIH program to develop such an assist device by 2009. The required output of the device is about 1 l/min. The simple geometric scaling of the pumps is described by Bachmann et al.^[53]

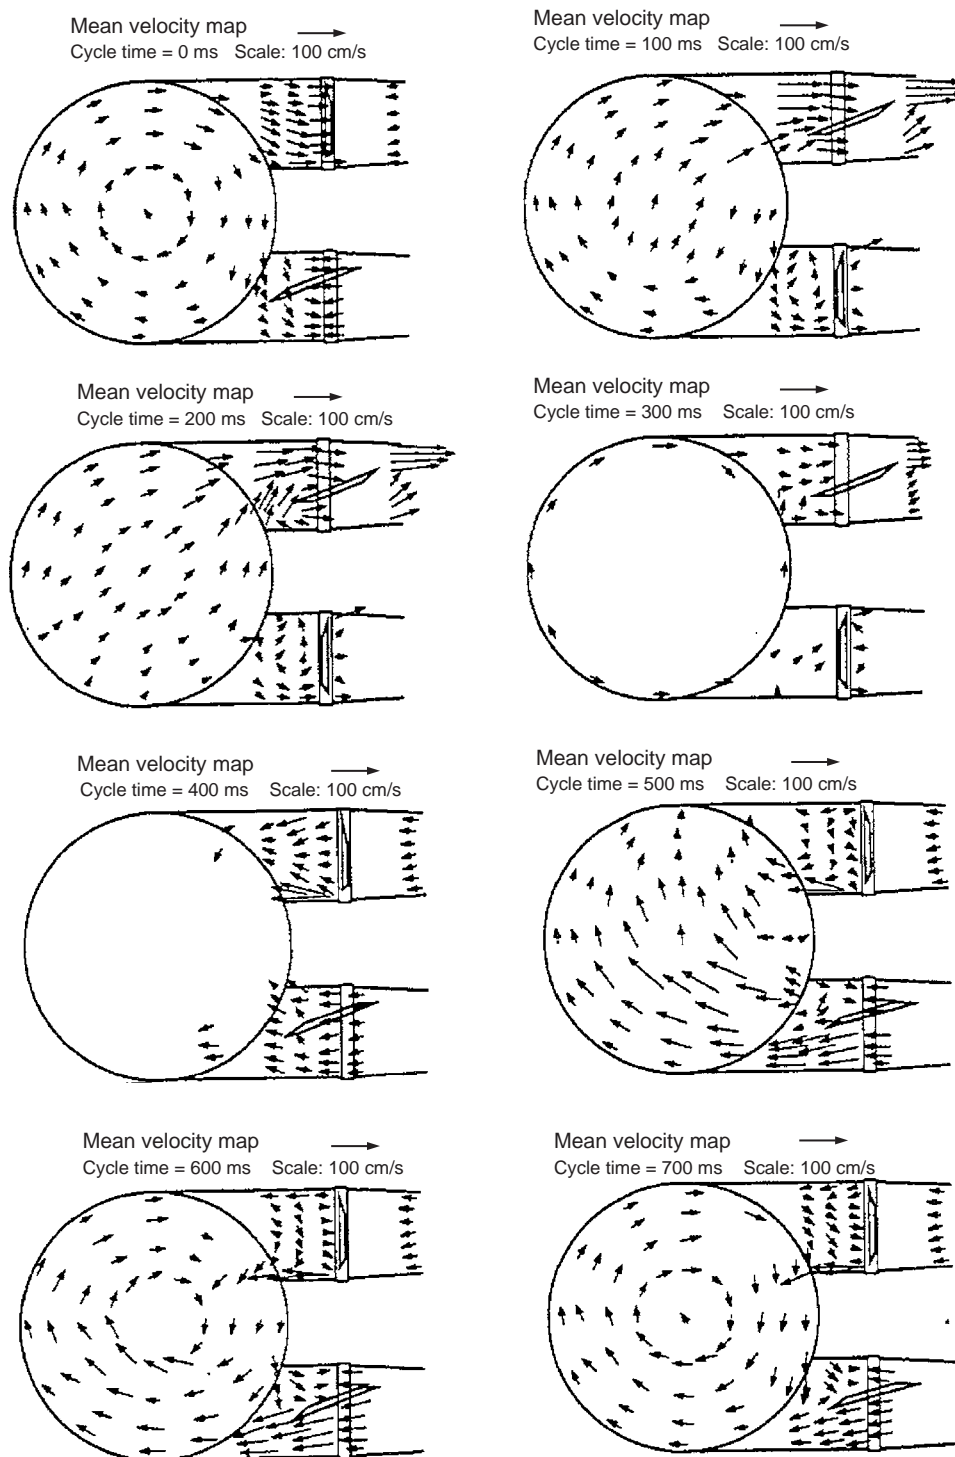

Fig. 2 Mean (ensemble averaged) velocity maps of a 70-cc device at 8 times during the cardiac cycle. Time zero is the onset of systole; diastole begins at 400 ms; and the cycle duration is 800 ms. Arrow lengths are proportional to mean velocity magnitude (see scale) and point in the direction of the mean velocity vector. The aortic (ejecting) port is located at the top and the mitral (filling) port is located at the bottom.

For example, to reduce the volume from 70 to 15 cc, one might reduce all linear dimensions by the cube root of the ratio of volumes. Assuming that the non-Newtonian nature of blood does not introduce any

additional parameters, the “global” fluid dynamics of the system is described by the Reynolds (Re) and Strouhal (St) numbers. In a study of 73 healthy subjects ranging in age from 5 days to 84 years, Gharib

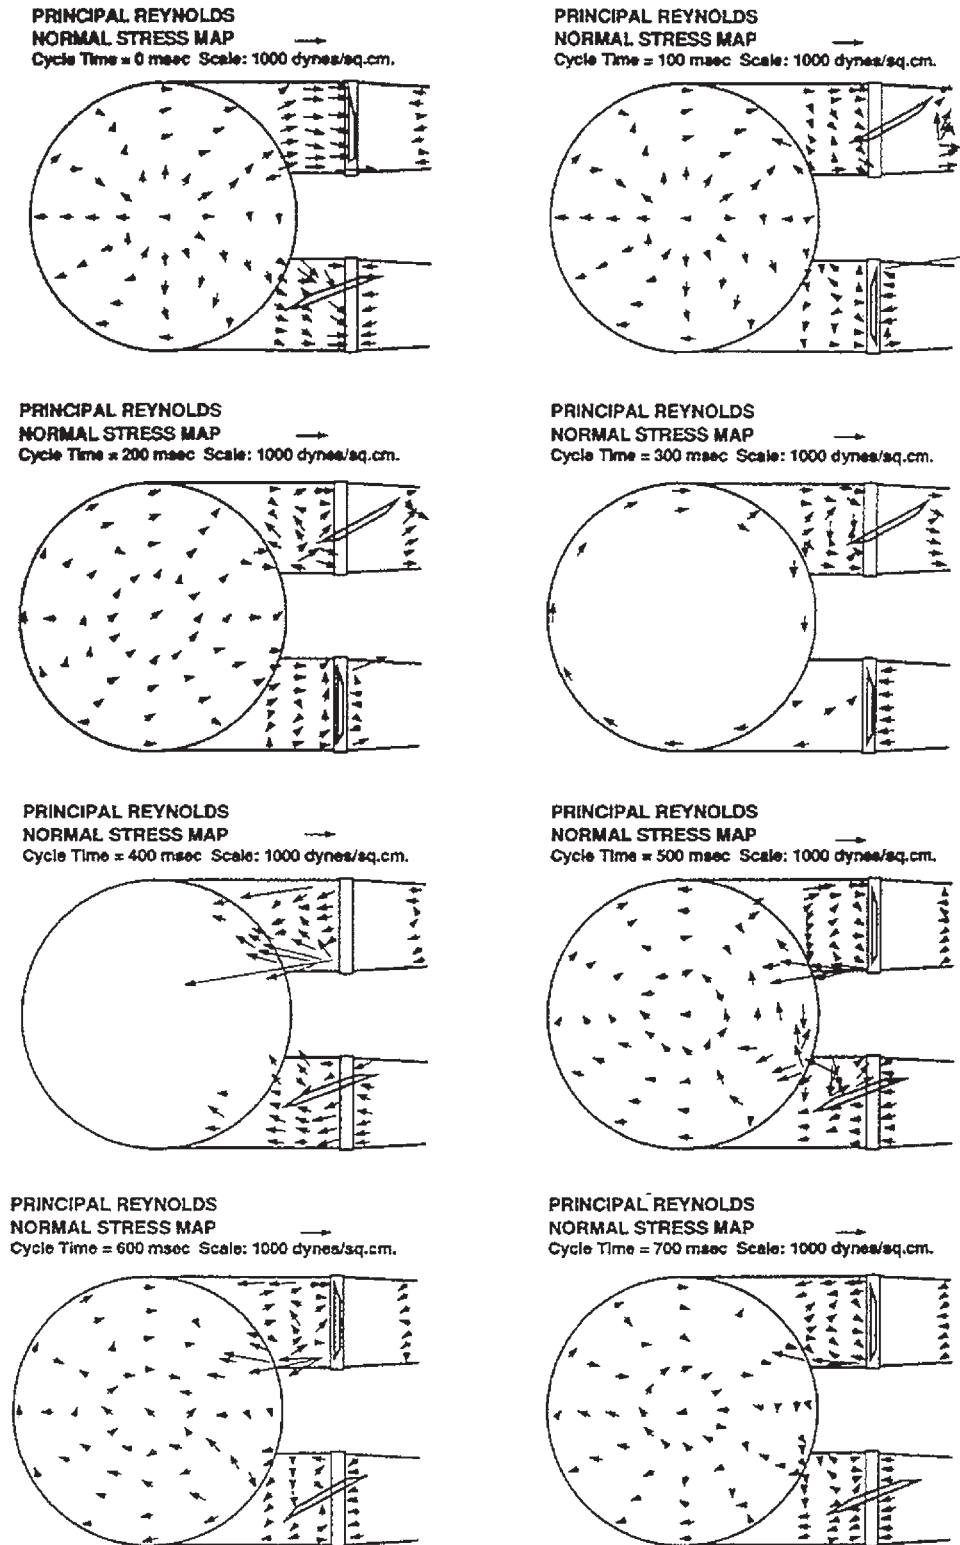

Fig. 3 Major Reynolds normal stress maps of a 70-cc device at 8 times during the cardiac cycle. Time zero is the onset of systole; diastole begins at 400 ms; and the cycle duration is 800 ms. Arrow lengths are proportional to normal stress magnitude (see scale) and point in the direction of the major axis of the principal stress axes. Fig. 4 The 15-cc Penn State pediatric ventricular assist device (circa 1995). The device measured 55 mm for the chamber outer diameter, 35 mm for the overall chamber thickness, 82 mm for the overall pump length with cannula connectors, and weighed 57 g.

et al.^[54] found that the Strouhal number remained fairly constant at 4–7. Bachmann et al.^[53] showed that geometrically similar pumps have constant Strouhal number.

Daily et al.^[20] and Bachmann et al.^[53] have both studied a roughly 15 cc pediatric assist device, shown in Fig. 4. Reynolds and Strouhal numbers for the devices, taken from Bachmann et al.^[53] are given in Table 1.

Table 1 Comparison of the Reynolds and Strouhal numbers for the 70, 50, and 15-cc artificial blood pumps

Pump size	Re	St
Penn state 70-cc device	2482	8.3
Penn state 50-cc device	1054	4.5
Penn state 15-cc device	1567	45.3
Yonsei 34-cc device	1500	7.7
Toyobo 20-cc device	988	6.3
MEDHOS-HIA 10-cc device	655	7.4
Berlin heart 12-cc device	785	8.8

The large increase in *St* for the 15 cc device is a result of undersizing the inlet port.

Daily et al.^[20] provided both PIV maps and clinical studies of the device that focused on the choice of MHVs—handmade ball and cage valves (which were initially used clinically) vs bileaflet valves. The PIV maps compared valve types for a single instant of diastole and a single instant of systole. They reported that for the bileaflet valve the inlet jet penetrated more deeply into the chamber and was more coherent; the diastolic rotational motion was formed sooner and the amount of fluid entrained by the outlet jet was greater. In addition, the pressure drop and mean energy loss through the ball and cage valves was much greater than that through the bileaflet. Moreover, they reported that animal experiments of the device with handmade ball and cage valves showed thrombus formation in the device—something rarely seen in larger pumps. Initial experiments with the bileaflet valves showed no such thrombus formation.

Bachmann et al.^[53] used a TSI Inc. two-component LDA system to measure mean and turbulence quantities in a pediatric ventricle with handmade ball and cage valves at normal physiologic conditions. By using beam expansion, they reduced each measurement volume to a roughly $200 \times 30 \mu\text{m}^2$ ellipse. At each of 75 locations, 250 ensembles were measured at distances from the wall opposite the pusher plate of 0.1, 0.3, 0.6, and 1.0 mm. The data reduction follows Baldwin et al.^[11] Both a sodium iodide solution and a Xanthan gum viscoelastic solution were used. The wall shear rate was estimated from the velocity measurement 0.1 mm from the wall, using the no-slip condition. A gray-scale contour map of the average wall shear stress over the filling portion of the cycle is shown for each fluid in Fig. 5 (the mitral port is located on the right side of the device). Large regions of very low wall shear stress are apparent. A similar plot for the wall shear stresses averaged over the ejection portion of the cycle is shown in Fig. 6. Again, we observe large regions of very low shear stresses. Differences between the results for each fluid, particularly on the inlet side of the model, are striking. Bachmann et al.^[53] compare the characteristics of the Penn State pediatric pump with other small pumps that have shown some clinical promise. These include pumps described by Park and Kim,^[55] who use Carbomedics bileaflet valves; by Taenaka et al.^[56] and Takano et al.^[57] who use Bjork-Shiley tilting disk valves; and by Konertz et al.^[58,59] who use polyurethane trileaflet valves. A consequence of using commercially available valves is a larger inlet length scale and reduced Strouhal number. Comparisons among the pumps, adapted from Bachmann et al.^[53] are shown in Table 1.

The 70–100 cc ventricles described earlier are too large, as the basis for implantable artificial hearts and

Fig. 5 The diagrams of a pediatric device design show wall shear stresses averaged over the filling portion of the cardiac cycle for both Newtonian (left) and non-Newtonian fluids (right).

blood pumps, to be used for much of the adult population. The development of smaller blood pumps that do not sacrifice cardiac output is a continuing research area. Hochareon et al.^[10,60-62] and Oley et al.^[63] recently presented a study of the mean velocity and wall shear stress in a 50 cc device using high-speed video and PIV. Hochareon et al.^[10] examined the opening pattern of the diaphragm using high-speed video. They determined that the opening pattern of the diaphragm, as it affected the diastolic jet and subsequent rotational motion, was a critical aspect of the overall flow. By comparison against flow visualization of the sac motion in a clinically approved 70-cc device, they also showed that the diaphragm motion was a good representative of the whole sac motion. Jin and Clark^[64] reported a similar study.

Hochareon et al.^[60-62] made PIV measurements in the transparent 50 cc pump model as a function of pump cycle time. The Reynolds and Strouhal number

are included in Table 1. All measurements were in the plane of the pusher plate. In this design, however, the inlet valve is rotated 30° from the pusher plate direction so that the light sheet is not aligned with the maximum jet velocity. The blood analog fluid was mineral oil. The pump was run at physiological conditions. A standard, planar TSI, Inc. PIV system was used to acquire 200 images at each condition. The light sheet was estimated at 0.5 mm thick and was initially centered 5 mm from the front edge. Cross-correlation of the images was performed by the TSI, Inc., Insight™ software. The final interrogation window size was 16 × 16 pixels. Both a global area and eight local areas (medial and lateral walls of the mitral and aortic ports and walls of the chamber body) were investigated. Resolution was 85 μm/pixel and 25 μm/pixel for the global and local maps, respectively. Components of the velocity gradient were calculated as central differences and wall shear rates estimated from the velocity point

Fig. 6 The diagrams of a pediatric device design show wall shear stresses averaged over the ejection portion of the cardiac cycle for both Newtonian (left) and non-Newtonian fluids (right).

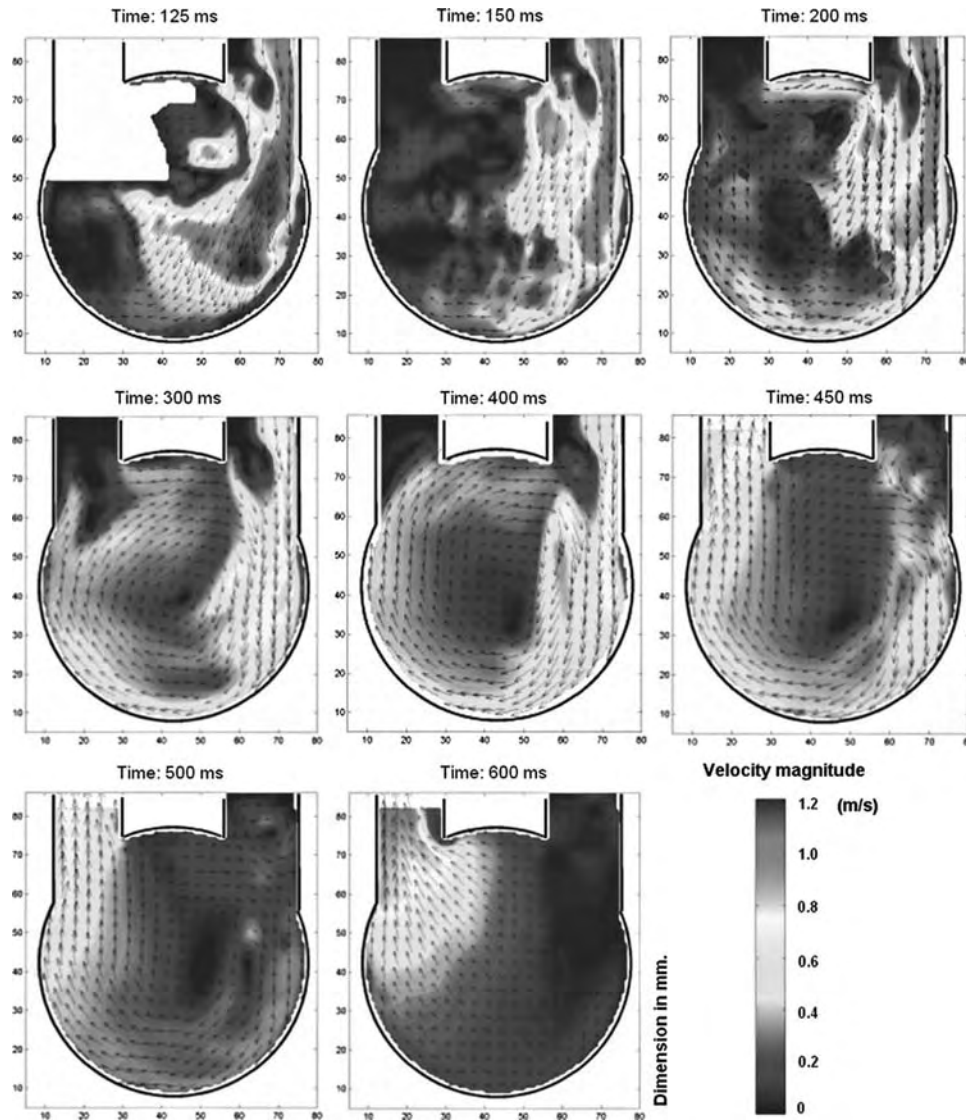

Fig. 7 The PIV velocity maps during early diastole (125 and 150 ms), middle to late diastole (200–400 ms), and systole (450–600 ms) for the 50-cc Penn State ventricular assist device. (Time reference is from the onset of diastole.) Source: Reprinted with permission from ASME (see Refs. [60–62]).

nearest the wall. The authors did not attempt to use PIV to estimate the turbulence levels.

Global flow maps are shown in Fig. 7. Note that diastole starts at 0 ms and systole at 430 ms with the mitral port on the right side of the chamber. The flow is again dominated by the diastolic jet and subsequent large-scale rotation. Peak velocities are the order of those observed by Baldwin et al.^[11] in a 70-cc device. The authors use vorticity maps to highlight the growth of the wall boundary layers. The local flow field near the mitral port at 200 and 400 ms is reproduced in Fig. 8. The associated wall shear rates shown in Fig. 9 never exceed some 3000 s^{-1} . The secondary inflow jet through the minor orifice of the mitral port had not been previously studied.

Fig. 9 The inlet port's average wall shear rate in time series in the beat cycle from (1) the lateral wall of the mitral port (the fully open valve tip position is at wall location approximately 16 mm), and (2) the medial wall of the mitral port (the fully open valve tip position is at wall location approximately 8 mm), of the 50-cc Penn State ventricular assist device. Source: Reprinted with permission from ASME (see Refs. [60–62]).

The local flow and vorticity fields near the bottom of the device are shown in Fig. 10. Shear rates for this region are $0\text{--}250\text{ s}^{-1}$. The authors note such low shear rates over the entire cycle are of concern. Similar shear rates are observed at the upper wall region between the valve ports. A rough summary of shear rates in the device is reproduced in Fig. 11. In general, the wall shear rates observed in the 50 cc device are much lower than those observed by Baldwin et al.^[27] in a 100-cc ventricle. Hochareon et al.^[61] developed refined methods to estimate the wall shear stress from PIV measurements in the artificial ventricle. Issues include the improvement of wall location estimates and the position of the velocity vector in the irregular measurement volumes nearest the wall. The influence of the size of the interrogation region was studied by

simulations. Hochareon et al.^[62] used the refined method for determining wall shear rate to obtain more extensive data in the bottom region of the 50 cc device. Yamanaka et al.^[65] performed an in vivo study of clot deposition in the 50-cc heart implanted in calves, which shows good correlation with regions of persistent low wall shear. Much more work correlating wall shear and clot formation is warranted.

Oley et al.^[63] recently completed a PIV study of the effect of beat rate and systolic duration on the global flow characteristics in the same 50-cc device. Shorter diastolic times produced a stronger inlet jet and an earlier and stronger diastolic rotation. However, the stronger the diastolic rotation, the larger the separated flow region on the inlet side of the aortic valve. The authors note that the relatively rapid acquisition of

whole-flow field data, using PIV may permit experiments to play a more active role in the design process for artificial devices.

CONCLUSIONS

For artificial ventricles suitable for large adults ($>/= 70$ cc), clot formation within the ventricle is not generally observed. The major problems are associated with the valves, both with the high stresses in the regurgitant jets and with the influence of cavitation. Activation of the clotting cycle is likely, although the clots do not adhere to the surface of the pump. Smaller pumps show some thrombus deposition in addition to the valve related problems. Maintaining the inlet Strouhal number near physiologic values is sensible, but clot deposition has been observed in a 50-cc device with a physiologic Strouhal number of about 4.

Analysis of the fluid mechanics of artificial blood pumps has helped to drive design modifications over the years. For example, measurements of stagnation led our group to move the inlet port of the 100-cc pump from the center to the periphery of the device, near wall stasis led us to redesign the inlet port to be more parallel to pump body in our 50-cc device, and extensive measurements helped determine that ball and cage valves would not be suitable for the pediatric device (15 cc). Details of the local fluid mechanics, particularly of the wall shear stresses, will be critical to the successful design of the smaller pumps. Oley et al.^[63] note that the relatively rapid acquisition of whole-flow field data using PIV will be useful in this regard, but we note that the motion of the formed blood elements and their interaction with the artificial materials are a parallel part of the problem not yet addressed by experiment. Computation of the flow field and motion of the formed elements would be extremely useful, but the problems facing a successful computation are formidable. The flow and species motion are unsteady with valve-induced turbulence (at modest Reynolds number) through some of the cycle. The fluid is shear thinning and viscoelastic; the flow is driven by a flexible sac. Work in this important area seems likely to continue for a long time.

Finally, a good deal of effort is currently directed toward the development and testing of rotary blood pumps including axial and centrifugal flow assist devices.^[66]

Artificial Muscles

Mohsen Shahinpoor

Artificial Muscle Research Institute (AMRI), School of Engineering and School of Medicine, University of New Mexico, Albuquerque, New Mexico, U.S.A.

INTRODUCTION

The first attempts to create artificial muscles date to the pioneering work of Kuhn and his student Katchalsky and his students in the late 1940s and early 1950s in connection with pH-activated muscles or simply pH muscles.^[1–6] Note also the other means of activating artificial muscles such as thermal,^[7–9] pneumatic,^[10] optical,^[11] and magnetic.^[12] Chemically stimulated polymers were discovered more than half a century ago when it was shown that collagen filaments could reversibly contract or expand when dipped in acidic or alkaline solutions, respectively.^[1] This early work pioneered the development of synthetic polymers that mimic biological muscles.^[3,5] However, electrical stimulation has always remained the best means of artificial muscle material actuation and sensing. Shahinpoor^[4,5,10,13–19] was one of the pioneers in making electrically active, in sensing and actuation, ionic polymer–conductor composites (IPCCs) and ionic polymer–metal composites (IPMCs). Zhang^[20] was able to observe a substantial piezoelectric activity in polyvinylidene fluoride trifluoroethylene (PVF2-TrFE) as early as 1998. The greatest progress in artificial muscle materials development has occurred in the last 10 years when effective materials that can induce strains exceeding 100% have emerged.^[21]

SPECIFIC ARTIFICIAL MUSCLE MATERIALS

Shape Memory Alloys (SMAs) and Polymers (SMPs)

The history of SMA and SMP artificial muscles is extensive and will not be reported here. However, the pioneering works of Liang and Rogers^[22,23] and Liang, Rogers, and Malafeev^[24] in developing SMA and SMP actuators are noteworthy. In their work, the load of a spring-biased SMA actuator was modeled as a dead weight. However, many practical applications involve varying loads, as in the cases of SMA rotatory joint actuators.^[13,25–27] A general design methodology of various types of bias force SMA actuators has been investigated by Shahinpoor and Wang.^[28] Heat-shrink polymers such as polyolefins, PVC, polypropylene,

and polyesters are also sometimes considered as heat-activated shape memory polymers and artificial muscles.

Magnetically Activated Artificial Muscles

Magnetically activated gels, so-called ferrogels, are chemically cross-linked polymer networks that are swollen by the presence of a magnetic field.^[29] Zrinyi has been a pioneer of this technology. Such a gel is a colloidal dispersion of monodomain magnetic nanoparticles. Such magnetic ferrogel materials deform in the presence of a spatially nonuniform magnetic field because its embedded nanoparticles move in reaction to the field. The ferrogel material can be activated to bend, elongate, deform, curve, or contract repeatedly, and it has a response time of less than 100 ms, which is independent of the particle size. Another group of magnetically activated artificial muscles are the magnetostrictive materials such as TERFENOL-D, which are the metallic elements terbium (TER), iron (FE), Naval Ordnance Labs (NOL), and Dysprosium-D^[30] and give rise to infinitesimal dimensional changes of the order of 0.1% or so, and magnetic shape memory materials (MSM) such as NiMnGa, which undergo gigantic martensitic-austenitic solid-phase transformation and can give rise to 6–8% dimensional change.^[31]

Electronic EAP/Ferroelectric Polymeric Artificial Muscles

The basic phenomenon is called ferroelectricity when a nonconducting crystal or dielectric material exhibits spontaneous electric polarization. These are based on the phenomenon of piezoelectricity, which is found only in noncentrosymmetric materials such as poly(vinylidene fluoride) (also known as PVDF). These polymers are partly crystalline, with an inactive amorphous phase and a Young's modulus of about 1–10 GPa. This relatively high elastic modulus offers high mechanical energy density. A large applied AC field (–200 MV/m) can induce electrostrictive (non-linear) strains greater than 1%. Sen et al.^[32] investigated the effect of mixing plasticizers (–65% wt.) with ferroelectric polymers hoping to achieve large strains

at reasonable applied fields. However, the plasticizer is also amorphous and inactive, resulting in decreased Young's modulus, permittivity, and electrostrictive strains. As large as 4% electrostrictive strains can be achieved with low-frequency driving fields having amplitudes of about $150 \text{ V}/\mu\text{m}$. As with ceramic ferroelectrics, electrostriction can be considered to be the origin of piezoelectricity in ferroelectric polymers.^[33] Unlike electrostriction, piezoelectricity is a linear effect, where not only will the material be strained when voltage is applied, a voltage signal will be induced when a stress is applied. Thus they can be used as sensors, transducers, and actuators. Depoling due to excessive loading, heating, cooling, or electric driving is a problem with these materials.

Dielectric Elastomer Electroactive Polymers (EAPs)

Polymers with low elastic stiffness modulus and high dielectric constant can be packaged with interdigitated electrodes to generate large actuation strain by subjecting them to an electric field. This dielectric elastomer EAP can be represented by a parallel-plate capacitor.^[21] The induced strain is proportional to the square of the electric field, multiplied by the dielectric constant and is inversely proportional to the elastic modulus. Dielectric elastomer EAP actuators require large electric fields ($100 \text{ V}/\mu\text{m}$) and can induce significant levels of strain (10% to 200%). Recently, Perline et al. have introduced a new class of polymers that exhibits an extremely high strain response.^[34] These acrylic-based elastomers have produced large strains of more than 200% but suffer from the fact that they require gigantic electric fields in the range of hundreds of megavolts per meter.

Liquid Crystal Elastomer (LCE) Materials

Liquid crystal elastomers were pioneered at Albert-Ludwigs Universität (Freiburg, Germany).^[35] These materials can be used to form an EAP actuator by inducing isotropic-nematic phase transition due to temperature increase via Joule heating. LCEs are composite materials that consist of monodomain nematic liquid crystal elastomers and conductive polymers that are distributed within their network structure.^[14,36,37] The actuation mechanism of these materials involves phase transition between nematic and isotropic phases over a period of less than a second. The reverse process is slower, taking about 10s, and it requires cooling, causing expansion of the elastomer to its original length. The mechanical properties of LCE materials can be controlled and optimized by effective selection of the liquid crystalline

phase, density of cross-linking, flexibility of the polymer backbone, coupling between the backbone and liquid crystal group, and the coupling between the liquid crystal group and the external stimuli.

Ionic EAP/Ionic Polymer Gels (IPGs)

Polymer gels can be synthesized to produce strong actuators having the potential of matching the force and energy density of biological muscles. These materials (e.g., polyacrylonitrile or PAN) are generally activated by a chemical reaction, changing from an acid to an alkaline environment causing the gel to become dense or swollen, respectively. This reaction can be stimulated electrically, as was shown by Shahinpoor et al.^[5,10,14–19] Current efforts are directed toward the development of thin layers and more robust techniques of placing electrodes on the surface of the composite. Progress was recently reported by researchers at the University of New Mexico using a mix of conductive and PANS fibers.^[38] The mechanism that is responsible for the chemomechanical behavior of ionic gels under electrical excitation is described by Osada and Ross-Murphy,^[39] and a model for hydrogel behavior as contractile EAP is described in Gong et al.^[40] A significant amount of research and development was conducted at the Hokkaido University, Japan, and applications using ionic gel polymers were explored. These include electrically induced bending of gels^[39,41] and electrically induced reversible volume change of gel particles.^[42]

Nonionic Polymer Gels/EAPs

Nonionic polymer gels containing a dielectric solvent can be made to swell under a DC electric field with a significant strain. Hirai and his coworkers at Shinshu University in Japan have created bending and crawling nonionic EAPs using a poly(vinyl alcohol) gel with dimethyl sulfoxide.^[43,44] A $10 \times 3 \times 2 \text{ mm}$ actuator gel was subjected to an electric field and exhibited bending at angles that were greater than 90° at a speed of 6 cm/s . This phenomenon is attributed to charge injection into the gel and a flow of solvated charges that induce an asymmetric pressure distribution in the gel. Another nonionic gel is poly(vinyl chloride) (PVC), which is generally inactive when subjected to electric fields. However, if PVC is plasticized with dioctyl phthalate (DOP), a typical plasticizer, it can maintain its shape and behave as an elastic nonionic gel.

Ionic Polymer–Metal Composites (IPMCs)

Ionic polymer–metal composite (IPMC) is an EAP that bends in response to a small electric field ($5\text{--}10 \text{ V/mm}$)

as a result of mobility of cations in the polymer network. In 1992, IPMC was realized, based on a chemical plating technique developed by Merlet, Pinneri, and coworkers in France and by Kawami and Takanake in Japan in the 1980s. The first working actuators were built by Oguro et al.^[45] in Japan and by Shahinpoor^[4] in the United States. The first working sensors of this kind were first fabricated by Shahinpoor^[4] and Sadehipour et al.^[46] in the United States. The operation as actuators is the reverse process of the charge storage mechanism associated with fuel cells^[47] and Kim et al.^[48,49] A relatively low electric field is required (five orders of magnitude smaller than the fields required for PVDF-TrFE and dielectric elastomers) to stimulate bending in IPMC, where the base polymer provides channels for mobility of positive ions in a fixed network of negative ions on interconnected clusters. In order to chemically deposit electrodes on the polymer films, metal ions (platinum, gold, palladium, or others) are dispersed throughout the hydrophilic regions of the polymer surface and are subsequently reduced to the corresponding zero-valence metal atoms.

Conductive Polymers (CPs)

Conductive polymers operate under an electric field by the reversible counterion insertion and expulsion that occurs during redox cycling.^[6,50] Oxidation and reduction occur at the electrodes, inducing a considerable volume change due mainly to the exchange of ions with an electrolyte. When a voltage is applied between the electrodes, oxidation occurs at the anode and reduction at the cathode. Ions (H^+) migrate between the electrolyte and the electrodes to balance the electric charge. Addition of the ions causes swelling of the polymer and conversely their removal results in shrinkage. As a result, the sandwich assembly bends. Conductive polymer actuators generally require small electric fields in the range of 1–5 V/ μm , and the speed increases with the voltage having relatively high mechanical energy densities of over 20 J/cm³, but with low efficiencies at the level of 1%. In recent years, several conductive polymers have been reported, including polypyrrole, polyethylenedioxythiophene, poly(p-phenylene vinylene)s, polyanilines, and polythiophenes. Operation of conductive polymers as actuators at the single-molecule level is currently being studied, taking advantage of the intrinsic electroactive property of individual polymer chains.

SMA ARTIFICIAL MUSCLES

Since SMA artificial muscle deformation is temperature-induced and rather small (4–6% linear strain), design

means must be incorporated to create larger strains to mimic biological muscles. For example, the human biceps contract more than 30%. Thus, the reader is referred to some design methodologies to create large-strain SMA muscles for biomedical applications.^[13,25–27] These papers discuss a new design for a rotatory joint actuator made with shape memory alloy contractile muscle wires. These papers also present a design of SMA rotatory joint actuators using both shape memory effect (SME) and pseudoelastic effect (PEE). The novelty of such mechanisms is the use of a pseudoelastic SMA wire as a replacement of the bias spring in a bias force type of SMA actuator. Besides the development of a general design methodology of bias force SMA actuators, these efforts by Wang and Shahinpoor intend to investigate a knee and leg muscle exerciser to be used by paraplegics or quadriplegics for exercising their knee and leg muscles. Refer to a dissertation by Guoping Wang^[28] for a complete and thorough coverage of SMA artificial muscles.

ELECTROACTIVE POLYACRYLONITRILE (PAN) FIBERS

Activated polyacrylonitrile (PAN) fibers, which are suitably annealed, cross-linked, and hydrolyzed, are known to contract and expand when ionically activated with cations and anions, respectively. The key engineering features of PAN fibers are their ability to change their length routinely more than 100% and their comparable strength to biological muscles. Described here are some recent results on electroactive PAN artificial muscles as well as a technique that allows one to electrically control the actuation of active PAN fiber bundles. Increasing the conductivity of PAN fibers by making a composite of them with a conductive medium such as platinum, gold, graphite, carbon nanotubes, and conductive polymers such as polyaniline or polypyrrole has allowed for electric activation of PAN fibers when a conductive polyacrylonitrile (C-PAN) fiber bundle is placed in a chemical electrolysis cell as an electrode. A change in concentration of cations in the vicinity of C-PAN fiber electrode leads to contraction and expansion of C-PAN fibers depending upon the applied electric field polarity. Typically close to 100% change in C-PAN length in a few seconds is observed in a weak electrolyte solution with tens of volts of DC power supply. These results indicate a great potential in developing electrically activated C-PAN muscles and linear actuators, as well as integrated pairs of antagonistic muscles and muscle sarcomere and myosin/actin assembly resembling actual biological muscles.

Activated polyacrylonitrile (PAN) fibers, which are suitably annealed, cross-linked, and hydrolyzed, are known to contract and expand when ionically activated with cations and anions, respectively. The change in length for these pH-activated fibers is typically greater than 100%, but up to 200% contraction/expansion of PAN fibers has been observed in our laboratories at AMRI. They are comparable in strength to human muscles and have the potential of becoming medically implantable electroactive contractile artificial muscle fibers.^[5,19,38,51] Increasing the conductivity of PAN by making a composite with a conductive medium (e.g., a noble metal such as gold, palladium, platinum, or graphite or a conductive polymer such as polypyrrole or polyaniline) has allowed for electrical activation of PAN artificial muscles when it is placed in an electrochemical cell. The electrolysis of water in such a cell produces hydrogen ions at a PAN anode, thus locally decreasing the cationic concentration and causing the PAN muscle to contract. Reversing the electric field allows the PAN muscle to elongate. Typically, close to 100% change in PAN muscle length in a few minutes is observed when it is placed as an electrode in a 10 mM NaCl electrolyte solution and connected to a 20-volt power supply. Recently, the response time has been reduced to a few seconds. These results indicate the potential in developing electrically active PAN artificial muscles and linear actuators.

Activated PAN contracts when exposed to protons (H^+) in an aqueous medium and elongates when exposed to hydroxyl ion (OH^-) in a strong alkaline medium. The length of activated PAN fibers can potentially more than double when going from short to long. A possible explanation for the contraction and elongation of activated PAN is the effect carboxylic acid groups have in the molecular geometry. At low cationic concentration, all acid groups are protonated, potentially contracting the polymer. Raw PAN fibers, which are composed of roughly 2000 individual strands of PAN (each about $10\mu m$ in diameter), are first annealed at $220^\circ C$ for 2 hours. The fibers can be bundled together at this point to form a PAN muscle. The PAN is then placed in a solution of boiling 1 N LiOH for 30 minutes, after which the PAN is elastic like a rubber band. At this point, the PAN can be ionically activated; flooding the activated PAN with a high concentration of cations such as H^+ induces contraction, while anionic concentration elongates the fibers. An assortment of such PAN muscles is shown in Fig. 1.

Polyacrylonitrile (PAN) has been studied for more than a half century in many institutions and now is popularly used in the textile industry as a fiber form of artificial silk. The useful properties of PAN include the insolubility, thermal stability, and resistance to

Fig. 1 An assortment of PAN artificial muscles in a variety of configurations.

swelling in most organic solvents. Such properties were thought to be due to the cross-linked nature of the polymer structure. However, a recent finding has shown that a number of strong polar solvents can dissolve PAN and thus has raised a question that its structure could be of the linear zigzag conformations^[52,53] with hydrogen bonding between hydrogen and the neighboring nitrogen of the nitrile group. Activated PAN fibers are elastic. The term “activated PAN fibers” refers to the PAN fibers acting as the elastic fibers of which length varies depending upon the ionic concentration of cations in the solution. They contract at low cationic concentration and expand at high cationic concentration. At high cationic concentration they appear to reject water out of the polymer network resulting in shrinkage due to their elastic nature. Conversely, they elongate at low cationic concentration, attracting water from outside into the polymer network. In our laboratory, it has been observed that activated PAN fibers can contract more than 200% relative to that of the expanded PAN. The use of PAN as artificial muscles is promising since they are able to convert chemical energy to mechanical motion, possibly acting as artificial sarcomeres or muscles. Other types of materials that have a capability to be electroactive are polyelectrolyte gels, such as

polyacrylamide (PAM), polyvinylalcohol-polyacrylic acid (PAA-PVA), and poly(2-acrylamido-2-methyl propane) sulphonic acid (PAMPS). Under an electric field, these gels are able to swell and de-swell, inducing large changes in the gel volume. Such changes in volume can then be converted to mechanical work. Yet one disadvantage of such polyelectrolyte gels is that they are mechanically weak. Artificial sarcomeres or muscles made from polyacrylonitrile (PAN) have much greater mechanical strength than polyelectrolyte gels, thus having a greater potential for application as artificial sarcomeres and muscles (or soft actuators).

The strength of activated PAN and its ability to change length up to 100% or more makes it an appealing material for use as linear actuators and artificial muscles. An attractive alternative is electrical activation. Shahinpoor and coworkers^[5,19,38,51] have reported considerable efforts on electrical activation of PAN artificial muscles. During the electrolysis of water, hydrogen ions are generated at the anode while hydroxyl ions are formed at the cathode in an electrochemical cell. Electrochemical reactions can then potentially be used to control the length of a PAN artificial muscle. This may be achieved by either locating a PAN muscle near an electrode where the ions are generated, or, if the conductivity of activated PAN can be increased, the PAN muscle can serve as the electrode itself.

The study reported herein takes the second approach, where platinum is deposited on PAN fibers to increase conductivity so the muscle can serve as the electrode directly. This procedure of depositing Pt on the polymer and activating it in an electrochemical cell was initially demonstrated a few years ago with a polyvinyl alcohol-polyacrylic acid copolymer, resulting in about a 5% decrease in length, with both contraction and elongation each taking about 12 minutes. However, our recent improvements^[19,38,51] to electroactive PAN muscles have reduced the activation time to a few seconds with muscle strength approaching human muscles in the range of 2 N per cm² of muscle fiber cross section.

In order to manufacture pH-active PAN fibers, the raw fibers are first annealed in air in a computer-controlled oven at an elevated temperature of 220–240°C. It is likely that the annealing process cross-links the polymer and creates a cross-linked structure of pyridine and cyano groups. The preoxidized or annealed PAN fibers show a dark brown or black color depending upon the level of cross-linking. Second, they are subsequently hydrolyzed by boiling in an alkaline solution (2 N NaOH for 20–30 minutes). Following this process, the PAN fibers become extremely pH active (pH muscles). In an approximate pH range of 2–14, the PAN fibers can contract and expand more than 200%.

Based upon the Donnan Theory of ionic equilibrium, the important forces arise from the induced osmotic pressure of free ions between activated PAN fibers and their environment, the ionic interaction of fixed ionic groups, and the charged network itself. Among them, the induced osmotic pressure of free ionic groups is the dominating force. PAN fibers can be activated electrically, by providing a conductive medium or electrode in contact with or within the PAN fibers to act like an anode electrode in a chemical cell with another cathode electrode separated from the PAN fibers. Upon applying an electric field across the electrodes, H⁺ evolves at the anode electrode via $2\text{H}_2\text{O} \Rightarrow \text{O}_2 + 4\text{H}^+ + 4e^-$, and the OH⁻ evolves at the cathode via $2\text{H}_2\text{O} + 2e^- \Rightarrow \text{H}_2 + 2\text{OH}^-$. Upon contact with H⁺ ions in the vicinity of the PAN anode electrode, the decreased pH causes the PAN fibers to contract. If the polarity of the electric field is reversed, then upon contact with OH⁻ ions in the vicinity of the cathode the increased pH causes the PAN fibers to expand.

IONIC POLYMER-CONDUCTOR COMPOSITES (IPCCs and IPMCs) AS EAPs

A large number of polyelectrolytes in a composite form with a conductive medium such as a metal (ionic polymer-conductor composites [IPCCs] or ionic polymer-metal composites [IPMCs]) can exhibit large dynamic deformation if suitable electrodes are mounted on them and placed in a time-varying electric field.^[4,5,10,13–19] Conversely, dynamic deformation of such polyelectrolytes can produce dynamic electric fields across their electrodes. A recently presented model by de Gennes, Okumura, Shahinpoor, and Kim^[54] describes the underlying principle of electrothermodynamics in such polyelectrolytes based upon internal transport phenomena and electrophoresis. It should be pointed out that IPMCs show great potential as soft robotic actuators, artificial muscles, and dynamic sensors in micro to macro size range. An effective way of manufacturing an IPMC starts with making a composite of polyelectrolytes with a metal by means of a chemical reduction process. The current state-of-the-art IPMC manufacturing technique^[5,10,14–19] incorporates two distinct preparation processes: initial manufacturing of a polyelectrolyte-metal composite, and the process of placing surface electrodes on the composite. Figure 2 shows illustrative schematics of two different preparation processes (top left and bottom left) and two top-view SEM micrographs for the platinum surface electrode (top right and bottom right).

The initial process of making a polyelectrolyte-metal composite requires an appropriate platinum salt

Fig. 2 Schematic diagrams showing two different preparation processes: (top left) a schematic showing initial process of making a polyelectrolyte–metal composite; (top right) its top-view SEM micrograph; (bottom left) a schematic showing the process of placing electrodes on the surface of the composite; and (bottom right) its top-view SEM micrograph where platinum deposited predominately on top of the initial Pt layer. Note that PIEM stands for perfluorinated ion exchange membrane.

such as $\text{Pt}(\text{NH}_3)_4\text{HCl}$ or $\text{Pd}(\text{NH}_3)_4\text{HCl}$ in the context of chemical reduction processes similar to the processes evaluated by a number of investigators including Takenaka et al.^[55] and Millet et al.^[56] The principle of the process of making a polyelectrolyte–metal composite is to metalize the inner surface of the material by a chemical reduction means such as LiBH_4 or NaBH_4 . The polyelectrolyte is soaked in a salt solution to allow platinum-containing cations to diffuse through via the ion-exchange process. Later, a proper reducing agent such as LiBH_4 or NaBH_4 is introduced to platinize the material.^[5,10,14–19] It has been experimentally observed that the platinum particulate layer is buried microns deep (typically 1–20 μm) within the IPMC surface

and is highly dispersed. The fabricated IPMCs can be optimized to produce a maximum force density by changing multiple process parameters. These parameters include time-dependent concentrations of the salt and the reducing agents. Applying the Taguchi technique to identify the optimum process parameters for such optimizations has been successful in the past.^[19,57] The primary reaction is,

In the subsequent process of placing electrodes on the surface of the composite, multiple reducing agents are introduced (under optimized concentrations) to carry out the reducing reaction similar to Eq. 1, in addition to the initial platinum layer formed by the initial process of making a polyelectrolyte–metal composite. This is clearly shown in Fig. 2 (bottom right), where the roughened surface disappears because of additional metals deposited on the surface. Figure 3 depicts a typical spectacular steady-state deformation mode of a strip of such ionic polymers under a step voltage.

LIQUID CRYSTAL ELASTOMER ARTIFICIAL MUSCLES

Recently, liquid single crystal elastomers (LSCEs) have gained a lot of importance in connection with artificial muscles technologies. See Finkelmann,^[35,71] Brand and coworkers,^[72,73] Shahinpoor,^[14] Ratna,^[36] and Finkelmann and Shahinpoor^[37] where the liquid crystalline phase structure is macroscopically orientated in the network. At the liquid crystalline to isotropic phase transformation temperature, when the liquid crystalline network becomes isotropic like a conventional rubber, the dimensions of the network change. Due to the anisotropy in the phase structure of liquid crystal elastomers, the networks shorten in the direction of the optical axis or director axis. De Gennes and coworkers^[74,75] have also alluded to the fact that such nematic networks present a potential as artificial

Fig. 3 Typical deformation of strips (10 mm \times 80 mm \times 0.34 mm) of ionic polymers under a step voltage of 4 volts.

muscles just like the IPMC materials mentioned before. For nematic LSCE synthesized from nematic LC side-chain polymers, the change of this length is normally more than 100% and sometimes up to 400%.^[38,51] The speed of this process is determined by the thermal heat conductivity of the network and not by material transport processes. If the sample thickness is limited, calculations indicate that the response time of the LSCE is similar to that of natural muscles and mainly determined by the relaxation behavior of the polymer chains or network strands.

The magnitude of changes in the dimensions of nematic LSCE with temperature is determined by the coupling between the nematic state of order and the conformation of the polymer main chains. In this regard, the conformation of nematic side-chain polymers is only slightly affected. For nematic main-chain polymers, where the mesogenic units are incorporated into the polymer main chain, large conformational changes should occur and be directly expressed in the thermoelastic behavior. The electrical activation of liquid crystal elastomers has also been reported by Shahinpoor^[14] and Finkelmann and Shahinpoor.^[37]

Making a composite of them with a conductor phase such as a metal or graphite powder does this. Joule heating of some new high-performance nematic LSCE developed by Finkelmann and coworkers^[35,71] that consists of a combination of LC side-chain and main-chain polymers has been successful. These materials have been synthesized previously by a hydrosilylation reaction of the monofunctional side-chain mesogen and the bifunctional liquid crystalline main-chain polyether with poly(methylhydrogensiloxane). Figure 4 displays the main chemical synthesis steps in producing liquid crystal elastomers by hydrosilylation reaction of the monofunctional side-chain mesogen. Note that a weakly cross-linked network is mechanically loaded. Under load, the hydrosilylation reaction is completed. The LSCE has a weight ratio between the mesogenic units in the main chain to those in the side chains of 57/43 and a nematic to isotropic phase transition temperature of $T_{n,i} = 104^{\circ}\text{C}$.

Thus, coelastomers containing network strands comprising LC side- and main-chain polymers exhibit exceptional thermoelastic behavior. These systems might be suitable as model systems for artificial muscles. Thus, liquid crystalline to isotropic phase transition can cause conformational changes of macromolecules, which are sufficient to obtain a large mechanical response of polymer networks.

The samples of monodomain (MD-72/28) nematic liquid side-chain crystal elastomers graphite (LSCE-G) composites under a stress of 100 kPa and contracts up to 400%.^[72] The composite of them with a conductor^[14] becomes a conductor and has an effective

Fig. 4 Synthesis of the nematic coelastomer in a liquid single crystalline coelastomer.

resistivity of about 1.6 ohms/square on its surface and about 0.8 ohm/square across its thickness. Upon applying a DC voltage of 0.5 to 5 volts to a typical sample for about 4 seconds, under a stress of about 10 kPa, the sample contracts quickly in about a second to about 18 mm lengthwise with an average linear strain of about 25%. The sample does not contract appreciably in the transverse direction and the thickness direction. The cooling is also quick and it takes the sample about 4.4 seconds to revert back to its initial length under stretching load of 10 kPa.

CONCLUSIONS

We began this article by discussing a brief history of artificial muscles. We then discussed the shape memory alloys and polymer-type artificial muscles followed by electrical activation of PAN artificial muscles through increasing the conductivity of PAN fibers. The conductivity of PAN was increased by either depositing a coat of metal on the fibers or interweaving it with graphite fibers. Electrochemical reactions were used to generate hydrogen ions or hydroxyl ions for the contraction and elongation, respectively, of these PAN-C muscles. Therefore, by increasing the conductivity of activated PAN, a PAN artificial muscle or linear actuator could be electrically activated in an antagonistic manner (push-pull, biceps, and triceps actions) suitable for industrial and medical applications. Increasing the conductivity of PAN fibers by making a composite of them with a conductive medium such as platinum, gold, graphite, carbon nanotubes, and conductive polymers such as polyaniline or polypyrrole was shown to allow for electric activation of PAN fibers when a conductive polyacrylonitrile (C-PAN) fiber bundle is placed in a chemical electrolysis cell as an electrode. Typically close to 100% change in C-PAN fiber length in a few seconds is observed in a weak electrolyte solution with tens of volts of DC power supply. These results indicate a great potential in developing electrically activated C-PAN muscles and linear actuators, as well as integrated pairs of antagonistic muscles and muscle sarcomere and myosin/actin assembly. The history of ionic polymer-metal composites (IPMCs) in artificial muscles was also discussed. The fundamental properties and characteristics of ionic polymer (polyelectrolyte)-metal composites as biomimetic sensors, actuators, transducers, and artificial muscles were also presented. Finally, a brief discussion was presented on liquid crystal elastomer artificial muscles. It was reported that liquid crystal artificial muscles have the capability of contracting more than 400%. For additional references on artificial muscles, please refer to Refs. [76-91].

Artificial Neural Networks: An Overview

A

Evangelia Micheli-Tzanakou

Department of Biomedical Engineering, Rutgers University, Piscataway, New Jersey, U.S.A.

INTRODUCTION

Neural networks have been a much publicized topic of research in recent years and are now beginning to be used in a wide range of subject areas. One of the strands of interest in neural networks is to explore possible models of biological computation. Human brains contain about 1.5×10^{11} neurons of various types, with each receiving signals through 10 to 10^4 synapses. The response of a neuron happens in about 1 to 10 msec. Yet, one can recognize an old friend's face and call him in about 0.1 sec. This is a complex pattern recognition task that must be performed in a highly parallel way, because the recognition occurs in about 100 to 1000 steps. This indicates that highly parallel systems can perform pattern recognition tasks more rapidly than current conventional sequential computers. As yet, very-large-scale integration (VLSI) technology, which is essential planar implementation with at most two or three layer cross-connections, is far from achieving these parallel connections that require 3-D interconnections.

Artificial Neural Networks

Although originally the neural networks were intended to mimic a task-specific subsystem of a mammalian or human brain, recent research has mostly concentrated on the ANNs, which are only vaguely related to the biological system. Neural networks are specified by 1) the net topology; 2) node characteristics; and 3) training or learning rules.

Topological consideration of the Artificial Neural Networks (ANNs) for different purposes is provided in review papers.^[1,2] Because our interests in the neural networks are in classification only, the feed-forward multilayer perceptron topology is considered, leaving the feedback connections to the references.

The topology describes the connection with the number of the layers and the units in each layer for feed-forward networks. Node functions are usually non-linear in the middle layers but can be linear or non-linear for output layer nodes. However, all of the units in the input layer are linear and have fan-out connections from the input to the next layer.

Each output y_j is weighted by w_{ij} and summed at the linear combiner, represented by a small circle in Fig. 1. The linear combiner thresholds its inputs before it sends them to the node function ϕ_j . The unit functions are non-linear, monotonically increasing, and bounded functions as shown at the right in Fig. 1.

Usage of Neural Networks

One use of a neural network is classification. For this purpose, each input pattern is forced adaptively to output the pattern indicators that are part of the training data; the training set consists of the input covariate x and the corresponding class labels. Feed forward networks, sometimes called multilayer perceptrons (MLP), are trained adaptively to transform a set of input signals, X , into a set of output signals, G . Feedback networks begin with the initial activity state of a feedback system. After state transitions have taken place the asymptotic final state is identified as the outcome of the computation. One use of the feedback networks is in the case of associative memories: upon being presented with a pattern near a prototype X it should output pattern X' , and as autoassociative memory or contents addressable memory by which the desired output is completed to become X .

In all cases the network learns or is trained by the repeated presentation of patterns with known required outputs (or pattern indicators). Supervised neural networks find a mapping $f: X \rightarrow G$ for a given set of input and output pairs.

Other Neural Networks

The other dichotomy of the neural networks family is unsupervised learning, that is clustering. The class information is not known or is irrelevant. The networks find groups of similar input patterns.

The neighboring code vectors in a neural network compete in their activities by means of mutual lateral interactions and develop adaptively into specific detectors of different signal patterns. Examples are the Self Organizing Map^[3] and the Adaptive Resonance Theory (ART) networks.^[4] The ART is different from other unsupervised learning networks in that it develops new clusters by itself. The network develops a

Fig. 1 (I) The linear combiner output $x_j = \sum_{i=1}^n y_i w_{ij}$ is

input to the node function ϕ_j given the output y_j .
 (II) Possible node functions: hard limiter (a), threshold (b), and sigmoid (c) non-linear function.

new code vector if there exist sufficiently different patterns. Thus, the ART is truly adaptive, whereas other methods require the number of clusters to be specified in advance.

Feed-Forward Networks

In feed-forward networks the signal flows only in the forward direction; no feedback exists for any node. This is perhaps best illustrated graphically in Fig. 2. This is the simplest topology and is good enough for most practical classification problems.^[5]

The general definition allows more than one hidden layer and also allows “skip layer” connections from

Fig. 2 A generic feed-forward network with a single hidden layer. For bias terms the constant inputs with 1 are shown and the weights of the constant inputs are the bias values, which will be learned as training proceeds.

input to output. With this skip layer, one can write a general expression for a network output y_k with one hidden layer,

$$y_k = \phi_k \left\{ b_k + \sum_{i \rightarrow k} w_{ik} x_i + \sum_{j \rightarrow k} w_{jk} \phi_j \left\{ b_j + \sum_{i \rightarrow j} w_{ij} x_i \right\} \right\}, \quad (1)$$

where the b_j and b_k represent the thresholds for each unit in the j th hidden layer and the output layer, which is the k th layer. Because the threshold values b_j , b_k are to be adaptive, it is useful to have a threshold for the weights, for constant input value of 1, as in Fig. 2. The function $\phi(\cdot)$ is almost inevitably taken to be a linear, sigmoidal ($\phi(x) = e^x / (1 + e^x)$) or threshold function ($\phi(x) = I(x > 0)$).

Rumelhart et al.^[6] demonstrated that the feed-forward multilayer perceptron networks can learn using gradient values obtained by an algorithm called error backpropagation.¹

This contribution is a remarkable advance since 1969, when Minsky and Papert^[7] claimed that the non-linear boundary required for the XOR problem can be obtained using a multilayer perceptron. The learning method was unknown at the time.

Rosenblatt^[8] introduced the one-layer single perceptron learning method called the *perceptron convergence* procedure and research on the single perceptron was active until the counter example of the XOR problem, which the single perceptron could not solve, was introduced.

In multilayer network learning the usual objective or error function to be minimized has the form of a squared error

$$E(\mathbf{w}) = \sum_{p=1}^P \|t^p - f(x^p; \mathbf{w})\|^2 \quad (2)$$

that is to be minimized with respect to \mathbf{w} , the weights in the network. Here p represents the pattern index, $p = 1, 2, \dots, P$ and t^p is the target or desired value when x^p is the input to the network. Clearly, this minimization can be obtained by any number of unconstrained optimization algorithms; gradient methods or stochastic optimization are possible candidates.

¹A comment on the terminology backpropagation is given in the next section. There, backpropagation is interpreted as a method of finding the gradient values of a feed-forward multilayer perceptron network rather than as a learning method. A pseudosteepest descent method is the learning mechanism used in the network.

The updating of weights has a form of the steepest descent method,

$$w_{ij} = w_{ij} - \eta \frac{\partial E}{\partial w_{ij}}, \quad (3)$$

where the gradient value $\partial E/\partial w_{ij}$ is calculated for each pattern being present; the error term $E(w)$ in the on-line learning is not the summation of the squared error for all P patterns.

Note that the gradient points are in the direction of maximum increasing error. In order to minimize the error it is necessary to multiply the gradient vector by -1 and by a learning rate η .

The updating method (Eq. 3) has a constant learning rate η for all weights and is independent of time. The original method of steepest descent has the time-dependent parameter η_k ; hence, η_k must be calculated as iterations progress.

Error Backpropagation

Backpropagation was first discussed by Bryson and Ho^[9], later researched by Werbos^[10] and Parker^[11], and rediscovered and popularized by Rumelhart et al.^[6,12] Each pattern is presented to the network and the input x_j and output y_j are calculated as in Fig. 3. The partial derivative of the error function with respect to weights is

$$\nabla E(t) = \left(\frac{\partial E(t)}{\partial w(t)} \dots \frac{\partial E(t)}{\partial w_n(t)} \right)^T \quad (4)$$

where, n is the number of weights and t is the time index representing the instance of the input pattern presented to the network.

The former indexing is for the on-line learning in which the gradient term of each weight does not accumulate. This is the simplified version of the gradient method that makes use of the gradient information of

Fig. 3 Error backpropagation. The δ_j for weight w_{ij} is obtained. δ_k 's are then backpropagated via thicker weight lines, w_{jk} 's.

all training data. In other words, there are two ways to update the weights using Eq. 4.

$$w_{ij}^{(p)} \leftarrow w_{ij}^{(p)} - \eta \left(\frac{\partial E}{\partial w_{ij}} \right)^{(p)} \quad \text{temporal learning} \quad (5)$$

$$w_{ij} \leftarrow w_{ij} - \eta \sum \left(\frac{\partial E}{\partial w_{ij}} \right)^{(p)} \quad \text{epoch learning} \quad (6)$$

One way is to sum all the P patterns to get the sum of the derivatives in Eq. 6 and the other way (Eq. 5) is to update the weights for each input and output pair temporally without summation of the derivatives. The temporal learning, also called on-line learning (Eq. 5), is simple to implement in a VLSI chip, because it does not require the summation logic and storing of each weight, whereas the epoch learning in Eq. 6 does. However, the temporal learning is an asymptotic approximation version of the epoch learning, which is based on minimizing an objective function (Eq. 2).

With the help of Fig. 3, the first derivatives of E with respect to a specific weight w_{jk} can be expanded by the chain rule:

$$\frac{\partial E}{\partial w_{jk}} = \frac{\partial E}{\partial x_k} \frac{\partial x_k}{\partial w_{jk}} = \frac{\partial E}{\partial x_k} y_j = \phi'_k(x_k) \frac{\partial E}{\partial y_k} y_j \quad (7)$$

Or

$$\frac{\partial E}{\partial w_{jk}} = \frac{\partial \phi_k(x)}{\partial x_k} \frac{\partial E}{\partial y_k} y_j = \delta_k y_j. \quad (8)$$

For output units, $\partial E/\partial y_k$ is readily available, i.e., $2(y_k - t^p)$, where y_k and t^p are the network output and the desired target value for input pattern x^p . The $\phi'_k x_k$ is straightforward for the linear and logistic non-linear node functions; the hard limiter, on the other hand, is not differentiable.

For the linear node function,

$$\phi'(x) = 1 \quad \text{with} \quad y = \phi_x = x,$$

whereas for the logistic unit the first-order derivative becomes

$$\phi'(x) = y(1 - y) \quad (9)$$

$$\text{when} \quad \phi(x) = \frac{e^x}{1 + e^x} \quad (10)$$

The derivative can be written in the form

$$\frac{\partial E}{\partial w_{ij}} = \sum_p y_i^p \delta_j^p, \quad (11)$$

which has become known as the *generalized delta rule*.

The δ 's in the generalized delta rule (Eq. 11) for output nodes, therefore, become

$$\delta_k = 2y_k(1 - y_k)(y_k - t^p) \quad \text{for a logistic output unit} \quad (12a)$$

and

$$\delta_k = 2(y_p - t^p) \quad \text{for a linear output unit.} \quad (12b)$$

The interesting point in the backpropagation algorithm is that the δ 's can be computed from output to input through hidden layers across the network; δ 's for the units in earlier layers can be obtained by summing the δ 's in the higher layers. As illustrated in Fig. 3, the δ_j are obtained as

$$\begin{aligned} \delta_j &= \phi'_j(x_j) \frac{\partial E}{\partial y_j} \\ &= \phi'_j(x_j) \sum_{j \rightarrow k} w_{jk} \frac{\partial E}{\partial x_k} \\ &= \phi'_j(x_j) \sum_{j \rightarrow k} w_{jk} \delta_k \end{aligned} \quad (13)$$

The δ_k 's are available from the output nodes. As the updating or learning progresses backward, the previous (or higher) δ_k are weighted by the weights w_{jk} 's and summed to give the δ_j 's. Because Eq. 13 for δ_j only contains terms at higher layer units, it can be calculated backward from the output to the input of the network; hence, the name backpropagation.

Madaline Rule III for multilayer network with sigmoid function

Widrow took an independent path in learning as early as the 1960s.^[13,14] After some 30 years of research in adaptive filtering, Widrow and colleagues returned to neural network research^[13] and extended Madaline I with the goal of developing a new technique that could adapt multiple layers of adaptive elements using the simpler hard-limiting quantizer. The result was Madaline Rule II (or simply MR II), a multilayer linear combiner with a hard-limiting quantizer.

Andes (unpublished, 1988) modified the MR II by replacing the hard-limiting quantizer, resulting in MR III by a sigmoid function in the Madaline, i.e., a single-layer linear combiner with a hard-limiting quantizer. It was proven later that MR III is, in essence, equivalent to backpropagation. The important difference from the gradient-based backpropagation method is that the derivative of the sigmoid function is not required in this realization; thus, the analog

implementation becomes feasible with this MR III multilayer learning rule.

A comment on the terminology backpropagation

The terminology backpropagation has been used differently from what it should mean. To obtain the partial derivatives of the error function (at the system output node) with respect to the weights of the units lower than the output unit, the terms in the output unit are propagated backward, as in Eq. 13. However, the network (actually the weights) learns (or weights are updated) using the pseudo steepest descent method (Eq. 3); it is pseudo because a constant term is used, whereas the steepest descent method requires an optimal learning rate for each weight and time instance, i.e., $\eta_{ij}(k)$. The error backpropagation is indeed used to find the necessary gradient values in the updating rule. Thus, it is not a good idea to call the backpropagation a learning method: the learning method is a simple version of the steepest descent method, which is one of the classical minimizer finding algorithms. Backpropagation is an algorithm used to find the gradient of E in a feed-forward multilayer perceptron network.

Optimization machines with feed forward multilayer perceptrons

Optimization in multilayer perceptron structures can be easily realized by gradient-based optimization methods with the help of backpropagation. In the multilayer perceptron structure, the functions can be minimized/maximized via any gradient-based unconstrained optimization algorithm, such as Newton's method or the steepest descent method.

The optimization machine is functionally described as depicted in Fig. 4 and consists of two parts: gradient calculation and weight (or parameter) updating.

The gradient of E of the multilayer perceptron network is obtained by error backpropagation. If this gradient is used in an on-line fashion with the constant learning rate, as in Eq. 3, then this structure is the neural network used earlier.^[12] This on-line learning structure possesses a desirable feature in VLSI implementation of the algorithm because it is temporal: no summation over all the patterns is required but the weights are updated as the individual pattern is presented to the network. It requires little memory but sometimes the convergence is too slow.

The other branch in Fig. 4 illustrates unconstrained optimization of the non-linear function. The optimization machine obtains the gradient information as before, but various and well-developed unconstrained optimizations can be used to find the optimizer. The

unconstrained non-linear minimization is divided basically into two categories: gradient methods and stochastic optimization. The gradient methods are deterministic and use the gradient information to find the direction for the minimizer. Stochastic optimization methods such as the ALgorithm Of Pattern Extraction (ALOPEx) are discussed in another section of this chapter and in other references.^[15–17]

Comparisons of ALOPEX with backpropagation are reported by Zahner and Micheli-Tzanakou.^[15]

Justification for gradient methods for non-linear function approximation

Getting stuck in local minima is a well-known problem for gradient methods. However, the weights (or the dimensionality of the weight space in neural networks) are usually much larger than the dimensionality of the input space $X \subset R^P$ that is preferred when searching for optimization. The redundant degrees of freedom used to find a better minimizer justify the gradient methods used in neural networks.

Another justification for use of the gradient method in optimization may result from the approximation of highly nonlinear functions using Taylor expansion,^[5] where the first- and second-order approximations, i.e., a quadratic approximation to the non-linear function, are used. The quadratic function in a covariate x has a unique minimum or maximum.

Training Methods for Feed-Forward Networks

Two basic methods exist to train the feed-forward networks: gradient-based learning and stochastic learning. Training or learning is essentially an unconstrained optimization problem. A number of algorithm optimizations can be applied to the function approximated by the network in a structured way defined by the network topology.

In gradient-based methods, the most popular learning involves the steepest descent/ascent method with the error backpropagation algorithm to obtain the required gradient of the minimizing/maximizing error function with respect to the weights in the network.^[6,12] Another method using the gradient

information is Newton's method, which is basically used for zero finding of a non-linear function. The function optimization problem is the same as the zero finding of the first derivative of a function; hence, Newton's method is valid.

All the deterministic (as opposed to stochastic) minimization techniques are based on one or both of the steepest descent and Newton's methods. The objective function to be optimized is usually limited to a certain class in network optimization. The square of the error $\|t - \hat{y}\|^2$ and the information theoretic measuring the Kullback–Leibler distance are objective functions used in feed-forward networks. This is because of the limitation in calculating the gradient values of the network utilized by the error backpropagation algorithm.

The recommended method of optimization according to Broyden, Fletcher, Goldfarb, and Shannon (BFGS) is the well-known Hessian matrix update in Newton's method of unconstrained optimization,^[18] which requires gradient values. For the optimization machine in Fig. 4, the feed-forward network with backpropagation provides the gradients and the Hessian approximation is obtained using the BFGS method.

The other dichotomy of the minimization of an unconstrained non-linear multivariate function is grouped into the so-called stochastic optimization. The representative algorithms are simulated annealing,^[19] Boltzmann machine learning,^[20] and ALOPEX.^[21,22] Simulated annealing^[19] has been successfully used in combinatoric optimization problems such as the traveling salesman problem, VLSI wiring, and VLSI placement problems. An application of feed-forward network learning was reported,^[23] with the weights being constrained to be integers or discrete values rather than a continuum of the weight space.

Boltzmann machine learning, by Hinton and Sejnowski,^[20] is similar to simulated annealing except that the acceptance of randomly chosen weights is possible even when the energy state is decreased. In simulated annealing, the weights yielding the decreased energy state are always accepted, but in the Boltzmann machine probability is used in accepting the increased energy states.

The simulated annealing and the Boltzmann machine learning (a general form of Hopfield network^[24] for the associative memory application) algorithms are mainly

Fig. 4 Functional diagram for an optimization machine.

A

for combinatoric optimization problems with binary states of the units and the weights. Extension from binary to M -ary in the states of the weights has been reported for classification problems^[24] in simulated annealing training of the feed-forward perceptrons.

The ALOPEX was originally used for construction of visual receptive fields,^[21,22,25,26] but with some modifications it was later applied to the learning of any type of network not restricted to multilayer perceptrons. The ALOPEX is a random walk process in each parameter in which the direction of the constant jump is decided by the correlation between the weight changes and the energy changes.

The ALOPEX

The ALOPEX process is an optimization procedure that has been successfully demonstrated in a wide variety of applications. Originally developed for receptive field mapping in the visual pathway of frogs, ALOPEX's usefulness, combined with its flexible form, increased the scope of its applications to a wide range of optimization problems. Since its development by Tzanakou and Harth in 1973,^[21,22] ALOPEX has been applied to real-time noise reduction,^[27] and pattern recognition,^[28] in multilayer neural network training, among other applications.

Optimization procedures in general attempt to maximize or minimize a function $F(\cdot)$. The function $F(\cdot)$ is called the cost function and its value depends on many parameters or variables. When the number of parameters is large, finding the set that corresponds to the optimal solution is exceedingly difficult. If N were small, then one could perform an exhaustive search of the entire parameter space to find the "best" solution. As N increases, intelligent algorithms are needed to quickly locate the solution. Only an exhaustive search can guarantee that a global optimum is found; however, near-optimal solutions are acceptable because of the tremendous speed improvement over exhaustive search methods.

Backpropagation, described earlier, being a gradient descent method, often gets stuck in local extrema of the cost function. The local stopping points often represent unsatisfactory convergence points. Techniques have been developed to avoid the problem of local extrema, with simulated annealing^[19] being the most common. Simulated annealing incorporates random noise, which acts to dislodge the process from local extremes. It is crucial to the convergence of the process that the random noise be reduced as the system approaches the global optimum. If the noise is too large, the system will never converge and can be mistakenly dislodged from the global solution.

The ALOPEX is another process that incorporates a stochastic element to avoid local extremes in search

of the global optimum of the cost function. The cost function or response is problem dependent and is generally a function of a large number of parameters. The ALOPEX iteratively updates all parameters simultaneously based on the cross-correlation of local changes, ΔX_i , and the global response change ΔR , plus additive noise. The cross-correlation term $\Delta X_i \Delta R$ helps the process move in a direction that improves the response (Eq. 14). Table 1 illustrates how this can be used to find a global maximum of R .

All parameters X_i are changed simultaneously in each iteration according to

$$X_i(n) = X_i(n-1) + \gamma \Delta X_i(n) \Delta R(n) + r_i(n). \quad (14)$$

The basic concept is that this cross-correlation provides a direction of movement for the next iteration. For example, take the case where $X_i \downarrow$ and $R \uparrow$. This means that the parameter X_i decreased in the previous iteration, and the response increased for that iteration. The product $\Delta X_i \Delta R$ is a negative number, and thus X_i would be decreased again in the next iteration. This makes perfect sense because a decrease in X_i produced a higher response; if one is looking for the global maximum then X_i should be decreased again. Once X_i is decreased and R also decreases, then $\Delta X_i \Delta R$ is now positive and X_i increases.

These movements are only tendencies because the process includes a random component $r_i(n)$, which will act to move the weights unpredictably, avoiding local extrema of the response. The stochastic element of the algorithm helps avoid local extrema at the expense of slightly longer convergence or learning periods.

The general ALOPEX updating equation (Eq. 14) is explained as follows. $X_i(n)$ are the parameters to be updated, n is the iteration number, and $R(\cdot)$ is the cost function, of which the best solution in terms of X_i is sought. Gamma, γ , is a scaling constant, $r_i(n)$ is a random number from a gaussian distribution whose mean and standard deviation are varied, and $\Delta X_i(n)$ and $\Delta R(n)$ are found using

$$\Delta X_i(n) = X_i(n-1) - X_i(n-2) \quad (15)$$

$$\Delta R(n) = R(n-1) - R(n-2). \quad (16)$$

Table 1 Combinations of parameter changes and their contribution to the ALOPEX convergence

	ΔX_i		ΔR	$\Delta X_i \Delta R$
$X_i \uparrow$	+	$R \uparrow$	+	+
$X_i \uparrow$	+	$R \downarrow$	-	-
$X_i \downarrow$	-	$R \uparrow$	+	-
$X_i \downarrow$	-	$R \downarrow$	-	+

The calculation of $R(\cdot)$ is problem dependent and can be easily modified to fit many applications. This flexibility was demonstrated in the early studies of Harth and Tzanakou.^[22] In mapping receptive fields, no a priori knowledge or assumptions were made about the calculation of the cost function, instead a response was measured with microelectrodes inserted in the brain. Using action potentials as a measure of the response,^[22,25,26] receptive fields could be determined using the ALOPEX process to iteratively modify the stimulus pattern until it produced the largest response. This response was obtained from the stimulated neurons. (This was the first computer-to-brain interfacing ever used with electrodes inserted in an animal brain to measure neuronal activity and use it as feedback to the computer.)

Because of its stochastic nature, efficient convergence depends on the proper control of both the additive noise and the gain factor γ . Initially, all parameters X_i are random and the additive noise has a gaussian distribution with mean 0 and standard deviation σ , initially large. The standard deviation decreases as the process converges to ensure a stable stopping point (Fig. 5). Conversely, γ increases with iterations (Fig. 6). As the process converges, ΔR

Fig. 5 Gamma vs. iterations.

Fig. 6 Gaussian noise standard deviation vs. iterations.

becomes smaller and smaller, requiring an increase in γ to compensate.

Additional constraints include a maximal change permitted for X_i , for a single iteration. This bounded step size prevents the algorithm from drastic changes from one iteration to the next.

These drastic changes often lead to long periods of oscillation, during which the algorithm fails to converge.

Multilayer Perceptron (MLP) Network Training with ALOPEX

An MLP can also be trained for pattern recognition using ALOPEX. A response is calculated for the j th input pattern based on the observed and desired output,

$$R_j(n) = \mathbf{O}_k^{\text{des}} - (\mathbf{O}_k^{\text{obs}}(n) - \mathbf{O}_k^{\text{des}})^2, \quad (17)$$

where $\mathbf{O}_k^{\text{obs}}$ and $\mathbf{O}_k^{\text{des}}$ (the observed and desired outputs, respectively) are vectors corresponding to O_k for all k . The total response for iteration n is the sum of all individual template responses, $R_f(n)$.

$$R(n) = \sum_{j=1}^m R_j(n) \quad (18)$$

In Eq. 18, m is the number of templates used as inputs. The ALOPEX iteratively updates the weights using both the global response information and the local weight histories, according to the following equations,

$$W_{ij}(n) = r_i(n) + \gamma \Delta W_{ij}(n) \Delta R(n) + W_{ij}(n-1) \quad (19)$$

$$W_{jk}(n) = r_j(n) + \gamma \Delta W_{jk}(n) \Delta R(n) + W_{jk}(n-1), \quad (20)$$

where γ is an arbitrary scaling factor, $r_i(n)$ is the additive gaussian noise, ΔW represents the local weight change, and ΔR represents the global response information. These values are calculated by

$$\Delta W_{ij}(n) = W_{ij}(n-1) - W_{ij}(n-2) \quad (21)$$

$$\Delta W_{jk}(n) = W_{jk}(n-1) - W_{jk}(n-2) \quad (22)$$

$$\Delta R(n) = R(n-1) - R(n-2). \quad (23)$$

After the network was trained, it was tested for correct recognition using incomplete or noisy input patterns. The results demonstrate the robustness of the system to noise-corrupted data. Regardless of which training

procedure was used, backpropagation or ALOPEX, the recognition ability of the system was the same. The only difference was in how the response grew with iterations.

The neural network's robustness is derived from its parallel architecture and depends on the network topology rather than the learning scheme used to train. The network used was a three-layer feed-forward network with 35 input nodes, 20 hidden nodes, and 10 output nodes. The network's recognition ability was tested with noisy input patterns. Each 5×7 digit of the training set was subjected to noise of varying gaussian distribution and tested for correct recognition. The single-value response feedback, as opposed to the extensive error propagation schemes of other neural network training algorithms, makes ALOPEX suitable for fast VLSI implementation.

In our laboratory, an analog VLSI chip was designed to implement the ALOPEX algorithm, as described in another section. Making full use of the algorithm's tolerance to noise, an analog design was chosen. Analog designs offer larger and faster implementations than digital designs.

Issues in Neural Networks

Universal approximation

More than 30 years ago, Minsky and Papert^[7] reported that simple two-layer (no hidden layers) networks cannot approximate the non-linearly separating functions (e.g., XOR problems), but a multilayer neural network could do the job. Many results on the capability of multilayer perceptron have been reported. Some theoretical analyses for the network capability of the universal approximator are listed below and are extensively discussed by Hornik et al.^[29]

Kolmogorov^[30] tried to answer the question of Hilbert's 13th problem, i.e., the multivariate function approximation by a superposition of the functions of one variable. The superposition theory sets the upper limit of the number of hidden units to $(2n+1)$ units, where n is the dimensionality of the multivariate function to be approximated. However, the functional units in the network are different for the different functions to be approximated, while one would like to find an adaptive method to approximate the function from the given training data at hand. Thus, Kolmogorov's superposition theory says nothing about the capability of a multilayer network or which method is best.

More general views have been reported. Le Cun^[31] and Lapedes and Farber^[32] demonstrated that monotone squashing functions can be used in the two hidden layers to approximate the functions. Fourier series expansion of a function was realized by a single-layer

network by Gallant and White^[33] with cosine functions in the units. Further related results using the sigmoidal or logistic units are demonstrated by Hecht-Nielsen.^[34] Hornik et al.^[29] presented a general approximation theory of one hidden layer network using arbitrary squashing functions such as cosine, logistic, hyperbolic tangent, etc., provided that sufficiently many hidden units are available. However, the number of hidden units is not considered to attain any given degree of approximation.^[29]

The number of hidden units obviously depends on the characteristics of the training data set, i.e., the underlying function to be estimated. It is intuitive to say that the more complicated functions to be trained, the more hidden units are required.

For the number of the hidden units Baum and Haussler^[35] limit the size of general networks (not necessarily the feed-forward multilayer perceptrons) by relating it to the size of the training sample. The authors analytically demonstrated that if the size of the sample is N , and we want to correctly classify future observations with at least a fraction $(1-\epsilon/2)$, then the size of the sample has a lower bound given by

$$N \geq 0 \left(\frac{W}{\epsilon} \log \frac{N}{\epsilon} \right),$$

where W is the number of the weights and N is the number of the nodes in a network. This, however, does not apply to the interesting feed-forward neural networks and the given bound is not useful for most applications.

There seems to be no rule of thumb for the number of hidden units.^[5] Finding the size of the hidden units can usually be performed by cross-validation or any other resampling methods. The usual starting value for the size is suggested to be about the average of the number of the input and output nodes.^[15] Failure in learning can be attributed to three main reasons^[29]:

- Inadequate learning;
- Inadequate number of hidden units; or
- The presence of a stochastic rather than a deterministic relation between input and target in the training data, i.e., noisy training data.

THE VLSI IMPLEMENTATION OF ALOPEX

Artificial neural networks have existed for many years, yet because of recent advances in technology they are again receiving much attention. Major obstacles in ANN, such as a lack of effective learning algorithms, have been overcome in recent years. Training algorithms have advanced considerably, and now VLSI

technology may provide the means for building superior networks. In hardware, the networks have much greater speed, allowing for much larger architectures.

The tremendous advancement in technology during the past decades, particularly in VLSI technology, renewed interest in ANNs. Hardware implementations of neural networks are motivated by a dramatic increase in speed over software models. The emergence of VLSI technology has and will continue to lead neural network research in new directions. The past few years saw a considerable advancement in VLSI. Chips are now smaller, faster, contain larger memories, and are becoming cheaper and more reliable to fabricate.

Neural network architectures are varied, with over 50 different types explored in the research.^[34] Hardware implementations can be electronic, optical, or electro-optical in design. A major problem in hardware realizations is often not a result of the network architecture, but the physical realities of the hardware design. Optical computers, while they may eventually become commercially available, suffer far greater problems than do VLSI circuits. Thus, for the immediate and near future, neural network hardware designs will be dominated by VLSI.

Much debate exists as to whether digital or analog VLSI design is better suited for neural network applications. In general, digital designs are easier to implement and better understood. In digital designs, computational accuracy is only limited by the chosen word length. Although analog VLSI circuits are less accurate, they are smaller, faster, and consume less power than digital circuits.^[36] For these reasons, applications that do not require great computational accuracy are dominated by analog designs.

Learning algorithms, especially backpropagation, require high precision and accuracy in modifying the weights of the network, which led some to believe that analog circuits are not well suited for implementing learning algorithms.^[37] Analog circuits can achieve high precision at the cost of increasing the circuit size. Analog circuits with high precision (8 bits) tend to be equally large compared with their digital counterparts.^[38] Thus, high-precision analog circuits lose their size advantage over digital circuits. Analog circuits are of greater interest in applications requiring only moderate precision.

Early studies demonstrate that analog circuits can realize learning algorithms, provided that the algorithm is tolerant to hardware imperfections such as low precision and inherent noise. Macq et al. present a fully analog implementation of a Kohonen map, one type of neural network, with on-chip learning.^[39] Because analog circuits have been proven capable of the computational accuracy necessary for weight modification, they should continue to be the choice of neural network research.

Analog circuits are far superior to digital circuits in size, speed, and power consumption, and these areas

constrain most neural network applications. To achieve greater network performance, the size of the network must be increased. The ability to implement larger, faster networks is the major motivation for hardware implementation, and analog circuits are superior in these areas. Power consumption is also a major concern as networks become larger.^[40] As the number of transistors per chip increases, power consumption becomes a major limitation. Analog circuits dissipate less power than digital circuits, thus permitting larger implementations.

Beside its universality to a wide variety of optimization procedures, the nature of the ALOPEX algorithm makes it suitable for VLSI implementation. The ALOPEX is a biologically influenced optimization procedure that uses a single-value global response feedback to guide weight movements toward their optimum. This single-value feedback, as opposed to the extensive error propagation schemes of other neural network training algorithms, makes ALOPEX suitable for fast VLSI implementation.

Recently, a digital VLSI approach to implementing the ALOPEX algorithm was undertaken by Pandya et al.^[41] Results of their study indicated that ALOPEX could be implemented using a single-instruction multiple-data (SIMD) architecture. A simulation of the design was carried out in software and good convergence for a 4×4 processor array was demonstrated.

The importance of VLSI to neural networks has been demonstrated. For neural networks to achieve greater abilities, larger and faster networks must be built. In addition to size and speed advantages, other factors, including cost and reliability, make VLSI implementations the current trend in neural network research. The design of a fast analog optimization algorithm, ALOPEX, is discussed below.

Let us assume that we have an array of 64 pixels that we call $I_i(n)$, where n represents the iteration. The additive gaussian white noise is denoted by $r_i(n)$ and $R_j(n)$ is the response (or cost function) of the j th template at iteration n .

Let us assume that there are 16 templates to choose from, each with 64 pixels. The ALOPEX process is run on each of them with the objective being to recognize (converge to) an input pattern. As a result of the iterative behavior, if allowed to run long enough ALOPEX will eventually converge to each of the templates. However a "match" can be found by choosing the template that took the least amount of time to converge.

By convergence we mean finding either the global maximum or the minimum of the response function. This response function can be calculated many different ways, depending on the application. To allow this chip to be general enough to handle many applications, the response is computed off the chip. A Programmable Read Only Memory (PROM) is used to compute

the response based on the error between the input, $I_i(n)$, and the template. The PROM enables the response function to be changed to meet the needs of the application.

Although the chip design is limited to only 64 ALOPEX subunits, the parallel nature of ALOPEX enables many chips to be wired together for larger applications. Parallel implementations are made easy because each subunit receives a single global response feedback, which governs its behavior. Backpropagation, on the other hand, requires dense interconnections and communication between each node. This flexibility is a tremendous advantage when it comes to hardwired implementations.

Originally, the ALOPEX chip was designed using digital VLSI techniques. Digital circuitry was chosen over analog because it is easier to test and design. Floating point arithmetic was used to insure a high degree of accuracy. The digital design consisted of shift registers, floating point adders, and floating point multipliers. However, after having done much work toward the digital design it was abandoned in favor of an analog design. The performance of the digital design was estimated and was much slower than that of an analog design. The chip area of the digital design was much larger than that of an analog design would be. Also, the ALOPEX algorithm would be tolerant of analog imperfections because of its stochastic nature. For these reasons, it seemed clear that a larger, faster network could be designed with analog circuitry.

The analog design required components similar to the digital design to implement the algorithm. The main requirements were an adder, a multiplier, a difference amplifier, a sample and hold mechanism, and a multiplexing scheme. These cells each perform a specific function and are wired together in a way that implements the ALOPEX process.

The chip is organized into 64 ALOPEX subunits, one for each pixel in the input image. They are stacked vertically, wiring by abutment. Each subunit is composed of smaller components that are wired together horizontally and contains the following cells: a group selector, demultiplexor, follower aggregator, multiplier, transconductance amplifier, multiplexor, and another group selector.

The gaussian white noise required for the ALOPEX process is added to the input before it reaches the chip. This will allow precise control of the noise, which is very important in controlling the stability of the algorithm. If there is too much noise, the system will not converge. If there is too little noise, the system will get stuck in local minima of the cost function. By controlling the noise during execution, using a method similar to simulated annealing^[19] where the noise decays with time, the convergence time can be improved.^[28] By having direct control of the added noise, the component and

functional testing can be performed with no noise added, greatly simplifying the testing.

The addition, multiplication, and subtraction required by the ALOPEX algorithm are performed by the follower aggregator, the Gilbert multiplier,^[36] and the transconductance amplifier, respectively. The follower aggregation circuit computes the weighted average of its inputs. By weighing the inputs equally, the circuit computes the average of the two inputs. The average was chosen instead of the sum because the circuit is more robust, in that the output never has to exceed the supply voltage. A straight summer is more difficult to design because voltages greater than the supply voltage could be required. The output of the follower aggregator is sent to the multiplier, where a C-switch acts as a sample and hold, to store the value of the previous iteration. The difference between these signals is one input to the multiplier. The previous two responses, calculated off chip, are the other two inputs. The output of the multiplier is controlled by the control signal γ . The error signal is computed by a transconductance amplifier.

In designing the chip, much effort was made in making it controllable and testable, while making the chip general enough that it could be used in a wide variety of applications. This is why the gaussian white noise is added off chip and also why the error signal is taken off chip for the computation of the response. This not only allows the response function to be changed to meet the requirements of the specific application, but also provides the operator with accessible test points.

Although backpropagation is the most widely used software tool for training neural networks, it is less suitable for VLSI hardware implementation than ALOPEX for many reasons. Whereas backpropagation converges quickly as a result of its gradient descent method, it can often get stuck in local extrema. The ALOPEX tends to avoid local extrema by incorporating the random noise component at the expense of slightly longer convergence times.

The major differences arise when hardware implementation is discussed. Backpropagation is computationally taxing because of the error computation required for each node in the network. Each error is a function of many parameters (i.e., all the weights of the following layer). In hardware, very complex interconnections between all nodes are required to compute this error.

The ALOPEX is ideal for VLSI implementation for a couple of reasons. First, the algorithm is tolerant to small amounts of noise; in fact, noise is incorporated to help convergence. Second, all parameters change based on their local history and a single-value global response feedback. This single-value feedback is much simpler to implement than the error propagation used in backpropagation.

NEUROMORPHIC MODELS

Since the era of the vacuum tube, a multitude of neuronal models composed of discrete components and off-the-shelf Integrated Circuits (ICs) have been published. Similar efforts in custom VLSI, however, are far fewer in number. A good introduction to a number of neuronal attributes was presented by Linares-Barranco et al.^[42] Complementary Metal Oxide Semiconductor (CMOS)-compatible circuits for approximating a number of mathematical models of cell behavior are described. In its simplest form, this model represents the cell membrane potential in the axon hillock as nothing more than a linear combination of an arbitrary number, n , of dendritic inputs, X , each of which is weighted by a unique multiplier, W , summed, and processed by a non-linear range-limiting operator, f . The mathematical equation for this relationship is

$$Y_k = f \left\{ \sum_{i=1}^n W_i X_i \right\} = f\{S_k\}, \quad (24)$$

This relationship is realized in a CMOS circuit. This circuit is totally static and makes no provision for time courses of changes in input or output signals or intracellular relationships. An operational transconductance amplifier (OTA), as described by Wolpert and Micheli-Tzanakou,^[43] is used in lieu of operational amplifiers for this and most other VLSI neural network applications. Highly compatible with CMOS circuit technology, it is structurally simple and compact, realizable with only nine transistors, and provides reasonable performance. The only consideration it warrants is that its transfer function is a transconductance. As such, operations performed on its output signals must be oriented to its current, rather than its voltage. When driving high load impedances, as is usually the case with CMOS circuitry, this is only a minor inconvenience, necessitating buffering for lower load impedances. In fact, under some circumstances, such as when algebraic summation is being performed, a current output may actually be an advantage, allowing output nodes to be simply tied together.

The non-linear range-limiting operator, f , mentioned earlier, is necessitated by the observation that, for a given biological neuron, there are limits on the strength of the electrochemical gradients the cell's ionic pumps can generate. This imposes limits on how positive and negative cell membrane potential may go. Because a neuron may receive inputs from many other neurons, there is no such limit on the aggregate input voltage applied. As a result, an *activation function*, a non-linearity of the relationship between aggregate input potential and output potential of a neuron, must be imposed. This is typically done in one of three ways: the binary hard-limiter, which assumes one of only two

possible states, active or inactive; the linear-graded threshold, which assumes a linear continuum of active states between its minimal and maximal values; and the sigmoid, which assumes a sigmoidal distribution of values between its negative minimal and positive maximal output values.

Which type of activation function is employed depends on the type of artificial neuron and network in which it is implemented. In networks where cell outputs are all-or-none, such as the McCulloch and Pitts models,^[44] the binary threshold model is used. In networks where neurons are theorized to have variable output levels applied to distinctly designated excitatory and inhibitory inputs, such as Hopfield networks,^[24] the linear threshold model is used. In networks where a synaptic connection must be both excitatory and inhibitory, depending on the level of activity, the sigmoid threshold is used. In either of the latter two activation functions, the slope of the overall characteristic can be varied to suit the sensitivity of the cell in question.

Another well-developed implementation of individual artificial nerve cells is that by Wolpert and Micheli-Tzanakou.^[43,45] Whereas most neuromorphic models are based on the Hodgkin–Huxley equations, this one uses a sequencer to synthesize the action potential in three distinct phases. It also employs a different formulation for cell membrane and threshold potentials known as an integrate-and-fire model, presented and implemented in discrete components by French and Stein in 1970.^[46] It makes use of the aforementioned leaky integrator and provides off-chip control over the response and persistence of stimuli assimilated into the membrane potential. The model affords similar controls over the resting level and time constant of the cell threshold potential and allows refraction to be recreated. This organization also affords control over the shape, resting level, and duration of the action potential and produces a Transistor-Transistor Logic (TTL)-compatible pulse in parallel with the action potential. These controls, all of which are continuously and precisely adjustable, make this model ideal for replicating the behavior of a wide variety of individual nerve cells, and it has been successfully applied as such.

The Wolpert and Micheli-Tzanakou model is organized around three critical nodes, the somatic potential, the axonal potential, and the threshold potential. Each of these nodes is biased off-chip with an R-C network so that its resting level and time constant are independently and continuously controllable. Stimuli to the cell are buffered and standardized by truncation into 10- μ sec impulses. Synaptic weight inputs on the excitatory and inhibitory pathways allow this value to be increased or decreased from off-chip. The impulses are then applied to a somatic potential by a push–pull Metal-Oxide-Semiconductor Field-Effect Transistor (MOSFET) stage and compared with threshold potential by an OTA

acting as a conventional voltage comparator. When threshold is exceeded, an action potential is synthesized and outputted. This waveform is then binarized and buffered to form a binary-compatible output pulse. At the same time, threshold is elevated to form the refractory period. The circuit consists of approximately 130 transistors plus a few on-chip and discrete resistors and capacitors and was implemented in a conventional CMOS technology, requiring a single-ended DC supply of 4–10 V DC and occupying 0.6 mm² of chip area.

With its critical nodes bonded out off-chip, Wolpert and Micheli-Tzanakou's neuromime rate of operation may be accelerated from a biologically compatible time frame over several orders of magnitude. This model was first implemented in 1986^[43] and was intended as a flexible and accurate esthetic, rather than a mathematical model of cell behavior. Since then, it has been used to successfully recreate a number of networks from well-documented biological sources. Waveforms obtained in these recreations have demonstrated a striking similarity to intracellular recordings taken from their biological counterparts. It has also been successfully applied to problems in robotics and rehabilitation.

Neurological Process Modeling

Lateral inhibition is the process in which a cell containing some level of information encoded as its output level acts to inhibit and is inhibited by a similar adjoining cell. For many years, this process has been observed with striking regularity in both 1- and 2-D arrays of sensory receptors in a variety of systems and a variety of organisms. In numerous morphological, mathematical, and circuit studies, it has been identified as a key image preprocessing step that optimizes a sensory image to facilitate fast and accurate recognition in subsequent operations. Lateral inhibition accomplishes this by amplifying differences, enhancing image contrast, lending definition to its outward shape, and isolating the image from its background. Whereas a digital computer would accomplish this process one pixel at a time, biological systems manage it in a manner that is both immediate and simultaneous.

Laterally inhibited behavior has been observed in pairs of cells implemented in hardware and software models by many researchers, but in dedicated VLSI by only a few. Among them, Nabet and Pinter of Drexel University and Darling of the University of Washington have extensively studied the stability and effectiveness of both pairs and linear strings of mutually inhibiting cells in CMOS VLSI and obtained results that correlate well with biological data.^[47] This line of work has been explored in two dimensions in another

series of VLSI-based models by Wolpert and Micheli-Tzanakou.^[48] Arrays of mutually inhibiting cells that inhibit via continuously active connections and cells that inhibit by dynamic or strobed controls both offered stable and variable control over the degree of inhibition. Arrays of hexagonally interconnected cells were more stable than the square array, which tended to “checkerboard” when significant levels of inhibition were attempted. Feedback inhibition, where one array is used to store both the initial and the inhibited images, was as effective, but less convenient to access than feed-forward inhibition, where separate input and inhibited images are maintained.

Characterization of lateral inhibition in the context of a more specific biological model has been pursued in another noteworthy effort by Andreou et al.^[49] Multiple facets of cell–cell interactions, including both mutual inhibition and leakage of information between adjoining cells, were implemented in VLSI as a model of early visual processing in the mammalian retina.^[49] There, adjacent cells on the photoreceptor layer intercommunicate through gap junctions, where their cell membrane potentials couple through a resistive path. Simultaneously, optical information from the photoreceptor cells is downloaded to corresponding cells of the horizontal layer, which have mutually inhibitory connections. One-dimensional arrays, and, subsequently, 2-D models of these relationships were implemented in analog VLSI and tested. Although little numerical data were published from these arrays, the 2-D array produced a number of optical effects associated with the human visual system, including Mach bands, simultaneous contrast enhancement, and the Herman–Herring illusion, all of which are indicative of the real-time image processing known to occur in the mammalian retina.

Finally, the definitive VLSI implementation of a 2-D array is the well-known silicon retina devised by Mead and described in his text, “Analog VLSI and Neural Systems.”^[50] Mead presents a comprehensive treasury of analog VLSI circuits for a variety of mathematical operations necessary to implement neural networks in VLSI. The book then goes on to discuss several applications of analog ANNs, culminating in an auditory model of the cochlea and a visual model of the retina.

Bioactive Glass

Marivalda M. Pereira

Larry L. Hench

Department of Materials, Imperial College London, London, United Kingdom

B

INTRODUCTION

Bioactive glasses are glasses designed to induce a specific biological activity; in most cases the desired biological activity is one that will result in a strong bonding to bone. The concept of a bioactive material capable of bone bonding was originally suggested by Larry Hench in the early 1970s. Since then, several glass compositions have been studied, tissue bonding mechanisms proposed, and clinical applications developed.^[1–3] The bone bonding mechanism includes a series of complex physicochemical reactions on the surface of the implanted material and the formation of a biologically active calcium phosphate layer. The surface reactions lead to the biochemical adsorption of growth factors and to a sequence of cellular events that lead to formation of new bone. The carbonated hydroxyapatite layer that forms is structurally and chemically equivalent to the mineral phase of bone, and the interfacial bonding is generally attributed to its formation.^[2,3] The resulting bonding exhibits high strength, equivalent to or even surpassing that of either bone or the implanted glass.

The bioactivity of glasses was initially observed for silicate glasses based on the system $\text{SiO}_2\text{--CaO--Na}_2\text{O--P}_2\text{O}_5$.^[4] Bioglass[®] is a trade name given to a series of such glass compositions. Other bioactive glass compositions, as well as other bioactive materials such as glass ceramics and calcium phosphate-based ceramics (referred to generally as bioactive ceramics), have also been developed.^[1–3] Among the bioactive ceramics, bioactive glasses have the highest levels of bioactivity based on their rates of reaction and bone bonding.

The following sections describe the structure and processing of bioactive glasses. The bioactivity mechanism and the effect of composition and structure on the bioactivity are discussed, and the mechanical performance of these materials and their clinical applications are briefly treated. Finally, the recent development of bioactive glass scaffolds for tissue engineering applications is described.

SYNTHESIS AND STRUCTURE OF BIOACTIVE GLASSES

At the atomic level, the absence of periodicity in the material structure is what distinguishes glasses from crystalline ceramics. The nonorganized tridimensional network of silicate glasses is based on the silica structure, i.e., silica tetrahedrons (silicon atoms surrounded by four oxygen atoms) bonded by two oxygen atoms. Alkaline and alkaline-earth atoms such as Na, K, Ca, and Mg occupy random sites in the silica network, modifying that structure and creating nonbridging oxygen atoms. Other atoms, such as P and Al, may be present as part of the network structure.

Glasses are normally prepared by cooling a mixture of raw materials from the liquid state.^[2] The cooling rate is important, because slow cooling rates may allow atomic arrangement that leads to crystallization of the material. However, silicate-based melted mixtures form a vitreous phase at normal cooling rates. The raw materials normally used are high-purity silica, calcium and sodium carbonate, and phosphorus oxide. For introduction of other elements such as Mg, Al, Zr, and others, into the glass composition, other oxides or salts are used. The melting temperature of silicate glasses is in the range of 1300–1400°C. Monolithic forms are produced by casting the melt in appropriate molds, whereas powder or granules are produced by rapid-cooling the melt in a liquid, such as acetone, to produce a coarse powder called a frit, followed by grinding and size-screening to a specific particle size range.

An alternative process used for bioactive glass production is the sol-gel method.^[2,5] This method leads to the formation of a highly microporous material with high surface area. The sol-gel route is based on the controlled hydrolysis and condensation of metal alkoxides to form a suspension of colloidal particles (sol), which upon polycondensation forms an interconnected network structure, the gel. Heat treatment stages (aging, drying, and stabilization) are then conducted, leading to the final glass structure. Precursors used to form the silica network of the gel-glasses are Si(OR)_4 ,

where R is normally CH_3 or C_2H_5 . Other metal atoms, such as Ca, P, Ti, and others, can be introduced into the structure as metal alkoxides or salts.

BIOACTIVITY

The search for materials adequate for use in the human body (biomaterials) was initially based on the concept of bioinertness, its principle being the fact that the material would not cause any reaction of the surrounding tissues. This concept has been changed, however, due to evidences that every material causes a certain tissue response, even a minimum one. The different tissue responses induced by a biocompatible material may be divided in three ways.^[2,3]

1. The material is biologically inert (or almost inert). It does not present significant chemical changes in the physiological environment, and a fibrous capsule of variable thickness forms around the implant. Examples of bioinert materials are aluminum oxide, surgical metals and alloys such as titanium and stainless steel, polymers such as poly(methyl methacrylate), polyethylene, and silicone, among others.
2. The material is biologically active. It presents a controlled reactivity and induces a specific biological response that leads to the formation of a continuous interface between the implanted material and tissue. Tissue bonding occurs. Bioactive glasses and calcium phosphate ceramics are examples.
3. The material is biodegradable or bioresorbable. It dissolves or is decomposed, and is substituted by surrounding tissue. The degradation mechanism is gradual and can be mediated by specific biological activity. Examples are polymers such as poly(lactic acid), tricalcium phosphate, and as we will see, some compositions of bioactive glasses.

Factors such as chemical composition, phase composition, pore structure, particle size, implantation site, animal species, and others affect the tissue response.

Based on the classification above, bioactivity can be defined as *the ability of the material to induce the formation of an interfacial bonding between the implant and living tissues, without the formation of a fibrous capsule separating the biomaterial and the tissue*. In the case of the bioactive glasses, various in vitro and in vivo studies show that a series of interfacial reactions occur that lead to the formation of a carbonated hydroxyapatite layer (HCA) on the glass surface responsible for bone bonding. Five reaction stages are identified:^[3]

1. Ion exchange: $\text{Si-O-Na}^+ + \text{H}^+ + \text{OH}^- \rightarrow \text{Si-OH} + \text{Na}^+ + \text{OH}^-$.

2. Loss of soluble $\text{Si}(\text{OH})_4$ and formation of Si-OH (silanols): $\text{Si-O-Si} + \text{H}_2\text{O} \rightarrow \text{Si-OH} + \text{OH-Si}$.
3. Condensation and repolymerization of a SiO_2 -rich layer on the surface.
4. Migration of Ca^{2+} and PO_4 groups to the surface, forming an amorphous $\text{CaO-P}_2\text{O}_5$ film.
5. Crystallization of the amorphous $\text{CaO-P}_2\text{O}_5$ film by incorporation of OH^- , CO_3 .

The surface reactions lead to the biochemical adsorption of growth factors (stage 6) and to the synchronized sequence of cellular events that leads to formation of new bone (stages 7–12).

6. Adsorption of biological moieties and growth factors on the HCA layer.
7. Action of macrophages.
8. Attachment of stem cells.
9. Differentiation of stem cells.
10. Generation of matrix.
11. Crystallization of matrix.
12. Proliferation and growth of bone.

The first five reaction stages occur very rapidly on the surface of most bioactive glasses because of rapid surface reactions. The formation of the silica-rich gel layer provides a favorable substrate for the rapid nucleation and growth of the biologically equivalent HCA layer. Surface compositional profiles resulting from stage 1 through stage 5 reactions have been measured for 45S5 bioactive glasses (a glass with a composition of 45% SiO_2 , 24.5% Na_2O , 24.5% CaO , and 6% P_2O_5) using Auger electron spectroscopy (AES) combined with argon-ion milling.^[6] The results (Fig. 1) show that a calcium and phosphorus-rich reaction layer, heterogeneously nucleated and crystallized from the silica-gel layer formed on the glass

Fig. 1 Chemical composition of the bilayer film formed on 45S5 bioactive glass after 1 hour of implantation in rat bone.

Fig. 2 Rates of bond formation with bone for implant materials with different bioactivity.

surface, has developed after only one hour in vivo. With time, the interfacial bonding zone between living and nonliving material continues to grow by incorporating calcium and phosphorus ions from body fluids. The final result is a gradient in composition that extends over several hundred micrometers, similar in dimension to the bonding zone that occurs naturally at bone interfaces.^[4,7]

Differences observed in the behavior of glasses with different compositions are related to the differences in the rate of formation of this HCA layer, as will be discussed in the next section. In the case of other bioactive ceramics, such as glass-ceramics or calcium phosphate ceramics, an HCA layer also forms in the physiological environment, both in vitro and in vivo.^[1,8,9] However, the rate of formation of the HCA layer is slower than the rate for bioactive glasses. The reactivity of the material and the rate of HCA formation are closely related to the formation of an interface between the material and bone tissue in vivo.^[11] The interfacial bone tissue formation time for bioceramics with different rates of reactivity is shown in Fig. 2. The level of bioactivity of the material can be related to the time for more than 50% of the interface to be bonded ($t_{0.5bb}$), and an index of bioactivity can be defined as $I_B = 100/t_{0.5bb}$. The bioactivity varies from the most bioactive material—the bioactive glass 45S5 with a bioactivity index of $I_B = 12$ —to almost inert ceramics with an index of $I_B = 0$.

EFFECT OF COMPOSITION ON BIOACTIVITY

The basic components of most bioactive glasses are SiO_2 , Na_2O , CaO , and P_2O_5 in specific proportions. Bonding to bone has been demonstrated for a certain compositional range of these glasses.^[1,4,10] Three important compositional features distinguish them from traditional soda–lime–silica glasses: <60 mol% SiO_2 , high Na_2O and CaO content, and a high $\text{CaO}:\text{P}_2\text{O}_5$

ratio. These compositional features make the surface highly reactive when exposed to an aqueous medium, such as body fluids. Figure 3 illustrates the compositional dependence (in weight percent) of bone bonding and soft tissue bonding for the $\text{Na}_2\text{O}-\text{CaO}-\text{P}_2\text{O}_5-\text{SiO}_2$ glasses.^[11] All glasses in Fig. 3 contain a constant 6 wt% of P_2O_5 . Compositions in the middle of the diagram (region A) form a bond with bone. Consequently, region A defines the bioactive bone-bonding boundary. When the concentration of SiO_2 in the glass network exceeds 55%, the rates of reaction decrease, and bonding to bone is very slow. At a concentration of 60% SiO_2 or higher, the rates of reaction are sufficiently slow that the material is biologically inert. Silicate glasses within region B behave as almost inert materials and elicit formation of a fibrous capsule at the implant-tissue interface. Glasses within region C are resorbable and disappear within 10–30 days of implantation. Glasses within region D are not technically practical and, therefore, have not been tested as implants.

Additional compositions of bioactive glasses based on the system $\text{Na}_2\text{O}-\text{K}_2\text{O}-\text{MgO}-\text{CaO}-\text{B}_2\text{O}_3-\text{P}_2\text{O}_5-\text{SiO}_2$ have been developed at Abo Akademi and the University of Turku, Finland, and the compositional dependence for bioactivity has been largely studied.^[11–13] Bioactivity occurs only within certain compositional limits and very specific ratios of oxides in this system. For the glasses containing <59 mol % SiO_2 , the silica-rich layer and the calcium phosphate layer were also observed in this system. In-vivo experiments showed that glasses in the investigated system are bioactive when they contain 14–30 mol % alkali oxides, 14–30 mol % alkaline earth oxides, and <59 mol % SiO_2 . Glasses containing potassium and magnesium bonded to bone in a way similar to that of bioactive glasses of the original system. Substitutions in the 45S5 formula of 5–15 wt% B_2O_3 for SiO_2 , or 12.5 wt% CaF_2 for CaO , or crystallizing the glass compositions to form glass-ceramics have little effect on the ability of

Fig. 3 Composition dependence (in wt%) of bone bonding and soft tissue bonding of bioactive $\text{Na}_2\text{O}-\text{CaO}-\text{SiO}_2$ glasses with a constant 6% P_2O_5 .

the material to form a bone bond. However, addition of as little as 3 wt% Al_2O_3 to the 45S5 formula prevents bonding. Glasses with substantially larger amounts of P_2O_5 do not bond to bone.

A layer of biologically active HCA must form for a bond with tissues to occur. This is the common characteristic of all the known bioactive implant materials. It is the rate of HCA formation (stage 4) and the time for onset of crystallization (stage 5) that vary greatly. When the rate becomes excessively slow, no bond forms, and the material is no longer bioactive. Although composition has a strong influence on bioactivity, the rate of HCA layer formation and bone formation depends not only on the glass composition but also on other aspects, such as particle size, medium composition and volume, adsorption of proteins, and the implantation site.^[14,15]

The aforementioned compositional dependence was defined for dense glasses produced by the conventional melt process. When the sol-gel method is used, the compositional bioactivity range is increased above 60%.^[6,16] In fact, bioactivity is observed even for pure SiO_2 gel-glasses as well as for other sol-gel-derived oxides.^[17] The high bioactivity of the sol-gel glasses is attributed to their high surface areas (up to $600\text{ m}^2/\text{g}$) and the large concentration of M-OH groups on the highly porous glass surface—both features associated with the sol-gel technique. These surface characteristics increase the rate of nucleation and growth of the HCA layer on the surface of the material. The bioactive gel-glasses also have another very important characteristic, which is their higher degradation rate compared to dense glasses.^[18] Therefore, depending on composition and physical characteristics such as particle size and pore structure, bioactive glasses may be considered biodegradable materials.

TISSUE ATTACHMENT AND INTERFACIAL STRENGTH

The formation of a stable interface between an implant material and the living host tissue is crucial to the success of an implant device. The nature and thickness of the tissue-implant interface and the consequent mechanism of tissue attachment are directly related to the type of tissue response at the implant interface.^[3,19] The different means of achieving attachment of prostheses to the musculoskeletal system are categorized as: 1) morphological fixation, achieved by mechanical interlocking on the surface irregularities, cementing the device into the tissue, or press-fitting into a defect; 2) biological fixation, achieved by tissue ingrowth into porous implants or surfaces; and 3) bioactive fixation, in which the material attaches directly by bonding with the tissue.

The relative level of reactivity of an implant influences the thickness of the interfacial zone, or layer, between the material and the tissue. Analysis of the failure of implant materials during the past 20 years generally shows failure originating from the bio-material-tissue interface.^[3] When biomaterials are almost inert and the interface is not chemically or biologically bonded, there is relative movement, causing progressive development of a nonadherent fibrous capsule in both soft and hard tissues. Movement at the biomaterial-tissue interface eventually leads to deterioration in function of the implant or of the tissue at the interface, or both. The thickness of the nonadherent capsule varies greatly, depending upon both the material and the extent of relative motion. The fibrous capsule in almost-inert materials such as pure titanium can be very thin when the implant achieves a tight mechanical fit. If relative movement occurs at the tissue-implant interface, however, the fibrous capsule can become several hundred micrometers thick, loosening the implant and generally leading to clinical failure.

The use of bioactive materials provides a solution to the problem of interfacial attachment. Bioactive materials form an interfacial bond with adjacent tissue, but the time dependence of bonding and the mechanism of bonding differ for the various materials, as discussed earlier. The thickness of the bonding zone and the strength of the bond depend on the material reactivity, and they appear to be correlated.^[3]

The failure strength of a bioactively fixed bond appears to be a nonlinear function of the bonding rate of the implant.^[1,3] Interfacial strength appears to be inversely dependent on the thickness of the bonding zone. For example, 45S5 Bioglass[®] with a very high bonding rate develops a gel-bonding layer of $100\ \mu\text{m}$ thickness that has a relatively low shear strength. In contrast, A/W glass-ceramic, with an intermediate rate of bonding, has an interface of $10\text{--}20\ \mu\text{m}$ and a very high resistance to shear.^[1,20] Therefore, interfacial strength is time-dependent and is a function of morphological factors, such as the change in interfacial area with time, the progressive mineralization of the interfacial tissues, and the resulting increase in elastic modulus of the interfacial bond. It is also a function of shear strength per unit of bonded area and the density and quality of bone bonded to the interface.

SOFT TISSUE BONDING

Although bioactivity is defined as the bonding of tissue to an implant, most of the data and evidence regarding bioactivity have come from bone implants, as shown in the previous discussion. In fact, early studies showed

that bioactive glasses did not bond to soft tissue. It was shown later, however, that a fibrous capsule that formed around bioactive glass implants in muscle was an artifact of the experiment caused by continuous micromotion at the implant-tissue interface.^[1,21] When the implant-tissue interface was immobilized, Wilson et al.^[21] proved that collagen fibers of the soft tissue became embedded and bonded within the growing silica-rich and HCA layers on the 45S5 bioactive glass. Soft tissue bonding was also observed in subcutaneous implants when they were sufficiently immobile.

There are situations in which both soft and hard tissue bonding are desirable, such as in maxillofacial implants and the treatment of periodontal disease. The use of 45S5 bioactive glass powder, with a large I_B value, showed attachment to both bone and soft connective tissue in the treatment of periodontal defects.^[1] Use of the highly bioactive material led to a more rapid and complete repair than was observed when the lower-bioactivity material hydroxyapatite was used, and it also resulted in reattachment of the periodontal ligament with little or no epithelial downgrowth. Bioactive implants with intermediate I_B value do not develop a stable soft tissue bond. Instead, a fibrous interface progressively mineralizes to form bone. Consequently, there appears to be a critical $isoI_B$ boundary beyond which bioactivity is restricted to stable bone bonding. Bioactivity inside the critical $isoI_B$ boundary includes both stable bone bonding and soft tissue bonding, depending on the progenitor stem cells in contact with the implant. Materials within the critical $isoI_B$ boundary have been designated to exhibit class A bioactivity.^[3] An important feature of class A bioactive materials is that they are osteoproliferative as well as osteoconductive. In contrast, class B bioactive materials exhibit only osteoconductivity, defined as the characteristic of bone growth and bonding along a surface. Osteoproliferation occurs when bone proliferates on the particulate surfaces of a mass as a result of enhanced osteoblast activity. Enhanced proliferation and differentiation of osteoprogenitor cells, stimulated by slow resorption of the class A bioactive particles, are responsible for osteoproliferation.

MECHANICAL PROPERTIES

Selected mechanical properties of bioactive glass 45S5 and, for comparison, the properties of bone and other bioactive ceramics are presented in Table 1.^[3] In general, bioactive ceramics present a large modulus of elasticity that determines their use as substitutes for hard tissue replacement. The elastic modulus value of most metals and inert bioceramics is much larger than that of bone. This mismatch of elastic modulus may affect the stress distribution and transfer to the host tissue. The elastic modulus of bioactive glasses is a close match to that of bone, but a low fracture toughness limits the use of bioactive glass implants to low-load-bearing applications or to compression loads. One of the primary restrictions is the uncertain lifetime under the complex stress states, slow crack growth, and cyclic fatigue that occur in many clinical applications. Therefore, current clinical applications of bioactive glasses are restricted to a few implant types or to particulate formulations used to fill spaces and improve the tissue repair processes, as will be presented in the next section.

One way to circumvent the limitation imposed by the mechanical properties of bioactive glasses is to combine them with other materials, improving mechanical behavior while still maintaining the bioactive characteristics of the surface. Two main approaches have been studied. The first approach is the use of bioactive ceramic coatings on metallic substrates, in which the bone-bonding ability of the coating is associated with the mechanical behavior of the substrate, particularly the higher strength and fracture toughness. This approach has been investigated mainly for calcium phosphate coatings.^[2,3] HA coatings can be obtained by different techniques, with plasma spray coating generally preferred. HA has been used clinically in load-bearing dental and orthopedic prostheses, and such coatings are used as an alternative to PMMA "bone cement" fixation of orthopedic devices. Bioactive glass coatings have also been investigated.^[2]

The other creative approach is to use bioactive particles or fibers as the reinforcing phase in polymer

Table 1 Mechanical properties of bioactive glasses and other bioactive ceramics

Property	Cortical bone	Cancellous bone	Bioactive glass 45S5	Glass ceramic A/W	Dense HA (> 99.2%)
Density (g/cm ³)	1.6–2.1		2.66	3.07	3.16
Hardness (HV)	100–230		460	680	600
Compressive strength (MPa)	50–150	2–12		1,080	500–1,000
Flexural strength (MPa)	7–30		42	215	115–200
Young modulus (GPa)	2–12	0.05–0.5	35	218	80–110
Fracture toughness, K_{IC} (MPa.m ^{1/2})				2.0	1.0

matrix composites. Properties equivalent to bone can be achieved by stiffening a compliant biocompatible synthetic polymer, such as polyethylene, with a higher-modulus ceramic second phase, such as bioactive glass or a calcium phosphate powder.^[3,22] The effect is to increase the Young's modulus, to decrease the strain to failure relative to that of the polymer phase, and to increase the fracture toughness relative to that of the ceramic phase. The development of bioactive composites is a research area with large potential. Biomaterials with engineered properties can be obtained through control of structure variables such as composition, type, size, and form of the components, and interface characteristics and properties.^[22,23]

CLINICAL APPLICATIONS

Bioactive glasses may be produced in various forms depending on the repair function they will serve. One of the most important clinical applications of bioactive glasses involves the particulate form that is implanted in an injured bone site. The particulate bioactive glass material has been used in a wide variety of clinical applications where bone grafting is needed to fill spaces or augment the natural repair process.^[1-3] One example is the treatment of periodontal (gum) disease, a clinical problem that affects tens of millions of people. Use of the bioactive glass material rapidly leads to new bone formation around the bioactive glass particles, by means of the reaction mechanisms summarized earlier. Because of the speed of formation of the new bone, the epithelial tissues are stopped from migrating down the tooth, a common problem if nothing is used to fill the space between the tooth and the repairing bone. The junction between the tooth and the periodontal membrane is stabilized by the use of bioactive glass particulate, and the tooth is saved. Similar procedures can be used to augment the jawbone when necessary to improve the stability of dental implants. Other orthopedic and maxillofacial applications that use bioactive glass particulate include repair of total hip and knee replacements that have required revision surgery, spinal fusion, and frontal sinus and calvarial bone defect obliteration, among others. Bioactive glass granules with varying composition and particle size range are currently available for clinical use.^[3,24,25]

Bioactive glasses can also be used as implants or prostheses to substitute for bone tissue. One difficulty surrounding this approach is that it is limited to applications involving no (or low) load bearing, due to the higher elastic modulus, low strength, and low fracture toughness of the material compared to the surrounding tissue. One such application is the use of bioactive glass implants to replace the small bones of the middle ear (ossicles) damaged by chronic infection,

a clinical problem called conductive hearing loss.^[26] Bioinert implants do not bond to the eardrum, and therefore they gradually erode through the tissue and are extruded through the eardrum within two to three years. In contrast, highly bioactive glasses form a bond with the collagen of the eardrum and also bond firmly to the remaining bone of the stapes footplate. They are thereby anchored on both ends, which prevents extrusion. Sound conduction is excellent, and there is no fibrous tissue growth to impair sound transmission. Moreover, there is no micromotion at the implant-tissue interface, so the implant remains stable and functions for the lifetime of the patient. This type of implant has been used successfully for more than 15 years.

Another application of bioactive glass implants, based upon bonding to both soft tissues and bone, preserves the jawbone of patients who have had their teeth extracted prior to being fitted with dentures.^[27] This type of implant, called an endosseous ridge maintenance implant (ERMI), is injection-molded in the shape of a cone, with several sizes available to match the sizes of roots of extracted teeth. X rays show that the implants are stable after many years in bone and have prevented resorption (wearing away) of bone under the dentures. Bioactive glass is also used as a bulk implant to repair damaged orbital floors and for other maxillofacial reconstruction surgeries.

BIOACTIVE GLASS SCAFFOLDS FOR TISSUE ENGINEERING

In the 1980s, emphasis in the field of biomaterials has shifted from bioinert to bioactive materials. However, the improved interfacial stability achieved with bioactive fixation did not improve implant survivability. Other problems related to the biomechanical mismatch of elastic moduli, production of wear debris, and maintenance of a stable blood supply still occur. In addition, all present-day implants lack two of the most critical characteristics of living tissues: the ability to self-repair and the ability to modify their structure and properties in response to environmental factors, such as mechanical load.

These observations and the growing need for long-surviving implants have led to a new shift in biomaterials research, in which the emphasis is on regeneration of tissues rather than on tissue replacement. There are now two biologically oriented approaches:^[28] 1) tissue regeneration, which involves the use of a scaffold that can be implanted into a defect to guide and stimulate tissue regrowth in situ (the scaffold should resorb as the tissue grows, leaving no trace of damage); and 2) tissue engineering, in which the scaffolds are seeded with cells in vitro to produce the basis

of a tissue before implantation. Cells could be extracted from a patient, seeded on a scaffold of the desired architecture, and the replacement tissue grown in the laboratory, ready for implantation.

Recent findings at Imperial College London, England, have established that there is genetic control of the cellular response to class A bioactive glass materials.^[29] Seven families of genes are upregulated when primary human osteoblasts are exposed to the ionic dissolution products of bioactive glasses. The enhanced gene expression occurs very rapidly, within 48 hours. The results indicate that the ionic dissolution products of Bioglass 45S5 may increase IGF-II availability in osteoblasts by inducing the transcription of the growth factor and its carrier protein, and also by regulating the dissociation of this factor from its binding protein. The unbound IGF-II is likely to be responsible for the increase in cell proliferation observed in the primary osteoblast cell cultures, and also in human clinical cases. Similar bioactive induction of the transcription of extracellular matrix components and their secretion and self-organization into a mineralized matrix is responsible for the rapid formation and growth of bone nodules and the differentiation of the mature osteocyte phenotype.

The findings cited in the preceding paragraph indicate that bioactive glass materials are a very interesting option for bone tissue regeneration and tissue engineering. Research has been conducted in this direction to develop scaffolds based on the bioactive glasses.^[30–33] One of the main criteria for a scaffold is that it comprises an interconnected network of pores with diameters in excess of 100 μm (macroporous materials) that allow tissue ingrowth, vascularization, and nutrient delivery. These characteristics have been attained in sol-gel-derived bioactive glass scaffolds developed by a foaming procedure.^[30,31] Foaming was directly achieved by vigorous agitation of the sol, with the aid of surfactants. The scaffolds can be produced with interconnected macropores that have porosities in the range of 60–90% and interconnected pore diameters of up to 500 μm . Figure 4 shows a scanned electron microscopy (SEM) micrograph of a bioactive glass foam

with a composition of 60% SiO_2 , 36% CaO , and 4% P_2O_5 .

Another scaffold material based on bioactive glass with the 45S5 composition was produced using a different processing route.^[32,33] Bioactive glass particles were mixed with a polymeric material, dry-pressed, and heat-treated to eliminate the polymer, leading to scaffolds with varying pore size and porosity depending on synthesis parameters. The porous bioactive glass substrates were capable of supporting the *in vitro* proliferation and maturation of osteoblastlike cells. *In vivo* studies using two tissue-engineered constructs were conducted: 1) osteoprogenitor cells that were seeded onto the scaffold prior to implantation (primary); or 2) those that were culture-expanded to form bonelike tissue on the scaffold prior to implantation (hybrid). The porous scaffolds were conditioned by immersion in simulated body fluid before cell culture. The amount of bone significantly increased for both groups over time as the bioactive ceramic gradually resorbed by 40% at 12 weeks. The authors concluded that porous, surface-modified bioactive glass is a promising scaffold material for tissue-engineered bone repair.

CONCLUSION

Bioactive glasses present a controlled reactivity and induce a specific biological response that leads to the formation of a continuous interface between the implanted material and tissue. The complex physicochemical reactions on the material surface lead to the formation of a biologically active carbonated hydroxylapatite layer, structurally and chemically equivalent to the mineral phase of bone. The reactivity of the material and the rate of HCA formation are closely related to the formation of an interface between the material and bone tissue *in vivo*. Bioactivity occurs only within certain compositional limits for glasses in the $\text{Na}_2\text{O}-\text{K}_2\text{O}-\text{CaO}-\text{MgO}-\text{P}_2\text{O}_5-\text{SiO}_2$ systems. These glasses may be produced by an alternative sol-gel method, in which case the compositional range of

Fig. 4 Optical and SEM micrographs of bioactive gel-glass foam.

bioactivity and the resorbability of the material increase. The sol-gel method and other methods can also be used to generate bioactive glass scaffolds, with high porosity and interconnected pore size above 100 μm . The more bioactive glasses, considered to be class A bioactive materials, form a continuous bonded interface with soft tissues as well as bone. Class A bioactive glasses are both osteopductive and osteoconductive. There is a genetic control of the cellular response to class A bioactive glass materials resulting from controlled release of critical concentrations of Si and Ca ions. All of these features indicate that bioactive glasses are an interesting option for bone tissue engineering. Bioactive glass scaffolds contribute high bioactivity, controlled resorbability, and the potential for the ionic dissolution products (Si and Ca) to control the cell cycle of the osteoblast progenitor cells, stimulating genes in the bone cells to differentiate and enhance bone regeneration.

Bioactive Materials and Scaffolds for Tissue Engineering

Qi-Zhi Chen

Aldo R. Boccaccini

Department of Materials, Imperial College London, London, United Kingdom

INTRODUCTION

Bioactive materials react with physiological fluids and form tenacious bonds to hard tissue through biological interdigitation of collagen fibers with the material surface layer. Thus, these biomaterials can be used to transfer loads to and from living bone. Prominent bioactive materials are inorganic, such as bioceramics, including selected compositions of silicate glasses and their derived glass–ceramics, as well as hydroxyapatite (HA) and related calcium phosphates. Like most ceramic materials, the major disadvantage of bioactive ceramics is their low fracture toughness (i.e., brittleness). They are thus often used in composites combined with polymers, both stable, e.g., poly(methyl methacrylate), and biodegradable, e.g., aliphatic polyesters. For tissue engineering applications, bioactive ceramics and the related bioactive composites are produced in highly porous 3-D structures known as tissue “scaffolds.” For bone tissue engineering, porosity of $\sim 90\%$ and pores of the order of $\sim 400\ \mu\text{m}$ are desirable, as well as high pore interconnectivity, to facilitate the attachment and proliferation of cells and the ingrowth of new tissues into the network, as well to enable mass transport of oxygen, nutrition, and waste products. Numerous methods to produce 3-D tissue scaffolds have been developed.^[1,2]

In this chapter, we describe first the key design factors of hard tissue engineering scaffolds, followed by an up-to-date review on bioactive materials. Then we focus on the state of the art in the field of fabrication technologies for bioactive and biodegradable scaffolds based on bioactive ceramics and related ceramic–polymer composites designed for bone tissue regeneration. The goal of this chapter is to allow readers to fully understand the advantages and disadvantages of various bioactive materials and scaffold processing technologies.

KEY DESIGN FEATURES OF TISSUE ENGINEERING SCAFFOLDS

An ideal scaffold for bone tissue regeneration must satisfy the following essential criteria determined by

both the chemistry of the material and the required morphology (pore structure):^[1,2]

1. Ability to deliver cells. The material should not only be biocompatible (i.e., non-toxic), but also foster cell attachment, differentiation, and proliferation.
2. Osteoconductivity. The material should encourage osteoconduction with the host bone. Osteoconductivity not only eliminates the formation of encapsulating tissue but also brings about a strong bond between the scaffold and host bone.
3. Biodegradability. The composition of the material, combined with the porous structure of the scaffold, should lead biodegradation in vivo at rates appropriate to tissue regeneration.
4. Mechanical properties. The mechanical strength of the scaffold, which is determined by both the properties of the biomaterial and the porous structure, should be sufficient to provide mechanical stability to constructs in load-bearing sites prior to the synthesis of new extracellular matrix by cells.

It is also equally important to meet requirements related to the fabrication technologies, as follows:

5. Porous structure. The scaffold should have an interconnected 3-D porous structure with porosity $>90\%$ and pore diameters in the range $300\text{--}500\ \mu\text{m}$ for cell penetration, tissue ingrowth and vascularization, and nutrient delivery.
6. Processability. The material should possess desired fabrication properties, e.g., the possibility of producing irregular shapes of 3-D scaffolds that match specific bone defects in individual patients.
7. Commercialization. The synthesis of the material and fabrication of the scaffold should be suitable to commercialization.

BIOACTIVE MATERIALS

In this section, the biocompatibility, bioactivity, biodegradability, and mechanical properties of various bioactive materials are reviewed. These properties

should be considered in the design of a tissue regeneration scaffold.

Calcium Phosphates

Because almost two thirds of the weight of bone is HA, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, it is logical to consider this bio-ceramic and related calcium phosphates (e.g., β - or tricalcium phosphate) the major components of scaffold materials for bone tissue engineering. Calcium phosphates have excellent biocompatibility as a result of their close chemical and crystal resemblance to bone mineral. They possess osteoconductive properties, as well as a remarkable ability to bind to bone through biological interdigitation of collagen fibers with calcium phosphate surface layers.^[3] Numerous *in vivo* and *in vitro* assessments have reported that calcium phosphates, regardless of their morphology (bulk, coating, powder, or porous structures) and which phases they are in (crystalline or amorphous), always support the attachment, growth, differentiation, and proliferation of relevant cells (such as osteoblasts and mesenchymal cells).

Typically, crystalline calcium phosphates have long degradation time *in vivo*, often of the order of years. Moreover, the dissolution rates of synthetic HA depend on the type and concentration of the buffered or unbuffered solutions, pH of the solution, degree of the saturation of the solution, solid/solution ratio, and composition and crystallinity of the HA. In the case of highly crystalline HA, the degree of micro- and macroporosity, defect structure, and amount and type of other phases present also have significant influence. Crystalline HA exhibits the slowest degradation rate compared with other calcium phosphates. The dissolution rate decreases in the following order: amorphous tricalcium phosphate > amorphous HA \gg all other crystalline calcium phosphates \gg crystalline HA.

The mechanical properties of synthetic calcium phosphates also vary significantly with their crystalli-

nity, grain size, porosity, and composition (e.g., calcium deficiency). In general, the mechanical strength of synthetic calcium phosphates decreases significantly with increasing content of amorphous phase, microporosity, and grain size. High crystallinity, low porosity, and small grain size tend to give higher stiffness, higher compressive and tensile strength, and greater fracture toughness. A comparison of the properties of HA and related calcium phosphates with those of cortical bone (Table 1) reveals that cortical bone has a reasonably good compressive strength, although lower than that of HA, and better tensile strength and significantly better fracture toughness than HA. The apatite crystals in bone tissue make it strong enough to tolerate compressive loading. The high tensile strength and fracture toughness of bone are attributed to the tough and flexible collagen fibers. Hence, calcium phosphates alone cannot be used for load-bearing scaffolds despite their good biocompatibility and osteoconductivity.

In summary, although the excellent biological performance of HA and related calcium phosphates has been well documented, the slow biodegradation of their crystalline phases and the low mechanical strength in their amorphous state limit their application in engineering of new bone tissue, especially at load-bearing sites.

Bioactive Silicate Glasses

As early as 1969, Hench and colleagues discovered that certain silicate glass compositions had excellent biocompatibility, as well as the ability of bone bonding.^[3] Through interfacial and cell-mediated reactions, bioactive glass develops a carbonated calcium phosphate surface layer that allows it to bond to host bone. This bone-bonding behavior (i.e., bioactivity) has been associated with the formation of a carbonated HA layer on the glass surface when implanted or in contact with biological fluids. Although many details of the

Table 1 Mechanical properties of solid bioactive materials and human cortical bone^[4]

Ceramics	Compressive strength (MPa)	Tensile (T) or bending (B) strength (MPa)	Elastic modulus (GPa)	Fracture toughness (MPa $\sqrt{\text{m}}$)
Hydroxyapatite	>400	~40 (T)	~100	~1.0
Other calcium phosphates	20–900	30–200 (T)	30–103	<1.0
45S5 Bioglass [®]	~500	42 (T)	35	0.5–1
Apatite–wollastonite (A–W)	1080	215 (B)	118	2.0
Parent glass of A–W	NA	72 (B)	NA	0.8
Bioverit [®] I	500	140–180 (B)	70–90	1.2–2.1
Cortical bone	130–180	50–151 (T)	12–18	6–8

bone-bonding mechanisms remain unknown at present, it is clearly recognized that for bonding with bone tissue to occur a layer of biologically active carbonated HA must form.^[3] This is in agreement with the fact that HA has a high capacity to bind the collagens of natural bone. Bioactivity is not an exclusive property of bioactive glasses. Hydroxyapatite and related calcium phosphates also demonstrate an excellent ability to bond to bone, as described above. The capability of a material to form a biological interface with the surrounding tissue is critical in eliminating scaffold loosening upon implantation (similar to orthopedic implants).

Bioactive glasses also support enzyme activity,^[3] enhance vascularization,^[5] foster osteoblast adhesion, growth, and differentiation, and induce the differentiation of mesenchymal cells into osteoblasts.^[6] An important finding is that the dissolution products from bioactive glasses exert a genetic control over the osteoblast cell cycle, affecting the rapid expression of genes that regulate osteogenesis and the production of growth factors.^[7] The above-mentioned advantages make bioactive glasses, in particular the composition 45S5 Bioglass,^{®[3]} the material of choice for several clinical applications, e.g., for treatment of periodontal diseases and as a bone filler material. Bioglass implants have also been used to replace damaged middle ear bone, restoring hearing to patients. More recently, bioactive glasses have gained attention as promising scaffold materials for tissue engineering.^[8]

The key advantage that makes bioactive glasses promising scaffold materials is the possibility of controlling their chemical composition and, thus, the rate of biodegradation. The structure and chemistry of glasses, in particular sol-gel derived glasses, can be tailored at a molecular level by varying either composition or thermal or environmental processing history. It is, in principle, possible to design glasses with degradation properties specific to a particular application of bone tissue engineering.

The primary disadvantages of bioactive glasses are their low mechanical strength and fracture toughness (Table 1). Hence, bioactive glasses on their own have limited applications in load-bearing situations. However, these materials can be used in combination with degradable biopolymers to form composite materials with tailored resorbability and bone repair capability, offering great potential for tissue engineering scaffold development.^[4]

Bioactive Glass–Ceramics

Glasses can be strengthened by the formation of a crystalline phase upon controlled heat treatment of the amorphous glass, forming glass–ceramics. Many

bioactive silicate glass–ceramics were developed over the years for the repair of damaged bone. Among them, apatite–wollastonite (A–W), Ceravital[®], and Bioverit[®] glass–ceramics have long been investigated, as reviewed by Hench and Wilson.^[9] However, these silicate glass–ceramics have not been considered extensively for tissue engineering scaffolds. Recently, a 45S5 Bioglass-derived glass–ceramic was developed specifically for the fabrication of bioactive and biodegradable scaffolds.^[8]

Crystallization of bioactive glasses tends to decrease the level of bioactivity and can even turn a bioactive glass into an inert material. This is one of the disadvantages that has limited the application of melt-derived bioactive glasses as scaffold materials, because full crystallization usually occurs prior to significant densification during heat treatment (i.e., sintering) of glass powders to form the scaffold structure. Extensive sintering is necessary to densify the struts of a (foam-like) scaffold, which would otherwise be made up of loosely packed particles and thus would be too fragile to handle. It is apparent that mechanical stability and biodegradability are difficult to achieve simultaneously in a single scaffold. Mechanically stable, usually crystalline, materials are generally bioinert, whereas degradable materials, which are usually amorphous or weakly crystalline, tend to be weak. This issue is not only relevant in bioactive silicate glasses, but also in HA and associated calcium phosphates, as discussed in the previous section.

A recent investigation at Imperial College London^[8] addressed the problem, focusing on sintered 45S5 Bioglass foam-like scaffolds. It was demonstrated that the mechanically strong crystalline phase $\text{Na}_2\text{Ca}_2\text{Si}_3\text{O}_9$, which forms during sintering of 45S5 Bioglass at 1000°C, can transform into a biodegradable amorphous calcium phosphate upon immersion in simulated body fluid at body temperature. This discovery led to the successful development of highly porous glass–ceramic scaffolds from melt-derived 45S5 Bioglass. Fig. 1 illustrates a typical scaffold microstructure. These novel scaffolds are superior to their HA counterparts in terms of both mechanical strength and biodegradability. Furthermore, a recent quantitative study revealed that the proliferation of osteoblast cells on the glass–ceramic materials is comparable to that on the non-crystallized 45S5 Bioglass.

Bioactive Composites

From a biological perspective, it is a natural strategy to combine polymers and ceramics to fabricate scaffolds for bone tissue engineering because native bone is the combination of a naturally occurring polymer and biological apatite. Moreover, from the materials

Fig. 1 Scanning electron microscopy image of a Bioglass[®]-derived glass-ceramic scaffold developed using the foam replica technique.^[8]

B

science point of view, a single material type does not always provide the necessary mechanical or chemical properties desired for a particular application. In these instances, composite materials designed to combine the advantages of both materials may be most appropriate.^[4] Polymers and ceramics that degrade *in vivo* should be chosen for designing biocomposites for tissue engineering scaffolds. Although massive release of acidic degradation from biopolymers, e.g., poly(lactic acid), causes inflammatory reactions,^[10] the basic degradation of calcium phosphate or bioactive silicate glasses would buffer the acidic by-products of the polymers and may eventually help to avoid the formation of an unfavorable environment for cells because of a decreased pH. Mechanically, bioceramics are much stronger than polymers and play a critical role in providing mechanical stability and structural integrity to scaffolds prior to the synthesis of new extracellular matrix by the cells upon implantation. However, ceramics and glasses are very fragile as a result of their intrinsic brittleness and flaw sensitivity, whereas polymers are flexible. To capitalize on their advantages and minimize their shortcomings, ceramics and glasses are combined with biopolymers to form bioactive composite biomaterials for fabrication of scaffolds.^[4]

Table 2 lists selected ceramic/glass-polymer composites, which have been developed as biomedical devices or scaffold materials for bone tissue engineering, and their mechanical properties. In general, all these synthetic composites exhibit outstanding biocompatibility and bioactivity. The research team led by

Laurencin, for instance, synthesized porous scaffolds based on poly(lactid-co-glycolic-acid) (PLGA) and HA, which were reported to combine the degradability of PLGA with the bioactivity of HA, fostering cell proliferation and differentiation, as well as bone mineral formation.^[11] Related composites of bioactive glass and polylactic acid (PLA) formed calcium phosphate layers on their surfaces and support rapid and abundant growth of human osteoblasts and osteoblast-like cells when cultured *in vitro*.^[4] Highly porous composites have also been produced from combinations of a poly(D,L-lactic acid) (PDLLA) matrix and Bioglass particle inclusions.^[12] These scaffolds have a well-defined and highly interconnected porous structure. At the same time, their mechanical properties are close to (but lower than) that of cancellous bone. Recently, PDLLA/Bioglass composite scaffolds containing up to 40 wt% Bioglass enhanced bone formation *in vivo* (animal model).^[12]

Table 3 summarizes the advantages and disadvantages of the bioactive materials discussed in the preceding sections.

FABRICATION OF BIOACTIVE SCAFFOLDS FOR TISSUE ENGINEERING

Bioactive Ceramic Scaffolds

Porous ceramics can be produced by a variety of different processes, which may be classified into two categories: 1) manual-based processing techniques and

Table 2 Bioactive composites designed for bone tissue engineering^[4]

Bioactive composite		Polymer	Percentage of ceramic (%)	Porosity (%)	Pore size (μm)	Compressive (C), tensile (T), flexural (F) strength (MPa)			Toughness (kJ/m^2)

Table 3 Advantages and disadvantages of bioactive biomaterials used in bone tissue engineering

Biomaterial	Positive	Negative
Calcium phosphates (e.g., HA, tricalcium phosphate)	(1) Excellent biocompatibility (2) Supporting cell activity (3) Good osteoconductivity	(1) Brittle (2) Generally, they biodegrade too slowly in their crystalline phase, and they are too weak in their amorphous phase
Bioactive glasses	(1) Excellent biocompatibility (2) Support cell activity (3) Good osteoconductivity (4) Enhance vascularization (5) Control of osteoblast gene expression (6) Tailorable degradation rate	(1) Mechanically brittle and weak
Bioactive glass-ceramic	(1) Excellent biocompatibility. (2) Supporting cell activity (3) Good osteoconductivity (4) 45S5 Bioglass [®] -derived glass-ceramics are mechanically comparable to hydroxyapatite	(1) Brittle (2) Generally, they degrade too slowly, (except for crystallized 45S5 Bioglass [®])
Bioactive composite	(1) Excellent biocompatibility (2) Supporting cell activity (3) Good osteoconductivity (4) Tailorable degradation rate (5) Improved mechanical properties	(1) Processing techniques for 3-D porous scaffolds can be complex

B

2) computer-controlled fabrication processes, i.e., solid free-form (SFF) technologies. Manual-based processing techniques can further be divided into conventional powder-forming processes and sol-gel techniques.

Powder-based methods

The powder-forming process starts with the preparation of a slurry, which is a suspension of ceramic powders in a suitable liquid (e.g., water and ethanol) that will be used to prepare green bodies. A green body is porous, and its structure largely determines that of the sintered product. After a programmed heat treatment of the green body, a porous ceramic is produced.

The methods of obtaining green bodies for 3-D porous ceramics include loose packing, compaction, slip casting, injection molding, phase separation, freeze-drying, polymer replication, and gel casting. These processes lead to different porous structures within green bodies. Here we focus on one of the most frequently used techniques for the production of highly porous 3-D bioactive scaffolds: the replication technique.

The foam replication technique is also called the “polymer-sponge” method. In this process, the green

bodies of ceramic foams are prepared by coating a polymer (e.g., polyurethane) foam with a ceramic slurry. The polymer foam, having already the desired pore macrostructure, simply serves as a sacrificial template for the ceramic coating. The polymer template is immersed in the slurry, which subsequently infiltrates the structure and ceramic particles coat the surface of the polymer substrate. Excess slurry is squeezed out, leaving a uniform ceramic coating on the foam struts. After being dried, the polymer is slowly burned out to minimize damage to the porous coating. Once the polymer has been removed, the ceramic is sintered to the desired density. The process replicates the macroporous structure of the polymer foam and results in a rather distinctive microstructure within the struts. This method has been applied for the preparation of highly porous bone tissue engineering scaffolds from a variety of materials including hydroxyapatite,^[13] SiO₂-CaO-CaF₂-Na₂O-K₂O-P₂O₅-MgO glass-ceramic,^[14,15] calcium silicate (CaSiO₃),^[16] calcium phosphates,^[17] and 45S5 Bioglass (Fig. 1).^[8]

Sol-gel methods

The sol-gel process can produce ceramic or glass materials in a wide variety of forms: ultrafine or

spherical-shape powders, thin film coatings, ceramic fibers, microporous inorganic membranes, monolithic ceramics and glasses, or extremely porous aerogel materials. In the processing, alkoxide precursors, such as tetraethyl orthosilicate (TEOS) and triethoxyl orthophosphate (TEP), undergo hydrolysis and condensation reactions to form a sol. Polymerization of -Si-OH groups continue after the completion of hydrolysis, beginning the formation of the silicate (-Si-O-Si-) network. The network connectivity increases until it spans the solvent medium. Eventually, a wet gel forms. The wet gel is then subjected to controlled thermal processes of aging to strengthen the gel, drying to remove the liquid by-product of the polycondensation reaction, and thermal stabilization (or sintering) to remove organic species from the surface of the material and to further densify the structure; as a result, a relatively strong, porous aerogel is produced.

Highly porous bioactive glass foams have been developed by mechanically stirring the sol with the use of a surfactant and catalysts.^[18] The precursors of the glass foams are $\text{Ca}(\text{NO}_3)_2$ and two alkoxides: TEOS and TEP. Sol-gel-derived bioactive glass foams demonstrated favorable results in both in vitro and in vivo tests for bone regeneration.^[18] However, the sol-gel process for cellular bioactive glasses involves hazardous chemicals, such as hydrofluoric acid (HF), which is used as a catalyst. A typical structure of a scaffold fabricated from the silica-calcia system by the sol-gel method is presented in Fig. 2.

Solid free-form techniques

Solid free-form techniques, also known as rapid prototyping (RP), are computer-controlled fabrication processes. They can rapidly produce highly complex 3-D objects using dates generated by computer-aided design (CAD) systems. In a typical application, an image of a bone defect in a patient can be taken and used to develop a 3-D CAD computer model. The computer can then reduce the model to slices or layers. The 3-D objects are constructed layer by layer using rapid prototyping techniques such as fused deposition modeling (FDM), selective laser sintering (SLS), 3-D printing (3D-P), or stereolithography. Calcium phosphate scaffolds have been produced using FDM, SLS, 3D-P,^[19] and stereolithography, as well as RP combined with the replication technique. However, SFF is not a cost-effective method compared with other techniques described above.

Generally, highly porous bioceramic scaffolds are very brittle. An approach to improve the mechanical properties of ceramic scaffolds is to coat the porous network with a polymeric layer.^[20] By comparing the porous structures of ceramic scaffolds made by different techniques with that of trabecular bone, it was possible to conclude that the porous structure produced by the replication technique^[8] is most similar to that of cancellous bone and contains completely interconnecting pores and solid material, forming only the foam struts. The ceramic foams synthesized by gel-casting and sol-gel techniques come next in terms of

Fig. 2 Scanning electron microscopy image of a bioactive glass (CaO-SiO_2) scaffold fabricated using the sol-gel method.

Table 4 Advantages of the replication technique for production of bioactive ceramic scaffolds

1.	Cancellous bone-like macroporous structure The porous structure produced by the replication technique is very similar to cancellous bone: highly porous and exhibiting open pores of size $\sim 400 \mu\text{m}$.
2.	High commercialization potential This technique is the simplest and most cost-effective method and thus most suitable for commercialization. Rapid-prototyping methods are expensive processes, but may, however, be suitable for producing specific and complex scaffold architectures.
3.	Safety The technique does not involve any toxic chemicals compared with sol-gel and gel-casting techniques, which use HF to accelerate polymerization.
4.	Irregular or complex shape production ability The technique can produce scaffolds of irregular or complex shapes compared with standard dry powder processing.

structural similarity to cancellous bone. Table 4 summarizes the advantages of the replication technique for production of foam-like scaffolds for bone tissue engineering.

Bioactive Composite Scaffolds

The development of fabrication techniques for ceramic-polymer composite scaffolds followed previous achievements in the area of polymeric scaffold production. Numerous techniques have been developed to process porous polymer scaffolds for use in tissue engineering and several reviews exist in the literature.^[1,2,4,21,22] Two of the polymer-foaming processes, namely solvent casting combined with particle leaching and thermally induced phase separation (TIPS) combined with freeze-drying, have been applied to the fabrication of polymer-ceramic composite scaffolds.^[4] In addition, two other methods of significance exist: microsphere sintering and foam coating were developed for the combination of ceramic and polymeric materials with the aim of producing composite scaffolds.

Solvent casting/particle leaching (SC/PL)

In this process, polymer microspheres are first formed from traditional oil/water emulsions. Solvent-aggregated polymer-ceramic scaffolds can then be constructed by

mixing solvent, salt or sugar particles, ceramic granules, and prehardened microspheres. A 3-D structure of controlled porosity is formed based on this method, combined with particle leaching and microsphere packing. The main advantage of this processing technique is the ease of fabrication without the need for specialized equipment. The primary disadvantages of solvent casting are: 1) the limitation in the shapes that can be produced (typically flat sheets and tubes are the only possible shapes); 2) the possible retention of toxic solvent within the polymer; and 3) the denaturation of the proteins and other molecules incorporated into the polymer by the use of solvents. The use of organic solvents to cast the polymer may decrease the activity of bioinductive molecules (e.g., proteins). Another potential drawback of the method is the limited interconnectivity of the pore structures that can be achieved.

Thermally induced phase separation

Porous structures can also be achieved through phase separation and evaporation. One approach to induce phase separation in polymers is to lower the temperature of the suspension of the polymer containing the ceramic additions, e.g., HA or bioactive glass particles. The solvent is solidified first, forcing the polymer and ceramic mixture into the interstitial spaces. The frozen mixture is then lyophilized using a freeze-dryer, in which the ice solvent evaporates. The typical microstructure of a PDLA/Bioglass (5 wt% Bioglass) composite foam scaffold obtained by TIPS is illustrated in Fig. 3, which indicates the high porosity (>90%) and pore interconnectivity achieved.^[12]

Microsphere sintering

In this process, composite microspheres composed of a polymer matrix and ceramic inclusions are synthesized first, using the emulsion/solvent evaporation technique. Sintering the composite microspheres together yields a 3-D porous scaffold.^[23]

Foam coating techniques

An alternative approach to combine a polymeric scaffold and a bioactive ceramic is to coat bioactive ceramic particles onto polymeric foams. This process was successfully demonstrated for the first time on bioactive glass-coated PDLA foams.^[24] Alternatively, a calcium phosphate layer can be grown on the surface of polymeric scaffolds in situ by a biomimetic method, e.g., by immersion of the scaffold in a simulated body fluid.^[25] The inverse method, namely polymer-coated

Fig. 3 Scanning electron microscopy images of a PDLLA/Bioglass composite scaffold fabricated by the TIPS technique (5 wt% Bioglass): (a) orthogonal to the pore direction and (b) parallel to the pore direction.^[4,12]

ceramic scaffolds, has also been investigated, for example, by applying a PDLLA coating layer on 45S5 Bioglass-derived glass-ceramic foams.^[20] The bioactivity of Bioglass-based foams was maintained after application of PDLLA coatings, whereas the mechanical stability of the scaffolds was considerably enhanced by the coating. The work of fracture of the PDLLA-coated foams is, on average, approximately 20 times greater than that of the uncoated foams. More importantly, in simulated body fluid the mechanical stability of the scaffolds was greatly improved by the PDLLA coating, which is the result of the in situ formation of a nanocomposite film of PDLLA and hydroxyapatite crystals on the strut surface of the foams.^[20] A similar approach has been investigated for calcium phosphate scaffolds with interconnected macropores ($> 200 \mu\text{m}$) and microporosity ($\sim 5 \mu\text{m}$), which were infiltrated with poly(lactic-co-glycolic acid) (PLGA) to achieve an interpenetrating bioactive ceramic/biodegradable polymer composite structure.^[17] The PLGA filled struts were further coated with a bioactive glass (33 wt%)–PLGA composite coating. The resulting scaffolds proved to be bioactive and exhibited relatively high compressive strength values (up to 7.7 MPa) and compressive moduli (up to 3 GPa), these values being comparable to those of natural spongy bone.

CONCLUSIONS

Numerous synthetic materials have been demonstrated to be cell-supportive, bioactive, and biodegradable. Various material processing techniques exist that can produce highly porous structures for convenient use as tissue engineering scaffolds. Porosity ($> 90\%$), pore size ($> 300 \mu\text{m}$), and high pore interconnectivity are critical design features for enabling 3-D tissue growth and sufficient vascularization. One of the major challenges encountered in hard tissue engineering is the design and fabrication of highly porous, bioactive, and biodegradable scaffolds suitable for load-bearing sites.

Although it might not be necessary to have a starting scaffold with a mechanical strength equal to that of bone because cells and extracellular matrix secreted by cells in vitro or in vivo can increase the scaffold strength, a scaffold should have an appropriate fracture strength and structural integrity for enabling its handling, as well as possessing the required biodegradability. With respect to this design concept, a suitable processing method (such as the replication technique) combined with biomimetic or coating techniques to tailor the scaffold surfaces (chemistry and topography) can be the technologies of choice for future developments in the field of bone tissue engineering.

Bioadhesion

INTRODUCTION

Bioadhesion may be defined as the state in which two materials, at least one of which is biological in nature, are held together for extended periods of time by interfacial forces. In the context of their medical and pharmaceutical use, the term bioadhesion refers to the adhesion of synthetic and biological macromolecules to a biological tissue. The biological substrate may be cells, bone, dentine, or the mucus coating the surface of a tissue. If adhesive attachment is to a mucus coating, the phenomenon is sometimes referred to as mucoadhesion.

Many examples of bioadhesion exist in nature, including such diverse events as cell-to-cell adhesion within a living tissue, barnacles binding to rocks, and bacteria binding to tooth enamel. In health care, bioadhesives were first used as wound dressings, skin adhesives, and denture fixatives. Over the last two decades, bioadhesives have been of interest within the pharmaceutical sciences for their potential to optimize drug delivery. Such drug delivery may be optimized at the site of action (e.g., on the cornea or within the oral cavity) or at the absorption site (e.g., in the small intestine or nasal cavity). Bioadhesives may also be used as therapeutic agents in their own right, to coat and protect damaged tissues (gastric ulcers or lesions of the oral mucosa) or to act as lubricating agents (in the oral cavity, eye, and vagina). Skin adhesives, tissue sealants, and dental and bone adhesives and cements are also defined as bioadhesives.

This article first focuses on the types of muco/bioadhesives currently used in the pharmaceutical sciences, from first-generation hydrophilic polymers to second-generation polymers and lectins. The nature of bioadhesive interactions, types of bioadhesive formulations developed, and regions of the human body to which they may be administered are also considered.

Other types of medical bioadhesives, such as those used in wound management, surgery, and dentistry, are also discussed.

PHARMACEUTICAL BIOADHESIVES

First-Generation Bioadhesives

These are the off-the-shelf and most widely investigated bioadhesives. They are hydrophilic macromolecules containing numerous hydrogen-bond-forming groups.^[1–5] Their first use as bioadhesives was in denture fixative powders or pastes.^[2] The presence of carboxyl or amine groups in the molecules appears to particularly favor adhesion. First-generation bioadhesives are called wet adhesives because they are activated by moistening and will adhere nonspecifically to most surfaces. Once activated, they show stronger adhesion to dry inert surfaces than to those covered with mucus. Unless water uptake is restricted, they may overhydrate to form a slippery mucilage. Like typical hydrocolloid glues, they can form very strong adhesive bonds if the formed adhesive joint is allowed to dry.

The poly(acrylic acid)s/carbomers are among the most important bioadhesive molecules. These are cross-linked acrylic acid-based polymers such as Carbopol 934 P, polycarbophil, and Carbopol 974 (Fig. 1a). Their molecular weight has been estimated to be in the range of $1\text{--}4 \times 10^6$ Da, but may be much higher. These materials form gels at relatively low concentrations (0.3–1%) in neutral pH solutions, and may be better described as water dispersible than as water soluble. They are also used as gelling agents, thickeners, tablet excipients, and emulsifiers.

Chitosan, another bioadhesive of great interest, is obtained by deacetylation of the natural product chitin, a polysaccharide extracted from the exoskeleton of Crustacea (e.g., crabs and shrimps). It is a linear polymer containing glucosamine and N-acetyl glucosamine units, linked by glycosidic bonds (Fig. 1b). Chitosan is cationic, and is water soluble only at lower pHs. It is available in a range of molecular weights (typically $50 \times 10^3\text{--}2000 \times 10^3$ Da) and degrees of acetylation. Although proposed for use as tablet excipient, drug carrier and controlled-release material, chitosin's

Fig. 1 Structure of some common bioadhesive polymers used in the pharmaceutical sciences.

use in pharmaceutical products has been limited. It has been widely marketed as a putative antiobesity product.

Alginates are polysaccharides extracted from marine algae or produced by bacteria, and consist of units of manuronic and guluronic acid (Fig. 1c). Three distinct regions are possible within an alginate molecule: polymannuronic acid segments (M blocks), poly(guluronic acid) segments (G blocks), and segments of alternating or randomly distributed mannuronic acid and guluronic acid units (MG blocks). Alginates' various pharmaceutical grades contain differing proportions of these blocks, and/or different molecular weight distributions. Alginates are used as thickeners, suspending agents, and tablet excipients. The specific gelling property of alginates with calcium ions is utilized in the production of a viscous gel (a raft) in the stomach to treat gastroesophageal reflux disease.

Cellulose derivatives are another important class of polysaccharide bioadhesives (Fig. 1d).

Some other bioadhesive polymers are listed in Table 1.

The Bioadhesive Bond

Mucous membranes line the walls of various body cavities (e.g., the gastrointestinal and respiratory tracts and the external surface of the eye). These are either simple single-layered epithelia (e.g., the stomach, small and large intestine, and bronchi) or multilayered

stratified epithelia (e.g., in the esophagus, vagina, and cornea). The former contain goblet cells that secrete mucus directly onto the epithelial surfaces; the latter contain or are adjacent to tissues containing specialized glands such as salivary glands that secrete mucus onto the epithelial surface. Mucus is present either as a gel layer adherent to the mucosal surface or in a luminal soluble or suspended form. The thickness of the attached mucus layer varies from 50–450 μm in the stomach to 0.7 μm in the oral cavity. The major functions of mucus are to protect and lubricate; mucus can be said to act as an antiadherent.

The mechanism of bioadhesion to mucosae is still not fully understood, despite many studies. Bioadhesion may arise with both dry (or partially hydrated) dosage forms (tablets or particles) and with hydrated dosage forms (i.e., gels and solutions, or fully swollen formulations such as particles administered into the gastrointestinal tract).^[6] The process by which the bioadhesive bond forms is likely to differ in each case.

For dry or partially hydrated dosage forms, two basic steps have been identified in the process of bioadhesion. Step one is the contact stage, in which intimate contact is formed between the mucoadhesive and mucous membrane; step two is the consolidation stage in which various physicochemical interactions occur to consolidate and strengthen the adhesive joint, leading to prolonged adhesion. Mucus gel dehydration by the bioadhesive polymer and macromolecular interpenetration have been

Table 1 Some bioadhesive polymers

Material	Composition	Solubility	Other uses
<i>Polysaccharides</i>			
Acacia	Calcium salt of arabic acid	Slowly water soluble	Suspending/emulsifying agent, tablet excipient
Carboxymethyl-cellulose (carmellose)	Carboxylated polyglucose ^a	Water dispersible	Suspending/emulsifying agent, tablet excipient, denture fixative
Dextran	A polyglucose	Water soluble	Plasma expander
Hyaluronic acid	N-acetyl glucosamine and glucuronic acid	Water soluble	Eye drops
Hydroxypropyl-cellulose	A polyglucose containing hydroxypropyl-groups	Soluble in cold water some alcohols	Tablet coating, tablet excipient, viscosity enhancer
Hydroxypropyl-methylcellulose (hypromellose)	Polyglucose containing hydroxypropyl- and methoxy-groups ^a	Soluble in cold water	Viscosity enhancer, tablet excipient (sustained release), emulsifier, stabilizer
Karaya gum (sterculia, Indian tragacanth)	Mixture of sugar residues	Sparingly water soluble	Denture fixative powders, ostomy adhesive, suspending agent
Methylcellulose	Polyglucose containing methoxy-groups	Soluble in cold water some alcohols	Viscosity enhancer, tablet excipient (sustained release), emulsifier, stabilizer
Pectin	Polygalacturonic acid containing methoxy-groups	Soluble in water	Viscosity enhancing/suspending agent
Starch	A polyglucose	Hot water soluble	Absorbant (dry) and thickener
Tragacanth	Mixture of sugar residues	Partially water soluble	Suspending/emulsifying agent
<i>Proteins</i>			
Gelatin	Contains hydroxyproline and other amino acids	Soluble in hot water	Capsule shells, gels, stoma and lesion products
<i>Synthetic polymers</i>			
Maleic anhydride co-polymers (Gantrez [®])	Synthetic polymers of methylvinylether and maleic anhydride	Water soluble	Toothpastes, ostomy products, denture fixatives
Polyethylene oxide	Poly oxyethylene	Miscible with water, soluble in some polar organic solvents	Hydrogel wound dressings, viscosity enhancer, tablet excipient, denture fixatives
Polyvinylalcohol	Vinyl alcohol polymer	Water soluble	Film-forming gel, viscosity enhancer, lubricant
Polyvinyl-pyrrolidone	Polymer of vinyl pyrrolidone	Water and alcohol soluble	Tablet excipient, suspending and dispersing agent

^aSee Fig. 1(d).

proposed as two ways in which strengthening of the mucus layer occurs.^[6] Adhesive joint failure will normally occur within the weakest region of the bioadhesive joint (Fig. 2). For weak adhesives this would be at the adhesive interface; for weakly gelling materials this would be at the hydrating layer. For stronger adhesives the weakest region would initially be the mucus layer, but later would be in the hydrating adhesive material.^[7]

The strength of the adhesive joint therefore depends on the cohesive nature of the weakest region.

Several factors have been identified as affecting the strength of the solid bioadhesive joint.^[4,5] Many studies have indicated an optimum molecular weight for bioadhesion, ranging from circa 10^4 Da to circa 4×10^6 Da, although characterizing the molecular weight of large hydrophilic polymers is very difficult. The flexibility of

Fig. 2 Regions within a bioadhesive joint upon application of dry formulation to moist mucous membrane. (a) Upon application; (b) after a period of contact.

polymer chains is believed to be important for interpenetration and entanglement. As the cross-linking of water-soluble polymers increases, the mobility of the polymer chains decreases. Bioadhesive polymers that are placed in aqueous media hydrate, swell, and form a gel. The strength of adhesion of such polymers has been shown to reach a maximum at an optimum degree of hydration. Studies have shown that the bioadhesive properties of polymers containing ionizable groups are affected by the pH of the surrounding media. For example, bioadhesion of poly(acrylic acids) is favored when the majority of the carboxylate groups are in the unionized form, which occurs at pHs below the pKa.

The strength of adhesion has been found to change with the initial consolidation force applied to the joint, and with the length of contact time prior to testing. Other factors that may affect bioadhesion include mucin turnover, temperature, formulation, metal ions, and polymer concentration.

Liquid and semisolid bioadhesion typically consist of a viscous liquid or gel clinging to and being retained on a mucous membrane such as the esophagus or vagina. The factors influencing bioadhesion and retention are:

- The thermodynamic affinity of the semisolid for the mucous membrane—in terms of surface energies, contact angles, and spreading coefficient
- Rheology—where a liquid with low viscosity would readily run off the surface, whereas a rigid gel would be less able to spread on and interact with the mucous membrane
- The stability of the gel in the biological system

For a semisolid formulation, characterizing bioadhesion is problematic because contact angle measurement (liquids) and adhesive strength measurements (solids) are inappropriate, resulting in most studies' consideration of the retentive properties of these systems in in-use conditions.

The term bioadhesion can also be used to describe the adsorption of polymers from solution onto mucous membranes, mimicking biopolymers like salivary and ocular mucins. Bioadhesive polymers (such as carbomers and chitosan) have been shown to adsorb onto buccal mucosal cells (and the stomach mucosa) from solution.^[8] The resulting reduction of interfacial free energies and formation of cooperative bonds will facilitate this polymer adsorption process.

Multifunctional Bioadhesives

In many formulations, bioadhesive polymers perform more than one role, acting not only as an adhesive, but also providing a gel matrix that regulates drug release. A more sophisticated development utilizes polymer phase change (liquid–solid) as a response to external conditions such as pH, ionic strength, and temperature as means to closely regulate drug release.^[4] Carbomers have been shown to inhibit proteases and facilitate absorption,^[9] whereas chitosan also has antimicrobial and cell proliferation activity.

Second-Generation Bioadhesives

To overcome the limitations of first-generation off-the-shelf bioadhesive materials, new types of materials have been investigated that allow specificity or prolong and strengthen the bioadhesion process.

One approach to producing improved bioadhesives has been to modify existing materials. For example, thiol groups (by coupling cysteine) have been placed into a range of bioadhesive polymers including the carbomers.^[10] The concept is that in situ they will form disulfide links between not only the polymers themselves, but also with the mucin layer, thus leading to improved adhesive performance. The incorporation of poly(ethylene glycol) into polyacrylic/polymethacrylic acid copolymers

Table 2 Some lectins studied in bioadhesive drug delivery

Source lectin	Type	Sugar specificity
<i>Lycopersicon esculentum</i> (tomato)	Glycoprotein	N-acetyl glucosamine
<i>Phaseolus vulgaris</i> (red kidney bean)	Glycoprotein	Galactose, N-acetyl-galactosamine
<i>Solanum tuberosum</i> (potato)	Glycoprotein	N-acetyl-glucosamine
<i>Triticum vulgaris</i> (wheat germ)	Glycoprotein	N-acetyl-glucosamine, N-acetylneuraminic acid
<i>Ulex europaeus 1</i> (gorse)	Glycoprotein	L-fucose
<i>Helix pomatia</i> (edible snail)	Protein	N-acetyl galactosamine
Bacterial adhesins	Proteins	Mannose
Bacterial invasins	Proteins	β_1 -integrin

has also been investigated.^[11] These comb copolymer films were shown to have favorable adhesion relative to poly(acrylic acid) alone. EDTA has been added to chitosan to enhance the enzyme inhibitory function.^[12]

Specific bioadhesives allow some targeting in the bioadhesion process by binding selectively to the required ligand. The most important members of this group are the lectins, which have the ability to target a dosage form and facilitate absorption.^[13–16] Lectins are defined as proteins or glycoproteins of natural origin capable of specific recognition of, and reversible binding to, carbohydrate moieties of complex glycoconjugates without altering the covalent structure of any of the recognized glycosyl ligands. Lectins of interest usually contain two or more sugar-binding sites; some of the more important in terms of bioadhesion potential are shown in Table 2.

Another interesting approach is to produce polymers containing the appropriate hapten sugars that bind to endogenous lectins on the mucosal surface.^[17]

Formulation Factors

First-generation bioadhesive polymers—as typified by the carbomers—present many challenges to the formulation scientist, often because of the properties that make them adhesive. They are hydrophilic, showing limited solubility in other solvents, and in solution they typically form highly viscous, pH-sensitive solutions at low concentrations. Dry polymers become adhesive on exposure to moisture, and so readily cohere, or adhere to manufacturing equipment or delivery devices.

Tablet formulations usually consist of a matrix containing a bioadhesive polymer into which the drug is distributed. In order to separate the adhesion and controlled-release functions, multilayer preparations have been produced (e.g., with an adhesive layer, a controlled-release layer, and a backing layer to facilitate application or direct drug delivery) (Fig. 3).^[18]

Bioadhesive polymers can be cast from solutions for use as films or patches. Although most of these materials will form good films, building up a substantial

layer may be limited by solution viscosity. Because these films are usually relatively thin, they will rapidly overhydrate and lose their adhesive properties unless access of water is restricted. A bioadhesive patch may be multilayered for the reasons described for tablet preparation.^[19] However, given that the bioadhesive layer will usually swell in contact with moisture, curling of the patch can occur unless it is carefully formulated.

Bioadhesive microparticles or capsules have been produced by a spray drying or oil-in-water emulsification procedure, or during the polymerization process. Lectins—especially plant lectins—are relatively robust protein/glycoproteins, and can be purchased already coupled to a range of markers including colloidal gold, while still maintaining their activity. Using processes like the carbodiimide coupling reaction, they can therefore be readily placed onto the surface of a formed microparticle while maintaining their lectin-binding activity.^[13,16]

Bioadhesive ointments and pastes consist of powdered bioadhesive polymers incorporated into a hydrophobic base. Because the base is anhydrous, the adhesive properties of the bioadhesive polymers are not activated, and it is a relatively simple process to manufacture.

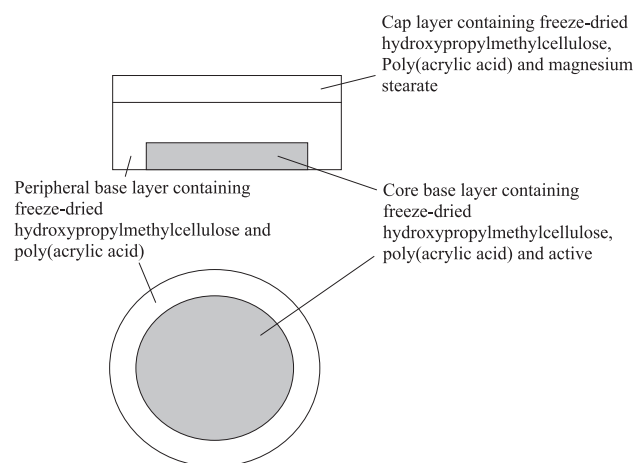

Fig. 3 Example of multilayered tablet formulation. (From Ref. [18].)

In use, the base allows restricted access of water from the saliva, and can therefore prolong the bioadhesive properties of the polymer. An oral paste (e.g., Orabase[®]) was one of the earliest bioadhesive formulations to be described.^[2] This consists of a mix of finely ground pectin, gelatin, and sodium carboxymethylcellulose dispersed in a polyethylene and mineral oil base, which has been used for local application in the oral cavity of steroids for the treatment of mucosal ulceration.

Although materials like the carbomers and cellulose derivatives have been used in aqueous gels in the pharmaceutical and cosmetic industries, these have not normally been considered to be bioadhesive (except perhaps for a polycarbophil-containing vaginal gel formulation).^[4] The content of bioadhesive polymer is normally relatively low (e.g., 0.5–1% for carbomers).

Solutions tend to be viscous and raise issues of polymer dissolution and stability; other proposed bioadhesive formulations include vaginal rods, pessaries, and suppositories.^[5]

Routes of Administration

The oral cavity is a site for local and systemic drug delivery. Local therapy treats conditions such as gingivitis and oral lesions; systemic therapy avoids first-pass metabolism and hostile conditions elsewhere in the gastrointestinal tract.^[20] Considerations associated with bioadhesive drug therapy within the oral cavity include rapid elimination of drugs through the flushing action of saliva, nonuniform distribution of drugs within saliva, organoleptic properties (taste), the relative impermeability of buccal mucosa, and the challenges of eating and drinking.

Suscard Buccal[®] (containing glyceryl trinitrate in a hydroxypropylmethylcellulose matrix) and Buccastem[®] (containing prochlorperazine in a ceratonia/xantham gum base) are two commercial examples of bioadhesive tablets for application to the oral cavity.^[20] Aphtach[®] (a thin double-layered tablet with steroid drug incorporated into a hydroxypropylmethylcellulose and poly(acrylic acid) base, whose upper layer is coated with lactose facilitate application via a nonstick surface) is an example of a multilayered tablet formulation. Adhesive patches have been developed as an alternative to tablets, and typically contain a film of bioadhesive polymer. Patches administered to the buccal mucosa measure up to 12 cm² in size (but typically are 1–3 cm²), and are ellipsoid in shape. Good flexibility of patches is required to ensure good adhesion and to prevent local discomfort.

Oral pastes (e.g., Orabase[®]) and ointments consisting of a bioadhesive polymer (such as carbomer or carmellose) in a mineral oil base have been used for local application to the oral cavity (e.g., to treat mucosal ulceration). After toothpastes, mouthwashes are one of the most widely used preparations for the

oral cavity. Bioadhesive polymers (chitosan, polycarbophil, and Carbopol 934) in dilute solutions have been shown to bind to buccal cells *in vitro*, and to bind and be retained *in vivo* for over 2 hours.^[21] Lectins in solution have also been shown to bind to the cells lining the oral cavity.

The peroral route (swallowing the dosage form) is generally the most favored for drug delivery, due to its acceptability to patients. However, it provides a range of challenges, and to date only limited success in developing bioadhesive formulations has been achieved.^[3–5,16] Challenges to the oral route of delivery include the mucus barrier (and its high turnover rate), the variable environment (particularly in terms of pH and luminal contents), the hostility of the environment (enzymes, pH, colonic microflora), variable and mainly uncontrollable transit rates, and intersubject variability. In addition, the bioadhesive must be delivered to its site of action, because it is rarely possible to locate it directly on its desired attachment site.

The most clinically significant example of bioadhesion in the gastrointestinal tract remains that of dry tablet formulations to the esophagus. Poor techniques of administration can lead to delayed onset of action and esophageal ulceration.^[22] Tablets and capsules are generally considered to be too large, with transit rates that are too variable to be used as gastrointestinal bioadhesives. A more promising approach would employ particulates, believed to distribute more evenly throughout the gastrointestinal tract. Particulates can be delivered in a suspension, or be released in the stomach from a hard gelatin capsule formulation. Much development activity is ongoing in this area, and several claims to enhanced drug delivery by bioadhesive polymer have been made (even on flimsy evidence). It has been shown that polyacrylates, when administered in solution, will bind to gastric mucosa *in vitro*.^[23] Particulate systems containing lectins or other locating agents on their surface have also been studied in cell culture and in animals, and represent a potential new means for enhancing drug delivery.^[13,14,16]

An eye drop is typically retained on the ocular surface for minutes only, thus limiting the time available for drug absorption; ointments can blur the vision and be uncomfortable for the patient. Ocular delivery systems must be sterile before application into the eye, and the rigors of the sterilization process can therefore limit which materials can be used in these formulations. The addition of bioadhesive polymers (carbomer, hyaluronic acid) has been seen to increase the bioavailability of drugs from eye drops. This is due in part to the effect of viscosity in reducing the rate of precorneal clearance. Bioadhesive polymers have also been formulated into adhesive ocular inserts, self-gelling systems, and micro-particles, which have been shown to enhance retention and bioavailability.^[4,5]

However, it has the advantages of avoiding first-pass metabolism, being readily accessible, encouraging particle deposition, and having good vasculature and relatively permeable mucosa (to smaller molecules). The nasal route has the disadvantages of possible local toxicity, rapid mucociliary clearance ($4\text{--}6\text{ mm min}^{-1}$), and being subject to pathological conditions that can adversely affect therapy (such as rhinitis). Bioadhesive solutions and particulate systems have been delivered nasally. The use of bioadhesive polymers would not intuitively be expected to confer a significant advantage, as a major physiological function of the nose is to capture and remove particulates from the inhaled air, clearing them using mucociliary clearance mechanisms. However, bioadhesive formulations (e.g., those containing chitosan or modified starch) have been reported to significantly extend retention in the nasal cavity, facilitating enhanced drug absorption.^[24]

Given that physicochemical properties (aerodynamic diameter) are critical for deposition in the lungs, a particle containing a typical hygroscopic, first-generation bioadhesive polymer would present formidable challenges to a formulation scientist (probably explaining the limited work in this area).

The vaginal route would appear to be highly appropriate for bioadhesive drug delivery systems, to retain systems for treating largely local (although some systemic) conditions, or for use in contraception. Traditional formulations have a relatively short retention period. Apart from menstruation or coitus, the major challenge to a bioadhesive device would arise from body movement and gravity effects. Along with rod, patch, and pessary formulations, a bioadhesive gel containing polycarbophil has been used commercially as a vaginal lubricant, and to deliver drugs such as progesterone.^[5]

MEDICAL BIOADHESIVES

Skin Adhesives

Skin is a squamous stratified (layered) epithelium, with a normally relatively dry, hydrophobic surface covered with lipids. Pressure-sensitive adhesives are used to attach a wide range of appliances, dressings, and devices.^[25] These materials differ greatly from the bioadhesives described previously in that they do not require water to become activated and therefore must possess inherent stickiness (tack). Skin adhesives must be sufficiently plastic and hydrophobic to interact with and adhere to the skin surface on application. They must also be nonirritating, remain adhesive for prolonged periods (typically days), and be removable without damaging the skin or leaving excessive residue. Rubber (polyisoprene) was the first commercial skin adhesive. Today the three main classes of adhesives are based on

polyisobutylenes (or other synthetic rubbers), acrylate polymers (such as 2-ethylhexyl-, butyl-, and octyl-acrylate copolymers), or silicone polymers (such as polydimethyl or poly(dimethyldiphenyl silicone)).

Hydrocolloid pressure-sensitive adhesives contain a combination of the water soluble polymers similar to those used for mucoadhesive drug delivery and the pressure-sensitive adhesives previously described.^[26] They are used in wound dressings because they have both adhesive and absorbent properties. A typical early formulation would contain a continuous phase of a low molecular weight polyisobutylene (circa 40%) into which would be dispersed combinations of hydrocolloids (such as pectin, sodium carboxymethyl cellulose, and gelatine). Later versions use a continuous phase of thermoplastic copolymers (such as styrene-isoprene-styrene) into which the hydrocolloid is dispersed, and may also contain a range of other materials such as tackifiers and antioxidants, cross-linking agents, and mineral oils (e.g., Duoderm[®] or Sigma Dress[®]).

Tissue Sealants

In recent years, adhesives for tissue repair (used in surgery as an alternative to staples, sutures, or surgical tapes) have become popular.^[27] Tissue sealants have the advantages of being relatively easily applied; acceptable, biodegradable, and relatively inexpensive; sealing more surely; reducing infection risk; and virtually eliminating scarring. In some cases, however, they may lack mechanical strength.

Fibrin sealants have been compounded for many years by individual surgeons, but are now available commercially (e.g., Tisseel[®]). They are composed primarily of the proteins fibrinogen and thrombin. These are the building blocks of a blood clot, and upon mixing, work by mimicking the final stage of the body's natural clotting mechanism. The formed fibrin clot is both adhesive and hemostatic, so is therefore particularly applicable to sealing bleeding wounds. The application procedure can be a little complex. Some variants are only activated by an external source (such as light), thus restricting the sealant to being activated only at the site of application.

Cyanoacrylates have been used as tissue adhesives in surgical procedures (e.g., when repairing corneal wounds). They essentially consist of cyanoacrylate monomer that, upon contact with trace amounts of water or bases on a biological surface, initiates polymerization and binds the surfaces together (Fig. 4). The original butyl cyanoacrylate superglues have now been replaced by octyl cyanoacrylates (e.g., Dermabond[®]) that are mechanically stronger and more flexible, and allow slower degradation and release of the potentially inflammatory by-products.

Fig. 4 Polymerization reaction of cyanoacrylate superglues (where R = butyl or octyl groups).

The protein albumin, when cross-linked with gluteraldehyde, forms a strong adhesive for internal surgery that is capable of withstanding high pressures (e.g., BioGlue[®]). The protein collagen can also be used as the matrix to which other materials such as fibrin, thrombin, or polyethylene glycols can attach. Derivatives of polyethylene oxide can be used as swellable hydrogels that rapidly arrest bleeding (e.g., Co-seal[®], Co-stasis[®]).

Dental Adhesives and Cements

Dental adhesives and cements adhere to the dental enamel and dentine of teeth in order to secure orthodontic devices. A range of materials is available, whose choice depends on the properties required for the procedure to be undertaken.^[28]

Zinc phosphate cement (e.g., Tenacin[®]) is based on the neutralizing reaction of zinc oxide with phosphoric acid in an aqueous environment to form solid zinc phosphate, a cement with high compressive strength. Zinc polycarboxylate cement (e.g., Durelon[®]) is the reaction product of zinc oxide with aqueous polyacrylic acid, which forms a cement that adheres to the calcium present in dentine and enamel. Zinc polycarboxylate is considered biocompatible but its mechanical properties limit its use. Glass ionomer cements (e.g., Fuji[®]) consist of polyacrylic or polymaleic acid mixed with an ion-leachable aluminosilicate glass that react together in water to form a cement that will adhere to enamel or dentine. These can be modified to allow a slow release of fluoride and also (via hydrogel domains) allow the release of calcium and other ions associated with tooth remineralization. Drying and low fracture resistance, however, restrict their use. Resin-modified ionomers (e.g., Avance[®]) are similar to the glass ionomers but also contain 10–20% resin monomers that can be polymerized by the application of light or chemical activators to give a more stable and physically stronger cement.

Resin adhesives (e.g., Panavia[®]) consist of resin monomers (such as the acrylate phosphate esters) that can be activated by light, initiators, or a combination of both. Resin adhesives often contain inert fillers. They cure purely through a polymerization process, so contain little water and are less brittle and more fracture resistant than cements. They can be chemically modified to contain polyacids, while aluminosilicate glass particles can also be incorporated to allow the release of remineralizing ions.

Bone Cements and Bone Graft Substitutes

Bone-filling cements have been used in surgery for the fixation of such prostheses as total hip replacements for over 40 years.^[29] The polymethyl methacrylates (PMMA) (e.g., Simplex P[®]) were the first bone cements used, but these can suffer from the mechanical and biological disadvantages of becoming loosened with time and being neither osteoconductive nor bioresorbable. They are prepared by the polymerization of methylmethacrylate monomer. A typical cement contains monomer, an initiator for polymerization (e.g., benzoyl peroxide), a radio-opaque substance (e.g., barium sulphate), and oligomers of PMMA. The initiator is added to the monomer solution prior to application and the properties of the resulting material can be modified by the addition of materials such as dimethyl toluidine or hydroxyapatite.

Although PMMA is still used to anchor hip and knee joint implants, a new class of biodegradable and biologically compatible cements has emerged, made with calcium phosphate (e.g., Norion SRS[®]), which in the form hydroxyapatite is a key component of human bone. These cements are easily accepted by the body and are sometimes used instead of bone graft surgery. They consist of a powder to which water is added to form a paste that hardens to form a material structurally similar to bone, which material can then be integrated into the new growth.

Other materials with adhesive properties that have been used as bone graft substitutes are similar to the materials used as dental cements.^[30] Bioactive glasses (e.g., NovaBone[®]) consist of sodium oxide, calcium oxide, phosphorous pentoxide, and silicon dioxide in varying proportions, and are solid and nonporous. They form a strong bond with bone as a result of a gel layer containing calcium and phosphate ions generated at the surface on exposure to physiological aqueous solutions forming hydroxyapatite. Glass ionomers (e.g., Fugix IX[®]), calcium sulphate (plaster of Paris), aluminium oxide (e.g., Alumina ceramic), and synthetic hydroxyapatite (Calcite[®]) have also been used as synthetic bone grafts.

Preventing infection is important in orthopedic surgery, so sterilisation and the incorporation of antibiotics are key issues in the use of these materials.

Other Adhesives

Muscle glue protein has also been investigated as a bioadhesive material.

As a result of their high surface-to-volume ratio, most nanoparticle systems would be expected to readily adsorb to surfaces, and have been reported as putative bioadhesives.^[16] A range of materials, including polyalkylcyanoacrylates and polymethacrylate copolymers, has been used to produce these nanoparticles. However, the low payload (dose of active agent that can be delivered) and the ease with which these may be flocculated by endogenous biopolymers can be factors limiting the use of these other adhesives.

CONCLUSION

For pharmaceutical bioadhesives, a range of new therapeutically active materials has resulted from advances in biotechnology. Despite the limitations of the first-generation, off-the-shelf bioadhesive polymers highlighted in this review, they have been used in several commercial preparations that are applied directly to the target surface. It should be a priority to design the second generation of polymers that are targetable, have predictable adhesive performance, and can be more readily accommodated in pharmaceutical formulations. To facilitate this, a clear understanding of the bioadhesive process is required.

Significant issues relative to second-generation, site-specific bioadhesives (lectins) remain to be resolved, such as access to their target sites and their toxicity profiles. The significant advances in bioadhesives with a range of medical applications (particularly those in the tissue sealants area) will inevitably result in their significantly expanded use.

Biocatalysis

Claire F. Komives

Ruizhen Rachel Chen

Chemical Engineering Department, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

The discovery that all life forms—from single cells to complex, multicellular organisms—require thousands of controlled chemical reactions to function has enabled the harnessing of naturally occurring catalysts for the fine chemicals industry. Biocatalysis is the use of natural or genetically modified enzymes or whole cells for chemical catalysis of organic molecules.^[1–3]

Enzymes are protein catalysts that accelerate chemical reactions inside a living organism by reducing the activation barrier of the transformation. For every step—from nutrient assimilation to the complex synthesis of bioactive natural molecules—an enzyme is involved. The use of enzymes for organic synthesis of chemicals, from industrial solvents to therapeutics, is now common in industry. This article covers the history of biocatalysis technology, and the use of enzymes and whole cells for the production of chemicals and materials, with a particular focus on biomaterials and biomedical applications.

Enzymes possess three types of selectivities that are unparalleled by traditionally employed chemical catalysts. Usually, enzymes can act on only one type of chemical functional group. This capability of enzymes is referred to as chemoselectivity. A substrate molecule that has more than one functional group from the same chemical family can be differentiated by enzymes possessing regioselectivity. Finally, enzymes can display stereoselectivity or enantioselectivity. Given a racemic mixture of a compound, these enzymes will react on only one type of enantiomer, leaving the other unreacted. A prochiral substrate may be transformed into an optically active product through the action of enzymes. The chiral selectivity of an enzyme is particularly important for drug development, because current regulations mandate either enantiomeric purity or comprehensive toxicity testing to demonstrate the lack of any adverse effects from the enantiomeric impurities. Another hallmark of enzyme biocatalysts is the phenomenal rate of accelerations achieved, the highest to date being 10^{23} with orotidine decarboxylase in the pyrimidine biosynthesis pathway.^[4]

Unlike most of the synthetic processes that necessitate high pressure, high temperature, and organic solvents, enzymes are remarkable in that they achieve this exquisite selectivity and high efficiency at very mild conditions, typically in aqueous solution and close to neutral pH, room temperature, and atmospheric pressure. Enzymes are also environmentally friendly catalysts. They are completely biodegradable and pose no risk to the environment. Using mild conditions in enzyme-catalyzed reactions also means lower energy utilization and less emission of greenhouse gases to the environment.^[5]

In recognizing the potential of biocatalysis, many companies (including large pharmaceutical and other chemical companies) have incorporated research groups with expertise in biocatalysis, because it has been shown in many cases that biocatalysis offers low-cost solutions for chemical synthesis.

HISTORY OF BIOCATALYSIS

The path to progress in the area of biocatalysis was not a linear one. Biocatalysis began with the use of whole cells for the production of ethanol, which is still a major product of biocatalytic reactions and dates back to uncharted historical territory. Because yeast produce ethanol under anaerobic conditions, these fermentations could be successful without an engineering understanding of oxygen mass transfer, and the necessary analytical techniques were those of the nose and eyes of a skilled brewer. Ethanol as a solvent was also produced by fermentation.^[6]

A significant milestone for biocatalysis, related to medicinal applications, was the production of penicillin.^[7] The large-scale fermentation process was initiated during WWII by a number of U.S. universities and pharmaceutical companies under the coordination of Albert Elder. In 1943, typical carbon content yields were 0.0001% and titers were about 0.1 mg/ml, presenting formidable challenges to purification, production rates, and to providing the drug at a reasonable cost for the war effort. Strains were improved through mutation, by X-ray and UV light

exposure, and by selection. By 1967 the titers increased 100-fold to 10 mg/ml. Since then, continuous strain improvements and process optimization have led to current titers reported in the public literature of approximately 40–50 mg/ml.^[8] Likewise, the current production host has been optimized from a strain of *Penicillium chrysogenum* that was screened from an overripe cantaloupe. Current strains show both an increase in copy number of the structural genes and a higher level of mRNA transcribed from the genes. Production was also improved by feeding the penicillin side chain, phenylacetate. However this is also one of the principle contributions to the cost of production. In the current semisynthesis of related β -lactam compounds such as ampicillin, penicillin acylase from *E. coli* or other microbial sources is used. In fact, penicillin acylase represents the best-known enzyme used in pharmaceutical industry with annual worldwide production of 6-aminopenicillanic acid (6-APA) reaching 7500 tons.

The use of microbial species to replace a traditional chemical catalyst was reported in a recent review^[9] to have begun at the UpJohn Company with a step in the production of cortisone, used for the treatment of rheumatoid arthritis.^[10] The oxidation of progesterone, fed in an acetone phase to α -Hydroxyprogesterone, was performed in a *Rhizopus nigricans* 240-liter fermentation with a conversion of 90–97%. This reaction is the first step in the bioconversion of progesterone to cortisone.

With the discovery that microbes and enzymes could be used to catalyze chemical conversions, considerable efforts were put into place for screening of microbes from sources all over the world to seek out enzymes with activities for the conversion of interest. Screening is still in use today by many companies that often possess stocks of microbes for such purposes. Indeed, Diversa Corporation has built its enzyme technology business around the screening of enzymes from unusual environments.^[11] Robots were developed to enable an increase in the rate of processing such experiments.

The infusion of recombinant DNA technology has made an important impact on progress in the biocatalysis field. Recombinant DNA technology has enabled a large number of enzymes to be overexpressed in a convenient host, and provided the enzymes in quantities required for large-scale synthesis with drastically reduced price. In addition, recombinant DNA technology allowed enzyme redesign through modification of the encoding gene. Based on available structural information, site-directed mutagenesis studies (or rational enzyme design), by modifying enzymes at positions important for substrate bindings and/or active sites,^[12] led to some success in improving enzymes for stability, turnover, lower Michaelis Constant

(Km), and substrate specificity, etc. More recently, directed evolution has emerged as a powerful tool in the redesign of enzymes for biocatalysis applications. It is expected that directed evolution will have much greater impact in the field than the rational design approach, because it does not require protein structural information, which is not only largely not available but also poorly predicts structural–functional relationships. In applications involving whole-cell catalyzed reactions, metabolic engineering (modification of cellular genetics to redirect nutrient throughput toward the production of a desired product) has continued to be used for the improvement of production host strains.^[13]

Many scientific disciplines have contributed to the current level of application of biocatalysis, and the history of each field is a story in itself. Considerable contributions of biochemical engineering have included reactor improvements for better mass transfer of oxygen for aerobic processes, methods for low-cost downstream processing, and other significant aspects enabling modern biocatalysis. Bioinformatics has brought about the rapid screening of sequence databases for genes with a high degree of homology with the gene of interest. The knowledge of highly conserved regions on a gene identifies portions of the gene and the protein sequences that are essential for a particular biocatalytic function. Were it not for the advent of high-speed computers, fields such as bioinformatics and many aspects of modeling and control would still be in their infancy.

WHOLE-CELL BIOCATALYSIS

Many industries employ whole-cell biocatalysts (mostly microbial cells) for carrying out chemical reactions, including pharmaceutical and biotech companies, bulk chemical manufacture, and wastewater treatment. A recent review discusses progress in the use of whole cells for oxygenation reactions leading to alcohols and lactones, nitrile and epoxide hydrolysis, and other reactions significant for organic synthesis.^[14] There may be many motivations for using whole cells instead of purified enzymes. Because purifying enzymes can require several steps to achieve adequate purity, using the cells in their native form can save time and effort, provided they do not also contain enzymes with undesirable or competing activities. If the enzyme-catalyzed transformation requires expensive cofactors, whole-cell systems are typically chosen because many cells already produce the necessary compounds. Whole-cell systems are generally more stable because the cell walls and membranes lend some protection to the intracellular enzymes.

A plethora of microbial species are used in whole-cell biocatalysis for products such as antibiotics, immunosuppressors, enzyme inhibitors, and many others. Many of these processes utilize wild-type cells that were isolated from their native habitat. The recent development of recombinant whole-cell biocatalysis has opened new horizons in the field, fueled by the prospect that novel, more potent products can be produced by the recombination of genes from different sources. In addition, it is possible that valuable products can be made more cost efficiently by reengineering the metabolic network of the microbial cells. In those applications, an important issue is host selection.

The reaction product is a primary factor in host selection in recombinant whole-cell biocatalysis. Fast-growing microbes with known genetic tools are the species of choice, especially *E. coli*, yeast, and certain species of fungi. The rapid growth rate of these organisms makes them easier to grow and maintain in a sterile state, and reduces total reaction time, not to mention their robustness in large reactors. Beyond personal preference dictating the selection of a host organism, the general rule for the choice of cells is to use *E. coli* whenever possible because their genetics are among the best known, they grow easily at a rapid rate (maximum doubling time of approximately 20 min) on minimal media, and they can be grown at high density by controlling the rate of carbon source fed.^[15] *E. coli* have an optimal growth temperature of 37°C, but can be adapted for growth at lower or higher temperatures when necessary. There are many commercial plasmids with various properties and markers for selection and expression that include tags for purifying gene inserts and protein products, including enzymes. The overexpression of a protein can be accomplished in *E. coli* in a relatively short time (a few weeks or less is possible). *E. coli* are facultative anaerobes; when given sufficient oxygen, and with carefully controlled feeding of carbon sources, they produce minimal quantities of metabolic by-products.

An example of the use of *E. coli* for the whole-cell, nicotinamide adenine dinucleotide (NADH)-dependent reduction of ketones and the enantioselective oxidation of racemic secondary alcohols at a Japanese pharmaceutical company was reported recently.^[16] The enzymes for the conversions were originally encountered from a yeast strain and expressed in *E. coli* at high levels. The reactions did not require the addition of cofactors and were performed with unpurified enzyme from *E. coli*.

Yeast genetics are also well known but because they are higher organisms, their genetics are much more complex than *E. coli*. and other prokaryotic microorganisms. Yeast are capable of utilizing a number of sugars, as well as highly reduced species such as alkanes or alcohols for production of organic acids. One

of the challenges of working with yeast is that even in the presence of sufficient oxygen, if the sugar carbon source reaches too high a concentration, the yeast metabolism behaves as though it were lacking oxygen, traditionally referred to as fermentation. This phenomenon, known as the Crabtree effect, can be avoided with proper feeding of the substrate. Yeast can have growth rates similar to *E. coli* and generally grow at a slightly lower temperature (25–30°C) than *E. coli*. *Candida* yeasts have been used for alkane oxidation, cellulose degradation, citric acid production, and many other applications.

Method of Use of Whole Cells

When used for a single step in a synthetic route, the cells can be grown, removed from the growth medium, and resuspended in buffer. Nonliving cells can be used for this purpose for some time. The cells can also be encapsulated in some porous material such as alginate that can be formed into beads. This procedure may stabilize the cells' activity and also facilitates the removal and reuse of the cells from the reaction broth. A recent example of this procedure is the production of 4-cyanopentanoic acid by *E. coli* encapsulated in carrageenan beads that were transformed for the overexpression of a nitrilase enzyme from *A. facilis*.^[17] A volumetric productivity of 79 g/l/hr was obtained using the immobilized biocatalyst.

For multistep reactions involving cofactors, living cells are generally used. Products of primary metabolism are produced most actively during the growth phase of the process. These compounds may not be of interest to the medical community. Secondary metabolites can be produced during the resting, or stationary, phase. This is a considerable advantage for process economics, because the duration of cell growth is short in the overall process, but the stationary phase can be extended through the proper feeding of nutrients and cell recycle. In addition, the concentration of cells in the reactor is the highest after the growth phase is completed. The net result is that many more reactions can be catalyzed per cell present in the reactor by resting cells than by growing cells. Once the cell-growth phase is completed, substrate for the reaction is fed to the reactor. Normally during this phase, a small amount of carbon source is fed for cell maintenance, assuming that the reaction substrate cannot be metabolized. It is not desirable that expensive substrates be burned for cell energy, so for efficient chemistry, enzymes resulting in the conversion of substrate to by-products should be knocked out of the organism, provided these steps are not critical for the growth of the organism. One caveat for the large-scale production of secondary metabolites is that the low native

cellular concentration of these compounds is often accompanied by some feedback regulation that prevents the concentration from going above some level. Enzyme engineering, removal of the feedback regulation, or enzyme replacement may be used to obviate the cells' drive to limit production of the compound of interest. Again, this is not as difficult to accomplish in *E. coli* as in other organisms whose genetics are not completely understood.

Metabolic Engineering

Metabolic engineering (or pathway engineering) is a tool for improving the catalytic properties of whole-cell biocatalysts used for carrying out multistep reactions starting from a substrate that the organism can use as a carbon and energy source. In general, the objective of microorganisms in consuming a carbon source is energy generation for growth and reproduction. This does not match the objectives of the pharmaceutical company whose purpose is production of chemicals that may be relatively useless for the microorganism, or even toxic at high concentrations. Effective pathway engineering involves the partial redirecting of carbon flux through the metabolic pathways leading to the product of interest. A number of reviews have covered this subject in detail.^[18,19] Because many organisms can be found to have similar metabolic routes, the enzymes for carrying out similar reactions may be available from a variety of microorganisms, animals, or plants. At times, an entire pathway may be taken from a single organism; at other times, combinations of genes may be used from various sources.

A recent industrial success story is the production of 1,3 propanediol in *E. coli*.^[20,21] The pathway to produce glycerol from glucose was taken from *Saccharomyces cerevisiae*, and the genes for the enzymatic path from glycerol to 1,3 propanediol was taken from *Klebsiella pneumoniae*. The process was dramatically improved by the knockout of the klebsiella dehydratase and the enzymatic activity was replaced with the nonspecific dehydratase from *E. coli*. This switch enabled a significant increase in the final titers. Many examples of successful process development are the result of metabolic engineering.

A technique used in directed evolution, DNA shuffling, has been applied to pathway engineering.^[22] Improvements in yield and titer of processes for the production of carotenoids, aromatics, secondary metabolites, alcohols, and many others have been achieved through DNA shuffling. In addition, novel molecules have been produced that can lead to the development of new drugs.

ISOLATED ENZYME BIOCATALYSIS

Microorganisms such as bacteria, yeast, and fungi are the most convenient sources of enzymes. Microbial cells can be produced in a bioreactor, or fermentor, that provides a controlled environment favorable to cell growth. Methods to facilitate recovery of enzymes excreted to the growth media have been developed. Cells can be removed by centrifugation or ultrafiltration and the enzyme can be removed from the broth. When enzymes are not secreted from the cells, the cells must be lysed and the cell debris must be removed. These crude preparations are adequate for use as catalysts in many industrial applications, in either liquid or dry powder form. For a higher degree of purity, recombinant enzymes expressed with a purification tag may be concentrated and purified in one or two process steps. Native enzymes can also be purified to yield the desired purity by a scheme of salt or solvent precipitation followed by one or more total chromatography steps.

Many enzymatic reactions of synthetic importance require expensive cofactors. For example, oxidoreductases typically require nicotinamide, and glycotransferases require sugar nucleotide as cofactors. Because these cofactors are prohibitively expensive to be used in stoichiometric ratio, an in situ cofactor regeneration system must often be in place. Typically this can be done by coupling another enzymatic reaction that regenerates the cofactors. Formate dehydrogenase is the most commonly used enzyme for regeneration of NADH using formate as the reductant. A variation of this method is to macromolecularize the cofactor by chemically attaching poly(ethylene glycol) of molecular weight over 10,000 to NAD⁺ so that it could be retained in a membrane reactor. This method was successfully used by Degussa in the commercial production of L-tert-leucine.^[5] A number of other approaches have been explored with varying degrees of success. A recent review describes some of the methods.^[23] The necessary reducing power for monooxygenase enzymes has been performed with the help of an electrode and metal reducing agents, and recently with the use of hydrogen peroxide.^[24]

Immobilized Enzymes

In order to reduce the cost of enzymes used in organic synthesis, the immobilization of enzymes on solid supports through covalent or noncovalent attachment is commonly used. The immobilized biocatalysts can be recovered from the reaction medium by settling or filtration and can then be reused. This approach can dramatically increase the stability of the enzyme, but may result in reduced activity. Much research has

improved immobilization of enzymes in recent years. Recent reviews discuss the most recent advances in enzyme immobilization.^[25,26] Recent research has involved the incorporation of functional enzymes into polymer matrices. A review describes research involving both dehydrated enzyme powders and soluble enzymes.^[27] Considerable success was achieved with the encapsulation of soluble protein—including subtilisin, *Candida Rugosa* lipase, and several others—in hydrophilic resins with 47–61% retention of activity. The cured polymers were clear and hard, and the relative proportion of enzyme to polymer was 0.5% to 10% by weight. Polymer properties such as hydrophilicity, hardness, and aqueous swelling capacity could be manipulated by the addition of fillers and by varying the precursor molecules for polymerization. Protein–polyurethane composites are also described, that have been prepared for a number of applications, including the degradation of nerve agents. Much of this research work was carried out by LeJeune and Russell at the University of Pittsburgh in collaboration with a small company, Agentase.^[28] Silicone-based biocatalytic composites have also been developed incorporating an enzyme as a dehydrated powder or attached to a solid polymer as filler. One important goal of biocatalytic polymer research is the development of biocompatible polymers that can resist biofilm formation. The immobilization of lumbrokinase and hirudin in polyurethane composites was recently shown to resist thrombus formation on an artificial heart valve.^[29,30]

Nonaqueous Enzymology

Recent research has demonstrated the capacity of enzymes to function in nonaqueous media. Original work in this area focused on the use of lyophilized enzymes.^[31] It was shown that the pH of the buffer in which the protein resided during the lyophilization process was the pH the enzyme “remembered” when suspended in organic solvent. Recent work in this area has shown a dramatic improvement in the catalytic rate of enzymes lyophilized with high concentrations of certain salts that enable the original conformation of the enzyme to be preserved throughout the dehydration.^[32] Initial efforts to solubilize the enzyme in the organic solvent included the use of enzymes in reversed micelles. Here the enzyme was soluble in the water core of the micelles that were separated from the organic solvent by only the surfactant interface. Finally, the direct solubilization of the enzymes in the organic solvents was achieved by linking the reactive moieties at the surface of the enzyme with poly(ethylene glycol) (PEG) (referred to as the PEGylation of the enzyme). Similar results were achieved by

attachment of the enzyme to certain surfactants. A summary of this work can be found in a recent review.^[33]

Extremozymes

In recent years, the discovery of organisms that grow under extreme conditions has introduced natural enzymes that also have the capacity to function at high temperature, high pressure, high pH, and high salts.^[34] These enzymes have a number of useful applications for organic synthesis. Some of the initial studies with enzymes with such unusual stabilities involved their comparison with enzymes capable of only functioning under mild conditions. These studies indicate that thermally stable enzymes usually possess only small amino acid differences when compared to their mesophilic counterparts. However, these subtle changes often result in increased noncovalent, intramolecular interaction and compaction sufficient to confer thermostability. Important to the practical use of extremozymes is that thermostable enzymes often exhibit enhanced stability to other normally disruptive factors such as denaturation by detergents and organic solvents.^[35]

A prime example of the use of extremozymes is the DNA polymerase from *Thermos aquaticus* (Taq) in the polymerase chain reaction (PCR), which revolutionized the way nucleic acids are being manipulated. Runnion et al. documented the interesting discovery of thermal stable urease from the screening of various sites in Yellowstone National Park.^[35]

Directed Evolution

The need to redesign enzymes for biocatalysis applications is obvious because the enzymes are required to work in drastically different environments in vitro than in their natural physiological conditions. Enhanced stability and activity in nonaqueous environments, and expanded substrate spectra, are a few desirable traits (among others) that are imposed by the biocatalysis conditions.

Using directed evolution to improve a biocatalyst involves three elements. The first is the method to generate enzyme variants. Error-prone PCR and gene shuffling are commonly used to generate a library of 10,000 or more enzyme mutants. The second element is a selection or screening process that allows the beneficial mutation to be selected. This often involves the ingenious design of selection methods that allow only the mutants with the desired trait to survive. When a phenotype is not amenable to such selection, then screening must be applied to all members in the library. In this case, the need to screen hundreds of thousands

of enzyme mutants entails a high-throughput screening mechanism. Some degree of automation in the analysis step is necessary.^[36] The third element of the use of directed evolution to improve a biocatalyst is the method to combine the beneficial mutation.

Many impressive examples of successful directed evolution of enzymes are reported in the literature. One important application is improving thermal stability using directed evolution. In one such study, subtilisin protease was subjected to directed evolution and a thermostable enzyme was generated. It was shown that eight amino acid changes were responsible for enabling the thermostability of the resulting protein.^[37] Simultaneous improvement in activity and stability in organic solvent were achieved by error-prone PCR and DNA shuffling coupled with a simple visual screening.^[38] Directed evolution was also successfully used to engineer enzymes to accept non-natural substrates. In an effort to extend the range of biotransformation of toluence dioxygenase, activity 5.6 times higher toward 4-picoline was achieved by a combination of random mutagenesis and saturation mutagenesis. A more stunning change in substrate specificity was reported by Matsumura and Ellington. The *E. coli* beta-glucuronidase evolved by in-vitro directed evolution into a beta-galactosidase with 500 times improved catalytic efficiency and 52 million-fold inversion in specificity.^[39] Other examples of successful use of directed evolution can be found in recent reviews.^[18,19,23]

CONCLUSION

In recent years, important progress has been made in the application of biocatalysis technology in the production of biomedically important products and materials. However, the enormous potential of biocatalysis and diversity in nature is far from exhausted. So far, about 3000 enzymes have been characterized. This represents only about 10% of all the enzymes believed to exist in nature; only about 300 are commercially available. An overwhelming majority of the catalytic power in nature remains untapped. Many scientific and technological advances have set the stage for the rapid progress of biocatalysis over the next decade.

INTRODUCTION

A biomaterial may be defined as any material or combination of materials used to replace, augment, or restore function of damaged or diseased tissues.^[1] Implicit in this definition is the idea that the materials used in devices must be safe in addition to effective. This characteristic or property of a material is termed biocompatibility. Biocompatibility may generally be regarded as the ability of a material to interact with living cells/tissues or a living system by not being toxic, injurious, or causing immunological reactions while performing or functioning appropriately. The spectrum of biomaterials used in medical applications is quite broad, ranging from cotton pads that stop bleeding of minor cuts within a few minutes; to catheters, dialysis tubes, and contact lenses designed to interact with tissues for a few hours to weeks; to sutures designed to slowly resorb over a few weeks to months; to implant devices like total replacement hips and heart valves intended to last 10–15⁺ years or the lifetime of the patient. To encompass this diversity of materials and applications, a consensus panel of experts has defined biocompatibility as the ability of a material to perform with an appropriate host response in a specific application.^[1] This definition thus accounts for not only the variety of applications of materials in medical devices, but also for the responses of both host tissues to material and material to host tissues. For example, cotton, which may be useful to initiate blood clotting in minor cuts, may not be suitable for use as an artificial blood vessel, because clotting would interfere with or block blood flow through the vessel. The physiological environment causes the release of low levels of metallic ions from biomedical alloys that may induce host metal hypersensitivity reactions such as Ni-allergy. For heart valves derived from animal tissues, the deposition and buildup of calcium from host fluids eventually increases material stiffness and interferes with valve opening and

closing, resulting in failure. It is hence important to realize that 1) no one material will be appropriate for all medical device applications; 2) the material, its composition, and degradation products may affect host cells and tissues; and 3) the host environment may also affect material properties and device performance.

The determination of the biocompatibility of materials and implant devices involves detailed characterization of the material (e.g., bulk and surface chemical composition; density; porosity; and mechanical, electrical, and degradation properties) and extensive testing, first at the protein/cell/tissue or in-vitro level, and then in in-vivo animal models and ultimately in human clinical trials. In-vitro tests are used to screen materials, their components, and or leachable/soluble/degradation products for cytotoxic, genotoxic, immunological, and hemolytic effects. Animal models are used to evaluate material–host tissue interactions and to predict how the device or prototype may perform in humans. Ultimately, the safety and effectiveness of the device must be evaluated in humans prior to widespread use by physicians and their patients. At each stage, biocompatibility data must be correlated with material properties and with manufacturing, sterilization, packaging, storage, and other handling procedures that also may influence test outcomes.

The design and use of biocompatibility testing protocols is provided by a variety of professional and regulatory organizations, including the American Society for Testing and Materials International (ASTM), the International Standards Organization (ISO), the American Dental Association (ADA), the National Institutes of Health (NIH), and the Food and Drug Administration (FDA). The use and documentation of biocompatibility tests are required by law in the United States and other countries, and are used to ensure that biomedical devices and their constituent materials are safe and effective under intended use conditions.^[2,3] This article provides a general introduction to the types of

biocompatibility tests. It is assumed that the physical, mechanical, electrical, and other properties of materials and device designs have been adequately evaluated and determined suitable prior to biocompatibility testing.

IN-VITRO TESTING

As compared with in-vivo and clinical studies, in-vitro environments such as cell or bacterial cultures provide a quick and relatively cheap way of estimating a material's biocompatibility. In-vitro tests allow a great deal of control over the test environment, in contrast to in-vivo tests, whose animal or human subjects may be influenced by variables such as sex, age, activity, diet, etc. If a material does not perform well in-vitro it most likely is not a good candidate for implantation. However, it must be noted that a material's in-vitro characteristics may not necessarily reflect its in-vivo performance, because dynamic cell/tissue interactions and hormonal and other physiological processes are not reproduced. The case of zinc-oxide eugenol dental cement is a classic example of the contradiction between in-vitro and in-vivo performance.^[4] In in-vitro tests, zinc-oxide eugenol cement exhibited severe toxicity, but when used in properly prepared tooth cavities, there is little if any dental pulp tissue reaction. This is because the dentin in the tooth structure acts as a barrier to reduce concentrations of molecules released from the cement to low levels. Therefore, in-vitro cytotoxicity testing should be used only to supplement in-vivo experiments.

There are many options for the type of in-vitro studies that may be performed, and the number is increasing as new technologies (e.g., quantitative polymerase chain reaction, DNA on a chip, cocultures) are developed. Common aspects of host response evaluated in vitro are cell or organelle survival, cell proliferation, metabolic and catabolic activity, cell morphology and function (alteration of shape, size, locomotive ability, phagocytic behavior, expression/response to cytokines/hormones, etc.), and cell damage, including chromosomal damage. Many of these tests are used to investigate and understand basic mechanisms of cell-material interaction that are not possible by other means, as well as to estimate the biocompatibility of materials. This section focuses on several common methods (Table 1) used primarily for estimating biocompatibility in vitro.

Cytotoxicity Tests

Cytotoxicity is the ability to cause death or damage at the cellular level by direct cell lysis or by fatally altering cellular metabolism. Inhibition of enzyme activity, changes in cell membrane permeability, and other sublethal effects may also be included in cytotoxic effects. Cytotoxicity assays are used as a screening mechanism to identify candidate materials for further biocompatibility tests. These tests measure the initial reaction of cells to the material and its components, and correlate fairly well with early tissue inflammatory, necrosis, and toxicity reactions at implant sites. Therefore, materials that do not perform well in cytotoxicity studies generally are not considered for human implantation. The three main types of cytotoxicity tests are elution, agar overlay, and direct contact. Specific test protocols may be found in ISO, ASTM, NIH, and related documents.^[5-8]

Elution tests

In elution tests, an extract or elute of a test material is taken and added to cells in culture. Serial dilutions of the elute are usually tested to determine toxic doses, and changes in cell growth or proliferation are measured and compared to nontreated cells over 24–78-hour periods. Cell proliferation or growth may be determined through direct cell counting using a hemocytometer or electronic cell counter, incorporation of radiolabeled thymidine (because thymidine is used only in DNA replication), or quantification of DNA material (because the amount of DNA is proportional to cell number). Changes in cell membrane permeability are used to estimate cell damage through the uptake of viability dyes (e.g., trypan blue or neutral red) or the release of intracellular enzymes such as lactate dehydrogenase, because large intracellular enzymes are only released from cells with severely damaged or disrupted cellular membranes. The conversion of tetrazolium salts by intracellular enzymes (primarily mitochondrial enzymes) to colored compounds that are read spectrophotometrically may also be used to estimate viability and proliferation because enzyme activity is retained only in viable cells, and because as cells grow, more dye is converted. Generally, a 50% or greater decrease in the number of cells, in the incorporation of

Table 1 Types of in-vitro tests for estimating biocompatibility

Cytotoxicity	Hemocompatibility	Mutagenecity	Hypersensitivity
Elution or extract test	Hemolysis assay	Ames test	Lymphocyte transformation test
Agar or agarose overlay test	Clotting and complement activation		Leukocyte migration inhibition test
Direct contact test			

radiolabeled compounds, or in the absorbance values of colored reagents compared to nontreated controls is associated with a severe cytotoxic response. This test is good for evaluating the toxicity of the leachable, soluble components from test materials, although the concentration of test substances must be carefully considered (because almost any material or chemical in high enough concentration will be toxic).

Agar overlay

In agar overlay tests, materials are placed on an agar or agarose layer covering the cells for 24 hours. Components from the test material are allowed to diffuse through the agar or agarose to the cells. Cytotoxicity of the diffusible components is determined by staining the cells with a viability dye and then measuring the zone of dead cells surrounding the test material. Materials that have no or only a limited zone of dead cells (limited to just under the sample) are given low cytotoxic scores, whereas materials with larger zones extending beyond the test sample are given higher cytotoxic scores. This method is good for low-density materials, powders, liquids, and high-density materials that may crush or damage cells if placed in direct contact. Care must be taken in comparing toxicity of different materials because different chemical compounds may have different diffusion rates and solubilities in the agar or agarose layer.

Direct contact tests

In direct contact tests, test materials are placed in direct contact with the cells. This may include simply growing cells on top of the test material or placing the test material on top of the cells in culture. Changes in cell growth or proliferation are measured in similar manner as in the elution tests, and changes in other cellular parameters (including morphology, intracellular ATP, intracellular signaling, chemokine/cytokine release, and total protein production/secretion) may also be measured. Zones of cell death or inhibited cell growth may also be measured in manner similar to the agar overlay tests, although care must be taken to not disturb the sample from its original position. This test is flexible with respect to testing a variety of materials and assessing of toxicity, although care must be taken with bioresorbable/degradable materials because degradation products may build up to nonrelevant toxic levels.

The degree of cytotoxicity of materials and their released components in these tests is determined in comparison to controls. Positive controls such as pure copper or latex rubber are materials that will cause an effect (e.g., cell death). Negative controls such as

Teflon[®] or titanium are materials that cause no or minimal effect.

Other factors affecting in-vitro tests are the types of cells (e.g., fibroblasts, osteoblasts, macrophage, endothelial, stem cell, etc.), species (e.g., human, rat, pig, etc.), source (normal tissues, tumor tissues, or tissues transformed by viral agents), period of exposure (hours to days), and culture parameters (type of medium, serum additions, number of cells per unit area).^[9] These factors must be considered in comparing results and in establishing experimental designs. Generally, cells derived from tumors or transformed cell lines are recommended for cytotoxicity tests because their characteristics are well-defined, they are less variable in genetic makeup and growth, and they are more readily available than normal (noncancerous, non-transformed) cells. Normal cells are more appropriate for investigating questions of specific cell-material interactions (such as cell attachment and spreading, elaboration of extracellular matrix, attachment and growth of osteoblasts, or activation of platelet or macrophage cells). Also, the selection of cell type should be appropriate for the intended application of the implant material.

Hemocompatibility Tests

Hemocompatibility tests are used to evaluate the effect of a material or released compounds on blood coagulation processes, thrombus formation, and hemolysis (the destruction of red blood cells). An upset in blood chemistry or damage to one of its components may be fatal, and therefore most medical devices that come into contact with blood are required to undergo hemocompatibility tests. Materials such as hypodermic needles that make only brief contact with blood need not be tested.

In hemolysis tests, test and control materials or their extracts are incubated with red blood cells, isolated from rabbits, mice, or rats for three hours with intermittent shaking to keep samples mixed and in contact with blood. The amount of hemoglobin released into the supernatant from the cells is determined spectrophotometrically and reported as percent hemolysis with respect to negative controls (materials that do not cause red blood cell lysis). The concentration of extracts and surface-to-volume ratio of solid or particulate materials to volume of red blood cells must be closely controlled to obtain reproducible results.

To evaluate the effects of materials and their surfaces on blood clotting, materials are exposed to whole blood serum. The time for the development of a clot on the material is compared to that of a reference material. Additionally, the serum may be tested for changes in different blood clotting factors after exposure to the

test material. However, because changes in blood flow may occur due to device design (e.g., turbulent flow may increase hemolysis and or clotting) the evaluation of test materials under flow conditions should be undertaken. For example, the number of adherent platelets may be determined per unit area after exposure to whole blood under controlled flow conditions.^[10] Because of their role in coagulation and thrombus formation, increased adhesion of platelets to the surface may indicate increased clotting rates. Ex-vivo tests are also popular for evaluating hemocompatibility under more in-vivo-like blood flow conditions. In ex-vivo tests, blood is temporarily shunted from an artery and vein of an experimental animal and allowed to flow over or through the test material inserted between inlet and outlet segments.

In addition to the limits of reproducing blood flow dynamics in vitro, the variability in blood from donors due to age, diet, health, etc. makes standardization of responses difficult. Hence, repeated tests with the same donor blood and use of appropriate reference materials are important considerations.

Mutagenicity and Genotoxicity

Mutagens are those materials that modify the genome of a host. Materials that have mutagenic effects on their host may therefore be classified as genotoxic. It is widely accepted that carcinogenic behavior proceeds via a mutation in the genome. It is thus expected that all carcinogens will be mutagens; however, the opposite is not necessarily true (i.e., a mutagen is not always a carcinogen).

One common method for studying mutagenicity is the Ames test. Briefly, the Ames test uses a mutant bacterial cell line (*Salmonella typhimurium* or *Escherichia coli*) that must be supplied with histidine to grow. The cells are cultured in a histidine-free environment, and only those materials that mutate the cells back to a state of histidine independence will allow the cells to grow. The Ames test is often used as an early screen for

mutagenicity, although it will not detect the full range of mutagens.

Hypersensitivity Tests

Tests such as the leukocyte migration inhibition and lymphocyte transformation tests have been used as in-vitro models to estimate delayed hypersensitivity reactions to implant materials and their released components.^[11–13] The use of these tests in screening the sensitization potential of materials is not well justified because genetic factors control individual sensitivity; however, the tests may be useful in assessing the sensitivity of individuals to particular materials and compounds.

IN-VIVO TESTING FOR BIOCOMPATIBILITY

Many systemic physiological processes are complex and cannot be simulated in vitro. Therefore in-vivo animal testing is necessary prior to human clinical testing. In-vivo tests (Table 2) are used to evaluate the local and systemic interactions of host tissues with implant materials or devices and their leachable/soluble/degradation components. These include physiological effects of the implant and its released components on local and systemic tissues, tissue response to the implant materials and designs, changes in extracellular matrices and regulatory biomolecules, and changes in the material and device due to host physiology.

Animal Welfare Issues

Use of animals for scientific purposes may cause them physical or psychological pain or harm. Thus, it is imperative that scientists use the least painful humane methods accepted in modern veterinary or laboratory practice. In-vivo animal testing should be done only when absolutely necessary. Whenever possible, a critical survey of the scientific literature and in-vitro testing

Table 2 Types of in-vitro tests for estimating biocompatibility

Short-term implantation tests	Long-term functional tests	Sensitization	Irritation	Other
Subcutaneous, intramuscular, and intraperitoneal implantation tests to evaluate general tissue necrosis, fibrosis, and inflammation	Devices or compositionally identical prototypes are implanted in appropriate animal models to replicate/simulate intended end-use in humans. Functionality of device and histopathological evaluations of tissues/organs are performed.	Guinea pig maximization test Occluded patch test Open epicutaneous test	Skin Ocular Mucosal	Genotoxic Carcinogenic Reproductive Cerebrospinal Hemocompatible

should be carried out before in-vivo tests are undertaken. In the United States, legislative, regulatory, and professional organizations have developed thorough guidelines for using animals in research.^[14–18] Similar laws and regulations exist in most other countries that provide protection for lab animals and strongly encourage

- Experimental designs based on the relevance to human or animal health, advancement of knowledge, or the good of society.
- Use of appropriate species, quality, and number of animals.
- Avoidance or minimization of discomfort, distress, and pain in concert with sound science.
- Use of appropriate sedation, analgesia, or anesthesia.
- Establishment of experimental end points.
- Conduct of experimentation on living animals only by or under the close supervision of qualified and experienced persons.

Animal and Implant Site Selection

No single species represents an ideal general model for the human species. A variety of sources are devoted to the selection of appropriate animal models.^[5–8,18–21] Anatomical, biochemical, physiological, pathological, and/or psychological characteristics must be considered when choosing an animal model.

Animal Tests

Guidelines to carry out animal biocompatibility tests are described by standards organizations and government regulatory agencies such as ASTM, ISO, NIH, FDA, ADA, U.S. and European Pharmacopeia, and others.^[5–8] The tests can be divided into functional and nonfunctional tests.

Nonfunctional tests

Nonfunctional tests are generally conducted first to study the direct interactions of the implant with the physiological environment. In these tests, it is assumed that acute toxic or inflammatory reactions are non-specific and thus may be evaluated in soft tissues (e.g., subcutaneous, intramuscular, intraperitoneal) because implantation in soft tissue requires minor surgery. Specialized sites such as the cornea and cerebral cortex are used for materials intended for those specific applications. After predetermined periods of time, the animals are euthanized and tissue reactions to the test materials are evaluated histologically and compared to

controls in the form of blanks or currently accepted implant materials that have a well-characterized known tissue response. Histological analyses may be scored or graded based on degree of tissue necrosis/degeneration, fibrosis, and types and amounts of inflammatory (polymorpho-nuclear leukocytes, macrophages, lymphocytes, etc.) and foreign body giant cells present. Because many factors of the implant device and design (such as functional loading and multicomponent interactions for a total hip) are not taken into account, such tests do not fully measure biocompatibility. Thus, they tend to be of short to intermediate duration, usually a few weeks to 24 months (e.g., ASTM F 763 Standard Practice for Short-Term Screening of Implant Materials or ASTM F 981 Standard Practice for Assessment of Compatibility of Biomaterials for Surgical Implants with Respect to Effect of Materials on Muscle and Bone). Fluid extracts from device materials may be used to determine the acute biological reactivity of possible leachable/soluble/degradation compounds when injected into soft tissues.

Functional tests

After evaluation in soft tissues, the next step is the selection of an animal model and implant site for the device or prototype to simulate the site that ultimately will be utilized in humans (i.e., functional testing). Functional tests require that the implant be placed, at least in some degree, in the functional mode that it would experience in human implant service. Animal model functional tests are obviously of much greater complexity because the design, fabrication, surface treatment, packaging, mechanical testing, and implantation of these device may be different in the device finally produced for human use. Variation in testing procedures with different animal models and variation in species histology can create difficulties in comparing, assessing, and interpreting results. Changes in animal behavior (for example, in preferentially not loading a limb with an implant) may also be important.

There are also specific in-vivo physiological assessment tests for genotoxicity, carcinogenicity, reproductive toxicity, delayed-type hypersensitivity, and systemic toxicity. Detailed protocols for these tests may be found in standards documents.^[5–8]

Genotoxicity testing

Genotoxic agents or genotoxins cause alterations in DNA or chromosomal structure or other DNA or gene

damage that result in permanent inheritable changes in cell function. The major genotoxic effects tested for are gene mutations, chromosomal aberrations, and DNA effects. Gene mutation and chromosomal aberration tests detect actual lesions in the DNA molecule, whereas DNA effects tests detect events that may lead to cell damage. Although in-vitro tests for genotoxicity/mutagenicity may be conducted using microorganisms or mammalian cells, an in-vivo animal model is also recommended when the scientific literature or in-vitro tests indicate potential genotoxicity of the implant or its components.^[22]

Gene mutation tests detect base-pair mutations, frameshift mutations, and small deletions. Chromosomal aberration tests detect chromosomal damage induced after one cellular division; structural changes in the chromosomes are evaluated while cells are in the metaphase stage of division. DNA effects tests (generally, mouse bone marrow micronucleus test) detect damage to the chromosomes or the mitotic apparatus of immature red blood cells found in bone marrow.

Carcinogenicity tests

Carcinogenicity testing is done to determine the tumorigenic potential of devices, materials, or extracts (after a single exposure or multiple exposures) over the total life span of the test animal. Specifically, such testing should be considered for a device that will have permanent contact (longer than 30 days) with tissues, either as an implant or as an externally communicating device.

Rodents are invariably chosen as the test species because their relatively short life spans make it practical to carry out lifetime studies. Although most investigators and regulatory agencies agree on undertaking carcinogenicity testing, many available standards lack specific information regarding the number of test animals to be used, the kinds of observations needed, the extent of histopathological evaluations, the number of survivors required at the end of the study, and the type of statistical evaluations to be used. The best scientific practices for carcinogenicity testing have been summarized.^[23]

Sensitization tests

Sensitization testing is done to determine whether chemicals or compounds that may be released from specific biomaterials and devices elicit sensitization reactions. Sensitization or hypersensitivity reactions are a result of immunologically mediated reactions resulting in redness (erythema) and swelling (edema). Because most such reactions are of the dermal cell-mediated type rather than the humoral or antigen-antibody type, the skin of laboratory animals (usually

guinea pigs because they exhibit dermal sensitivity similar to humans) is used in sensitivity testing.^[24] Three common tests are the guinea pig maximization test, the occluded patch test, and the open epicutaneous tests. Typically, the material or material extract is injected subcutaneously. Then one to two weeks after exposure, the test material or solution is reapplied to the skin and the degree of erythema and edema is graded. The use of adjuvants that enhance the immunological response (Freund's adjuvant, sodium lauryl sulphate) may be used during initial exposure to help identify weakly sensitizing materials. These common tests do not detect compounds released from the material that may also act as an adjuvant, or responses to antigens such as the plant proteins found in natural latex. Kimber et al. and Merritt have reviewed sensitization testing.^[12,25]

Irritation tests

Irritation is a localized inflammatory response to single, repeated, or continuous exposure to a material without involvement of an immunological mechanism. The intracutaneous, primary skin, and ocular irritation tests are three in-vivo, nonclinical tests commonly used to evaluate materials for possible contact irritation. The intracutaneous test is similar to the sensitization test. Fresh extract is injected intracutaneously at multiple sites on the shaved backs of albino rabbits and then 24, 48, and 72 hours after injection, the test and control sites are observed and scored for the severity of erythema or edema. Extracts that produce a significantly greater response than controls are considered irritants. In the primary skin irritation test the portions of the test material itself are simply placed on the shaved backs of rabbits with the aid of an occlusive dressing and the response after 24 hours is evaluated by methods similar to those used in the intracutaneous test.

The ocular irritation test is usually performed for ophthalmological materials. A small sample of material (powder or fluid extract) is placed directly into the pocket formed by withdrawing the lower eyelid of a rabbit. The rabbit's other eye is left untreated as a control. After 72 hours, the eye is evaluated for redness and swelling of the conjunctiva, response of the iris to light, corneal opacity, and presence of discharge. Scores are compared with standards to determine the degree of eye irritation. In addition to the intracutaneous, primary skin, and ocular irritation tests, mucosal (oral, rectal, penile, and vaginal) irritation tests may be carried out as necessary.^[26]

Systemic effects

Systemic toxicity may occur when chemicals and compounds released from implant materials are distributed

by the blood and lymphatic system and damage organs and tissues remote from the implant site. The various routes used for sample administration are topical or dermal, inhalation, intravenous, intraperitoneal, and oral. The material may be tested in powder, fluid extract, or solid forms and evaluations may be based on a single or multiple doses. Systemic effects are categorized on the basis of time to initiate adverse effects: acute (within 24 hr), subacute (in 14–28 days), subchronic (10% of an animal's life span), and chronic (longer than 10% of an animal's life span). Test methods used in longer-term systemic toxicity studies are much the same as those used in acute toxicity tests, except that larger groups of animals are used.

Reproduction toxicity tests evaluate the potential effects of devices, materials, or extracts on reproductive function, embryonic development, and prenatal and early postnatal development. Reproductive/development toxicity tests should only be conducted when the device has potential impact on the reproductive system.^[26]

The selection of evaluation in in-vivo protocols depend on the animal used (mice, rabbit, dog, etc.) and the implant material/device. Tests performed during the in-life phase often include measurements of body weight and food consumption, blood and urine analyses, and eye examinations. Recommended hematology test parameters are hematocrit, hemoglobin percentage, erythrocyte counts, and total and differential leukocyte counts. Platelet counts and measurements of prothrombin and thromboplastin concentrations and clotting time are usually performed for blood contacting materials and devices. Clinical pathology protocol should include assays that test proper electrolyte balance, carbohydrate metabolism, and liver and kidney function. Postmortem analyses include gross observations at necropsy, organ weighing, and microscopic examination of selected tissues. Considerable care must be taken in the design of subchronic and chronic studies to make certain they provide assurance of the device's safety.

CLINICAL TRIALS OF BIOMEDICAL IMPLANTS

Clinical trials are designed to test the safety of a new device in humans and are conducted only after they have been extensively evaluated by in-vitro and in-vivo animal models. Although clinical trials do provide vital information on the effectiveness of a biomedical implant device, they do not specifically test the biomaterial; rather, they test the device composed of the biomaterial(s) in a specific application. Unlike in-vivo animal studies, the implants in clinical trials remain exposed to the experimental subject even after the period of observation ends. As time passes and more subjects are exposed to the device without adverse

results, confidence in acceptable biological performance increases.

It is standard practice in new drug trials to employ a double-blind study in which a placebo is randomly administered to a portion of the defined group of patients to ensure that neither doctor nor patient know whether the active drug is being administered. In implant testing, however, it is not possible to pair the implanted patient with a placebo-treated patient, because it is not possible to conceal the implantation site from surgeon or patient. For clinical trials of implant materials, comparisons must be made between the condition of the patient before and after implant surgery. An implanted patient must also be compared with a patient with similar implants made of different materials, as well as a nondiseased (control) individual of the same age, sex, and similar home/workplace environment.

Because comparisons must be made between patients, certain standards exist for the selection and treatment of patients. Inclusion/exclusion criteria of the target patient population clarify the intended use of the device. The exclusion criteria serve to eliminate factors that increase operative risk or that may confound the outcome of the study. Medical care administered in a clinical trial must be under the care of a medical professional, and the patients must give informed consent to any experimental procedure.^[27–29] Patients must be informed of any possible benefits or risks of the procedure, and the identity of the patients must be protected and confidentiality of their medical records preserved. Also, there must be a reasonable possibility of benefit combined with reasonable assurance of usual risk.

Clinical trials are divided into three phases. Phase I (early trial) involves simply selecting a new treatment from several options for further study. The biomaterial is tested on a small group of people (~60–80). Phase II studies a larger group of subjects (~100–300) to test the effectiveness and further evaluate the safety of the biomaterial. It is divided into phase IIA and phase IIB. If the new treatment selected in the early trial is not effective, phase IIA (preliminary trial) examines whether further studies should be performed or the treatment abandoned. Otherwise, phase IIB (follow-up trial) estimates the effectiveness of the new treatment if it appears promising. Phase III is a comparison of the effectiveness of the new treatment with a standard of management or some other treatment, and is also divided into phase IIIA and phase IIIB. A large study group of approximately 1000–3000 people is used. If the new implant improves the clinical outcome (phase IIIA), the treatment is refined and examined further in phase IIIB, usually by multiple investigators and institutions.

Clinical trials must be performed under the control of a defined prospective protocol that describes the

implant device and outlines the indications of the surgical procedure, the uniform surgical procedure used, and the postoperative treatment and follow-up schedule. The number of patients included and needed to complete the trial to demonstrate benefit or improvement of the device is also critical to the study design, because too few patients will reduce significance, and too many may waste time and resources. Inclusion of and consultation with biostatisticians in developing clinical trial designs will help ensure that the device is adequately evaluated for potential use. Other considerations important in the design of a clinical trial include the study duration, examination schedule, and reporting of adverse events. Adverse events are noted and serious intraoperative and postoperative adverse events reported. A list of possible adverse events should also be included in the protocol of the study. To ensure that a clinical trial is conducted ethically and that the rights of the study participants are protected, an institutional review board or independent committee of physicians, statisticians, and community advocates is selected to help prepare the protocols and review the procedures and safeguards in any experimental program involving human subjects before the clinical trial begins.

The reports of clinical trials should discuss the accuracy and precision of all measurements as well as define a minimum confidence level for all statistical measures of data (usually $p < 0.05$). The reports must also include confidence intervals or other measures of significance associated with all derived parameters, and must indicate the significance of any conclusion arrived at by analysis of the trial.

The complication incidence rate for many biomedical materials/devices is extremely small. A study of the costs and benefits associated with research to improve then current orthopedic prosthetic devices concluded that failure/complication rates, even in the 1970s, were acceptably small and that the investment needed to significantly reduce these rates would be unreasonable with respect to the resulting benefits.^[30] In many cases in which the present technology is extremely successful, newer developments cannot demonstrate statistically superior outcomes because of limitations of size and duration of clinical trials. In these cases, the decision to pursue further improvements in the material or device depends on the argument that the human and financial costs to individuals as a result of device malfunction and failure is greater than the financial costs to the manufacturers and research institutions. Because the test of adequate performance described in the legal system is that the device be "safe and effective" and pose no "unreasonable" risk or hazard to the patient, decisions on what may be considered acceptable failure rates remain subjective, and depend on public opinion, expert advice, and administrative action.

Retrieval of implants and associated tissues (due to failure or other complications or at patient death) provides valuable information about the long-term biocompatibility of implants and their materials. Thorough analysis of failed implants provides insights into material design, selection, and manufacture and handling; implant design; surgical protocols; and the interaction between implant and host tissues as they relate to biocompatibility of the device. This information may be used to improve material design, selection, and manufacture, and to revise surgical protocols. Retrieval of implants and tissues is also important because the data provide a true assessment of the safety and efficacy of the device and document long-term host-material interactions. Evaluation of both device failure and success is necessary for improving understanding of the biocompatibility of implant materials and devices.

CONCLUSION

Evaluating the biocompatibility of biomedical materials and devices involves extensive testing at the in-vitro (protein/cellular/tissue), in-vivo animal, and human clinical use levels to determine how the materials and devices will perform in their intended applications. The success of a material and device depend on how the materials and device design affect the host and how the host affects device function and material properties. In-vitro tests have evolved to provide quick and relatively fast biocompatibility screening of candidate biomedical materials, but they are not yet capable of accurately predicting the clinical success of implant devices. However, with societal pressures to develop alternatives to animal testing, and with advances in cell and molecular biology techniques, advances in in-vitro methods for the prediction of clinical success are continuing. The use of in-vivo animal models is necessary to evaluate the interaction of an entire physiological system with the device and its components, and to establish safety and performance capabilities prior to use in humans. It is imperative that great care and planning are used in planning in-vivo animal tests to ensure that relevant and significant biocompatibility data are obtained. Only in clinical studies can the biocompatibility of a material or device and their ability to replace, restore, or augment the function of damaged or diseased human tissues be evaluated. This requires close evaluation of not only patients during the study period, but also of patient health records and of retrieved devices (failed devices and successful devices retrieved at death), even after the planned clinical study time frame to establish epidemiologically successful biomedical materials and devices. Finally, it is noted that methods and evaluation criteria for determining biocompatibility are routinely reviewed

and amended as additional information is collected. New methods and standards are being developed as new hybrid devices are developed and refined that involve both biological and synthetic materials (e.g., a patient's stem cells grown on resorbable substrate).

INTRODUCTION

Currently, there is a high demand to develop new materials that can be used to repair or replace damaged tissue owing to injuries, diseases, and/or genetic malformations. The term “biocomposite” means a material that consists of two or more distinct constituents to obtain complex physicochemical, mechanical, and biological properties, which are required by biomedical applications and cannot be satisfied by any individual components. Owing to the widespread use of biocomposites in regenerating bone, orthopedic applications will be emphasized here. In the U.S.A. in 1995, there were 216,000 total knee replacements, 134,000 total hip replacements, and close to 100,000 bone grafting procedures. In all, musculoskeletal conditions cost the U.S.A. \$214.9 billion in 1995.^[1] Traditionally, autografts, allografts, xenografts, and metal implants have been used to repair bone fractures and other skeletal defects. However, these substitutes are far from ideal as each has its own problems and limitations. For example, autografts are associated with donor shortage and donor site morbidity, whereas allografts and xenografts have the risk of disease transmission and detrimental immune responses. Most common metal implants are made of stainless steel, cobalt–chromium alloys, and titanium-based alloys. Major problems of those metals for implant applications are their mismatched mechanical properties compared to host tissue, which causes necrosis of the surrounding tissue and subsequent implant loosening owing to the well-documented “stress shielding” effect.^[2] It has also been well documented that metals do not possess surface properties that allow for sufficient quick new bone growth.^[2] Collectively, the above-mentioned problems (as well as others) with orthopedic implants have led to an average 10–15 yr current functional implant lifetime before clinical failure necessitates a replacement. To overcome such limitations of these traditional materials, over the past

25 yr, researchers have been interested in developing biocomposites that provide for a wide diversity of properties necessary for successful orthopedic implants.^[1–5] This desire comes from considering that living tissues are composites themselves with a number of levels of hierarchy. In almost all biological systems, a range of tissue properties (such as physicochemical, mechanical, biological, etc.) is present. All properties are of great importance and are key to the success of a tissue. Because of this, often a clinical need can only be fulfilled by a material that exhibits a similar complex combination of properties. The development of biocomposites offers great promise to improve the efficacy of current tissue substitutes that are too frequently single-phase materials that lack such property diversification.

Owing to similarities with the chemical composition of bone, polymer/ceramic composites were one of the first biocomposites considered for orthopedic implant applications.^[3] Specifically, for polymer/ceramic biocomposites, it is possible to obtain a wide range of mechanical and biological properties by modifying the type and distribution of the ceramic phase in the polymer matrix. Importantly, increased interactions between biocomposites and host tissue can be achieved by optimizing polymer/ceramic composites. For this reason, a wide variety of biocomposites have been synthesized and fabricated for various biomedical applications during these years.^[4] This article systematically addresses biocomposites applied to repair or replace damaged tissue (in particular bone) in a comprehensive manner emphasizing polymer/ceramic composites and their applications in tissue engineering.

For biocomposites to be successful, advanced manufacturing techniques must be exploited to take full advantage of their potentially tailorable properties. In this light, this article focuses on three main areas. First, the requirements of biocomposites for bone tissue-engineering applications are described. Second, the article introduces natural tissues as composites to

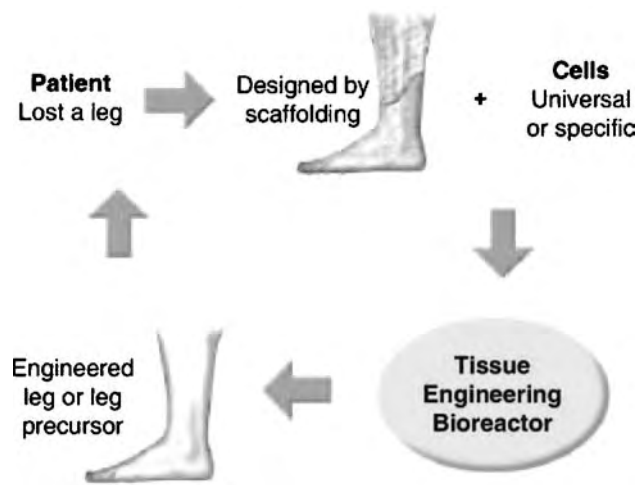

Fig. 1 Schematic diagram of the bone tissue-engineering concept using a hypothetical example of leg regeneration. (From Ref. [15].)

emulate in synthetic biocomposites stressing their mechanical properties. The third area concerns the description of various manufacturing techniques that can be used to control desirable biocomposite properties, including examples of the design and fabrication of three-dimensional composite scaffolds for tissue-engineering applications.

BIOCOMPOSITES USED AS BONE TISSUE-ENGINEERING SCAFFOLDS

A material that is designed to interact with biological systems to solve problems in repair and reconstruction of lost, damaged, or deceased tissue can be regarded as

a biomaterial.^[4] Biomaterials are widely used in implants and medical devices such as artificial hip and knee joints, dental implants, and internal as well as external bone fracture fixators. Of course, there are many applications of biomaterials in orthopedic applications. Most of the research is based either on those polymer/ceramic biocomposites that involve nondegradable materials for use as coatings to promote bone growth or on those that involve degradable materials to fully replace bone while dissolving.^[4] Owing to its current popularity, this section will introduce the application of biomaterials in bone tissue engineering.

Tissue engineering offers a promising opportunity for tissues to regenerate in a natural way. Some would argue that this would be the best approach to healing a bone fracture rather than inserting a permanent material intended to be in the patient for the remainder of their lifetime. Figs. 1 and 2 illustrate the bone tissue-engineering concept using a hypothetical example of leg regeneration.^[15] In this context, scaffolds are designed as temporary three-dimensional mirror matrices onto which cells grow and regenerate the desired tissue. Because the scaffold materials are biodegradable, they will fully resorb after completing the template functions. Importantly, both ceramics and polymers may degrade over time, and thus, have been used extensively in bone tissue-engineering applications.

However, the optimal combination of polymer and ceramic has not been found to date and with good reason.^[4] Currently, the scientific challenges in bone tissue engineering are: 1) developing suitable three-dimensional scaffold fabrication techniques that allow for the creation of appropriate templates for cell adhesion, growth, and proliferation in favorable three-dimensional orientations; 2) understanding cell

Fig. 2 Schematic diagram of basic functions of scaffolds to promote cellular infiltration over time.

functions on these scaffolds; and 3) combining these two concepts for the construction of an optimal bone regenerative material. This problem is further complicated owing to the multitude of material choices available. In terms of these material solutions, there are several crucial requirements to optimize tissue-engineering scaffolds. The scaffolds should be: 1) cytocompatible; 2) biodegradable with a controllable degradation and resorption rate that matches new cell/tissue ingrowth; 3) favorable to cellular attachment, migration, proliferation, and differentiation leading to the formation of a desirable extracellular matrix; 4) favorable to tissue integration and vascularization owing to proper interconnecting pores (or three-dimensional structure); 5) able to adequately support physiological loads through appropriate mechanical properties that match those of the intended site of implantation; and 6) fabricated through inexpensive but reliable high resolution techniques to match the tissue morphology.^[16] Bearing all of these requirements in mind, several types of polymers and ceramics (as well as fabrication techniques) have been developed for synthesizing biocomposite scaffolds with some success; this is the focus of the sections that follow.

NATURAL AND SYNTHETIC BIOCOMPOSITES

As mentioned, the term “biocomposite” means a material that consists of two or more distinct constituents to obtain complex physicochemical, mechanical, and biological properties that are required by biomedical applications and cannot be satisfied by any individual components.^[4] Thus, biocomposites combine various properties of two or more components to meet the multitude of requirements for select applications. In this respect, there are two main types of biocomposites: natural biocomposites and synthetic biocomposites, which are described in the following sections.

Natural Biocomposites

At the molecular and microstructural level, tissues are natural composite materials with a complex collection of entities (such as organic/inorganic phases) assembled in a controlled manner that allows for a tissue to function. In general, tissues of our body are grouped into hard and soft tissue classifications. Soft tissues (such as cartilage, ligament, tendon, blood vessel, skin, etc.) are formed from elastic (elastin) and nonelastic (collagen) fibers with a cellular matrix actively being remodeled between these fibers. Biological structures such as tendons (which link muscles to bones) are low in elastin content, thus, allowing muscle

Table 1 The relative mass percentages of the four basic components of typical cortical bones

Component	Mass %
Organic—Type I collagen fibers	16%
Inorganic—HA ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$)	60%
Ground substance (proteins, polysaccharides, and mucopolysaccharides)	2%
Water	22%

(From Ref. [3].)

movement to be translated to bone.^[3] However, ligaments (which links tissue to bone) are high in elastin content allowing movement between bones but retaining sufficient support to stop joints from dislocating.^[3]

Hard tissues (such as bones and teeth) are formed from four basic components as shown in Table 1.^[3] Of course, hard tissues generally have higher elastic moduli and higher strengths than soft tissues. The relative fractions of each component vary between bone type (i.e., cancellous or porous bone and cortical or dense bone) and condition of the patient (specifically, age, health, disease, etc.). The two most important naturally occurring forms of bone are cancellous and cortical (Fig. 3). Cancellous bone (also called trabecular or spongy bone) is a sponge-like structure, which closely resembles an isotropic material when not fully mature. Although immature, cancellous bone might structurally resemble an isotropic material, its chemical composition is quite diverse and, thus, better suited for composite replacement. In contrast, cortical bone is structurally highly anisotropic with reinforcing fibers along its loading axis. It has a highly organized blood supply called a Haversian system. The relative percentages of mass for typical cortical bones are included in Table 1.

The collagen fibers provide the framework and architecture of bone with the hydroxyapatite (HA) particles located in between the fibers. The ground substance is formed from proteins, polysaccharides, and mucopolysaccharides, which act as a bioactive cement filling the spaces between collagen fibers and HA mineral. These components are important and form the bulk of the bone. However, the living parts of bone are present in its voids that are fluid filled and contain cells that create (osteoblasts) and resorb (osteoclasts) the surrounding bone. It is this part of the bone that governs its structure, state of health, and is difficult to recreate using single-phase materials. Bone is just one simple example of a complex composite material naturally found in our body that researchers are trying to mimic using synthetic materials.

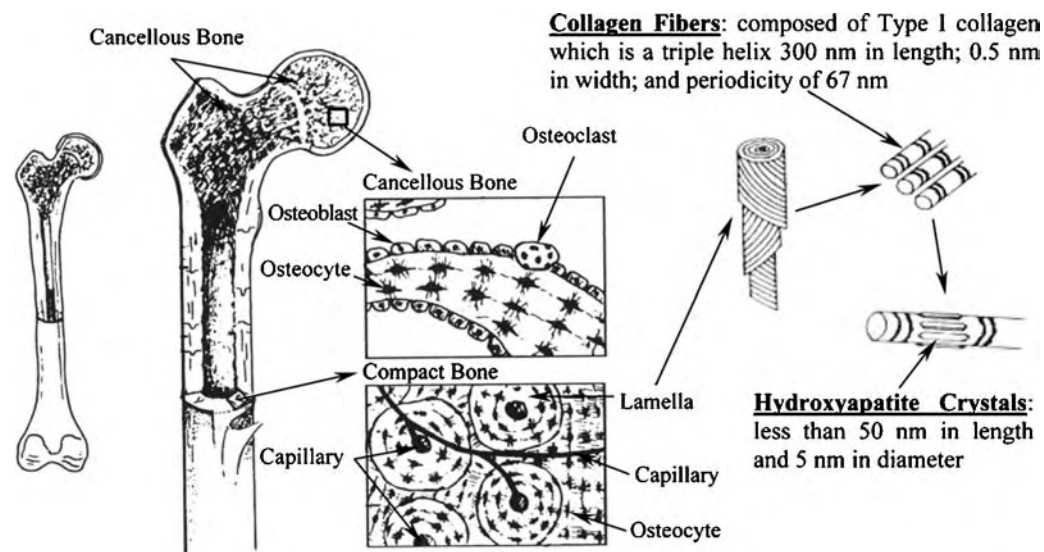

Fig. 3 Schematic composite architecture of the human femur. (From Ref. [17].)

Synthetic Biocomposites

To emulate this complex structure of bone, a wide variety of polymers and ceramics have been studied. Table 2 lists some of these biocomposite formulations and their various implant applications.^[4] These composite formulations can be further broken into resorbable compared to nonresorbable polymer or ceramic components; these are further described in the following sections.

Resorbable compared to nonresorbable polymer components

Polymer/ceramic biocomposites can be classified into resorbable and nonresorbable components

according to their extent of biodegradability. Resorbable biocomposites are composed of a reinforcing phase and a matrix in which at least one component is fully degradable in body fluids; such composites are mainly proposed to bridge small bone fractures. Clearly, the advantage of these resorbable materials is that they do not need to be removed later when the bone has healed, thus reducing the additional risk and pain associated with a subsequent surgery. Moreover, degradable materials are quite useful to provide for a prolonged, controlled release of pharmaceutical agents [like bone morphogenetic proteins (BMPs)] for orthopedic applications. However, most polymers utilized today in orthopedics are non-resorbable (such as those used as polyethylene acetabular cups). These nonresorbable biocomposites

Table 2 Some applications of synthetic biocomposites

Applications	Biocomposites
External fixators	Epoxy resin/carbon fibers (CF)
Spinal surgery	Polyurethane (PU)/bioglass, Polyetheretherketone (PEEK)/CF, epoxy/CF, polysulfone (PS)/CF, and polyethyleneterephthalate (PET)/hydrogel
Bone cements	Polymethymethacrylate (PMMA)/HA, PMMA/ultrahigh molecular weight polyethylene (UHMWPE) fibers
Hip prosthetic stems	Polyether-imide (PEI)/CF-Glass fiber (GF), epoxy/CF, PEEK/CF, PS/CF, UHMWPE/CF, and polytetrafluoroethylene (PTFE)/CF
Bone filling, regeneration	Polypropylene fumarate (PPF)/TCP, PLGA/HA fibers, polyethylene glycol (PEG)-Polybutyleneterephthalate (PBT)/HA, Starch/HA
Tendons and ligaments	PET/Hydrogels, PU/CF, PU/GF
Vascular grafts	PU/polyethylene-oxide-co-lactic acid (PELA), PET/gelatin
Abdominal wall prosthetics	PET/PU, PET/collagen
Dental bridges	PMMA/UHMWPE, PMMA/CF, PMMA/Kevlar (KF)

(From Ref. [4].)

are useful as they provide specific long-lasting mechanical properties necessary for the repair of very large bone defects.

It is important to note that most resorbable biocomposites are so based on the bioresorbable characteristics of the synthetic polymer matrix. The most commonly used polymers in synthetic biocomposites are biodegradable aliphatic polyesters. The degradation products of these polymers can be removed by natural metabolic pathways. Poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and their copolymers poly(lactic-co-glycolic acid) (PLGA) as a family of aliphatic polyesters are some of the most popular degradable scaffolds.^[18,19] Poly(glycolic acid) degrades rapidly in aqueous solutions *in vivo* because of its relatively hydrophilic nature, which loses mechanical integrity between two and four weeks.^[5] For a PLA scaffold, months or even years are required before mechanical integrity is lost *in vivo*.^[6] The extra methyl group in the PLA repeating unit (compared with PGA) provides for more hydrophobic properties, thus, reducing its molecular affinity to water, which leads to a slower hydrolysis rate. Overall, these polymers degrade through nonenzymatic hydrolysis of the ester bonds. The degradation products of PGA, PLA, and PLGA are nontoxic, natural metabolites, and are eventually eliminated from the body in the form of carbon dioxide and water. The degradation rates of these polymers can even be tailored to satisfy the biological requirements from several weeks to several years by altering chemical composition (e.g., the ratio of lactic to glycolic acid in the PLGA copolymers), crystallinity, molecular weight, and molecular weight distribution.^[7] Importantly, these polymers (PLA, PGA, and PLGA) are approved by the US Food and Drug Administration (FDA) for certain human clinical applications.

There are other less common aliphatic polyesters used in bone tissue engineering, such as poly(ϵ -caprolactone) (PCL). The PCL degrades at a significantly slower rate than PLA, PGA, and PLGA.^[8] A slow degradation rate makes PCL less attractive for general tissue-engineering applications, but more attractive for long-term fixation devices. Poly(ϵ -caprolactone)-based copolymers have recently been synthesized to improve degradation properties of other polymer/ceramic biocomposites.^[9] In addition, poly(propylene fumarate) (PPF) is an important synthetic biodegradable polymer gaining in popularity, as it can degrade through hydrolysis of the ester bonds similar to glycolide and lactide polymers. As the mechanical properties of PPF can vary greatly according to the synthesis method and the cross-linking agents used, the versatility of PPF is being explored in numerous orthopedic applications from small to large bone fractures.^[10]

Resorbable compared to nonresorbable protein components

Naturally derived polymers such as collagen have also been used in biocomposite scaffold fabrication. Collagen is a fibrous protein and a major natural extracellular matrix component of many tissues. Collagen, as the most popular natural polymer for tissue regeneration by far, has very useful biological properties desirable for bone tissue engineering, such as degradability, cell adhesiveness, and biocompatibility.^[18] However, there are concerns with regard to the use of collagen because of inconsistent sample preparation, poor mechanical properties as a stand alone orthopedic material, and a less controllable biodegradability compared to the synthetic polymers mentioned above.^[18] Denatured collagen (also called gelatin) has also been processed into porous materials for tissue repair. Importantly, these naturally derived proteins have been incorporated with synthetic polymers and ceramics and have shown promise for orthopedic applications.^[18]

Resorbable compared to nonresorbable ceramic components

For the inorganic component of resorbable polymer/ceramic biocomposites, calcium phosphates [such as calcium tetraphosphate ($\text{Ca}_4\text{P}_2\text{O}_9$), tricalcium phosphate (TCP, $\text{Ca}_3(\text{PO}_4)_2$), HA, $(\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), and its derivatives, as well as their combinations] are frequently used in orthopedic applications as they resemble the natural inorganic component of bone.^[18] However, calcium phosphate derivatives possess a wide range of degradation properties based mostly on their degree of crystallinity. Specifically, less crystalline materials (like TCP) have higher dissolution rates than more crystalline materials (like HA). These are the most common types of ceramics used to fabricate scaffolds to accommodate bone tissue regeneration. These ceramics are widely considered to be osteoconductive because their surface properties support osteoblast (bone-forming cells) adhesion, growth, and differentiation. They are also reported to be osteoinductive (capable of inducing bone formation) resulting from their capacity to bind and concentrate BMPs *in vivo*.^[11] Moreover, selected ceramics such as HA and TCP can react with physiological fluids and form tenacious bonds to hard and soft tissues through cellular activity; thus, they have been termed “bioactive.” The atomic ratio of Ca/P in calcium phosphates can be varied from 1.5 to 2 and the degradability of calcium phosphates generally varies with Ca/P ratio. Further studies have shown that HA and TCP have different characteristics *in vivo*,

although both forms have Ca/P ratios (1.50~1.67) within the range known to promote bone ingrowth. In general, HA has been found by many to be more osteogenic, while TCP has advantages as it degrades much faster, thus, possibly providing for improved bone integration.^[12] In addition, bone growth factors can be easily embedded in TCP and owing to its degradability it can be released in a controllable fashion to increase bone growth. Although these bioceramics are biocompatible, can promote bone ingrowth, and have a long history in orthopedics, they are inherently brittle, difficult to process into complex shapes, and cannot by themselves match the mechanical properties of true bone.^[18]

Design of optimal biocomposite properties

The design of polymer/ceramic composites offers an exceptional approach to combine the advantages of biodegradable polymers and bioactive ceramics to optimize physical and biological properties of scaffolds for bone regeneration. First, in polymer/ceramic composites, osteoblast functions (such as adhesion, proliferation, and deposition of calcium containing mineral) can be enhanced owing to improved osteoconductivity properties provided by the bioactive ceramic phase. Second, ceramic particles (such as HA and TCP) used as inclusions in biodegradable polyesters can provide a pH buffering effect at the polymer surface to tailor the desired degradation and resorption kinetics of the polymer matrix. This

prevents acceleration of polymer degradation, avoiding the formation of an unfavorable environment for the cells, and reducing the harmful side-effects (such as inflammation) that arise from acidic polymer degradation by-products.^[13]

Third, the mechanical properties may be improved by adding a stiffer particulate ceramic phase in the polymeric matrix. Typical mechanical properties for soft tissues, hard tissues (bone), synthetic bioactive ceramics, degradable polymers, and their composites are shown in Table 3.^[14] As mentioned, one mode of failure for orthopedic implants is stress and strain imbalances at the bone-implant interface owing to a mismatch in mechanical properties. From Table 3, it can be seen that the addition of HA increases the elastic modulus of PLGA closer to bone. This is because pure PLGA has an elastic modulus of 1400–2080 MPa, while pure HA has an elastic modulus of 95,000 MPa. As expected, when combining PLGA and HA, the elastic modulus increases to 4200 MPa, which is closer to the elastic modulus of cortical bone (as measured in either the longitudinal or the transverse directions) (Table 3).^[14] Thus, as can be expected, composites can have mechanical properties that match that of a host tissue, whereas the individual components do not. In this manner, polymer and ceramic individual components do not have optimal properties for bone tissue-engineering applications when used individually, but may (as the next section will further emphasize) when combined. Clearly, however, such individual components must be assembled properly for these advantages to be realized.

Table 3 Mechanical properties of selected biocomposites compared to natural tissue

Materials	Strength (MPa)	Elastic modulus (MPa)	Elongation (%)
Tendon (low elastin content)	46.5–53.0	402	9.4
Skin (high elastin content)	7.6	0.1–0.2	78
Elastin	1.0	—	100
Ligament	29.5	303	—
Collagen	50–100	—	10
Cortical bone (longitudinal)	130–133	12000–17700	3
Cortical bone (transverse)	52–60	12800–13400	1
Cancellous bone	2–7.4	390–400	2.5
Bioglass [®]	42	35	—
HA	50	95000	—
PLLA	55.2–82.7	2400–4200	5–10
PGA	68.9	6900	15–20
PLGA	41.4–55.2	1400–2080	3–10
PCL	20.7	34500	300–500
PLGA/HA	24.9	4200	—

(From Ref. [14].)

BIOCOMPOSITE FABRICATION TECHNIQUES

Biocomposites can be fabricated using a wide range of technologies. The selection of the most appropriate manufacturing technology is also influenced by the production volume capability and allowable cost. But most importantly, fabrication systems must be developed, which can match the complex three-dimensional organization of tissues; this was often

ignored in the first generation of biocomposite synthesis methods. To engineer functional tissues and organs successfully, the scaffolds have to be designed to facilitate cell distribution and guide tissue regeneration in three dimensions. Understandably so, this has been the focus of numerous more sophisticated fabrication techniques^[17,20–50] that are summarized in Table 4^[28] and are elaborated below.

Table 4 Comparison of biocomposite fabrication methods

	Resolution (μm)	Advantages	Disadvantages
<i>Acellular 3-D scaffolds</i>			
Fabrication using heat micro molding ^[28,29]	20–30	Use of well-established fabrication methods, usually automated Simple, reusable molds	Must seed cells postprocessing, less control in cell placement and distribution Limited to thin membranes, each layer must be a contiguous structure, manual alignment required
Selective laser sintering ^[30–32]	400	High porosity, automated	High temperatures during process, powder may be trapped
FDM ^[30,33,34]	250–700	No trapped particles or solvents, automated	High temperatures during processing
3-D plotting ^[45]	1000	Use of hydrogel materials, automated	Limited resolution
Fabrication using light stereolithography ^[31,35]	70–250	Ease of use, easy to achieve small features, automated	Limited choice of materials (must be photosensitive and biocompatible), exposure of material to laser
Fabrication using chemical 3-D printing ^[36–38]	200–500	Versatile, high porosity, automated	Limited choice of materials (e.g., organic solvents as binders), difficult to reduce resolution below polymer particle size
Pressure-assisted microsyringe ^[29]	10	High resolution, not subjected to heat, automated	Viscosity dependent, no inclusion of particles
Fabrication by matrix molding ^[39]	200	Use of biological matrix materials (collagen), mold fabrication can use automated methods	Features must be interconnected, weaker mechanical properties
<i>Cell-laden 3-D scaffolds</i>			
Cellular assembly organ printing ^[40–42]	100	Precise placement of cells throughout construct, ability to place multiple cell types Incorporation of cell aggregates or tissue explants, precise cell placement, automated	Limited fabrication conditions (sterility, temperature, pH), still in earlier phases of development Lack of structural support, dependence on self assembly
Laser-guided deposition ^[43]	<1	Precise single cell placement, automated	Has yet to be extended to 3-D structures, lack of structural support
Cell/biopolymer hybrids hydrogel photopatterning ^[44]	100	Incorporation of living cells within scaffold, leverages existing hydrogel chemistry (incorporation of peptides, degradation domains), versatile	Not yet automated, exposure of cells to ultraviolet light, diffusion of large molecules limited by hydrogel pore size

(From Ref. [27].)

Solvent-Casting Particulate-Leaching

One of the oldest biocomposite techniques developed, which significantly advanced the field is solvent-casting particulate-leaching.^[19] Although particulate-leaching has been widely used to fabricate scaffolds for tissue-engineering applications, to date they have not proved to be sophisticated enough to accurately match the complex structures found in bone (Fig. 3). Briefly, this technique involves producing a suspension of polymer/ceramic composites in a solvent. Salts are ground into small particles, which are then transferred into a mold. The polymer/ceramic suspension is then cast into the salt-filled mold. After the evaporation of the solvent, the salt crystals are leached out (using water) to form a porous structure. The main advantage of this process is its simplicity and control over pore properties. The pore size can easily be controlled by the size of the salt crystals and the porosity by the salt/composite ratio. However, certain critical variables (such as pore shape and interpore openings) are not well controlled using solvent-casting particulate-leaching techniques. Other porogens instead of salt (like gelatin) can allow the manufacturer to control pore structures, such as the creation of spherical as opposed to fractal pores. Fig. 4 illustrates a PLGA/HA scaffold that was fabricated by solvent-casting particulate-leaching techniques.^[47] Sodium hydroxide chemical treatment was further used to increase pore wall roughness that promoted bone ingrowth compared to those with traditional smooth pore walls.^[47] Authors attributed increased bone cell function to pore wall roughness that approximated those found in natural bone. Thus, these early biocomposite fabrication techniques can be modified to create a next-generation, more successful scaffold.

Gas Foaming

Owing to the importance of porosity properties in controlling bone formation in biocomposites, a number of additional techniques have been developed. For example, a polymer/ceramic suspension can be saturated with carbon dioxide (CO₂) at high pressures to control porosity properties through a technique called gas foaming.^[28] The solubility of the gas in the polymer then decreases rapidly by allowing the CO₂ pressure to come back to atmospheric level. This results in nucleation and growth of gas bubbles in the polymer/ceramic matrix as pores with sizes ranging between 100 and 500 μm are created. But the porosity of composites produced by this technique is limited by the solubility of gas in specific solvents. In addition, limited control of pore interconnectivity exists through the use of gas foaming. Nonetheless, gas foaming provides another easy process to control pore sizes in polymer/ceramic biocomposites.

Melt Molding

Several techniques also exist in biocomposite fabrication to control pore interconnectivity, which is important for the exchange of nutrients/wastes from pore to pore.^[28-30] One such process involves filling a Teflon mold with PLGA powder and gelatin microspheres of known dimensions and then heating the mold to above the glass transition temperature of PLGA while applying pressure to the mixture. This treatment causes the PLGA particles to bond together in a controllable fashion, thus, providing for control over pore interconnectivity. Once the mold is removed, the gelatin microspheres are dissolved by immersing the mixture in water and then the scaffolds

Fig. 4 Increased PLGA/HA pore wall roughness by solvent-casting particulate-leaching techniques enhances bone cell function. Increased pore wall roughness was prepared by chemically etching PLGA/HA scaffolds by solvent-casting particulate-leaching techniques. Bar = 10 μm. (From Ref. [47].)

are dried. Scaffolds produced by this method assume the shape of the mold. Fig. 5 highlights the transfer of unique pore wall surface roughness values in PLGA/titania biocomposites using such molding techniques.^[46] Specifically, the study pictured in Fig. 5 attempted to determine the influence of osteoblast responses on pore walls with nanometer scale features.^[46] These nanoscale pore wall features (both in the original and cast formulations) mimic those found naturally in bone. Results of this study demonstrated that compared to respective smooth pore wall biocomposites, both the molds and PLGA/titania biocomposites prepared from those molds with higher wall nanometer surface roughness values increased bone formation.^[49]

Interestingly, the melt molding process has been easily modified to incorporate other ceramics, specifically short fibers of HA.^[13] The uniform distribution of HA fibers throughout a PLGA scaffold was accomplished by using a solvent-casting technique to prepare a composite material of HA fibers, PLGA matrix, and gelatin (or other salt porogens), followed by a melt molding process. Thus,

similar to the above techniques, various manufacturing techniques can be combined to provide for unique biocomposite properties that can direct bone formation.

Freeze Drying

The primary advantage of adding a ceramic to a polymer phase is to enhance mechanical properties.^[25] For example, increased mechanical properties have been reported for HA and gelatin composites fabricated into foams via novel freeze-drying and cross-linking techniques.^[28] Specifically, in this study, HA powder was added at up to 30 wt.% into a gelatin solution, and the mixtures were freeze-dried and further cross-linked. The pure gelatin foam had a well-developed pore configuration with porosity and pore size diameters of $\sim 90\%$ and 400–500 μm , respectively. With the addition of HA, as expected, the porosity decreased and the pore shape became more irregular. However, the hydrophilicity and degree of water adsorption decreased when HA was added to the

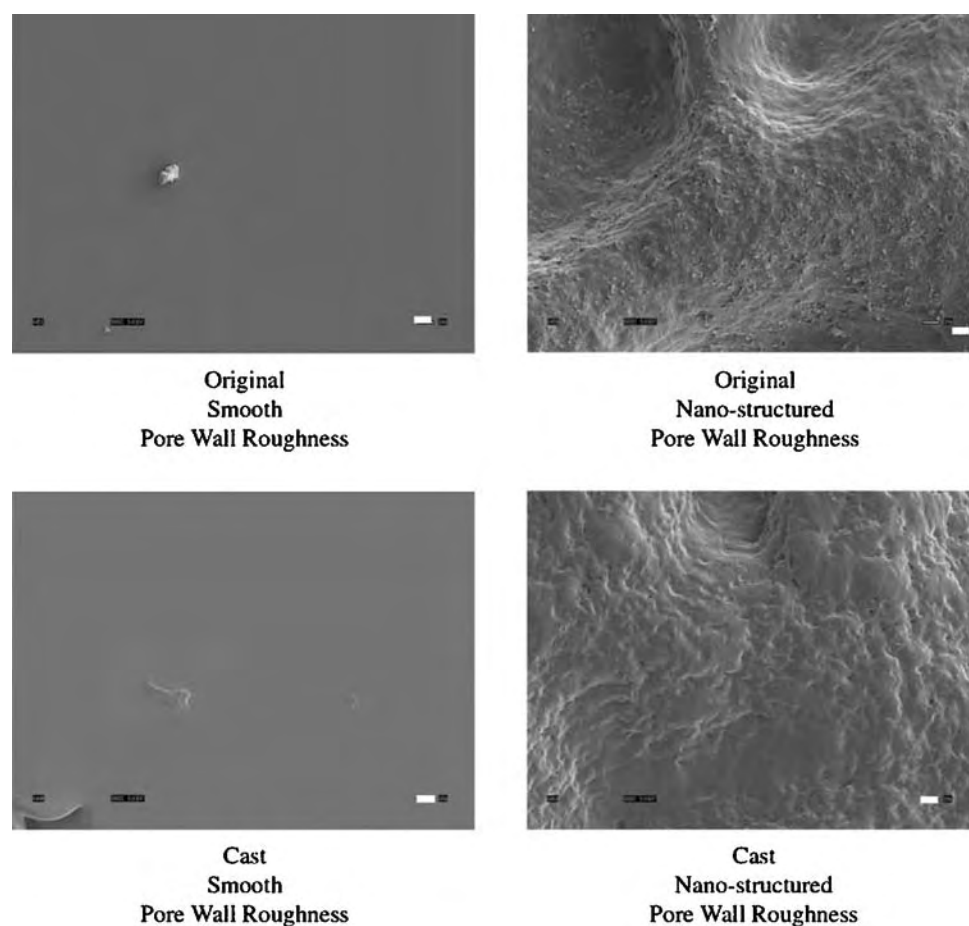

Fig. 5 Increased pore wall roughness in PLGA/titania biocomposites prepared by melt molding techniques enhances bone cell function. Bars (lower right in white) = 1 μm . (From Ref. [46].)

Fig. 6 Altered porosity properties owing to the addition of HA to PLGA. Note the decreased pore size and change in pore wall roughness owing to the presence of HA in PLGA. Increased bone formation was observed on porous PLGA with 30 wt.% HA compared to PLGA without HA. Bar = 10 μm . (From Ref. [49].)

gelatin foams. Clearly, the addition of HA increased the strength of the foam that allowed these composites to be more applicable to the orthopedic tissue-engineering community (i.e., increasing HA amount in the foams allowed for higher compressive stresses and provided for higher elastic moduli in both dry and wet states). The influence of changes in pore properties in biocomposites on bone growth, though, is only beginning to be investigated. An example of this change in pore structure and size owing to ceramic addition to a polymer is presented in Fig. 6. In this study,^[49] the HA particulates, in sizes of about 2–5 μm , were distributed within the PLGA network homogeneously to increase surface roughness, which promoted bone growth. Thus, although more studies are needed, two potential advantages can be obtained simultaneously when adding a ceramic component to polymers: 1) increased mechanical and 2) cytocompatibility properties.

Phase Separation

A number of disadvantages are present when combining polymer and ceramic phases.^[27] Namely, under certain conditions, multiphase materials become thermodynamically unstable and tend to separate into more than one phase to lower the free energy of the system. While investigators have overcome some of these limitations (by using sonication or chemical functionalization)^[27] to increase dispersion of the ceramic into the polymer phase, agglomeration is still an important issue for biocomposite synthesis. Fig. 7 illustrates the reduction of titania agglomeration in PLGA biocomposites using sonication.^[27] Increased bone formation has been documented on well-sonicated PLGA/titania biocomposites.^[27] Authors attribute greater bone cell responses on well-sonicated PLGA/titania biocomposites to matching the dispersion of organic and inorganic phases in natural bone.

Fig. 7 Altered dispersion of HA in PLGA. Note the increased dispersion of HA in PLGA owing to sonication, which increased bone formation. Bars (lower right in white) = 10 μm . (From Ref. [27].)

On the other hand, phase-separation can be quite useful in the fabrication of biocomposites. For example, phase-separation techniques have been used to fabricate porous membranes for filtration and separation.^[28] Phase separation can also be achieved by lowering the temperature to induce solvent crystallization from a polymer/ceramic suspension. This process is often defined as a solid–liquid phase separation (solid phase formation in a liquid phase). After the removal of the solvent crystals (sublimation or solvent exchange), the space originally occupied by the solvent crystals becomes porous. This technique is quite versatile and can be used to fabricate scaffolds from many types of polymers and ceramic composite materials.^[28]

By manipulating the phase separation conditions, various pore structures can be achieved. For example, many tissues (such as nerve, muscle, tendon, ligament, and dentin) have oriented tubular or fibrous bundle architectures.^[3] To facilitate the organization and regeneration of such tissue types, a scaffold with a high porosity and an oriented array of open microtubules may be desirable. To achieve this goal, a novel phase separation technique has been developed to orient rod-shaped crystals from a polymer solution.^[29] After the removal of these rods, a parallel array of microtubules that can guide tissue growth is formed. This oriented tubular scaffold has anisotropic mechanical properties similar to fibrillar and tubular tissues, and has been shown to facilitate cell organization into oriented tissues.

Moreover, in a novel bone tissue-engineering application, Liu et al.^[20] prepared collagen/HA composite scaffolds by phase-separation techniques. Hydroxyapatite powder was added into a collagen solution and homogenized by a speed stirrer.^[20] Mixtures with different compositions were poured onto 100 mm culture dishes and then rapidly transferred into a refrigerator at -30°C to solidify the mixture and induce solid–liquid phase separation. The solidified mixture was kept at that temperature for two hours and then lyophilized for two days. Resulting collagen/HA scaffolds were porous with three-dimensional interconnected fiber microstructures with pore sizes of 50–150 μm . However, the pores formed using this technique usually have diameters on the order of a few to tens of microns and are often not uniformly distributed. Such small pore sizes not well distributed in biocomposites limit tissue ingrowth and result in poor mechanical properties problematic for many tissue-engineering applications, particularly for those in orthopedics. Controlled phase separation processes, primarily thermally induced phase separation, have recently been explored for scaffold fabrication to overcome these problems.^[28]

Closed-Mold Processes

To mimic the natural orientation of HA and collagen in bone in biocomposites, closed-mold processes are often used.^[40] These techniques gained popularity for producing ceramic fiber-reinforced plastic materials. Closed-mold processes involve the use of a molding apparatus into which mechanical force is applied. While ceramic fiber-reinforced polymer composites possess numerous mechanical property advantages (such as matching the anisotropic mechanical properties of long bones), recent cytocompatibility advantages leading to greater bone growth have been reported.^[50] In this study, carbon nanofibers (CNF) of similar dimensions to HA and collagen in bones were aligned into micropatterns on a model polymer [polycarbonate urethane (PCU)] surface using a closed-mold process. This was accomplished by pressing a mixture of CNF and soluble PCU into micron-patterned gaps (20 μm in width) of a mold placed on the surface of PCU. After allowing the polymer to cure, aligned micron regions of CNF were formed, which directed calcium phosphate mineral deposition by bone cells (Fig. 8). In this manner, substrates were created which promoted osteoblasts to deposit aligned regions of HA and collagen similar to what is observed in long bones (such as the femur).^[50] Current materials used as orthopedic implants for long bones (specifically titanium) do not promote osteoblasts to deposit aligned calcium phosphate minerals.

In addition to the example given above, another example of a process that can be used to align fibers in a biocomposite to mimic the microstructure of long bones is continuous pultrusion (Fig. 9).^[18] The first step in this pultrusion process is the production of a reinforcement supply that usually consists of ceramic fibers impregnated with polymers. These composite fibers are then fed into a heated die, which maintains their orientation while applying compression. Moreover, by altering dimensions of the die (or mold) used in this step, final geometries of the oriented fiber composite can be controlled. Geometries in the final product can be further controlled through the use of pull rollers. Lastly, the finished part is removed after cooling. Pultrusion is an extremely fast and inexpensive technique that has applications from chopped fiber-reinforced thermoplastic composites to bone plates and screws.^[18] Furthermore, continuous pultrusion is a process used for the manufacturing of ceramic fiber-reinforced plastics of constant cross-section, such as structural shapes, beams, channels, pipe, and tubing. Highly oriented parts cut from this stock can then be used in other structures or they can be used alone in such applications as intramedullary rodding or pin fixation of

Fig. 8 Micron alignment of CNF for controlling calcium phosphate deposition by bone cells. Directed calcium phosphate deposition by osteoblasts can be achieved by micro-aligning CNF in polymers. Such alignment of calcium phosphate crystals matches the alignment of HA in long bones of the body. Bars = (A) 1 μm ; (B) 20 μm ; and (C) 10 μm .

bone fragments. Clearly, highly aligned ceramic fibers in polymer matrices through continuous pultrusion are attractive to match the anisotropic properties of HA and collagen in bone.

Fiber Meshes/Fiber Bonding

Owing to their similarity to biological entities (like collagen and HA), fibers produced by textile technology have been used to make nonwoven scaffolds of PGA and PLLA.^[16,19] The lack of structural stability of these nonwoven scaffolds often resulted in significant deformation owing to contractile forces from cells seeded on the scaffold. This has led to the development of a fiber-bonding technique to increase the mechanical properties of the scaffolds. Specifically, this is achieved by dissolving PLLA in methylene chloride and casting the polymer over a PGA mesh. The solvent is allowed to evaporate and the construct is then heated above the melting point of PGA. Once the PGA–PLLA construct has cooled, the PLLA is removed by dissolving in methylene chloride again. This treatment results in a mesh of PGA fibers joined at multiple cross-points, which increases mechanical stability. Again, while mostly used for pure polymer matrices, this technique can be easily adapted to polymer/ceramics biocomposites.^[19]

Rapid Prototyping Techniques

Lastly, one of the more exciting biocomposite fabrication techniques is rapid prototyping.^[37–39,41–45] As a common shortcoming of the fabrication technologies discussed above is the lack of automation and resolution when creating three-dimensional porous scaffold architectures, a number of investigators have been actively seeking methods to achieve a high degree of spatial control. To tackle this problem, solid free form fabrication (also known as rapid prototyping) techniques are being developed. The main advantage of these techniques is their ability to produce complex shapes rapidly from a computer-aided design (CAD) model. Thus, the goal here is to have a known bone fractal geometry, which could easily be duplicated in a biocomposite through CAD for use immediately at the surgical table.

Of these rapid prototyping techniques, three-dimensional printing was the first to process biodegradable polymer scaffolds for tissue-engineering applications.^[33] This process generates components by ink-jet printing a binder onto sequential powder layers. The operation parameters such as the speed, flow rate, and drop position can be computer controlled to produce complex three-dimensional polymer scaffolds. Biological agents such as bone growth factors or those that reduce the foreign body response can also be incorporated into the scaffolds in the printing process. However, rapid prototyping techniques have inherent shortcomings such as limited material selection and inadequate resolution. The resolution is determined by

Fig. 9 The pultrusion process for producing aligned fiber-reinforced polymer composites. Fibers impregnated with polymer are fed into a heated die and are then slowly drawn as a cured composite with a constant cross-sectional shape. Compression can be applied in the heated die. (From Ref. [18].)

the size of binder drops as well as the jet and powder particles, which makes it difficult to design and fabricate scaffolds with fine microstructures. The porosity of the scaffolds fabricated with this method is low, and the mechanical properties of the scaffolds have to be significantly improved. Thus, techniques that could easily incorporate ceramic particles would be most welcome to increase mechanical integrity necessary for bone applications. Similarly, other rapid prototyping techniques such as fused deposition modeling (FDM) and stereolithography have been explored for composite fabrication.^[35,36]

Three-dimensional ink-writing techniques can be divided into two approaches: 1) droplet-based or 2) continuous (filamentary) inks. As the name implies, droplet-based ink-writing uses distinct material drops, while continuous (filamentary) ink-writing uses a continuous material stream. For either approach, three-dimensional periodic structures offer the greatest challenge for designing inks because they contain self-supporting (or spanning) features. Inks are typically formulated from colloidal, polymeric, or polyelectrolyte building blocks suspended or dissolved in a liquid or heated to create a stable, homogeneous ink with the desired and reproducible rheological (or flow) behavior. The important rheological parameters for a given ink design include its apparent viscosity, yield stress under shear and compression, and viscoelastic properties, which are tailored for the specific direct-write technique of interest.

Three-dimensional printing (3DP), direct ink-jet printing, and related approaches such as hot-melt printing involve patterning materials using an ink-jet print head, similar to those used in desktop document printing.^[37] These approaches require either low viscosity fluids that must be removed by absorption and evaporation or wax-based inks that are heated during droplet formation and then solidify upon impact cooling. Cima and Sachlos pioneered the concept of using ink-jet printing (3DP) to assemble materials.^[38,39] In 3DP, low viscosity binder droplets are printed onto a powder bed to locally “fuse” material

together in a desired pattern. After defining a given two-dimensional layer, an additional powder layer is spread across the bed surface and subsequently patterned. In other ink-jet approaches, three-dimensional structures (such as high-aspect ratio walls of concentrated nanofiber inks) can be made; however, clogging issues still arise when $D/2a \sim 150$, where D is the finest nozzle used (30 μm in diameter) and a is the radius of largest ink particles. These three-dimensional meso-scale structures may find potential applications as tissue-engineering scaffolds if constructed from a bioactive ceramic material (e.g., HA) or as structural composites if the pore space is filled with a second phase. But clearly, the use of a ceramic phase is still problematic owing to nozzle clogging.

In addition, the resulting constructs have structural heterogeneity because of the “pixel assembly” nature of the rapid prototyping fabrication process. To overcome this shortcoming, a reverse fabrication technique has been developed to form a negative replica of the scaffold.^[42] A polymer/ceramic suspension is cast into such a mold and solidified after the removal of the solvent. The mold is then dissolved away to form the scaffold with the designed three-dimensional pore network. The scaffold is more homogeneous, but the feature resolution is not improved. As will be discussed in the next section, resolutions down to the nanoscale can increase bone regeneration, so this may be problematic and should be addressed in rapid prototyping techniques.

To achieve higher resolution for scaffolds with well-controlled interconnected spherical pores, paraffin spheres have been fabricated by dispersion methods.^[28,46] These paraffin spheres (on the tens of micron size scale) are then transferred into a three-dimensional mold of the desired shape. The spheres are bonded together through a heat treatment process. A composite suspension is then cast into the paraffin assembly in the mold. After removal of the solvent, the paraffin sphere assembly is dissolved away. In this way, an interconnected spherical pore structure is created. Importantly, the features generated (on the hundreds of

Fig. 10 Atomic force microscopy (AFM) scan illustrating the nanometer roughness of bone. Scan size = 100 nm by 5 μm by 5 μm (Z by X by Y). RMS (root-mean-square surface roughness value) = 33 nm.

nanometer scale) have significantly better resolution than those achieved with current rapid prototyping techniques (tens of microns). In addition, investment in expensive equipment is not required, which allows this technology to be easily adapted to an industrial setting.

Clearly, many adaptations can be made to rapid prototyping techniques for specific outcomes.^[31–46] But, as will be discussed in the next section, those that enable the construction of nanoscale surface features are highly desirable to promote bone growth.

NANOTECHNOLOGY AND BIOCOSITES

One of the biggest advantages to use biocomposites is the ability to match the properties (specifically, mechanical and surface) of natural tissue. That is, if desirable, polymer/ceramic composite scaffolds can be formulated to mimic the constituent components of natural bone (Fig. 10) (naturally present in/on bone). Natural bone is a composite material composed of a polymer matrix (organic compounds, mainly collagen) reinforced with nanometer ceramic particles (inorganic compound, mainly carbonated HA). Moreover, the collagen fibers and HA crystals of natural bone are within the nanometer scale proving for a unique heterogeneous nanosurface roughness to bone cells. Therefore, bone itself is a nanostructured composite composed of nanometer size HA well dispersed in a mostly collagen matrix.

Nanotechnology is the creation and use of materials with dimensions less than 100 nm in at least one direction. For this reason, through the use of nanotechnology, it may be possible to create biocomposites that more accurately mimic the nanoarchitecture of

natural tissues. Indeed, recent research in the biocomposite field has suggested better osteoconductivity on synthetic materials that incorporate nanoscale particles.^[21,23–26,47–50] Compared to respective micron-sized particles, this has been demonstrated for polymers that combine nanoparticles of ceramics (alumina, titania, HA, zinc oxide, etc.), metals (CoCrMo, c.p. Ti, Ti6Al4V, etc.), or CNF/nanotubes.^[23,24,47–50] For example, five times more bone growth was measured on PLGA, which contained nanometer compared to micron-sized titania particles.^[49] In all material cases, increased bone synthesis was attributed to the presence of nanoscale particles that provided for subsequent biologically inspired nanometer roughness to bone cells.

Specifically, when determining the mechanism of increased bone synthesis on nanoceramic biocomposites, studies have demonstrated significantly increased select protein adsorption (fibronectin and vitronectin) that led to promoted osteoblast function on the nano biocomposites compared to traditional micron-sized ceramics in polymers.^[23–25] It was further determined that the reason for altered protein interactions was the unique surface energetics of the biocomposites provided by the nanoparticles. It has been well established that nanomaterials have increased percentages of atoms at their surface, greater defects at their surface, and altered electron distributions;^[23–25] all of which contribute to a greater surface reactivity of nanomaterials compared to conventional materials.

Clearly, scaffold materials with surface properties similar to physiological bone (characterized by surface grain sizes in the nanometer regime) would aid in the formation of new bone at the tissue/biomaterial interface.^[26] Mechanical properties (such as flexural rigidity) are also much closer to natural bones when

nanoceramics as opposed to conventional ceramics are added to polymers.^[25] Although further studies are needed, there could be a significant advantage gained in biocomposite efficacy if nanotechnology is employed.

CONCLUSIONS

While numerous advances have been made toward the use of biocomposites in tissue engineering, much more research is still needed. This article highlighted some advances that have been made toward material selection and fabrication techniques to formulate biocomposites more similar to properties of natural tissue. However, before the field can take advantage of the ability of biocomposites to mimic natural tissues, the following research areas need to be expanded:

1. Improved fabrication techniques for polymer/ceramic composites, emphasizing resolution and preciseness of three-dimensional structures.
2. Improved mechanical properties closer to natural tissue, such as strength and elastic modulus of polymer/ceramic composites.
3. Improved cytocompatibility, emphasizing nano-scale surface properties that favor cell growth and consequently improves the composite-tissue interface.
4. Improved understanding of the degradation behavior of biodegradable polymer and bioactive ceramic composites, especially the effect of the ceramic phase on degradation kinetics and degradation products of the polymer.
5. Understanding of how to most effectively incorporate drugs and growth factors into biocomposite scaffolds for proper diffusion to further promote tissue growth.

In conclusion, we will not be able to fully comprehend the advantages biocomposites can make to the field of tissue engineering until we understand all of the intricate complexities involved when two or more different types of materials are combined. It is clear, though, that as our tissues are composites themselves arranged in a well-controlled manner, we need to develop materials that match this diversity. The perfect biocomposite materials will not be obtained until this is accomplished.

Biodegradable Polymers: An Overview

Chih-Chang Chu

Fiber & Polymer Science Program, Department of Fiber Science & Apparel & Biomedical Engineering Program, Cornell University, Ithaca, New York, U.S.A.

B

INTRODUCTION

Interests in biodegradable polymers increased dramatically during the past decades as a result of their successful clinical applications in a wide range of biomedical areas. This success is because of the fact that this class of biomaterials has two major advantages that non-biodegradable biomaterials do not have. First, they do not elicit permanent chronic foreign-body reaction because they would be gradually absorbed by the human body and do not permanently retain traces of residual in the implantation sites. Second, some were recently found to be able to regenerate tissues, so-called tissue engineering, through the interaction of their biodegradation with immunologic cells such as macrophages. Hence, surgical implants made from biodegradable biomaterials could be used as a temporary scaffold for tissue regeneration. The approach of using biodegradable polymers as a temporary scaffold either to grow cells/tissues in vitro for tissue engineering application or to regenerate tissues in vivo has very recently become an important aspect of research and development that broadens biodegradable polymers beyond their traditional use in wound closure and drug control/release biomaterials. The scaffolds used in either tissue engineering or regeneration are to provide support for cellular attachment and subsequent controlled proliferation into predefined shape or form. A biodegradable scaffold is preferred because of the elimination of chronic foreign-body reaction and the generation of additional volume for regenerated tissues.

The earliest and most commercially significant biodegradable polymeric biomaterials originated from linear aliphatic polyesters such as polyglycolide and polylactide from poly(α -hydroxyacetic acids). Recent introductions of several new synthetic and natural biodegradable polymeric biomaterials extend the domain beyond this family of simple polyesters. These relatively newer, commercially significant biodegradable polymeric biomaterials include poly(orthoesters), polyanhydrides, polysaccharides, poly(ester amides), tyrosine-based polyarylates or polyiminocarbonates or polycarbonates, poly(D,L-lactide-urethane), poly(β -hydroxybutyrate), poly(ϵ -caprolactone), poly[bis-(carboxylatophenoxy)phosphazene], poly(amino acids), pseudo-poly(amino acids), and copolymers derived

from amino acids and non-amino acids. These commercially important biodegradable polymeric biomaterials are frequently used in one of the following physical forms: fibers, fabrics, gels, microspheres, or films.

The earliest and most successful and frequent biomedical application of biodegradable polymeric biomaterials was in wound closure.^[1] All biodegradable wound closure biomaterials are based on the glycolide and lactide family. This family of biodegradable polymeric biomaterials is also the most studied in chemical, physical, mechanical, morphological, and biological properties. Some of the above materials have been commercially used as surgical meshes for hernia and body-wall repair. Other important biomedical applications of biodegradable polymeric biomaterials that are commercially satisfactory are drug control/release devices and orthopedic fasten devices or implants and dental reconstruction. Biodegradable polymeric biomaterials, particularly totally resorbable composites, have also been used in the field of orthopedics, mainly as components for internal bone fracture fixation devices like bone screws, plates, and pins. Beside the commercial uses described above, biodegradable polymeric biomaterials have been tested as vascular grafts, vascular stents, vascular couplers for vessel anastomosis, nerve growth conduits, augmentations of defective bone, ligament/tendon prostheses, intramedullary plugs during total hip replacement, anastomosis rings for intestinal surgery, and stents in ureteroureterostomies for accurate suture placement.

This chapter provides a brief overview of the commercially most significant and successful biomedical biodegradable polymers based on linear aliphatic polyesters, the effects of some new extrinsic factors on the degradation of the commercially most significant biodegradable polymers, a new theoretical approach to model the hydrolytic degradation of glycolide/lactide-based biodegradable polymers, some of the latest research and development in important classes of synthetic biodegradable polymers outside the conventional aliphatic polyester family. In this chapter, the term “biodegradable” is loosely associated with absorbable, erodable, and resorbable, and refers to materials that could be broken down by nature either through pure hydrolytic or enzyme-catalyzed

mechanisms. The details of the applications of this family and other classes of biodegradable polymeric biomaterials and their chemical, physical, mechanical, biological, and biodegradation properties exist in many other reviews.^[2–13]

Commercially Important Biodegradable Polymers from Linear Aliphatic Polyesters

Biodegradable polymers from linear aliphatic polyesters are the most successful, important, and commercially widely used biodegradable biomaterials in both biomedicine and surgery and were the most extensively studied in terms of degradation mechanisms and structure–property relationship. Among them, polyglycolide or polyglycolic acid (PGA), poly-L-lactide (PLLA), and poly- ϵ -caprolactone (PCL) are the most important building blocks because most other biodegradable polymers are based on these three types of homo- and copolymers, e.g., poly(glycolide-L-lactide) copolymer, poly(glycolide-L-lactide- ϵ -caprolactone) copolymer (Caprosyn™), poly(glycolide-L-lactide-trimethylene carbonate) copolymer (Gore Resolut®), poly(glycolide- ϵ -caprolactone-trimethylene carbonate) copolymers, or modified glycolide monomer, e.g., poly-*p*-dioxanone. Poly(hydroxyalkanoate) (PHA) is an unusual family member of aliphatic polyesters and is mainly derived from genetically engineered microorganisms such as *Escherichia coli*. PHA will be described later. Table 1 illustrates important properties of a few selected commercially important synthetic biodegradable polymers used as biomaterials.

Glycolide, Lactide, and ϵ -Caprolactone-Based Polymers

PGA is the first synthetic biodegradable polymer synthesized for biomaterial application and also the simplest linear aliphatic polyester. For biomedical applications, stannous chloride dihydrate or trialkyl-aluminum is the preferred catalyst for ring-opening polymerization. PGA exhibited an orthorhombic unit cell with dimensions $a = 5.22 \text{ \AA}$, $b = 6.19 \text{ \AA}$, and c (fiber axis) = 7.02 \AA . The planar zigzag-chain molecules form a sheet structure parallel to the ac plane and do not have the polyethylene type arrangement, and the tight molecular packing and the close approach of the ester groups might stabilize the crystal lattice and contribute to the high melting point, T_m ($224\text{--}230^\circ\text{C}$). The glass transition temperature, T_g , ranges from 36 to 40°C . The specific gravities of PGA are 1.707 for a perfect crystal and 1.50 in a completely amorphous state. The heat of fusion of 100% crystallized PGA is 12 KJ/mol (45.7 cal/g). The four Fourier transform infrared spectroscopy bands at 850 , 753 , 713 , and 560 cm^{-1} are associated with the amorphous regions of the PGA and could be used to assess the extent of hydrolysis. Peaks associated with the crystalline phase include those at 972 , 901 , 806 , 627 , and 590 cm^{-1} .

Other commercially successful glycolide-based biodegradable polymeric biomaterials are the copolymers of glycolide with other monomers within linear aliphatic polyesters such as lactides, carbonates, and ϵ -caprolactone. The glycolide–lactide random copolymers are the most studied and have a wide range of properties and applications, depending on the composition ratio of glycolide to lactide. For wound

Kimura, CRC Press, Boca Raton, Florida, and Chu, C.C., von Fraunhofer, J.A., and Greisler, H.P., 1996. *Wound Closure Biomaterials and Devices*. CRC Press, Boca Raton, Florida.

closure application, a high concentration of glycolide monomer is required for achieving proper mechanical and degradation properties. Vicryl[®] sutures, sometime called polyglactin 910, contain a 90/10 molar ratio of glycolic to L-lactide. This molar ratio is important for the Vicryl suture to retain crystalline characteristics. Contrary to the conventional high PGA content in the glycolide–lactide copolymers, Ethicon introduced a copolymer of PGA and PLLA with 5-to-95 molar ratio (Panacryl[®]). Because of the high L-lactide component in the copolymer, Panacryl biodegrades much more slowly than Vicryl. Panacryl was recently pulled from the biomedical market. If DL- instead of L-lactide is used as the comonomer, the U-shape relationship between the level of crystallinity and glycolide composition disappears. This is because polylactide from 100% DL-lactide composition is totally amorphous. Infrared (IR) bands associated with Vicryl molecules in the amorphous domains are 560, 710, 850, and 888 cm⁻¹, whereas 590, 626, 808, 900, and 972 cm⁻¹ are associated with the crystalline domains. Like PGA, these IR bands could be used to assess the extent of hydrolysis.

A block copolymer of glycolide and carbonates, such as trimethylene carbonate, has been commercialized as Maxon[®] suture and is made from a block copolymer of glycolide and 1,3-dioxan-2-one (trimethylene carbonate GTMC) and consists of 32.5% by weight (or 36 mol %) trimethylene carbonate. The weight ratio of glycolide to trimethylene carbonate in the middle block is 15:85, and the two ends of this middle block are capped by additional glycolide monomers to form the final triblock copolymer. Maxon is a poly(ester carbonate). The latest glycolide-based copolymer to become commercially successful is Monocryl[®] suture. Monocryl is a segmented block copolymer consisting of both soft and hard segments. The purpose of having soft segments in the copolymer is to provide good handling properties such as pliability, whereas the hard segments provide adequate strength. The soft segment consists of a prepolymer of glycolide and ϵ -caprolactone; like Maxon, the two ends of the prepolymer are capped by polyglycolide, which act as hard segments. Monocryl has a composition of 75% glycolide and 25% ϵ -caprolactone for adequate mechanical property required by sutures. The most unique aspect of Monocryl monofilament suture is its pliability, as claimed by Ethicon, and the force required to bend a 2/O suture is only about 2.8×10^4 lb-in² for Monocryl, whereas the same size PDSII and Maxon monofilament sutures require about 3.9 and 11.6×10^4 lb in² force, respectively. This inherent pliability of Monocryl is because of the presence of soft segments and T_g resulting from the ϵ -caprolactone comonomer unit. The T_g of Monocryl is expected to be between 15 and -36°C .

Poly(*p*-dioxanone) (PDS[®]) is derived from the glycolide family for better flexibility. It is polymerized from ether-containing lactones, 1,4-dioxane-2,5-dione (i.e., *p*-dioxanone) monomers with a hydroxylic initiator, and tin catalyst. The resulting polymer is semicrystalline, with T_m about 106 – 115°C and T_g -10 to 0°C . The improved flexibility of PDS relative to PGA as evidenced in its lower T_g is a result of the incorporation of the ether segment in the repeating unit, which reduces the density of ester linkages for intermolecular hydrogen bonds. Because of the less dense ester linkages in PDS compared with PGA or glycolide-L-lactide copolymers, PDS is expected and has been shown to degrade at a slower rate in vitro and in vivo. Recently, an advanced version of PDS, PDSII, was introduced. PDSII was achieved by subjecting the melt-spun fibers to a high temperature (128°C) for a short period of time. This additional treatment partially melts the outermost surface layer of PDS fibers and leads to a distinctive skin-core morphology. The heat employed also results in larger crystallites in the core of the fiber than in the untreated PDS fiber. The tensile strength loss profile of PDSII sutures is better than that of PDS sutures. A variety of copolymers with high molar ratios of PDS to other monomers within the same linear aliphatic polyester family were reported for the purpose of improving mechanical and biodegradation properties. For example, the copolymer of PDS (80%) and PGA (up to 20%) has an absorption profile similar to that of Dexon[®] and Vicryl sutures, but it has compliance similar to that of PDS. The copolymer of PDS (85%) and PLLA (up to 15%) results in a more compliant (low modulus) suture than homopolymer PDS but with similar absorption profiles as PDS.

Copolymer fibers made from PDS and monomers other than linear aliphatic polyester, such as morpholine-2,5-dione (MD), exhibit interesting biodegradation properties. The copolymer fibers were absorbed 10–25% earlier than PDS. However, the copolymer retained a tensile breaking strength profile similar to that of PDS, with a slightly faster strength loss during the earlier stage, i.e., the first 14 days. This ability to break the inherent fiber structure–property relationship through copolymerization is a major improvement in the biodegradation property of absorbable sutures. It is interesting to recognize that a small percentage (3%) of MD in the copolymer suture is sufficient to result in a faster mass loss profile without the expense of its tensile strength loss profile. The ability to achieve this ideal biodegradation property might be attributed to both an increasing hydrophilicity of the copolymer and the disruption of crystalline domains as a result of MD moieties. As described later, the loss of suture mass is mainly a result of the destruction of crystalline domains, whereas the loss of tensile breaking strength

is chiefly a result of the scission of tie-chain segments located in the amorphous domains. The question is, Why does MD-PDS copolymeric suture retain its strength loss similar to PDS? The possible explanation is that the amide functional groups in MD could form stronger intermolecular hydrogen bonds than ester functional groups. This stronger hydrogen bond contributes to the strength retention of the copolymer of PDS and MD during *in vivo* biodegradation.

To improve γ -irradiation stability of linear aliphatic polyesters, radiostabilizers like poly(ethylene 1,4-phenylene-bis-oxyacetate) (PEPBO) have been copolymerized with glycolide and PDS to form segmented copolymers. Because of the well-known adverse effect of γ -irradiation on the mechanical properties of aliphatic polyester-based synthetic biodegradable polymers, they are generally sterilized by the tedious ethylene oxide process. A great need exists to develop γ -irradiation sterilizable synthetic biodegradable polymers to take advantage of the highly convenient and reliable method of sterilization. The incorporation of about 10 mol % of a polymeric radiostabilizer like PEPBO into PGA backbone chains would make the copolymer sterilizable by γ -irradiation without a significant accelerated loss of mechanical properties upon hydrolysis compared with the unirradiated copolymer control (morpholine-2,5-dione glycolide, or MPG). The changes in tensile breaking force of both MPG and PGA sutures implanted intramuscularly and subcutaneously in rats for various periods demonstrate the great advantage of such copolymers. MPG fibers γ -irradiated at 2.89 Mrad did not demonstrate any loss in tensile breaking force during the first 14 days post-implantation compared with unimplanted samples. On the contrary, PGA sutures γ -irradiated at 2.75 Mrad lost 62% of their tensile breaking force of their unimplanted samples. No tensile breaking force remained for the irradiated PGA at the end of 21 days, whereas both 2.89 and 5 Mrad-irradiated MPG retained 72% and 55% of their corresponding 0 day controls, respectively. The inherent, more hydrolytic resistance of MPG must be attributed to the presence of an aromatic group in the backbone chains, which is also responsible for the observed γ -irradiation stability. The incorporation of 5–10% of such stabilizer in PDS not only improved γ -irradiation resistance considerably, but also increased the compliance of the material. For example, PEPBO-PDS copolymer retained 79%, 72%, and 57% of its original tensile breaking strength at 2, 3, and 4 weeks *in vivo* implantation, whereas PDS homopolymer retained only 43%, 30%, and 25% at the corresponding periods. It appeared that an increasing (CH₂) group between the two ester functional groups of the radiation stabilizers improved copolymer resistance toward γ -irradiation. PEPBO was also incorporated

into glycolide via copolymerization to achieve γ -irradiation capability.

Poly lactides, particularly PLLA, and copolymers having > 50% L- or DL- lactide have been explored for medical use without much success, mainly because of their much slower absorption and difficulty in melt processing. PLLA is a semicrystalline polymer with $T_m = 170^\circ\text{C}$ and $T_g = 56^\circ\text{C}$. This high T_g is mainly responsible for the observed extremely slow biodegradation rate at body temperature. The molecular weight of lactide-based biodegradable polymers suitable for medical use ranges from 1.5 to 5.0 dl/g inherent viscosity in chloroform. Ultrahigh-molecular-weight polylactide has been reported and an intrinsic viscosity as high as 13 dl/g was reported. High-strength PLLA fibers from this ultrahigh-molecular-weight polylactide was made by hot-drawing fibers from solutions of good solvents. The resulting fibers had tensile breaking strength close to 1.2 GPa. Because of the dissymmetric nature of lactic acid, however, the polymer made from optically inactive racemic mixture of D and L enantiomers, poly-DL-lactide is an amorphous polymer.

Lactide-based copolymers with a high percentage of lactide have recently been reported, particularly those copolymerized with aliphatic polycarbonates such as trimethylene carbonate (TMC) or 3,3-dimethyltrimethylene carbonate (DMTMC). The major advantage of incorporating TMC or DMTMC units into lactide is that the degradation products from TMC or DMTMC are largely neutral pH and, hence, considered advantageous. Glycolic- or lactic-acid-rich degradation products have the potential to significantly lower the local pH in closed and less body-fluid-buffered regions surrounded by bone. This is particularly true if the degradation process proceeds with a burst mode (i.e., a sudden and rapid release of degradation products). This acidity tends to cause abnormal bone resorption or demineralization. The resulting environment may be cytotoxic. The increase in local acidity as a result of a faster accumulation of the highly acidic degradation products also leads to an accelerated acid-catalyzed hydrolysis in the immediate vicinity of the biodegradable device. This acceleration in hydrolysis could lead to a faster loss of mechanical property of the device than expected. Copolymers of composition ratio of 10 DMTMC/90 LLA (L-lactide) or 10 TMC/90 LLA appear to be a promising absorbable orthopedic device. Other applications of this type of copolymer include nerve growth conduits, tendon prostheses, and coating materials for biodegradable devices.

Although the copolymer of L-lactide with glycolide (e.g., Vicryl) resulted in commercial success, the copolymer of L-lactide with other aliphatic polyesters such as ϵ -caprolactone is not as well known. Recently,

a copolymer of L-lactide- ϵ -caprolactone and acrylic acid was reported.^[14] The most unique aspect of this new L-lactide- ϵ -caprolactone-acrylic acid copolymer is that the free pendant carboxylic acid group along the acrylic acid backbone was used to attach biologically active species, such as tempamine nitroxyl radicals.

Another unique example of L-lactide copolymer is the copolymer of L-lactide and 3-(S)[(alkyloxy-carbonyl) methyl]-1,4-dioxane-2,5-dione, a cyclic diester. The most unique aspect of this new biodegradable copolymer is the carboxyl acid pendant group which, makes the new polymer not only more hydrophilic, resulting in faster biodegradation, but also more reactive toward future chemical modification through the pendant carboxyl group. These carboxyl-reactive pendant sites could be used to chemically bond antimicrobial agents or other biochemicals such as growth factors, creating future wound closure biomaterials with new and important biological functions. Unfortunately, no reported data evaluate the performance of these new absorbable polymers for biomedical engineering use up to the present time.

Block copolymers of PLLA with poly(amino acids) were also reported as a potential controlled drug delivery system. This new class of copolymers consists of two distinctive blocks in the backbone, the block with only amide linkage and the block with only ester linkages, and is sometimes referred as poly(depsipeptides).^[4] As described later, a new family of poly(ester amide)s (PEA) has both ester and amide linkages within the same repeating unit, instead of being located at two different blocks as above.

The introduction of poly(ethylene oxide) (PEO) into PLLA in order to modulate the hydrophilicity and degradability of PLLA for drug control/release biomaterials has been reported. An example is the triblock copolymer of PLLA/PEO/PLLA. Biomaterials with an appropriate PLLA and PEO block length had hydrogel properties that could deliver hydrophilic drugs as well as hydrophobic ones such as steroids and hormones. Another unique biodegradable biomaterial consisting of a star-block copolymer of PLLA, PGA, and PEO was also reported for protein drug delivery devices. This star-shape copolymer has four or eight arms made of PEO, PLLA, and PGA. The T_g and the crystallinity of this star-shape block copolymer were significantly lower than that of the corresponding linear PLLA and PGA.

Because of the slow biodegradation rate of PLLA and because the copolymers have a high composition ratio of PLLA, their biomedical applications have been limited to mainly orthopedic and dental surgery, drug control/release devices, coating materials for suture, vascular grafts, and surgical meshes to facilitate wound healing after dental extraction.

In addition to glycolide- and lactide-based biodegradable polymers as biomaterials, ϵ -caprolactone-

based biodegradable polymers, particularly pure PCL homopolymer, have not enjoyed the same level of commercial success as their siblings, probably because of their slow biodegradation rate and relatively lower thermal and mechanical properties. Because of its low T_m of 57°C, it is difficult to thermally process poly- ϵ -caprolactone, and its low T_g , near -60°C, would make it difficult for tissue repairs that require high mechanical strength and rigidity. Because of the relative disadvantages of pure PCL homopolymer as biomaterials, research and development efforts have been geared toward the formation of either copolymers as the case with L-lactide or multiarms and gel network structure. The two most recent examples of the latter approach are the synthesis of three-arm star polymers having PCL arms with functionalized arm ends^[15] and the four-arm network structure with gel characteristics.^[16]

Non-glycolide-, lactide-, and ϵ -caprolactone-based linear aliphatic polyesters

The most unique family of biodegradable polymers outside glycolide, lactide, and ϵ -caprolactone is from linear aliphatic polyesters based on poly(ω -hydroxy acids), and the most well-known are poly(3-hydroxybutyrate) (P3HB), poly(3-hydroxyvalerate) (PHV), and the copolymers of P3HB/PHV.^[4] PHB and PHV belong to the family of poly(hydroxyalkanoates) and are mainly produced by a prokaryotic type of microorganism such as *Pseudomonas oleovorans* or *Alcaligenes eutrophus* through biotechnology. PHB and PHV are the principal energy and carbon storage compounds for these microorganisms and are produced when there are excessive nutrients in the environment. These naturally produced PHB and PHV are stereochemically pure and isotactic. They could also be synthesized in laboratories, but the characteristic of stereoregularity would be lost.

This family of biodegradable polyesters is considered environmentally friendly because they are produced from propionic acid and glucose and could be completely degraded to water, biogas, biomass, and humic materials. Their biodegradation requires enzymes. Hence, PHB, PHV, and their copolymers are probably the most important biodegradable polymers for environmental use. However, the biodegradability of this class of linear aliphatic polyesters in human or animal tissues has been questionable. For example, high-molecular-weight PHB or PHB/PHV fibers do not degrade in tissues or simulated environment over periods of up to 6 months. The degradability of PHB could be accelerated by γ -irradiation or copolymerization with PHV.

Because of its brittleness, P3HB has not been commercially successful as a biomaterial. Recently, a

close relative of P3HB was introduced by Tephra. This new biodegradable polymer, poly-4-hydroxybutyrate (P4HB), exhibits unusual elastomeric property with elongation at break as high as 1000% and tensile modulus of 70 MPa. P4HB has a low T_g (around -51°C) and low T_m (about 60°C). Because of its unusual elastomeric characteristic, P4HB may have potential in soft tissue repair.

An interesting derivative of P3HB, poly(β -malic acid) (PMA), was synthesized from β -benzyl malolactonate followed by catalytic hydrogenolysis. PMA differs from P3HB in that the 3-(CH_3) substituent is replaced by $-\text{COOH}$.^[3] The introduction of the pendant carboxylic acid group would make PMA more hydrophilic and easier to absorb than P3HB.

Poly(ester amide)s

The rationale for designing PEAs is to combine the predictable hydrolytic-induced degradability and biocompatibility of linear aliphatic polyesters with the high performance and enzymatically catalyzed biodegradability of polyamides and the potential chemical reactive sites of amide in polyamides into one single entity. Instead of using the block copolymer approach to provide both ester and amide linkages in a polymer backbone, PEAs have both ester and amide linkages within the same repeating unit, and different versions of PEAs have been reported.

Two basic types of PEAs exist: non-amino-acid based PEAs synthesized from polyesterification of amidediol monomers (which contain preformed amide linkages from aliphatic diamines)^[13] and amino-acid-based PEAs synthesized from solution polycondensation of amino acids, diols, and dicarboxylic acids.^[17-19] PEAs obtained from amidediol (i.e., non-amino-acid based) cannot be considered bioassimilative polymers because the water-soluble amidediols (first product of biodegradation) were extensively excreted without change (i.e., without the liberation of toxic diamine) in the urine. The approach of using amino acid, diols, and dicarboxylic acid building blocks to form PEAs appears to be a better one because of the biocompatibility of the amino acids used to provide amide linkages.

These amino-acid-based PEAs consisted of naturally occurring and non-toxic building blocks and had excellent film- and fiber-forming properties. PEAs of M_w from 24,000 to 167,000 with narrow polydispersity ($M_w/M_n = 1.20-1.81$) were successfully synthesized via solution polycondensation of di-*p*-toluenesulfonic acid salts of bis(α -amino acid) α,ω -alkylene diesters and di-*p*-nitrophenyl esters of diacids.^[18] These PEA polymers are initially semicrystalline polymers from solution polycondensation, but some amino-acid-based PEAs, such as L-phenylalanine and L-leucine,

become amorphous after first melting and cooling. This lack of crystallization capability from melt may be attributed to either the extensive inter- and intramolecular hydrogen bond capability from both the amide and the ester linkages in the PEA backbones that retards the chain mobility required for crystallization or the bulky side group that makes regular chain packing difficult. The T_g of these PEA ranged from 11 to 109°C .

The first generation PEAs are of saturated nature (SPEA): saturated carbon-to-carbon linkages on the backbone, i.e., the lack of $>\text{C}=\text{C}<$ double bond functionality in the PEA backbone. Recently, a new generation of PEAs, unsaturated PEAs (UPEA), was reported.^[19] The most unique aspect of these UPEAs is that there are $>\text{C}=\text{C}<$ double bonds built into either the diamide or the diester segments of the polymer backbones. As a result, UPEAs have a much higher T_g and T_m than saturated PEAs because of the rigidity of the $>\text{C}=\text{C}<$ bonds. These $>\text{C}=\text{C}<$ bonds also provide potential reactive sites for either synthesizing additional derivatives or attaching biologically active agents to render biological activity to UPEAs. An example of synthesizing additional derivatives from UPEA is the reported study of UPEA-based hydrogels via photocrosslinking with poly(ethylene glycol) diacrylate precursor,^[20] and these unique hydrogels were used as the paclitaxel carrier for its controlled release. Fig. 1 illustrates a scanning electron microscopic image of a UPEA-based hydrogel.

Beside the UPEA approach, another effort could also provide chemical functionality to SPEAs, the copolymer approach. Jokhadze et al.^[21] recently reported that, via L-lysine comonomer, the resulting co-PEAs would have pendant-free carboxylic acid over a wide range of desirable concentrations. These free carboxylic acids provide the reactive sites for the attachment of biologically active agents, such as nitric oxide derivative, and the resulting co-PEAs would have biological activity and intelligence similar to that of nitric oxide.

An effort to integrate saturated PEA with UPEA into one single entity was recently conducted^[22] and the major advantage of such an integration is to combine the merits of both saturated and unsaturated PEAs into one single entity via chemical linkages so that a wide range of physical, chemical, thermal, and biological properties could be obtained by simply changing the composition ratio of saturated to unsaturated PEAs.

Both saturated PEAs and UPEAs were easily biodegraded by enzymes such as lipase or α -chymotrypsin; however, their biodegradability in pure saline buffer is slow. It appears that an increase in the hydrophobicity of PEAs (via longer methylene groups in diols and dicarboxylic acid segments) leads to a faster enzyme-catalyzed biodegradation.^[19] In addition to the hydrophobicity factor to interpret this relationship

Fig. 1 The scanning electron microscopic image of unsaturated poly(ester amide)-based hydrogel after 1 day of swelling in a buffer solution.

Source: K. Guo and C. C. Chu, "Synthesis, characterization and swelling behaviors of novel biodegradable unsaturated poly(ester amide)s/poly(ethylene glycol) diacrylate hydrogels," *J. Polym. Sci. Polym. Chem. Ed.*, 43: 3932–3944 (2005).

between the length of methylene groups and enzyme-catalyzed biodegradation rate, the lack of intermolecular hydrogen bonds resulting from misalignment of the adjacent PEA macromolecules was also suggested as a possible cause behind such a relationship.

The saturated PEAs were clinically tried as a biodegradable coating on drug-eluting stents. Their biocompatibility data in an *in vivo* porcine model suggest that these new biodegradable polymers are as biocompatible as bare stents under a dynamic vessel condition.^[23] In a reported *in vitro* study of blood and cellular response to saturated PEAs, the proliferation of endothelial cells adhered to SPEA substrates was much higher than on non-biodegradable polymers like poly(*n*-butyl methacrylate) or polyethylene vinyl acetate copolymer.^[24] The amount of ATP release from human platelets on SPEAs (an indication of hemocompatibility) was twofold lower than on the above non-degradable polymers. In addition, monocytes adherent onto saturated PEA induced far less secretion of proinflammatory cytokines such as interleukin (IL)-6 and IL-1 β when comparing tissue culture-treated polystyrene control. Therefore, saturated PEAs appear to support a more natural wound healing process by promoting re-endothelialization and lowering inflammatory response.

Biodegradation Property of Synthetic Biodegradable Polymers

The reported *in vitro* and *in vivo* biodegradation studies of a variety of biodegradable polymeric biomaterials led to the following conclusions:

- Mechanical strength loss always proceeds before mass loss.
- Absorption delay, defined as the difference in time between complete mass loss and mechanical strength loss, is a good indicator for determining the useful life of biodegradable polymers.
- Molecular weights also decrease with duration of biodegradation, and the rate of molecular weight reduction correlates with the profiles of mechanical strength loss, e.g., faster molecular weight loss leads to faster mechanical strength loss. The reduction in molecular weight in an *in vitro* condition is similar to that in an *in vivo* environment.
- Oriented polymers like fibers show little change in birefringence and crystal lattice parameters during the period of mechanical strength loss, an indication of little disruption of overall fiber structure, particularly the crystalline domains.
- Biodegradation property depends on many intrinsic and extrinsic factors, such as pH, enzymes, bacteria, lipids, temperature, γ -irradiation, electrolytes, medium, free radicals, annealing treatment, plasma surface treatment, external stress, orientation, polymer morphology, and type and location of tissues.^[1]
- During the course of biodegradation, the level of crystallinity of biodegradable polymers increases first, reaches a peak, and then decreases thereafter. Thus, the time for the appearance of the crystallinity peak could be used as an indicator of degradation rate.
- Except under the influence of superoxide, the morphological features of biodegradable polymers/fibers upon either *in vitro* or *in vivo* biodegradation exhibit the formation of surface cracks; and the level of surface cracks and their orientation depend on the duration of biodegradation, the severity of the treatment, and the morphological nature of the polymers (e.g., orientation, level of crystallinity). The

onset of apparent surface morphological changes is frequently associated with the onset of mass loss.

- The role of enzymes on the biodegradation of linear aliphatic polyesters remains controversial. It appears, however, that reducing the molecular weight of these aliphatic polyesters by an external means such as γ -irradiation could facilitate subsequent enzyme-catalyzed hydrolysis. Enzymes, however, demonstrate a significant catalytic effect on the biodegradation of biodegradable polymers made from amino acids such as PEAs, which have both ester and amide linkages in their repeating units.
- Superoxide has a profound adverse effect on the mechanical property of synthetic biodegradable polymers and could shorten the duration of complete strength loss from several weeks/months to within 48 hr. The surface morphology from the superoxide-induced biodegradation of linear aliphatic polyester suture fibers reveals a moon-crater-type isotropic impression that defies the anisotropic nature of fibers.
- The degradation products of aliphatic polyesters are of acidic nature, and this acidity build-up, if inside a bulky implant, could lead to acid-catalyzed premature loss of mechanical property. Such acid-catalyzed degradation would become profound if the acid generated could not be neutralized easily as a result of poor circulation, avascular tissue, or size of the biodegradable implants.
- The level of tissue response to biodegradation depends on the biodegradation stage. In addition to the surgical trauma-induced tissue response, the bio-material-induced response would reach a peak during biodegradation and then subside after the polymer mass becomes smaller and eventually disappears.

Table 2 summarizes the structural factors that can be used to control polymer degradability.

Theoretical modeling of degradation property

Computational chemistry was used as a tool to conduct a systematic theoretical modeling study of the degradation properties of biodegradable biomaterials^[1] and the effects of a variety of hypothetical substituents that could exert either steric or inductive effects on the degradation properties of glycolide/lactide-based biodegradable polymers. This new approach could provide scientists with a better understanding of the relationship between the chemical structure of biodegradable polymers and their degradation behavior at a molecular level. It may also help the future research and development of biodegradable polymers through the intelligent prediction of structure–property relationships. Linear aliphatic polyester

Table 2 Structural factors to control polymer degradability

Factors	Methods of control
• Chemical structure of main chain and side groups	Selection of chemical bonds and functional groups
• Aggregation state	Processing, copolymerization
• Crystalline state	Polymer blend
• Hydrophilic/hydrophobic balance	Copolymerization, introduction of functional groups
• Surface area	Micropores
• Shape and morphology	Fiber, film, composite

(PGA) was used as a model compound for such a theoretical modeling.

Chu et al.^[1] demonstrated a decrease in the rate of hydrolysis by about a factor of 10^6 with isopropyl α -substituents, but nearly a sixfold increase with *t*-butyl α -substituents. The role of electron-donating and electron-withdrawing groups on the rate of hydrolytic degradation of linear aliphatic polyesters was also theoretically modeled. Electron-withdrawing substituents to the carbonyl group would be expected to stabilize the tetrahedral intermediate resulting from hydroxide attack, i.e., favoring hydroxide attack but disfavoring alkoxide elimination. Electron-releasing groups would be expected to demonstrate the opposite effect. Similarly, electronegative substituents on the alkyl portion of the ester would stabilize the forming alkoxide ion and favor the elimination step. The rate of ester hydrolysis was greatly affected by halogen substituents, primarily because of charge delocalization. Chu et al.^[1] suggest that the magnitude of the inductive effect on the hydrolysis of glycolic esters decreases significantly as the location of the substituent moves further away from the α -carbon because the inductive effect is distance sensitive. In all three locations of substitutions (α , β , and γ), Cl and Br substituents exhibited the largest inductive effect compared with other halogen elements.

Therefore, the rate of ester hydrolysis was greatly affected by both alkyl and halogen substituents, primarily because of either steric hindrance or charge delocalization. In the steric effect, alkyl substituents on the glycolic esters cause an increase in activation enthalpies and a corresponding decrease in reaction rate, up to about three carbon sizes, whereas bulkier alkyl substituents than isopropyl make the

rate-determining elimination step more facile. It appears that aliphatic polyesters containing α -isopropyl groups or slightly larger linear alkyl groups, such as *n*-butyl, *n*-pentyl, etc., would be expected to show longer strength retention given the same fiber morphology. In the inductive effect, α -substituents on the acyl portion of the ester favor the formation of the tetrahedral intermediate through charge delocalization, with the largest effect seen with Cl substitution, but retard the rate-determining alkoxide elimination step by stabilizing the tetrahedral intermediate. The largest degree of stabilization is caused by the very electro-negative F substituent.

The role of free radicals in degradation property

Literature data demonstrated that the biodegradation of synthetic biodegradable polymers is closely related to macrophage activity through the close adhesion of macrophage onto the surface of the polymer. Inflammatory cells, particularly leukocytes and macrophages, are able to produce highly reactive oxygen species such as superoxide (O_2^-) and hydrogen peroxide during inflammatory reactions toward foreign materials. These highly reactive oxygen species participate in the biochemical reaction, frequently referred to as respiratory burst, which is characterized by the one electron reduction of O_2 into superoxide via either NADPH or NADH oxidase. The resulting superoxide radicals are then neutralized to H_2O_2 via cytoplasmic enzyme superoxide dismutase. These reactive oxygen species may be partially responsible for the biodegradation of polymeric implants through the production of highly reactive, potent, and harmful hydroxyl radicals OH in the presence of metals such as iron, as illustrated in the following series of redox reactions.

The net reaction will be

and is often referred to as the metal-catalyzed Haber–Weiss reaction.

The level of H_2O_2 production has been linked to the presence of foreign biomaterials including biodegradable polymers.^[1] Over a period of 14 days in rats, the amounts of H_2O_2 production by leukocytes adherent onto biodegradable PGA mesh consistently reached the highest level and was close to 200 times greater

than non-biodegradable silicone elastomer. Based on Eq. 3 above and Eq. 4 below, a higher H_2O_2 production would lead to more $\bullet OH$ and may be partially responsible for the biodegradation phenomenon of biodegradable polymers in vivo. Although the role of free radicals in the hydrolytic degradation of synthetic biodegradable polymers is largely unknown, a recent study of using absorbable sutures such as Vicryl in the presence of aqueous free radical solution prepared from H_2O_2 and ferrous sulfate, $FeSO_4$, raised the possibility of the role of free radicals in the biodegradation of synthetic biodegradable polymers.^[1] As illustrated below, both $\bullet OH$ radicals and OH^- are formed in the process of oxidation of Fe^{+2} by H_2O_2 and could exert some influence on the subsequent hydrolytic degradation of Vicryl sutures.

Scanning electron microscopy (SEM) results indicated that Vicryl sutures in the presence of free radical solutions exhibited many irregular surface cracks at both 7 and 14 days in vitro, whereas the same sutures in the two controls (H_2O_2 or $FeSO_4$ solutions) did not have these surface cracks. Surprisingly, the presence of surface cracks in Vicryl suture treated in the free radical solutions did not accelerate the tensile breaking strength loss, as would be expected. Thermal properties of Vicryl sutures under the free radical and 3% H_2O_2 media demonstrated the classic well-known maximum pattern of change in the level of crystallinity with hydrolysis time. The level of crystallinity of Vicryl sutures peaked at 7 days in both media (free radical and 3% H_2O_2). Based on the time for the appearance of the crystallinity peak as an indicator of degradation rate, it appears that the two media accelerated the degradation of Vicryl sutures compared with regular physiological buffer solution. It is unknown whether the OH^- species could be more potent than $\bullet OH$ toward hydrolytic degradation of synthetic biodegradable polymers. This is because hydroxyl anions are the sole species that can attack carbonyl carbon of the ester linkages during alkaline hydrolysis. Because an equal amount of $\bullet OH$ and OH^- is generated in Fenton reagents, the observed changes in morphological, mechanical, and thermal properties could be partially attributed to OH^- ions as well as $\bullet OH$ radicals.

Beside hydroxyl radicals, the production of superoxide ions and singlet oxygen during phagocytosis has been well documented. Although the role of superoxide in simple organic ester hydrolysis has been known since the 1970s, its role in the hydrolytic degradation of synthetic biodegradable polyester-based biomaterials has barely been addressed.^[25–27]

Because of the extreme reactivity of superoxide ion, the effect of superoxide ion-induced hydrolytic

degradation of PDLLA and PLLA was significant in terms of their changes in molecular weight and thermal properties. The superoxide ion-induced fragmentation of PDLLA results in a mixture of various species with different chain lengths. A combined Gel Permeation Chromatography (GPC) method with a chemical tagging method revealed that the structure of oligomer species formed during the superoxide-induced degradation of PDLLA and PLLA was linear. The significant reduction in molecular weight of PDLLA by superoxide ion was also evident in the change of thermal property such as T_g . The effect of the superoxide ion-induced hydrolytic degradation on the molecular weight of PLLA was similar to that of PDLLA but with a much smaller magnitude. The mechanism of simple hydrolysis of ester by superoxide ion proposed by Forrester et al. was subsequently modified to interpret the data obtained from the synthetic biodegradable polymers.

In addition to PDLLA and PLLA, superoxide ions have a significant adverse effect on the hydrolytic degradation of synthetic biodegradable sutures.^[25] There was a significant reduction in molecular weight and mechanical and thermal properties of these sutures over a wide range of superoxide ion concentration, particularly during the first few hours of contact with superoxide ions. For example, PGA suture lost almost all of its mass at the end of 24-hr contact with superoxide ions at 25°C, whereas the same suture would take at least 50 days in in vitro buffer for a complete mass loss. The surface morphology of these sutures was also altered drastically. As illustrated in Fig. 2, spherical moon-crater impression of different sizes appeared on the surface of biodegradable suture fibers biodegraded in superoxide medium. This

morphological feature is very different from the longitudinal and circumferential surface cracks observed in PBS degradation medium. The exact mechanism, however, is not fully known yet; the possibility of simultaneous occurrence of several main-chain scissions by three different nucleophilic species was suggested.

The addition of Fenton agent or hydrogen peroxide to the degradation medium retards the well-known adverse effect of the conventional γ -irradiation sterilization of synthetic absorbable sutures.^[27] Lee et al. reported that these γ -irradiated sutures retained better tensile breaking strength in the Fenton medium than in the regular buffer medium. They postulated that the γ -irradiation-induced α -carbon radicals in these sutures react with the hydroxyl radicals from the Fenton agent medium and hence neutralize the adverse effect of α -carbon radicals on backbone chain scission. This mechanism is supported by the observed gradual loss of Electron Spin Resonance (ESR) signal of the sutures in the presence of Fenton agent.

In contrast to the adverse effect of superoxide and hydroxyl free radicals on the degradation properties of synthetic biodegradable polyesters, an innovative approach of covalent bonding nitroxyl radicals onto aliphatic polyesters such as PGA and PLLA so that the nitroxyl radical attached polymers would have biological functions similar to nitric oxide has been proposed.^[28] A preliminary in vitro cell culture study of these new biologically active biodegradable polymers based on PGA and PLLA indicated that they could retard the proliferation of human smooth muscle cells as native nitric oxide does. The same approach was recently extended to functionalized co-PEAs so that these co-PEAs would have biological functionality similar to nitric oxide.^[21]

CONCLUSION

Synthetic biodegradable polymers have become one of the most promising biomaterials for human body repair/reconstruction because of the lack of undesirable permanent chronic foreign-body reactions as well as the potential to serve as temporary scaffolds for tissue regeneration and engineering. The commercially most important and successful synthetic biodegradable polymeric biomaterials are based upon linear aliphatic polyesters. Among the family of aliphatic polyesters, the three most important building blocks used by the medical industry to design synthetic biodegradable polymers and copolymers are polyglycolic acid, polylactic acid, and poly- ϵ -caprolactone. The biodegradation of these aliphatic polyester-based biomaterials is of hydrolytic nature, but the effect of superoxide on their biodegradation was more unusual than normal hydrolytic degradation in terms of the changes in surface morphological and mechanical strength. Recently, biologically intelligent synthetic biodegradable polymers have been designed with designated biological functionality, depending on the type of biological active species incorporated. This new family of synthetic biodegradable polymers derives from PEAs. By grafting nitric oxide derivatives onto the polymer backbones, PEAs were able to retard the proliferation of human smooth muscle cells, as nitric oxide does. This new family of PEAs has been clinically tested as the coating of drug-eluting stents to reduce or eliminate the restenosis problem.

B

INTRODUCTION

The ability of microorganisms to grow attached to surfaces as biofilms has become a topic of immense interest and importance for understanding multicellular behavior, cell–cell interactions, and the induction of altered physiological states. These phenomena are important for understanding the behavior of pathogens and their role in disease as well as in the wider context of microbial lifestyles in natural environments.

This entry describes the current knowledge about how microorganisms commit to a biofilm lifestyle and describes some of the features that are important for cell attachment, colonization, and maturation. Mature microbial biofilms have been likened to primitive tissues in which there appears to be a clear definition of cell function. The role of quorum sensing (QS) mechanisms for successful development of bacterial biofilms is described, particularly for pathogenic species. Because we now have sophisticated genomic technologies, it is possible to identify which genes are expressed during biofilm development, particularly those involved in secretion of extrapolymeric matrices that help anchor and provide stability to biofilm cells. Finally, the importance of the biofilm lifestyle for pathogenic species is discussed and the importance of the altered physiological states that result from cell attachment highlighted. The most important of these appears to be the development of tolerance to inimical processes, especially to antibiotics, which makes control and inhibition of biofilm development a difficult problem in the clinical environment.

BACKGROUND

In natural environments bacteria preferentially exist as biofilms, a growth mode that has been defined as: “Communities of microorganisms attached to a surface that can comprise single or multiple microbial species that attach to a range of biotic and abiotic surfaces and that are encased in an extracellular matrix.”^[1,2] Mixed species biofilms are the norm in natural ecosystems and the ways in which these are formed and respond to environmental fluctuations is complex. Most information concerning biofilm formation stems from

laboratory-based single species studies and this entry will concentrate on this aspect while acknowledging the importance of mixed species biofilms.^[3] Valuable insights into biofilm formation and growth have improved our understanding of the behavior of many microbial pathogens, e.g., *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Candida albicans*, which are often problematic in the clinical environment.

The switch from planktonic to biofilm growth is a complex process divided into the stages of initiation, early attachment, maturation, and dissolution. Environmental signals that trigger initiation of biofilm formation appear to differ from one bacterial species to another and enable different species to colonize their preferred environment efficiently. In contrast, environmental cues that regulate the development and structure of mature biofilms, such as nutrient availability and QS, are not species specific.^[4] Nutrient availability controls the depth of the biofilm resulting in large numbers of cells that are exposed to suboptimal concentrations of nutrients. At the extremes of nutrient availability (nutrient rich or limited) there are more cells in the planktonic phase, where they either have more access to nutrients (in excess conditions) or can migrate and access more favorable habitats (nutrient limited). Similarly, QS ensures the development of optimal biofilm architecture (e.g., channels and pillar-like structures) for more efficient liquid flow for movement and availability of nutrients.^[4] Bacteria in biofilms have elevated tolerance to a range of antimicrobial agents, biocides, physical insults, and nutrient limitation but not seemingly to metal cations and oxyanions.^[5–8] Biofilms display a high level of differentiation by means of multicellularity within microcolonies, localized degradation of the biofilm matrix for dispersal of cells, and death of subpopulations within microcolonies.^[9–12]

BIOFILM FORMATION

Overview

A number of reasons have been proposed to explain why bacteria preferentially switch from a planktonic growth lifestyle to sessile, highly differentiated communities.^[13] These include protection against inimical

processes; colonization by establishment and growth in nutrient rich areas; altruism to derive the cooperative benefits of living within a community; and attached growth as the default growth mode of bacteria. It is well known that bacteria display genome plasticity enabling them to express only those genes required for growth and/or survival in a particular environment. Biofilm formation is an example of bacterial adaptation and differentiation that involves cooperative gene expression and is emerging as an important aspect of hospital-acquired infections despite extensive cleaning procedures. Many nosocomial infections are now considered to be due to the surface contamination of indwelling medical devices such as urinary catheters, stents, and central and peripheral venous catheters.^[14] Other medical devices with significant infection problems include peritoneal dialysis catheters, endotracheal tubes, cardiac pacemakers, heart valves, and orthopedic implants.^[15] Intravascular and urinary tract catheters are the most commonly used indwelling medical devices and are also the most commonly infected.^[16] Nosocomial urinary tract infections account for almost 40% of all hospital-acquired infection. Most significantly, the formation of a biofilm is a major virulence factor in device-associated infections that include osteomyelitis, heart valve endocarditis, dental caries, middle ear infections, and chronic lung infections, e.g., cystic fibrosis patients.

Biofilms form as a result of surface attachment of “pioneer” cells and it is thought that bacteria are able to sense contact with a surface leading to gene expression that in turn results in the promotion of attachment. Attachment requires that the surface is preconditioned by adsorbed molecules binding to the surface. At this

early stage, attachment is reversible and bacteria are able to detach from surfaces. Once triggered to form a firm attachment, cells grow and divide to produce microcolonies that require cell–cell interactions, sometimes production of extracellular polysaccharides (EPS), and cell–cell signaling. Signaling often involves QS, a process that has been proposed as a target for prevention or disruption of biofilm formation. Biofilms quickly adopt an antibiotic tolerant phenotype and the failure to control and reduce bacterial infections arising as a result of biofilm formation is well documented. Bacterial biofilms, therefore, seem to be regulated by surface attachment, microcolony formation, cell–cell signaling, depth, and architecture of the biofilm.^[4] The later events are regulated by more conserved processes, largely mediated by events such as QS. The stages of biofilm formation are summarized in Fig. 1.

Early-Attachment Events

Biofilm formation depends on nutrient status—oligotrophic environments produce only a sparse covering of cells with little structural complexity.^[17] Initial contact with surfaces can result in reversible attachment of cells (Fig. 1) and there has been much effort devoted to identifying the surface molecules involved. In *Pseudomonas*, a role for lipopolysaccharide (LPS) synthetic genes has been proposed in attachment but LPSs are more important for regulating surface protein integrity. Treatment of *Pseudomonas fluorescens* cells with low amounts of protease resulted in loss of the ability to attach to a surface, implicating a role for surface proteins.^[18] In *Pseudomonas aeruginosa*, flagella are

Fig. 1 Formation and developmental stages of biofilm.

important for movement of cells on a surface and after attachment twitching motility, which depends on type IV pili and on cell–cell contact, provides a means for cells to aggregate into a microcolony.^[19]

In the early stages of biofilm formation, microcolonies can move as one across the surface. Mutants defective in type IV pili form only small aggregates and/or dense monolayers of cells compared with wild-type cells that form characteristic mounds. A flagellar mutant of *P. aeruginosa* was unable to colonize a glass flow cell as efficiently as a parental strain.^[17] The *crc* gene (catabolite repression control) has been proposed as part of a signal transduction pathway that relays input signals about carbon availability to the cell regulating the switch from planktonic to biofilm growth. The *crc* gene is also involved in twitching motility and helps regulate the genes needed for type IV pili synthesis.^[20] Alginate synthesis is upregulated in attached *P. aeruginosa* cells presumably by, some form of surface sensing. This polymer is a major constituent of the EPS matrix that helps preserve biofilm integrity. Large numbers of *sad* (surface attachment defective) mutants of *P. aeruginosa* have been described, defective in such properties as flagellum-mediated motility and/or biogenesis of type IV pili. These mutants often attach as a monolayer but fail to form the microcolonies typical of early biofilm development.^[3] *Vibrio cholerae* requires flagella-mediated motility, type IV pilus, and synthesis of the major EPS to form a biofilm. Motility appeared to aid surface colonization because flagellar mutants had larger voids between the microcolonies.^[17] Flagella-mediated motility may be necessary for bacteria on the surface to spread out across the surface and in flagellum minus mutants, for those cells that do attach, the resulting biofilm is identical to that of a wild type implying that flagellar attachment is not a prerequisite for downstream development.^[18] In *Escherichia coli* flagella, type 1 pili and curli fimbriae have been implicated in biofilm formation. Flagellar mutants can still attach but cannot move out across the surface. The importance of LPS is suggested from evidence that signals from the outer membrane or periplasm are important in regulating biofilm development.^[21,22]

Several nonmotile Gram positives such as streptococci, staphylococci, and mycobacteria readily form biofilms. *Streptococcus mutans* is implicated in dental caries as well as, occasionally, infective endocarditis.^[23] It grows and survives as a biofilm in its natural habitat of dental plaque where it is subjected to a variety of stresses. These include periods of starvation and acid stress generated by sugar utilization. Comparisons of acid tolerance of planktonic and biofilm cells has shown that starved bacteria exhibit higher acid tolerance than nonstarved cells and that biofilm cells showed greater resistance to acid shock promoted by

lactic acid than did planktonic ones.^[24,25] In *S. aureus* or *S. epidermidis* attachment is initially via cell–surface interactions mediated via MSCRAMMs (microbial surface components recognizing adhesive matrix molecules) as well as *altE*, which encodes an autolysin that may act as an adhesion factor. Subsequent to cell–surface interactions there is an accumulative phase of biofilm formation involving cell–cell interactions and the formation of cell aggregates on the surface. A polysaccharide intercellular adhesion (ICA) factor has been implicated in this process encoded by the *ica* genes. Once a biofilm is established, expression of a number of adhesins is repressed suggesting that the main role of adhesions, pili and flagella is in the early attachment phase and that they are no longer needed during differentiation into a mature biofilm. The cyclic peptide dependent accessory gene regulator (Agr) QS system of *S. aureus* represses several surface adhesions that mediate contact with the host matrix. These include fibronectin/fibrinogen-binding proteins. Under certain conditions *agr* mutants adhere more efficiently than wild types.

Colonization and Maturation—The Role of QS

In biofilms, higher cell densities and close proximity means that high concentrations of metabolites and secreted molecules exists. Close proximity aids in acquisition of new genes via recombination and horizontal gene transfer. Cell–cell interactions are extremely important and for most species QS is important for biofilm development. The study of this interactive lifestyle has been termed sociomicrobiology to describe the group behavior of microorganisms.^[26] Quorum sensing has been extensively investigated in planktonic cultures, which provide a tractable system for assessing the effects of known concentrations of signaling molecules on different cell types. This is more difficult for biofilms because of the different chemical and physical gradients that exist. The two best understood QS systems are the acyl-homoserine lactone (acyl-HSL) systems of gram-negative bacteria and the secreted peptide signals of many gram-positive species.^[26] A third type of system, found in both gram-positive and -negative species, involves a furanosyl borate diester as the signaling molecule that is synthesized by the *luxS* gene product.

In gram-negative bacteria, acyl-HSL molecules vary in hydrophobicity depending on the length of the acyl side chain. Biofilms are usually encased in EPS that also contains proteins, nucleic acids, and dead cells and acyl-HSLs are assumed to diffuse freely through this matrix, although depending on the relative hydrophobicity of EPS components and the acyl-HSLs themselves, EPS can act as a sink sequestering the signaling molecules. Natural environments pose additional problems of

species that degrade acyl-HSLs as a carbon and energy source, e.g., *Bacillus*. The physiological status of a cell will determine the concentrations of cell metabolites destined for signal production and cells deep in the biofilm may have reduced metabolic activity and lowered concentrations of available acyl-ACP (acyl, acyl carrier protein) and SAM (shoot apical meristem)—the precursors for synthesis of acyl-HSL. Different signal generation rates explain why mature biofilms display cell heterogeneity. Recently, simultaneous treatment of a *P. aeruginosa* biofilm with an antibiotic and a brominated furanone (an HSL analog that blocks the QS response) resulted in killing of the cells, suggesting that inhibition of HSL-mediated QS converted antibiotic tolerant cells to sensitive ones.^[27]

The architecture of mature biofilms can be flat and homogenous or highly structured characterized by liquid flow through channels and pillars of cells encased in EPS. The three-dimensional structure produces physicochemical gradients, which will affect the resistance of cells to inimical processes, e.g., antibiotic resistance. In a tightly packed arrangement of cells, QS must also have a potentially important role in governing the properties of the biofilm. For example, acyl-HSL QS affected the maturation of *Serratia liquefaciens* biofilms, probably by influencing swarming/motility behavior. Wild-type biofilms were heterogenous with cell aggregates of long filamentous cells but in a *swrI* mutant thin biofilms lacking aggregates of cells and filaments were formed.^[26] *CepI/R* QS genes of *Burkholderia cepacia* also control biofilm maturation and mutants in either *cepI* or *cepR* formed biofilms arrested at the microcolony stage of growth.^[28] *AhyR/I* of *Aeromonas hydrophila* were required for biofilm maturation shown by an *ahyI* mutant that formed structurally less well-developed biofilms compared with the wild type. Acyl-HSL controls cell aggregation in *Rhodobacter sphaeroides* and a *cer* mutation (community escape response) resulted in hyperaggregation of cells in liquid culture. *Yersinia pseudotuberculosis*, an enteric pathogen, shows a similar phenotype for QS mutants in the *YpsR/I* system because mutation in *ypsR* caused cells to aggregate in liquid culture. The plant pathogen *Xanthomonas campestris* produces a signal termed DSF (diffusible signal factor) encoded by *rpfF*. A two-component system senses the signal (*rpfC* and *rpfG*) and mutations in the system result in increased aggregation in liquid culture and increased biofilm formation. *V. cholerae* uses QS to regulate production of secreted polysaccharide encoded by the *vps* operon. Repression of *Vps* results in overproduction of EPS and a smaller wrinkled colony phenotype on solid medium. *Vps* overproduction via QS stimulates biofilm formation and aggregation and may protect cells during passage through the acid pH of the human stomach.^[26] Because QS acts as a global regulator it is probably not

surprising that it affects the biofilm formation in many different ways and is not confined to a single biofilm associated event. The primary QS system for *P. aeruginosa* is *lasR/I*, which controls the expression of the second system *rhlR/I*.^[29] Nutrient availability affects the expression of *lasR/I* and *las I* mutants that formed flat, densely packed biofilms compared with the wild type that formed well-differentiated mature biofilms.^[30]

Hitherto, we have discussed the role of QS as a cell density dependent chemically mediated response. Intriguingly, there is now emerging evidence that environmental factors can also influence the expression of QS genes. Recently, the expression of *lasR* was studied at different concentrations of iron and pO₂ and evidence was obtained to show that iron concentration influenced *lasR* expression, which was highest at low iron and triggered by oxidative stress. Under oxygen limitation, *lasR* expression was strongly dependent on iron concentration. A proteomic analysis demonstrated that many proteins upregulated as a result of iron limitation were QS regulated proteins showing that for *P. aeruginosa* there is a strong link between iron/oxygen concentration and QS.^[31] Furanones from the red alga *Delisea pulchra* interfere with biofilm formation by interfering with the QS system by acting as molecular mimics to acyl-HSLs that inactivate LasR. Rhamnolipid is required for maintenance of *P. aeruginosa* biofilm architecture and swarming motility is also QS dependent. Mutants in the *las* or *rhl* systems are deficient in swarming motility although the link between swarming and biofilm development has not been shown for *P. aeruginosa*. Quorum sensing also regulates iron acquisition systems such as biosynthesis of the siderophore pyoverdine—iron limitation inhibits biofilm formation.

Gram-positive organisms like *Streptococcus intermedius* secretes competence stimulating peptide (CSP) as a cell-cell signaling molecule that increases competence of cells for transformation by exogenous DNA and enhances acid tolerance during biofilm formation.^[32] LuxS type QS in *S. mutans* has also been shown to be important for the formation of an ordered and structured biofilm whereby a mutant in *luxS* resulted in mature biofilms of lower biomass and abnormal architecture. Biofilm cells are 10-fold more competent than the corresponding planktonic ones. *S. pneumoniae*, *S. gordonii*, and *S. mutans* also synthesize CSP and the enhanced competence they display is thought to enable cells to acquire useful genes via DNA uptake, e.g., antibiotic resistance. In *S. pneumoniae* CSP interacts with its receptor ComD to initiate a cascade of four temporally distinct transcription profiles—early, late, delayed gene induction, or delayed gene repression. Early competence genes encode proteins for cell-cell signaling including CSP precursor ComC, its histidine kinase receptor comD, a cognate response regulator

ComE, and an alternate sigma factor ComX. The latter induces later waves of transcription and many of the genes expressed control DNA uptake and its integration (late competence genes), stress related functions (delayed class), and protein synthesis (repressed class).^[33] Other roles for the CSP signal in streptococci include biofilm formation, acid tolerance, bacteriocin production, and virulence.^[34] The CSP mediated QS in biofilm formation is illustrated in *S. gordonii*, whereby a mutant in *comD* was defective in biofilm formation. Also in *S. mutans* inactivation of any component of its *comCDE* pathway resulted in a competence and biofilm defective phenotype that had diminished acid tolerance.^[34]

The Role of EPS

Extracellular polysaccharides have been identified in many bacteria. Colanic acid in *E. coli*, alginate, glucose- and mannose-rich Pel, and PLS matrix components in *P. aeruginosa*, cellulose and β -1,6-GlcNAc polymer in *Salmonella* and *E. coli* have all been reported to play important roles in biofilm formation.^[35] These EPS are key elements that shape, provide structural support, and hold the biofilm microcolony cells together in a slime matrix.^[36] Extracellular polysaccharides synthesis is stimulated during nutrient excess and when nutrients become depleted, bacteria detach from the biofilm and become planktonic, presumably for dissemination to another, more favorable site. Structural complexity of *P. aeruginosa* mushroom/mound structures, which develop in mucoid biofilms of wild-type cells isolated from cystic fibrosis (CF) lung, was suppressed in a nonmucoid mutant that formed patchy flat biofilms. Alginate is assumed to be important for tolerance to antibiotics in the CF lung but it is the altered phenotype of biofilm cells that makes them apparently antibiotic resistant, not the alginate barrier. Quorum sensing appears to be involved in EPS formation via *lasI/lasR* as evidenced by the observation that a *lasI* mutant attaches but fails to develop the biofilm architecture of the wild-type cells.

Other EPS have a similar role in other species. Glucose- and galactose-rich EPS in *V. cholerae* was required for complex structural biofilm formation. Increased production of EPS by *V. cholerae* correlated with reduced intestinal colonization in mouse intestine. A strain defective in EPS production was defective in the early stages of biofilm development. In *E. coli* mature biofilms had a similar architecture to that of *P. aeruginosa*. Colanic acid—the major EPS in *E. coli*—is necessary for formation of this characteristic architecture but not in early attachment. Upregulated genes in developing biofilms of *E. coli* include *ompC* porin and the *wca* locus (needed for colanic acid synthesis), whereas *fliC* for flagellar synth was downregulated.^[35]

Some gram-positive pathogens also produce EPS, for example, polysaccharide intercellular adhesin (PIA) and poly-*N*-acetyl galactosamine (PIA-NAG) are encoded by the *icaABCD* locus in *S. aureus* and *S. epidermidis*.^[35] In *S. epidermidis* nutrient limitation can be a trigger for slime (EPS) production. Production of capsular PS/A is closely associated with EPS production. *S. aureus* also makes EPS in a phase-variable manner and σ^B may play a role in cell-cell interactions in the biofilm. After attachment, bacteria adapt further and two major properties include increased synthesis of EPS and development of antibiotic tolerance. These help create a protective environment so that biofilms become a serious problem in the clinical environment because of the problems associated with eliminating them.

B

Gene Expression During Biofilm Development

During biofilm development, a program of gene expression is seen whereby some genes are induced during the early-attachment phases while others are expressed later on during the development and later maturation phases only. Diverse genetic factors are therefore involved in biofilm development. *Shewanella oneidensis* is a facultative Fe(III)- and Mn(IV)-reducing bacterium involved in dissolution of Fe and Mn oxide minerals in soils and sediments where it forms biofilms on mineral surfaces. A total of 173 insertion mutants, of the 15,000 screened, after transposon mutagenesis had defects in initial attachment and/or early stages of biofilm formation and 71 mutants had a nonswimming phenotype suggesting that motility was important in biofilm formation. Disruption mutants in motility genes *flhB*, *fliK*, and *pomA* did not affect initial attachment but stopped biofilm development and differentiation. Mutants defective in mannose-sensitive hemagglutinin type IV pilus biosynthesis and in pilus retraction (*pilT*) showed severe defects in adhesion to abiotic surfaces and biofilm formation.^[37]

Sauer et al examined the changes in protein and gene expression in *P. aeruginosa* over 12 days to identify five distinct stages of biofilm development.^[10] The 2-DE monitored phenotypic differences during each stage to identify 57 biofilm specific proteins that differed from the planktonic profile. Of these 23 were further analyzed by MALDI-ToF (matrix-associated laser desorption ionization-time of flight mass) and found to be associated with metabolic processes such as carbon and lipid metabolism. Evidence was also obtained for the production of multiple phenotypes with time.

A DNA array study of gene expression in a 5-day *P. aeruginosa* biofilm showed relatively few genes (ca. 1%) that were differentially expressed in planktonic and biofilm cells. Specifically, *rpoS*, flagella, and pili genes were downregulated in biofilm cells. Flagella are

not thought to be necessary for later maturation stages of biofilm development because flagellum-encoding genes are repressed soon after bacteria arrive at a surface.^[36] DNA microarrays were also used to look at gene expression in biofilms and planktonic cells by means of a chemostat in which cells grew near to μ_{\max} and into which granite pebbles were placed as surfaces for biofilm growth so that both planktonic and attached cells were exposed to similar cultural conditions.^[38] Only 1% of genes showed differential expression in the two growth modes—about 0.5% of genes were activated and 0.5% repressed in the biofilm cells. Some of the regulated genes are known to affect antibiotic sensitivity of *P. aeruginosa* in free-living cells. Exposure of biofilms to tobramycin caused differential expression of 20 genes. The most highly activated genes in *P. aeruginosa* biofilm cells (not exposed to tobramycin) were those of a temperate phage closely related to the filamentous bacteriophage Pf1. The genome of *P. aeruginosa* PAO1 contains 11 out of 14 Pf1 genes. Phage induction might therefore be important for gene transfer within the biofilm. Genes for pili and flagella were repressed in biofilm cells and therefore these appendages, although important for early attachment, may not have a role in mature biofilms.^[38]

An *rpos* minus mutant showed enhanced biofilm formation and increased tolerance to tobramycin. *Crc* (global carbon metabolism regulator) minus mutants of *P. aeruginosa* produced an attenuated biofilm ascribed to type IV pili expression/function. *CsrA* (global carbon regulator in *E. coli*) disruption led to increased biofilm formation and overexpression of *csr* was inhibitory. Most of the biofilm cells not in contact with nutrient fluids will be subject to limitations of oxygen and nutrients. In *E. coli* a significant part of the biofilm response involves stationary phase induced genes. In WT *B. subtilis*, out of 121 biofilm induced genes 60% are activated during sporulation. However, in many species induction of the stationary phase transcriptional activator *rpoS* has been shown to be repressed twofold or slightly activated in *P. aeruginosa* and its role in biofilms of *E. coli* is debatable.^[36]

The ability to form biofilms by some species is associated with virulence, e.g., *P. aeruginosa*, *S. aureus*, *S. mutans*, and *Enterococcus faecalis*. The majority of clinical isolates of *E. faecalis* have the ability to form biofilms and a secreted zinc metalloprotease controlled by a signal transduction pathway plays a key role. The enzyme is gelatinase, a thermolysin-like M4 protease similar to those found in other pathogens.^[39] It cleaves to a wide range of substrates such as Azocoll, casein, gelatine, hemoglobin, plasmid conjugation factors, collagen, fibrin, and an autolysin. It is encoded by *gelE*, the expression of which is dependent on *fsr* genes that encode a two-component transduction system. Mutants defective in *fsrA* are also impaired in biofilm formation.

FsrC (*FsrA*'s cognate kinase) disruption also impaired biofilm formation as did that for *gelE*. In the disrupted mutants, biofilm formation could be rescued through insertion of a plasmid harboring *gelE*.^[40]

Stress responsive genes have been identified in *S. mutans* and include AP-185 (acid stress protein) and GSP-781 (general stress protein), which is upregulated in response to high osmolarity, temperature, and low pH.^[23] Chaperonin proteins have also been identified as possible candidates for the protection of *S. mutans* cells against numerous stresses and include a degP-like protease that probably degrades damaged proteins resulting from heat shock and oxidative damage and DnaK and GroE, which help protect cells against acid stress and starvation in oral biofilms.^[41,42] A homolog of the HtrA family of stress-response proteases was identified from a partial genome sequence of *S. mutans* and insertional inactivation of the gene resulted in bacterial clumping in liquid media, altered colony morphology, and a reduced ability to withstand high temperature, extremes of pH, and oxidative stress.^[43]

It is clear that bacteria growing in biofilm communities handle stresses and environmental perturbations quite differently from planktonic cells and understanding the nature of protein expression and global gene regulation within biofilm should improve our ability to understand biofilm lifestyles. For example, a recent report highlights the potential disparity between protein synthesis in planktonic and biofilm cells of *S. mutans*. Of the 694 proteins examined, 57 were upregulated and 78 were downregulated in biofilm cells compared with planktonic ones.^[24] No further analysis of these proteins was undertaken. Some of the stress-induced genes that have been identified in bacterial biofilms are listed in Table 1.

Detachment and Dissolution

Cells can actively leave biofilms as dispersal mechanisms for colonization of new surfaces. Active detachment of cells from bacterial biofilms is a critical but poorly understood stage. Detachment of *Shewanella oneidensis* cells from biofilms could be induced by stopping the flow of medium in a hydrodynamic biofilm system. Detachment occurred predominantly in cells most exposed to medium flow while in thin biofilms up to 80% of biomass could be induced to detach. Swimming motility was not required for detachment and the trigger appeared to be the decrease in oxygen tension resulting from cessation of flow. *ArcA* and *crp* were implicated as regulatory genes for detecting changes in oxygen and the induction of detachment.^[44] Biofilms grown under no or low flow tend to dislodge clumps of cells more easily than those developed under high flow. The authors proposed

Table 1 Some stress responses that have been identified in bacterial biofilms

Function	Gene or protein	Organism
Prophages	Pf1	<i>P. aeruginosa</i>
	PBSX	<i>B. subtilis</i>
Proteases	Clp protease	<i>L. monocytogenes</i>
DNA repair	RecO	<i>L. monocytogenes</i>
SOS response	RecA, DinI, SulA	<i>E. coli</i>
Chaperones	DnaK, DnaJ	<i>E. coli</i>
Heat shock	Htpx, HtpG	<i>E. coli</i>
Oxidation stress	Sod proteins, CysK	<i>L. monocytogenes</i>
	SodB	<i>P. aeruginosa</i>
	SoxS	<i>E. coli</i>
Envelope stress	<i>Cpx</i> and <i>rpoE</i>	<i>E. coli</i>
	pathways	<i>E. coli</i>
	<i>Psp</i> pathway	
Sigma factor	σ^w -mediated response	<i>B. subtilis</i>

(From Ref. [36].)

three dispersal strategies: 1) swarming dispersal (e.g., *P. aeruginosa*); 2) clumping dispersal (e.g., *S. aureus*); and 3) surface associated sliding motility due to liquid flow followed by dispersal.^[44] A possible signal for detachment may be starvation. Overexpression of alginate lyase can promote detachment in *P. aeruginosa* and production of proteases that degrade adhesions may also be another mechanism that promotes detachment. Biofilms consist of large numbers of cells and detachment and dissolution have implications for pathogen transmission and disease. For example, *V. cholerae* has an infective dose of approximately 10^4 – 10^6 cells and this is most likely to be attained by detachment of cells as clumps from biofilms rather than in the planktonic mode of growth.

DOES ALTRUISM ENSURE STABILITY OF BIOFILMS?

Biofilms have been likened to multicellular organisms in which bacterial species display cooperation and unselfish behavior for the good of the community.^[45] In the complex architecture of mature biofilms and the prevailing physical and chemical gradients that exist it is not surprising that there is a great deal of heterogeneity that results in phenotypic diversity manifest even in single-species biofilms. The situation in multi-species biofilms is even more complex and difficult to study. Phenotypic diversity can also be viewed as a form of division of labor and therefore altruistic. Bacteria in biofilms communicate using QS leading to

concerted programs of gene expression. There is evidence that bacteria in biofilms undergo programmed cell death, again suggesting multicellularity and altruistic behavior. However, the role of autoinducing signals in biofilms is ambiguous. A role for the *luxS* system in *S. mutans* has been suggested but in the other work no role could be identified. In *lasR/lasI* in *P. aeruginosa* similar contradictory work has been published. Biofilms may also be hot spots for gene transfer because of the close proximity of cells and the induction of prophage genes that can stimulate genetic exchange mechanisms, which in turn may also help spread antibiotic-resistant genes. For example *P. aeruginosa* was grown in flow glass reactor cells from which small colony variants (SCVs) developed. Their emergence correlated with that of plaque-forming Pf1-like filamentous phage, designated Pf4, from the biofilm. It was observed that only SCV cells had high densities of Pf4 filaments on the surface and not the parental cells. These phage filaments were often interwoven into complex lattices surrounding the cells. Infection of planktonic *P. aeruginosa* cells with Pf4 caused emergence of SCVs in culture that exhibited enhanced attachment and accelerated biofilm development, suggesting that Pf4 can mediate phenotypic variation in *P. aeruginosa* biofilms.^[46]

BIOFILMS AND PATHOGENS

Bacteria

Biofilms can act as a reservoir for dispersal of large numbers of cells that subsequently cause disease, a serious problem in the clinical environment when dissolution of cells growing on indwelling medical devices such as catheters occurs. Because biofilms are heterogeneous in nature and promote phenotypic heterogeneity, it is possible that such a milieu also influences virulence genes of pathogens. Quorum sensing in *P. aeruginosa* biofilms induces large numbers of genes that encode virulence determinants. Biofilm development by *V. cholerae* aids in its persistence in the environment, thought to occur in stages consisting of attachment of flagellated cells to surfaces such as exoskeletons of crustaceans; formation of a monolayer of cells that degrades surface polysaccharide polymers generating a nutrient-rich environment; generation of signals for decreased flagellar gene expression, and increased transcription of genes for ICA and EPS production. *V. cholerae* cells growing as biofilms would, during sloughing, be expected to generate significantly high concentrations of cells.^[17] Materials commonly used in clinical environments include silicone elastomer, polyurethanes, and polyvinylchloride in catheter applications, while metal alloys and other polymers are used

in orthopedics. There have been significant developments in the past 20 yr in understanding the interactions that take place between tissues and these materials, often referred to as biomaterials, and how such interactions may be manipulated to improve biocompatibility and biofunctionality. Prevention of device-related infection and biofilm development has been less successful and efforts have mainly been directed toward chemically modifying the biomaterial substrate to provide an antimicrobial coating.^[47,48] In recent years researchers have investigated the effects of substrate topography.^[49–51] Primarily, such studies are intended to design substrates that provide a more acceptable biomaterial/tissue interaction, but recent studies have indicated the potential for nanotopography to inhibit mammalian cellular attachment.^[52] Bacterial attachment to the surface of a medical device is mediated by surface charge attraction, hydrophilic/hydrophobic interaction, specific protein interaction, and surface topography. Many of these factors have been exhaustively investigated; however, relatively little information is available with respect to the influence of the biomaterial substrate.

A number of microbial species have been implicated in biofilm development associated with medical devices.^[53] These include gram-negative bacteria (*E. coli*, *Proteus mirabilis*, and *Pseudomonas aeruginosa*), biofilms of which have been implicated in urinary tract infections and CF; gram-positive bacteria (*Staphylococcus epidermidis* and *S. aureus*), important as skin commensals and implicated in many hospital acquired infections and acquisition and transfer of broad-spectrum antibiotic resistance, i.e., MRSA (methicillin-resistant *S. aureus*); and fungi (*C. albicans* and *Candida tropicalis*) that are opportunistic pathogens, grow as biofilms, and cause infections that range in severity from irritation (e.g., thrush) to life threatening as in the case of immunocompromised patients.^[15,54–63] A list of some human infections that involve biofilms are shown in Table 2.

Candida Biofilms

Candida spp. are associated with infections in humans, which range from irritation (thrush) to life-threatening infections usually associated with immunocompromised patients. They are also major agents of hospital-acquired infections and rank fourth behind coagulase-negative staphylococci, *S. aureus*, and streptococci as the cause of bloodstream infections.^[63] *C. albicans* is the best studied and it has now emerged as one of the most important causes of nosocomial infections. A major reason appears to be the dimorphic nature of this yeast whereby it grows as budding yeast cells or as a hyphal form. Transition from yeast cell to mycelium can be

Table 2 List of some human infections involving biofilms

Infection or disease	Common bacterial species involved
Dental caries	Acidogenic streptococci
Cystic fibrosis pneumonia	<i>P. aeruginosa</i> <i>Burkholderia cepacia</i>
Endocarditis	Viridans group streptococci, staphylococci
Musculoskeletal infections	Gram-positive cocci
Biliary tract infections	Enteric bacteria
Infectious kidney stones	Gram-negative rods
Contact lenses	<i>P. aeruginosa</i> , gram-positive cocci
Sutures	Staphylococci
Arteriovenous shunts	Staphylococci
Urinary catheter infections	<i>E. coli</i> , gram-negative rods
In-dwelling catheters	<i>Candida albicans</i>
Human epithelial cells	<i>Candida</i> spp.

(From Ref. [63,64].)

triggered in the presence of serum and there is evidence that the hyphal form may be the mechanism by which the yeast invades host tissues and establishes itself as a biofilm growing on epithelial cells.^[65] Recently, the mechanisms thought to be important for adherence and pathogenesis have been probed using DNA array analysis of the transcriptome of *C. albicans* growing via germ tubes on polystyrene petri dishes.^[65] This work demonstrated that 77 genes were overexpressed in adherent germ tubes and some of these encoded enzymes were involved in lipid, protein, and carbohydrate metabolism. Some of these were also known to be linked to pathogenesis. Interestingly, nearly 50% of the overexpressed genes were of unknown function.

In recent work, we have been investigating whether fabricated nanoparticulate surfaces that inhibit attachment of mammalian cells to surfaces can be used to control or inhibit attachment of microbial cells to surfaces.^[52] Fig. 2 shows interesting preliminary data whereby *C. albicans* yeast cells were grown in the presence of horse serum on a glass surface (Fig. 2A) and on the same surface coated with silica beads of 14 nm diameter (Fig. 2B). The yeast cells grew and began to produce germ tubes after 4 hr incubation, largely stimulated by the presence of horse serum. On the nanoparticulate surface there was little growth and a failure to differentiate into germ tubes. After 24 hr the glass surface was completely covered by a mixture of yeast cells and hyphae (Fig. 2C) whereas the nanoparticulate-coated surface was also more covered than at 4 hr but

Fig. 2 Response of *C. albicans* grown for 4 hr in the presence of horse serum on a glass surface (A); on the same surface coated with 14 nm-diameter nanoparticles (B); and after 24 hr incubation on glass (C) and 14 nm silica (D).

with a film of yeast cells only. Therefore, not only had the silica nanoparticles reduced the coverage of the yeast to about 15% of that of the untreated glass, but it had also apparently prevented the differentiation of yeast cells to a hyphal mycelium. This work is continuing to assess why this occurs, whether other nanoparticulate surfaces have the same effect, and how the nanoparticulate surface can be manipulated to provide total prevention of yeast cell attachment and proliferation (Edwards and others, unpublished data).

CONCLUSIONS

Biofilm formation has now been recognized as a developmental and possibly the natural mode of growth for microbial populations. Common responses identified during biofilm maturation include repression of flagellum synthesis and hyperexpression of genes for adhesion and ribosomal protein.^[2] Further, work using high-throughput technologies of DNA arrays and proteomics will no doubt begin to identify the molecular basis for biofilm formation. These new techniques should also address the heterogeneity that exists within biofilm populations, even for single-species cultures, and help to unravel the multifaceted roles of these heterogeneous subpopulations. Recently, the concept of “persister cells” helps explain why biofilm cells have

altered properties, particularly antibiotic tolerance.^[66] In *E. coli* and some other bacteria, persister cells arise in a cell density dependent manner to reach ca. 1% of the population in stationary phase liquid cultures or biofilms. These cells neither grow nor die in the presence of bactericidal agents and exhibit multidrug tolerance and appear to be responsible for the robustness and tolerance of biofilms to inimical processes.^[66] Nanotechnology may have a role in modifying cell behavior at surfaces by either altering surface topography (“roughness”) or anchoring biocidal molecules to surface-bound carrier nanoparticles. An area yet to be addressed is that of the ways in which biofilms operate in natural ecosystems and what contribution they make to the global biogeochemical cycling of key elements.

Biofunctional Polymers

Jennifer L. West

Department of Bioengineering, Rice University, Houston, Texas, U.S.A.

INTRODUCTION

In many applications utilizing polymeric biomaterials, such as in scaffolds for tissue engineering, investigators can choose from natural materials, such as collagen or fibrin, or synthetic polymers such as poly(lactic-co-glycolic acid) (PLGA). Each choice has its unique advantages and disadvantages. For example, the extracellular matrix (ECM) proteins have evolved over billions of years to have specific cellular interactions and activities, to be remodeled by cellular activity, and even to guide tissue formation processes. However, the isolation, purification, and processing of these materials can be difficult, mechanical properties are often poor, and there are some concerns about the possibility for disease transmission. Synthetic polymers, on the other hand, offer easier handling and processing as well as a greater degree of control of material properties. Unfortunately, when using synthetic materials such as PLGA, cellular interactions with the material are mediated by nonspecifically adsorbed proteins and are generally difficult to control. In order to obtain some of the advantages of natural bioactive compounds, such as ECM proteins, while gaining the ease of processing and safety of synthetic materials, a number of researchers have developed hybrid materials that are primarily composed of standard synthetic polymers but are also grafted, tethered to, or copolymerized with biologically functional segments such as peptides. Examples discussed in this article include the development of ECM-mimetic materials for use in tissue engineering applications, as well as the development of pharmacologically active biomaterials.

ECM-MIMETIC MATERIALS

In natural tissue, cells grow within a scaffold consisting of a variety of proteins and polysaccharides—the extracellular matrix (ECM). The ECM does far more than just provide mechanical support for the cells, which is all that many of the tissue engineering scaffolds in current use are capable of doing. Rather, the ECM has direct biological interactions with the entrapped cells, influencing cell growth, migration, morphology, and differentiation. Using natural polymers

such as collagen or fibrin gels allows one to reconstitute some of these interactions, but controlling these interactions and other properties of the materials is difficult. Modifying synthetic polymers that have the appropriate mechanical properties and processing conditions with biofunctional moieties that provide some of the ECM interactions may allow one to get the benefits of a synthetic material with many of the advantages normally associated with natural materials.

Cell-Adhesive Materials

In tissues, cell-adhesive interactions occur between cell surface receptors, such as the integrins, and specific ligands on ECM proteins. A number of short peptide sequences derived from adhesive ECM proteins have been identified that are able to bind to cell surface receptors and mediate cell adhesion with affinity and specificity similar to that obtained with intact proteins. Oligopeptides are preferable to intact proteins because they are not subject to denaturation and may be less susceptible to proteolysis. Some of these, along with their biological sources, are shown in Table 1. A number of methods for incorporating peptides into biomaterials have been investigated, including physicochemical adsorption, chemisorption, and covalent attachment. Only covalent attachment will be addressed in this article. Covalent attachment may be in the form of surface grafting, grafting to polymer chains, or incorporation into polymer backbones. Important considerations in designing these types of biohybrid materials include the hydrophobicity of the synthetic substrate, steric hindrance, peptide orientation, and whether interactions need to be two- or three-dimensional. When modifying materials with adhesive peptides, however, one must be aware that activation of these cell-signaling pathways can alter many other cellular activities, including proliferation, migration, and synthesis of new ECM.^[1,2]

Perhaps the most extensively studied cell adhesion peptide is the sequence Arg–Gly–Asp (RGD). It is found in many cell adhesion proteins and binds to integrin receptors on a wide variety of cell types.^[3] Modification with RGD peptides may enhance cell adhesion to a biomaterial and activate integrin

Table 1 Peptide sequences that can mediate cell adhesion

Peptide sequence	ECM protein
RGD	Fibronectin, vitronectin, laminin, collagen
YIGSR	Laminin
IKVAV	Laminin
REDV	Fibronectin
DGEA	Collagen
VGVPAG	Elastin

signaling pathways. A number of studies have been performed with RGD-containing peptides grafted to polymers. In initial studies, RGD peptides were immobilized on a polymer-modified glass substrate, and cell adhesion parameters were correlated with peptide density.^[4] A peptide density of 10 fmol/cm² was sufficient to support adhesion and spreading of fibroblast cells, clustering of integrin receptors, and organization of actin stress fibers. At 1 fmol/cm² the cells were fully spread, but the morphology of the stress fibers was abnormal, and the cells did not form focal contacts.

In addition to grafting RGD peptides to polymeric surfaces, peptides can be incorporated into polymer matrices to allow adhesion throughout the material. For example, a biodegradable copolymer of polylysine and poly(lactic acid) has been used for the attachment of RGD peptides.^[5] These types of materials can be processed into highly porous sponges to allow cells to permeate into the matrix and adhere throughout.^[6,7] When these copolymers were modified with RGD peptides, significant enhancement of cell adhesion was observed.

When designing peptide-modified materials, it is often desirable to start with intrinsically cell-non-adhesive polymers, effectively providing a blank slate upon which one can build desired biological interactions. Polyethylene glycol (PEG)-based materials, such as photocross-linked PEG hydrogels, have been particularly interesting for this approach.^[2,8,9] Figure 1 shows the interaction of fibroblasts with an unmodified PEG hydrogel and with a RGD-containing PEG hydrogel, demonstrating adhesion and spreading only with inclusion of the adhesion ligand. In addition to providing controlled and specific biological interactions, modification of cell-nonadhesive materials can allow one to generate cell-specific materials, i.e., materials that are adhesive only to certain cell types, if adhesion ligands with appropriate selectivity are utilized. For example, the peptide REDV has been shown to be adhesive to endothelial cells but not to smooth muscle cells, fibroblasts, or platelets,^[10] and thus it may be useful in the development of vascular grafts.

Proteolytically Degradable Polymers

The majority of biomaterials currently used in tissue engineering applications are designed to degrade via hydrolysis. With many of these materials, such as poly(lactide-co-glycolide), the degradation rate can be tailored to some degree by altering factors such as the copolymer composition, degree of crystallinity, or initial molecular weight. However, in these types of applications, it can be very difficult to predict a priori what the rate of tissue formation will be and, thus, what the rate of polymer degradation should be. In the ECM, during processes such as wound healing, the rate of scaffold (ECM) degradation is precisely matched to the rate of tissue formation. ECM is degraded by proteolytic enzymes, such as the matrix metalloproteases and plasmin, produced by cells during cell migration and tissue remodeling.^[11] Many of the natural polymer scaffolds, such as collagen and fibrin, are degraded by the same cellular mechanisms. Recently, synthetic biomaterials have been designed that are similarly degraded by cellular proteolytic activity.^[2,12] These materials are block copolymers of synthetic polymers, such as polyethylene glycol (PEG), and peptides that are substrates for proteolytic enzymes. When exposed to solutions containing the targeted protease, PEG-peptide copolymer hydrogels degraded, whereas they remained stable in the absence of protease or in the presence of a nontargeted protease.

Fig. 1 Fibroblasts were seeded on the surfaces of either PEG hydrogels (A) or PEG hydrogels with tethered RGD peptide (B). Cells are able to adhere to and spread on these materials only in the presence of an immobilized adhesion ligand. If cell-selective adhesion ligands were used, one could generate a biomaterial that would allow adhesion of only certain cell types.

Furthermore, cells can migrate through PEG-peptide hydrogels that contain both proteolytically degradable peptide sequences and cell-adhesive sequences.^[13] In this case, degradable sequences are required so that the cells can create pathways through the solid structure for migration, and the cell adhesion ligands are required so that cells can develop the traction force required for migration.

PHARMACOLOGICALLY ACTIVE BIOMATERIALS

Pharmacologically active polymers are another class of biofunctional materials, with the goal of being used for prolonged, site-specific pharmacotherapy. Covalent modification of materials by means of pharmacological agents has been investigated for a number of applications. Most commonly, the objective is simply to develop a more biocompatible biomaterial, for instance, to improve blood compatibility. In tissue engineering applications, the goal may be to stimulate or inhibit specific cellular processes, such as proliferation or ECM synthesis. The majority of applications of pharmacologically active biomaterials have been performed by grafting the pharmacological agent to the synthetic polymer substrate, though other material designs are possible. A wide range of pharmacological agents have been employed, including polysaccharides, polypeptide growth factors, enzymes, anti-inflammatory agents, and nitric oxide.

Polysaccharides

Heparin has been the most extensively studied polysaccharide for biomaterials modification. Heparin is a polymer of heterogeneously sulfated L-iduronic acid and D-glucosamine, with molecular weights ranging from 2–50 kDa. Heparin has been commonly used as an anticoagulant and antiplatelet agent due to its binding and potent activation of antithrombin III.^[14] Covalent immobilization of heparin onto blood-contacting materials should provide thromboresistance for prolonged periods of time. Numerous synthetic polymers have been covalently heparinized, including polyurethanes,^[15,16] polyethylene terephthalate,^[17] polyvinyl alcohol,^[18,19] poly(dimethylsiloxane),^[20] polypyrrole,^[21] and polylactide.^[22]

Synthesis of covalently heparinized materials often involves the use of a hydrophilic spacer molecule in order to increase the bioavailability of the bound heparin. PEG is often used as a spacer, usually being coupled to the biomaterial and the heparin through diisocyanate groups. PEG has several advantages for this application. PEG is widely known to be highly

resistant to platelet adhesion, so the PEG spacers themselves help to create a more hemocompatible surface. Additionally, when heparin is immobilized through a PEG spacer, it retains its ability to bind both thrombin and antithrombin III, though to a slightly lesser extent than unmodified heparin.^[23] When directly immobilized, however, the heparin is able to bind only to thrombin.

Hyaluronic acid, a linear copolymer of D-glucuronic acid and N-acetylglucosamine, is also generating interest for biomaterials applications. It has been shown to be both antithrombotic and angiogenic.^[24–27]

Hirudin

Hirudin is a 65-amino acid polypeptide, originally derived from the salivary glands of the leech, that acts as an anticoagulant through its ability to directly inhibit thrombin. Both recombinant hirudin and synthetic hirudin are now available. Hirudin has been covalently attached to the surfaces of PET and polyurethane vascular grafts, using bovine serum albumin as a spacer, in order to improve their blood compatibility.^[28,29] Hirudin immobilized in this manner retained its ability to bind and inhibit thrombin. Hirudin has also been directly coupled to PLGA using glutaraldehyde, demonstrating improvements in several aspects of blood compatibility.^[30] Unfortunately, the binding between hirudin and thrombin is irreversible, leading to decreased bioactivity over time.^[30]

Plasminogen Activators

During fibrinolysis, circulating plasminogen is converted to the active enzyme plasmin by plasminogen activators, as depicted in Fig. 2. Plasmin is then able to degrade fibrin to lyse the clot structure (Fig. 2). Plasminogen activators include tissue plasminogen activator (tPA), urokinase, streptokinase, and lumbrakinase. Immobilization of plasminogen activators on blood-contacting materials may be a mechanism to impart thromboresistance. Additionally, immobilization of these enzymes may stabilize them, imparting

Fig. 2 Plasminogen activators convert circulating plasminogen to the active enzyme, plasmin, which then lyses fibrin clots.

greater resistance to temperature, pH, and proteolytic activity.^[31]

Urokinase, a plasminogen activator expressed in many tissue types, has been immobilized to a wide variety of polymeric materials including polyurethanes,^[32] poly(tetrafluoroethylene),^[33] poly(vinylchloride),^[34] and poly(hydroxyethyl methacrylate).^[35] Thrombus formation on these materials has been shown to be greatly reduced with enzyme immobilization. Similarly, lumbrinase, derived from an earthworm, and streptokinase, derived from streptococcal bacteria, have been immobilized to polymeric materials and shown to improve blood compatibility.^[36,37] However, there are significant concerns regarding adverse immunological interactions with materials modified with these foreign proteins.

Growth Factors

Growth factors are polypeptides involved in the regulation of a variety of cellular activities such as growth and differentiation, as well as many metabolic processes. Many different growth factors have been described in the literature, with potential applications ranging from accelerated wound healing to the induction of bone growth into implanted biomaterials. Modification of biomaterials with growth factors may target activity to the desired tissue and may maintain biological function for a prolonged period of time. Growth factors that have been covalently immobilized to polymeric biomaterials include epidermal growth factor (EGF), basic fibroblast growth factor (bFGF), and transforming growth factor-beta (TGF-B).

EGF is a 6 kDa polypeptide that is mitogenic and chemotactic for many of the cell types involved in wound healing. EGF was also the first growth factor that was shown to remain active after covalent immobilization. In that first study, EGF was immobilized to aminated glass via a star PEG spacer molecule and was shown to retain mitogenic activity, whereas physically adsorbed EGF showed no activity.^[38] Prior to this work, it was believed that receptor dimerization and internalization were required for growth factor activity, and thus that immobilization would not be effective. However, that does not appear to be true. More recently, EGF has also been immobilized on poly(methyl methacrylate)^[39] and polystyrene,^[40] with good retention of bioactivity.

bFGF is a 16 kDa polypeptide that is mitogenic for many cell types and that appears to play an important role in angiogenesis. bFGF binds strongly to heparin, so heparinized materials have been widely used for the complexation and presentation of bFGF.^[41–43] For example, polyurethane vascular grafts with

coimmobilized heparin and bFGF have been shown to support enhanced endothelialization.^[42]

Although in many cell types it does not stimulate growth, TGF-B plays a very important role in regulating ECM metabolism. For example, synthesis of collagen and elastin is greatly upregulated in vascular smooth muscle cells upon exposure to TGF-B. In tissue engineered vascular grafts, a potential strategy to improve mechanical properties is to increase ECM deposition. Thus, PEG-based hydrogel scaffolds have been synthesized with TGF-B tethered to the hydrogel network.^[44] Tethering TGF-B to the polymeric biomaterial actually enhanced its ability, relative to soluble TGF-B, to stimulate ECM protein production by encapsulated vascular smooth muscle cells. This effect may be due to the ability of the cells to interact with TGF-B via the appropriate receptors, while not being able to internalize it. In addition, engineered tissues formed with tethered TGF-B in the scaffold formulation were shown to have improved tensile strength.^[44]

Anti-Inflammatory Biomaterials

Salicylic acid, the active component of aspirin, is commonly used as an anti-inflammatory agent in a broad spectrum of medical applications. Polymeric materials have been synthesized with salicylic acid incorporated into the backbone of the polymer.^[45–47] These materials are polyanhydride esters composed of alkyl chains linked to salicylic acid by ester bonds. Hydrolytic degradation occurs as the ester bonds are cleaved, producing salicylic acid. These materials may be useful in wound closure and wound healing applications, where they could not only release an anti-inflammatory agent but could also serve as a biodegradable scaffold for tissue regeneration. This material could also have use in the treatment of Crohn's disease, a chronic inflammation of the intestine. In this application, the release of salicylic acid following oral ingestion of the polymer would be enhanced in the intestinal tract, due to enhanced polymer degradation at basic pH.

Nitric Oxide-Generating Materials

Nitric oxide (NO) acts on most tissues in the body through its ability to upregulate cGMP.^[48] For example, in the vascular system, NO inhibits platelet adhesion and aggregation, increases endothelial cell proliferation, and suppresses smooth muscle cell proliferation. Thus, NO is attractive for use as a therapeutic agent for the prevention of restenosis or for the improvement of vascular graft or stent performance. A number of small-molecule drugs, referred to as NO

Fig. 3 Pretreatment of mepacrine-labeled whole blood with NO-producing hydrogel materials significantly reduced platelet adhesion to a model thrombogenic surface, collagen-coated glass. A, control hydrogel; B, NO-generating hydrogel.

donors, have been developed that undergo hydrolysis to generate NO in the body.^[49] However, systemic NO therapy for applications such as restenosis has generally failed, due to the difficulties in achieving therapeutic dosages at the appropriate site without incurring substantial systemic side effects.^[50] Bioactive polymers containing NO donor groups may allow the creation of local delivery vehicles for NO therapy, or even NO-generating medical devices.

Diazeniumdiolates have been attached to pendant groups of a polymer chain to provide NO release for up to five weeks.^[51] Diazeniumdiolates attached to crosslinked polyethyleneimine (PEI) inhibited the proliferation of smooth muscle cells in vitro. PTFE vascular grafts were also coated with the PEI-NO polymer and implanted in a baboon arteriovenous shunt model. Platelet adhesion to the NO-releasing grafts was reduced almost five-fold relative to control biomaterials. Microspheres can also be formed from the PEI-NO material.^[52] Diazeniumdiolate NO donors have also been covalently bound to polyurethane and polyvinyl chloride films.^[53] NO release from these materials ranged from 10 to 72 hr, and the NO-modified polymers successfully reduced platelet adhesion in vitro.

Hydrogel materials have been formed by photocrosslinking copolymers of PEG with NO donors, such as diazeniumdiolates and S-nitrosothiols, to achieve NO delivery for periods ranging from hours to months.^[54] Exposure of blood to NO-generating hydrogels dramatically decreased platelet adhesion to collagen-coated surfaces, as shown in Fig. 3. Furthermore, these materials dramatically reduced smooth muscle cell proliferation. These types of hydrogel materials can be polymerized in situ to form thin coatings on the luminal surface of a blood vessel following angioplasty or stent deployment,^[55] which provides highly localized treatment for the prevention of thrombosis and restenosis.

CONCLUSION

The development of bioactive biomaterials is expanding the capabilities and performance of materials used in a variety of biomedical applications. In particular, the development of ECM-mimetic polymers may significantly improve the ability to manipulate cell differentiation and behaviors while growing engineered tissues. As advances are made in cellular and molecular biology, the functionality that can be built into these hybrid materials should greatly expand, hopefully providing solutions to many currently unmet medical needs, such as synthetic small-diameter vascular grafts.

INTRODUCTION

In the early seventies, bioceramics were employed to perform singular, biologically inert roles, such as to provide parts for bone replacement. The realization that cells and tissues perform many other vital regulatory and metabolic roles has highlighted the limitations of synthetic materials as tissue substitutes. Demands of bioceramics have changed from maintaining an essentially physical function without eliciting a host response, to providing a more integrated interaction with the host. This has been accompanied by increasing demands from medical devices to improve the quality of life, as well as extend its duration. Bioceramics, especially hydroxyapatite, incorporating biological additives can be used as body-interactive materials, helping the body to heal, or promoting regeneration of tissues, thus restoring physiological functions.

The crystallography and characterization of biologic and synthetic apatites are very complex. This review attempts to cover over four decades of research on one of the most intriguing and fascinating fields of research.

BACKGROUND

Apatite (Gr, to deceive) was the name given first by Werner in 1788 to describe a group of mineral crystals appearing with various tints (yellow, green, pink, etc.) that were often confused with more precious minerals or gems, such as aquamarine, amethyst, topaz, etc. These minerals have the general formula $M_{10}(RO_4)_6X_2$, where M could be one of several metals (usually calcium, Ca), R is most commonly phosphorus (P), and X is commonly hydroxide (OH), or a halogen such as fluorine (F) or chlorine (Cl). In later years and currently, the name “apatite” describes a family of compounds having similar structure (hexagonal system, space group, $P6_3/m$) in spite of a wide range of composition.^[1,2] The unit cell (smallest building unit) of calcium hydroxyapatite, HA, contains ten calcium (Ca), six PO_4 , and two OH groups, arranged as shown

Fig. 1.^[3] The OH groups located in the corners of the unit cell are surrounded by two sets of Ca (II) atoms arranged in a triangular patterns at levels $z=0$ and $z=1/2$; by two sets of PO_4 tetrahedra, also arranged in triangular patterns at levels $z=1/4$ and $z=3/4$, and by a hexagonal array of Ca (I) atoms at a distance.^[3] Critical to the apatite structure is the network of PO_4 groups in tightly packed arrangements.^[2] Substitutions in the apatite structure affect lattice parameters (a - and c -axis dimensions), infrared absorption characteristics, morphology, dissolution properties, and thermal stabilities.

Biologic apatites are the inorganic phases of calcified tissues (teeth and bones). Similarity in composition of calcined bone to the apatite mineral was proposed by Proust and Klaproth in 1788^[4] and similarity in the x-ray diffraction patterns of bone and mineral apatites (hydroxyapatite, HA and fluorapatite, FA) and similarity in composition (principally, calcium and phosphate ions) led to the conclusion that the inorganic phases of bones and teeth are basically calcium hydroxyapatite.^[5,7] Detection of carbonate associated with biologic apatites led to the speculation that these mineral phases are carbonate-containing apatites similar to the minerals dahllite (carbonate-containing apatite) or staffellite (carbonate and fluoride-containing apatite).^[8] Studies on synthetic carbonate-substituted apatites demonstrated that carbonate substitution in the apatite structure can proceed in two ways: CO_3 -for-OH, or Type A,^[9,10] and CO_3 -for- PO_4 or Type B, coupled with Na-for-Ca^[11,12] and combined analyses of synthetic and biologic apatites using x-ray diffraction, infrared spectroscopy and chemical analyses demonstrated that biologic apatites are carbonate apatites approximated by the formula, $(Ca,Mg,Na)_{10}(PO_4,CO_3, HPO_4)_6(CO_3, OH)_2$.^[12-14]

Early studies on synthetic apatites, and related calcium phosphates, were made to gain a better understanding of the structure, composition and properties of biologic apatites, especially of human enamel apatites. However, studies on synthetic apatites in the last 25 years had focused on their preparation, their applications in medicine and dentistry, and their use as

Fig. 1 The unit-cell (smallest building block) of hydroxyapatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$.

scaffolds for bone and teeth regeneration. Current commercial synthetic calcium phosphate biomaterials classified on the basis of composition include: hydroxyapatite (HA), $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$; tricalcium phosphate (β -TCP), $\text{Ca}_3(\text{PO}_4)_2$; and biphasic calcium phosphate, BCP, an intimate mixture of HA and β -TCP with varying HA/ β -TCP ratios.^[15–19] Other commercial HA biomaterials are derived from biologic materials, (e.g., processed human bone, bovine bone-derived, hydrothermally converted coral, or derived from marine algae).^[20–22]

This paper is a brief review of biologic and synthetic apatites used as biomaterials, updating reviews published earlier by the authors.^[13,20,23,24]

BIOLOGIC APATITES

Normal and pathologic calcified tissues are composites of organic and inorganic phases. For bone, dentin, and cementum, the organic phase is principally collagen (about 25% by weight) with smaller amounts of non-collagenous proteins.^[25] On the other hand, the main organic phase in enamel is a noncollagenous protein (amelogenin) comprising about 1%, by weight, of the

enamel. In normal calcified tissues, such as in teeth and bones, in fish enameloids (teeth or calcified scales of some species), and in some species of shells, only carbonate- (carbonate hydroxyapatite, CHA) or carbonate- and fluoride-containing apatite (CFA) occurs as the principal inorganic phase.^[13,24,26,27] In pathologic calcifications (dental calculus, urinary stones, vascular calcification, and other soft-tissue calcifications), biologic apatite may occur as one of the mineral phases that include other calcium phosphates, e.g., amorphous calcium phosphate (ACP), Ca_xPO_4 ; dicalcium phosphate dehydrate (DCPD), $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$; octacalcium phosphate (OCP), $\text{Ca}_8\text{H}_2(\text{PO}_4)_6 \cdot 5\text{H}_2\text{O}$; magnesium-substituted tricalcium phosphate (β -TCMP), $(\text{Ca},\text{Mg})_3(\text{PO}_4)_2$, calcium pyrophosphate dihydrate (CPPD), $\text{Ca}_2\text{P}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$.^[24,28]

Enamel, Dentin, and Bone Apatite

Enamel, dentin, and bone apatite differ in crystallinity, reflecting crystal size (Fig. 2) and in concentrations of minor constituents, mainly, Mg and CO_3 (Fig. 3A) (Table 1).^[13,24,29] Enamel apatite contains the lowest concentrations of these ions and the highest crystallinity

Fig. 2 X-ray diffraction profiles of biological apatites from adult human enamel (A), dentin (B), and bone (C).

(larger crystals), compared to either dentin or bone apatite, which shows much lower crystallinity (smaller crystals) and greater concentrations of Mg and CO_3 (Table 1). These apatites also differ in solubility, decreasing in the order: bone > dentin >> enamel. These differences in crystallinity (crystal size) and solubility may be attributed to the differences in the concentrations of the minor constituents (e.g., Mg, Na, CO_3 , and HPO_4). Studies on the effect of Mg and CO_3 ions on the properties of synthetic apatites demonstrated that incorporation of these ions independently and synergistically cause the growth of smaller and more soluble apatite crystals.^[13,24,29–32] The effects of CO_3 incorporation on apatite crystal size and morphology and on dissolution properties are much more pronounced than that of Mg^[13,24,32] Proteins^[25] and/or other ions (e.g., pyrophosphate, citrate)^[12,24] may also inhibit the crystal growth of biologic apatites.

Biologic apatites are usually calcium-deficient (i.e., with Ca/P molar ratio less than the stoichiometric value of 1.67 obtained for pure HA, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$). Calcining above 900°C of human enamel and dentin apatite results in the loss of the CO_3 constituent and formation of HA and Mg-substituted tricalcium phosphate, β -TCMP^[13,24] Calcining of bone (human or bovine) above 900°C results in the loss of CO_3 and formation of mostly HA with small amounts of calcium oxide, CaO.^[13,24]

Partial dissolution of biologic apatites and precipitation of other calcium phosphates (DCPD, OCP, β -TCMP) is believed to occur in human enamel and dentin caries, characterized by the dissolution of the tooth mineral (carbonate apatite) by acids produced by oral bacteria.^[33,34] The nonapatitic calcium phosphates (e.g., DCPD, OCP) may, in turn transform to apatites

by hydrolysis or by dissolution and reprecipitation processes.^[13,24,34]

Biologic apatites have been idealized as calcium hydroxyapatite (HA), $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$.^[5–8] However, the difference in lattice parameters: a-axis for enamel, 0.9442 nm vs. 0.9422 nm for HA, Ca/P stoichiometry (e.g., about 1.63 for enamel or dentin apatite vs. 1.67 for HA), and the association of other ions, notably, magnesium (Mg) and carbonate (CO_3) with biologic apatites (Table 1) have caused many years of disagreements and research on the structure and composition of biologic apatites.^[8,9,13,35]

The nature of CO_3 incorporation in biologic apatites, especially in human enamel apatite had been a preoccupation of several researchers. The larger a-axis dimension of human enamel apatite, compared to pure or mineral HA, was first attributed to the CO_3 -for-OH substitution (Type A) in these apatites.^[9] Such type of substitution was observed in synthetic carbonate apatites prepared by diffusing CO_2 into HA at 1000°C under very dry conditions, resulting in an expanded a-axis and contracted c-axis dimensions compared to pure HA.^[9,10] However, studies on synthetic apatites prepared at much lower temperatures (60 – 95°C) by precipitation or hydrolysis methods showed a partial CO_3 -for- PO_4 substitution (Type B) coupled with a partial Na-for-Ca substitution, resulting in a contracted a-axis and expanded c-axis dimension compared to CO_3 -free apatites.^[11–13] The observed expanded a-axis of enamel apatite may be attributed to partial Cl-for-OH substitution^[36] and HPO_4 -for- PO_4 substitution,^[37] rather than the CO_3 -for-OH substitution in the apatite. A possible H_3O -for-OH was also offered as a possible cause for the expanded a-axis dimension.^[8] Additional evidence for the dominant partial CO_3 -for- PO_4 substitution in enamel, and all biologic apatites, is the similarity of the characteristic CO_3 absorption bands between the IR spectra of enamel apatite with those of synthetic apatites exhibiting CO_3 -for- PO_4 substitution as shown in Fig. 3B.^[3,24,38]

Studies in synthetic systems also showed that F incorporation (F-for-OH substitution) have the following effects: contraction in the a-axis dimension and no significant effect on the c-axis dimension compared to F-free apatites^[13,24] growth of larger and less soluble apatite crystals,^[13,24,39] and greater structural stability.^[3] Such studies elucidated the nature of fluoride (F) incorporation in some biologic apatites (from modern and fossil teeth and bones). For example, the smaller a-axis dimension of shark enameloid compared to HA or human enamel apatite is due to the high fluoride (F) concentration in shark enameloid (Table 1).^[13,27,40] The therapeutic use of fluoride in dentistry (sealants, topical gels, tablets) was based on the observation of low caries in areas of fluoridated water (1 ppm F).^[41] Fluoride treatment (topically or by the use of fluoridated dentifrices) of enamel and dentin leads to the formation

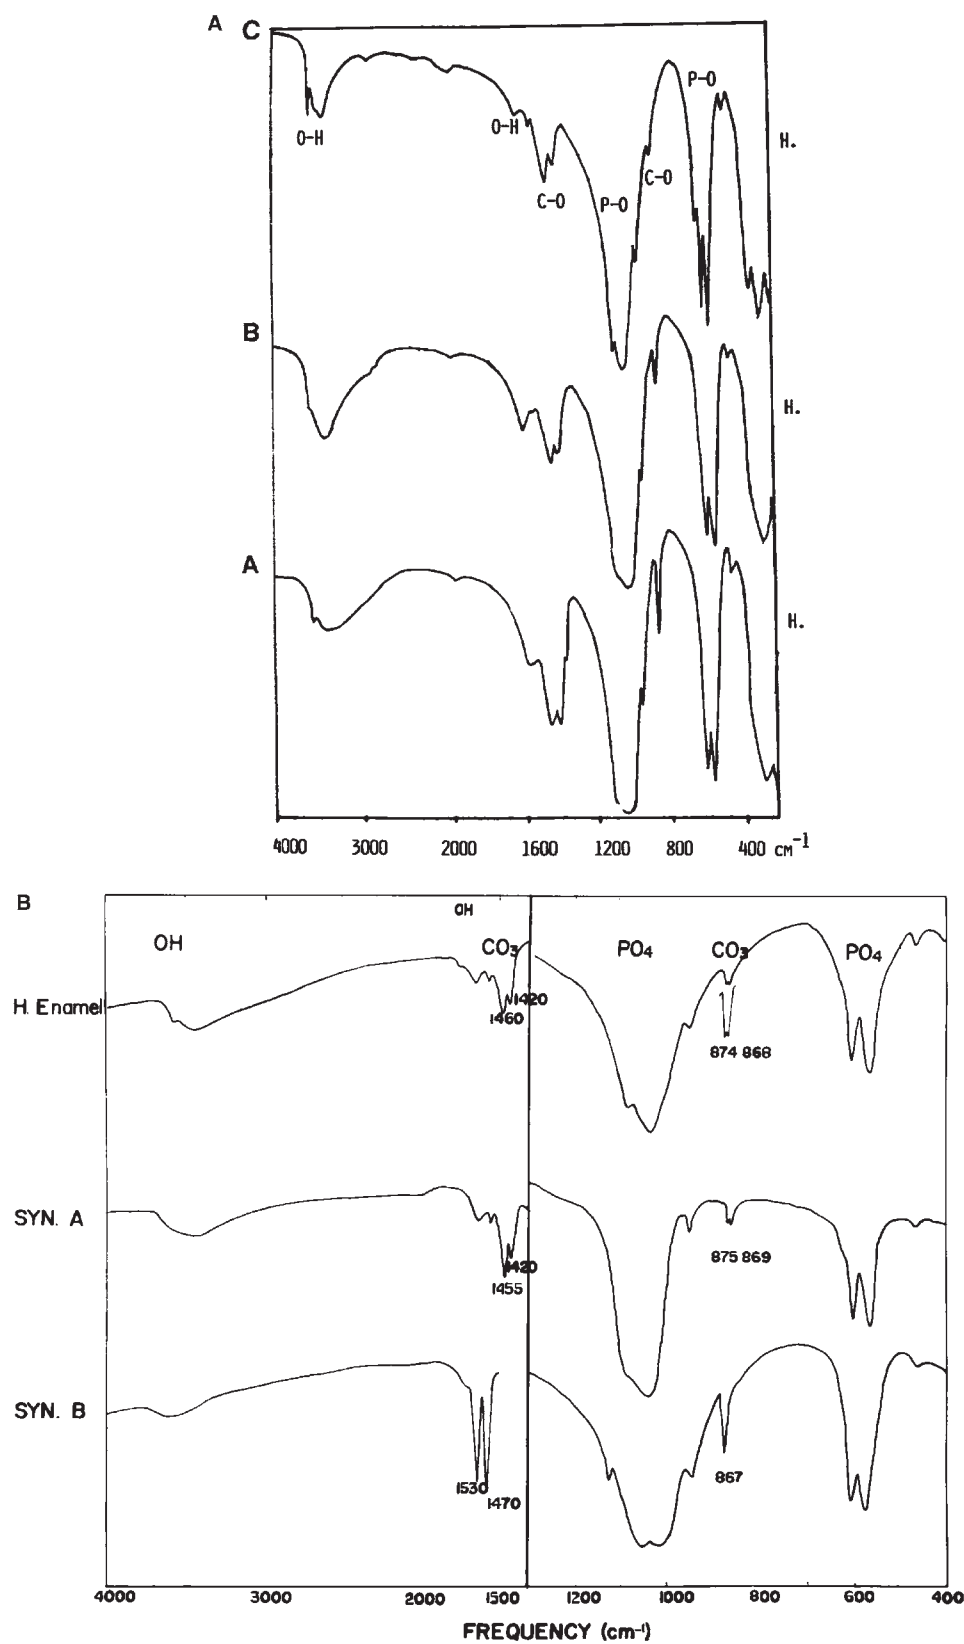

Fig. 3 (A): IR spectra of biological apatites from adult human enamel, dentin, and bone. Note the higher resolution of the P-O (for PO_4 groups) absorption spectra of enamel (C), compared to those of dentin (B) and bone (A) apatites. B: IR spectra comparing the characteristic C-O (for CO_3 groups) absorption bands in human enamel apatite compared to those in synthetic apatite with type A (CO_3 -for-OH) substitution (syn A) and in type B (CO_3 -for- PO_4) substitution (syn B).

of partially-substituted (F,OH) apatite that is more resistant to acid dissolution, (i.e. dental caries).^[29,33,34,39] Administration of F in the drinking water was shown to increase the crystal size and decrease the extent of

dissolution of rat bones^[42] and increase crystal thickness of enamel apatite.^[43] Fluoride therapy (as NaF) has been recommended for the management of osteoporosis to increase bone density.^[44,45]

B

SYNTHETIC APATITES

Earlier extensive studies on synthetic apatites were made to gain a better understanding of biologic apatites and their properties. Because biologic apatite was idealized as hydroxyapatite HA, most of the studies centered on HA preparation and evaluation of HA properties. Studies on synthetic apatites in the last 30 years were motivated by development of calcium phosphate-based biomaterials (principally, HA) for bone repair, substitution, augmentation, and as scaffolds for tissue engineering in bone and teeth regeneration. The rationale for developing HA biomaterials was their similarity in composition to the bone mineral.

Synthetic HA can be made by solid-state reactions or by precipitation or hydrolysis methods and subsequent sintering at high temperatures, usually 1000°C and above. Synthetic apatites can also be prepared using hydrothermal,^[46,47] microwave,^[48,49] or sol-gel^[50,51] method. Apatite nanocrystals are obtained when

prepared by precipitation or hydrolysis at lower temperatures (25°C–60°C). Synthetic apatite crystals approximating the size of human enamel apatite may be obtained by precipitation or hydrolysis methods with reaction temperature, 80°C–95°C (Fig. 4). Apatites may also be prepared in gel systems,^[52] by electrodeposition,^[53,54] or biomimetic precipitation on metallic or polymeric^[55,56] substrates.

Apatites obtained by precipitation involve the reaction of calcium salts (e.g., CaNO₃, Ca(OH)₂, CaCl₂, Ca(Ac)₂) and phosphate salts (Na-, NH₄- or K- phosphates).^[24,57] Hydrolysis of nonapatitic calcium phosphates (e.g., ACP, DCPD, DCPA, OCP, β-TCP, α-TCP) or calcium compounds (e.g., CaCO₃, CaMg(CO₃)₂, CaF₂), in solutions containing OH, CO₃, or F, results in the formation of apatite, CO₃- or F-containing apatites.^[24,32,36,58] Apatites prepared by precipitation or hydrolysis methods when prepared at pH between 5 and 9 are calcium deficient apatites (CDA) and subsequent sintering results in the formation of biphasic calcium

Fig. 4 X-ray diffraction profiles of precipitated apatites obtained at different reaction temperatures. The nanoapatite crystals similar to bone apatite are prepared at 37°C (A) or at room temperature. The narrowing of diffraction peaks reflects increased crystallinity; the broader the diffraction peak the smaller the crystals.

phosphate (BCP), an intimate mixture of HA and β -TCP.^[59] Sintering, or firing, of synthetic apatites results in an increase in crystal size and decrease in microporosity. Sintering of HA at temperatures above 1200°C results in decomposition of apatite-forming other calcium phosphates, such as β -TCP, α -TCP, and possibly even mixed with ACP. Combination of calcium phosphates (e.g., ACP, DCPA, DCPD, CDA, α -TCP, β -TCP) with other calcium compounds ($\text{Ca}(\text{OH})_2$, CaCO_3 , mixed with phosphate solutions or organic acids, results in the formation of apatitic calcium phosphate cements.^[60,61]

Studies on synthetic apatites showed that substitutions for Ca, PO_4 , or OH ions in the apatite structure results in changes in lattice parameters (Table 2) and crystallinity (reflecting crystal size and/or strain) and dissolution properties. For example, CO_3 -for- PO_4 coupled with Na-for-Ca substitution has the following effects on apatite properties: (a) smaller a- and larger c-axis dimensions compared to CO_3 -free apatites, (b) change from needle-like to rod-like to plate-like with increasing CO_3 incorporation, (c) lower resolution of the P-O (for PO_4) absorption bands in the IR spectra, (d) higher solubility, and (e) lower thermal stability.^[11–13,24,31,32,38] Such studies helped explain the contributions of some ions associated with biologic apatites, as well led to the development of some therapies and manufacture of calcium phosphate-based biomaterials.

Synthetic Apatites as Bone-Substitute Materials

The first successful use of a calcium phosphate reagent in bone repair was reported by Albee in 1920,^[62] followed more than 50 years later by the first clinical study by Nery et al.^[63] on periodontal bony defects using porous calcium phosphate identified by the authors as “tricalcium phosphate (TCP)”. X-ray diffraction analysis of Nery’s material years later revealed that the “tricalcium phosphate” consisted of a mixture of hydroxyapatite (HA) and beta-tricalcium phosphate (β -TCP) with a β -TCP/HA ratio of 20/80^[20] and was thus renamed, “biphasic calcium phosphate” or BCP.^[64] Similarity in composition of the synthetic apatite to biologic apatite was the rationale for the development of calcium-phosphate based biomaterials for bone repair, substitution, augmentation, and as scaffolds for bone and tooth regeneration. These calcium phosphate bioceramics include: hydroxyapatite (HA), tricalcium phosphate (β -TCP), biphasic calcium phosphate, BCP (consisting of an intimate mixture of HA and β -TCP of varying HA/ β -TCP ratios), bovine-bone derived apatites (unsintered and sintered), and coral-transformed apatite (Fig. 6). Commercialization of HA as bone graft materials was largely due to the independent efforts of Jarcho,^[15] deGroot,^[16] and Aoki.^[17] Basic studies on BCP led to its commercialization and popularity as bone graft materials and as scaffolds for tissue engineering.^[18,59,64–69]

Commercial HA biomaterials are usually prepared by precipitation at high pH and subsequent sintering at about 1000–1100°C.^[15–17] Coral-derived HA, or coralline HA, is prepared by the hydrothermal reaction of coral (CaCO_3 , in aragonite form) with ammonium phosphate (Fig. 5).^[70] Bovine-bone-derived HA is prepared by removing the organic phase (resulting in bone apatite) or removing the organic phase and sintering at high temperatures. These different preparations and origin (synthetic vs. biologic) are reflected in the difference in their initial crystallinity reflecting crystal size (Fig. 6) and their dissolution rates,^[71] increasing in the order:

HA \ll coralline HA
 \ll bovine bone apatite (sintered)
 $\ll\ll$ bovine bone apatite (unsintered).
 HA \ll BCP \ll β – TCP

Synthetic HA in Implant Surfaces and Coatings

HA and related calcium phosphates, in spite of their many desirable properties, are not strong enough to be used in load-bearing areas.^[15,16] The rationale for the

Table 2 Lattice parameters of mineral and synthetic apatites compared to biologic apatite

^bPrepared at 95°C either by precipitation or by hydrolysis of CaHPO₄ in solutions containing the desired substituent.^[12,13,24,58]

development of H-coated orthopedic and dental implants is to combine the strength of the metal (usually titanium or titanium alloy) and the bioactive properties of HA and other calcium phosphates. Dense HA particles are used as the source material for depositing implant coating by the plasma-spray technique.^[15,16,72] The high temperatures (about 30,000°C) and other variable parameters involved in the plasma spray process (e.g., velocity of feeding the HA powder, distance of the gun from the metal substrate) result in the partial transformation of the original HA into ACP and minor amounts of α -TCP, β -TCP, tetracalcium phosphate (TTCP, Ca₄P₂O₉).^[73] Plasma-sprayed HA coatings have nonhomogenous composition (principally ACP/HA ratio), varying from the layer closest to the metal substrate to the outermost layer, and varying from one manufacturer to another.^[73] Alternatives to the plasma-spray method are: electrochemical

deposition,^[53,54] precipitation, or chemical deposition;^[55,56] the latter method being also applicable to nonmetallic substrates.^[56] These other methods provide homogenous implant coating of the desired composition, (e.g., HA, FA, CHA, OC)^[53–56,74] and allows coating deposition at much lower temperatures, thus permitting the incorporation of bioactive molecules and growth factors.

In recent years, HA or BCP has been used as an abrasive material for grit-blasting to roughen the surface and provide a more bioactive surface (compared to alumina or silica abrasive), thus enhancing osseointegration of the implant.^[75]

Synthetic HA in Composites

HA and related calcium phosphates are used as the inorganic component in composites with natural (e.g.,

Fig. 5 Scanning electron micrograph of coralline apatite.

collagen, chitosan) or synthetic (polylactic acid or poly(lactide-co-glycolide), PLA or PLGA, high-molecular-weight polyethylene) polymers.^[76,77] The rationale for developing composite biomaterials is the fact that bone is a composite of a biological polymer (collagen) and inorganic phase (carbonate apatite).

Synthetic HA and BCP as Scaffolds for Tissue Engineering

Several investigators have reported that mesenchymal stem cells (MSC) from bone marrow can be cultured in

porous calcium phosphate biomaterials (ceramic HA, coralline HA, BCP ceramic) in vitro and implanted as a tissue engineered material for bone regeneration.^[78,79]

Critical Properties of Synthetic HA and Related Calcium Phosphates: Porosity, Biocompatibility, Bioactivity, Osteoconductivity, and Osteoinductivity

Porosity (interconnecting macro-porosity) is an important property of biomaterials that allows bony ingrowth and vascularization.^[80,81] Macro-porosity is introduced in HA and other calcium phosphates by the incorporation of porogens, such as naphthalene,^[82] H₂O₂, or sugar molecules. Biocompatibility of a material is determined in vitro from the cell response (proliferation, attachment, phenotypic expression) to the material. Material surface composition, surface roughness, or topography influences cell response.^[83] Bioactivity is defined as the property of the material to develop a direct adherent, and strong bonding and interface with the bone tissue.^[84,85] Bioactivity is demonstrated in vitro and in vivo by the ability of the material to form carbonate apatite on the surface from the simulated body fluid in vitro^[56] or biological fluid in vivo in osseous or nonosseous sites.^[65,66,86,87] Osteoconductivity is the property of the material that allows attachment, proliferation, migration, and phenotypic expression of bone cells, leading to formation of new bone in direct apposition to the biomaterial.^[84] Osteoinductivity is the property of the material that allows osteoprogenitor cell growth and development for bone formation to

Fig. 6 X-ray diffraction profiles of apatite biomaterials (A,B,C). (A) Ceramic hydroxyapatite (Calciite™), (B) Coralline Hydroxyapatite (Interpore™), (C) Unsintered apatite, calcium-deficient (Osteogen™). The arrow on (b) indicates presence of Mg-substituted β -TCP.

occur^[88] and is usually determined by the formation of bone in non-bone-forming sites (e.g., under the skin or in muscle). HA and related calcium phosphates are generally considered to have all of the above properties, except osteoinductivity. However, it has been reported that with the appropriate composition, geometry and architecture, osteoinductive properties can be promoted.^[89,90]

CONCLUSION

The total analysis of the results obtained over four decades of research in this fascinating field of science suggests that, with newer scientific tools and with further refinement, we will succeed to address problems relating to the structure, morphology, and analysis of the biologic materials and produce synthetic apatites or composites that will emulate the structure and characteristics of natural soft and hard tissues.

Biological Adhesives from Nature

Lloyd D. Graham

CSIRO Molecular and Health Technologies, Sydney Laboratory, Riverside Life Sciences Centre, New South Wales, Australia

INTRODUCTION

This entry reviews some of the adhesive secretions used by organisms for attachment, construction, obstruction, defense, and predation. These glues often have to work on surfaces that are wet, dirty, or otherwise refractory—conditions that confound even the best synthetic adhesives. The entry reviews what is known of the natural glues produced in marine and other wet environments (by fish, holothurians, molluscs, arthropods, worms, bacteria, algae, and fungi) and those produced on land (by amphibians, spiders, insects, molluscs, etc.). The entry also considers whether some of these glues may prove useful in medical contexts, such as wound healing, surgical repair, or dentistry. There is a significant unmet clinical need for strong, elastic, and biocompatible adhesives that work in moist environments, and this entry reviews the steps that have been taken toward meeting this need with materials based on the design of high-performance glues found in nature.

An adhesive must engage in bonding interactions both with the adherends (adhesion) and within the adhesive layer (cohesion). The set glue should have a high elastic modulus (stiffness) and/or a high loss modulus (viscosity), as it must resist flow and be able to dissipate energy by deformation.^[1] Most biological adhesives rely on polymers—typically, proteins or polysaccharides—to form adhesive interactions with the substrata and cohesive interactions with each other. The concentration of the glue components is an important consideration.^[2] The “interpenetrating network” required for cohesion may be achieved either by providing preformed chains of high molecular mass or by linking smaller units in situ, either noncovalently or covalently. Many natural glues are of the second type; they probably owe their cohesive strength to a mixture of intermolecular forces acting in concert, where the possibilities for interaction include polymer chain entanglement, noncovalent association, joint coordination of metal ions, and covalent bonding.^[2] Glues of the second type also have the advantage of relatively low initial viscosities, which facilitates their mechanical engagement with the surface irregularities of the adherends and enhances their adhesive strength when set. Of the types of biological glues that have

been examined biochemically, 18 are thought to be predominantly protein, 7 involve proteins and carbohydrates in comparable amounts, and 3 consist mainly of carbohydrate (Table 1). Of course, the apparent bias toward protein-based adhesives may simply reflect the fact that it is generally easier to characterize and manipulate proteins than polysaccharides.

Sequences are known for some 37 protein families found in biological glues (Table 1). These often have similarities with the sequences of structural and elastomeric proteins: many are Gly-rich and contain repeated motifs and posttranslational modifications (PTMs). Common PTMs include glycosylations, which give rise to N- or O-linked glycoproteins, and hydroxylations, which give rise to 3,4-dihydroxyphenyl-L-alanine (Dopa), 4-hydroxyproline (Hyp), 5-hydroxylysine (Hyl), or 4-hydroxyarginine. Both types of PTM increase the number of hydroxyl groups present, and therefore enhance the potential for hydrogen bonding, metal coordination, and so on. Dopa has very specific properties in this regard, and its contribution to bioadhesion has been explored in detail. Despite their prominence in the literature, adhesive mechanisms that depend on Dopa are actually likely to be quite rare.^[3] Dopa-based reactions (e.g., quinone tanning) do, however, play important roles in other biological processes, such as the sclerotization of insect cuticles. Intermolecular cross-linking via covalent bonds or high-affinity metal coordination might be expected to contribute to the high cohesive strength of many irreversible biological adhesives (e.g., those intended for permanent attachment), and such bonds are known to occur *inter alia* in mantid ootheca and in the adhesives used to anchor marine algae and mussels. Glues designed to produce temporary adhesion (e.g., for short-term anchorage, prey capture, or predator evasion) are more likely to rely on noncovalent interactions and chain entanglement. Table 2 indicates the range of bond strengths associated with natural adhesives.

Many adhesive proteins are rich in Gly, Pro, or Ser, residues that have high β -turn potential.^[4] Indeed, tandem repeats of Pro- and Gly-rich motifs can form a range of specialized poly-Pro/ β -turn conformations called pro- β helices.^[5] The dipeptide Pro-Gly is particularly likely to constitute the center of a type II β -turn, and tandem turns of this type constitute a

Table 1 Key features of natural adhesives mentioned in the text

Algal attachment	I	PC, C		Polyphenolics
Microbial EPS	I	C		No

For brevity, specialized cell-surface interactions between microbial pathogens and their host tissues are not included. The type of adhesion is presumed from the purpose of the attachment to be I, irreversible or long-term, or R, reversible or short-term. The main type of organic component in the adhesive is indicated by P, protein; C, carbohydrate; F, lipid or fatty acid; two letters denote two components in comparable amounts. Items in parentheses may be of secondary importance or only present in some circumstances or species; items preceded by “?” are uncertain or speculative. Protein sequences are usually deduced from cloned genes, and homologs are generally counted as a single sequence. The heading “Covalent-like cross-links” is mainly directed toward intermolecular tethering via covalent bonds, high-affinity metal coordination, etc., but the entry “(Disulfides)” may refer to intramolecular bridges that are important to adhesive function.

^aFor brevity, some references are not the original sources of the data but do cite the originals.

^bNormal tenacity, i.e., force exerted at right-angles to adhesive layer (butt joint).

^cMixture of tensile and shear data, or uncertain which format was used.

^dForce exerted parallel to the adhesive layer so that the surfaces slide over one another (lap joint).

^eJoint undergoes progressive separation from one end to the other in response to a force applied (usually at right-angles to adhesive layer) to one end of a flexible adherend.

Abbreviations: W, wet or humid environment (relative humidity of $\geq 80\%$); D, dry environment (relative humidity of $\leq 40\%$); M, midrange environment (relative humidity 41–79%); WD, moist bonding environment followed by rapid test in dry; W + D, bonding or testing in a variety of environments; %, grams per 100 ml solution; MAP, mussel adhesive proteins; XL, covalently cross-linked; ST, soft tissue; cart, cartilage; GRG, gelatin/resorcinol/glyoxal; GRF, gelatin/resorcinol/formaldehyde; MAP, mussel adhesive proteins, without covalent cross-linking unless otherwise indicated; alb/gluteral, albumin cross-linked with gluteraldehyde; P, hydroxyproline; Y, Dopa; PVA, polyvinylacetate; [] indicates an assumed condition or interpolated value. Where a material was tested with different surface textures, the result for the smoothest one is cited.

β -turn spiral (nanospring) that is thought to be highly elastic.^[4,6] There is, however, no uniformity in the secondary structures encountered in protein-based adhesives. Some (e.g., mantid oothecal protein and keratin-like tick proteins) are believed to form α -helical coiled coils, others (e.g., silk sericins, *Drosophila* mating plug protein) probably contain β -sheets or β -turn spirals, while yet others (e.g., collagen-like tick proteins, mussel glue repeat motifs) are likely to adopt poly-Pro type II helices. In terms of tertiary structure, the need to form an interpenetrating polymer network suggests that proteins will be more useful in long extended conformations than in compact globular folds.

AQUATIC ADHESIVES

Mussel Glue

The adhesive plaque material of *Mytilus* sp. has been under detailed scrutiny for several decades and has been reviewed extensively (e.g., Refs. [3,7–10]). The components of *Mytilus* adhesive plaque are mostly basic polyphenolic proteins that are soluble in dilute acids. The genes encoding many of the *Mytilus edulis* foot proteins (Mefp) have been cloned and sequenced; the gene products span the size range 5–120 kDa and typically contain repetitive sequences. Selected Tyr, Pro, and Arg residues in these proteins undergo PTMs (hydroxylations) so that they are present as Dopa, Hyp, and hydroxyarginine residues, respectively, in the mature proteins. The Dopa content of the various Mefps varies from 3 to 30 mol%, and the proteins with

the highest Dopa contents (Mefp-3 and -5) tend to predominate at the interface with the substratum.

Tyrosinase (also known as catechol oxidase or diphenol oxidase) can convert peptidyl Tyr residues into Dopa residues, and can further convert Dopa into *o*-quinone or its tautomer, α,β -dehydroDopa.^[8,9] Recently, Jonathan Wilker's group at Purdue has confirmed (for mussel plaque, Mefp-1 and -2, and model peptides) that the Dopa residues chelate iron, mainly as Fe(Dopa)₃ (Fig. 1).^[11] This complex alone can account for much protein–protein cross-linking (cohesion). However, the iron also facilitates the oxidation of Dopa by molecular oxygen to generate quinone-like radicals; these radicals may possibly go on to react with each other or with Dopa to form C–C linked rings (cohesion), or alternatively they may react with the substratum (adhesion).^[8] While the generation of Dopa in mussel plaque is probably enzymatic, further conversions associated with curing need not be. Indeed, Monahan and Wilker found that optimal curing (i.e., hardening and darkening) of Dopa-containing Mefp-1 and -2 was achieved by metal ion oxidizing agents (Fe³⁺, MnO₄[−]), and that enzymes (tyrosinase, laccase) were completely ineffective.^[12]

Other interactions may also serve to enhance the adhesive and cohesive strength of mussel plaque. During adhesion, the numerous hydroxyl groups of the Dopa/Ser/Thr/Hyp/Hyl residues in the mussel adhesive proteins may compete with and displace surface-bound water molecules, leading to zipper-like chemisorption of extended polypeptides.^[7] The Dopa side chain is particularly effective at hydrogen bonding, and it also chelates metals/metal oxides, allowing binding to mineral surfaces. Dopa and other residues

Fig. 1 Metal-protein cross-link proposed for mussel adhesive proteins. (From Ref. [11].)

(e.g., hydroxyarginine) can engage in pi-based interactions that allow binding to aromatic surfaces.^[3,9] The numerous basic residues in the mussel adhesive proteins promote binding to natural surfaces, which typically carry a net negative charge. Although the reaction of Dopa/quinones with Lys amino groups, Cys thiols, or any of the numerous hydroxyl groups is no longer thought to occur as a primary mechanism of cross-linking, Lys amino groups are now believed to form Schiff bases with completed diquinone cross-links.^[3] It is thought that the covalent cross-linking of Dopa residues probably enhances cohesion at the expense of adhesion.^[3] The interactions between surface-bound Mefp-1 and Mefp-2, including effects due to cross-linking, have recently been investigated.^[13]

The properties of the key proteins in the adhesive plaque of *M. edulis* may be summarized as follows:^[3,7-9]

- Mefp-1 (110 kDa, calculated $pI > 10$, 13 mol% Dopa) contains up to 80 repeats of the decapeptide Ala-Lys-Pro-Ser-Tyr-Hyp-Hyp-Thr-Dopa-Lys, and probably adopts a poly-Pro type II helix. Mefp-1 is found as a protective lacquer at byssus-seawater interfaces. Each molecule binds 50–75 Fe^{3+} with huge affinity, and for this reason Mefp-1 has been likened to armor plating. It is strongly adhesive in vitro and is considered to be the main ingredient of Cell-Tak™, the cell/tissue adhesive sold by BD Biosciences.^[3] An NMR study of the isolated Mefp-1 decapeptide concluded that it was a bent helix based on a type III β -turn involving the Hyp residues, possibly stabilized by hydrogen bonding and Tyr/Dopa ring stacking.^[14] More recent NMR of a synthetic decapeptide (with Tyr in place of Dopa) robustly concluded that it adopted a standard poly-Pro type II helix, which

leaves all of the hydroxyls free for adhesive or cohesive interactions.^[15]

- Mefp-2 (40 kDa, calculated $pI \sim 9$, 3 mol% Dopa) is the dominant bulk adhesive (to 40% w/w of plaque) and contains EGF domains interspersed with acidic Dopa-rich regions.
- Mefp-3 (6 kDa, calculated $pI > 11$, 20 mol% Dopa) is the surface primer; it is a family of >10 proteins rich in hydroxyarginine and Dopa.
- Mefp-4 (80 kDa, 4 mol% Dopa) is the other bulk adhesive; it is elevated in Gly, Arg, and His, contains Dopa, and may contain Tyr-rich octapeptide repeats.
- Mefp-5 (9 kDa, calculated $pI \sim 9$, 30 mol% Dopa) has >75 mol% of its Dopa residues adjacent to basic residues (e.g., Dopa-Lys) and contains phosphoserine (Ser-P) in putative mineral-binding motifs.^[16]

Barnacle Cement

Unlike mussel adhesive proteins, barnacle cement proteins do not contain Dopa; rather, they are rich in Gly, Ser, Thr, and Ala residues.^[7,17] The adhesive strength of barnacle cement is comparable to that of the mussel glue, and may even exceed it (Table 2).^[17,18] Barnacle cement proteins are not solubilized by 8 M urea or 6 M guanidinium hydrochloride, but they generally do dissolve when heated in the presence of sodium dodecyl sulfate (SDS) and reducing agents.^[17] Interestingly, adult barnacles of different species appear to use different adhesive proteins, as described below, and at least eight gene sequences have been patented.^[18]

Balanus eburneus

Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) revealed constituent proteins

with molecular masses of 7, 22, 36, 52, and 58 kDa. Oddly, an 80 kDa species (apparently with the same N-terminus as the 36 kDa species) was also detected when samples had been reduced with 2-mercaptoethanol.^[17] Amino acid compositions have been determined and many peptide sequences have been obtained. The 36 kDa protein is the most abundant one, and is elevated in Tyr (10 mol%), Pro (10 mol%), and Leu.

Semibalanus balanoides

Like the cement of *B. eburneus*, the base plate and hemolymph of *S. balanoides* contains a prominent protein around 35 kDa in size. This has been cloned and sequenced; the encoded protein has homology to filensin, an intermediate filament protein found in eye lenses, and to pernin, a self-aggregating mussel hemolymph protein.^[18,19] Toward the C-terminus, there are repeats of a His-Asp-Asp-His motif which may bind metals, perhaps allowing adhesion to metal surfaces or metal-mediated protein cross-links.

Balanus crenatus

Initially, major proteins were seen at 84, 50, 47, 39, and 15–19 kDa in SDS-PAGE of reduced samples.^[20] In later work by the same group, more than six defined bands (3–50 kDa) were observed in SDS-PAGE of nonreduced samples, but reduced samples gave only a smear which was dominated by material of <5 kDa.^[17] Accordingly, it was suggested that the upper smear comprised multimers of a <5 kDa monomer corresponding to the *B. eburneus* 7 kDa protein, and that the proteins homologous to the other *B. eburneus* ones seen earlier must have remained insoluble.^[20] The cured cement is a trabecular mesh.^[20] One patent reports a 35 kDa protein for *B. crenatus* that has a similar N-terminal sequence to the corresponding protein from *B. improvisus* and *S. balanoides*.^[19]

Balanus perforatus

This cement seems to be a mixture of very hydrophobic proteins cross-linked through disulfide-linked Cys residues. Sodium dodecyl sulfate-PAGE revealed bands of 65, 62, 39, 24 and 15 kDa; the N-terminal sequence of the 39 kDa protein has been determined.^[20]

Megabalanus rosa

This cement can be completely solubilized by 7 M guanidinium hydrochloride containing 0.5 M

dithiothreitol at 60°C. Three proteins (Mr_{cp}-100k, Mr_{cp}-68k, and Mr_{cp}-52k) account for >90% (w/w) of the cement, while a fourth (Mr_{cp}-20k) accounts for >2% (w/w).^[21,22]

Mr_{cp}-100k was cloned and sequenced; it contains no repeat sequences, and has a high content of hydrophobic residues dominated by Leu (11 mol%) and Gly (10 mol%).^[21,23] Interestingly, the calculated pI value rises along the polypeptide chain, ranging from pI~5 (near the N-terminus) to pI~11 (near the C-terminus). The low Cys content for this protein (1.4 mol%) is at odds with the need for reducing agents to solubilize it. The investigators speculate that this protein may form β-strands with alternating hydrophobic and hydrophilic residues. A cyanogen bromide fragment from *B. eburneus* cement has homology to Mr_{cp}-100k.

Mr_{cp}-68k, which was originally called the “60 kDa protein,” is rich in Ser, Thr, Ala, and Gly.^[24] In the absence of 2-mercaptoethanol a band of ~180 kDa is the only one seen in SDS-PAGE, suggesting that the protein forms disulfide-mediated trimers. A patent specification provides sequence information for a 47 kDa protein that seems to be a truncation product of Mr_{cp}-68k.^[25] Another patented sequence (546 residues) is also likely to relate to Mr_{cp}-68k.^[26]

Mr_{cp}-20k accounts for >2% (w/w) of *M. rosa* cement.^[22,27] It readily dissolved without reduction and was isolated by reversed-phase high-performance liquid chromatography. The DNA-derived amino acid sequence indicates a protein rich in Cys (17 mol%) and charged residues (Asp, Glu, and His all feature at ~10 mol%) with a calculated pI~4.7. Somewhat surprisingly, all of the Cys residues are involved in intramolecular (rather than intermolecular) disulfides. The protein's sequence comprises six repeats based loosely on the motif, [Xaa]₄₋₁₄CysAsn[Xaa]₂[His/Ala]ProCys-Tyr[His/Arg]Cys[Xaa]₅₋₁₀CysXaaCysXaaCys. Interestingly, the Cys-Xaa-Cys-Xaa-Cys motif is shared with silk protein sp185 of *Chironomus* sp., which is used in making the larval tubes of these aquatic midges. There are also similarities with the mussel protein Mefp-2, which has clusters of acidic residues and contains multiple EGF domains featuring six conserved Cys residues. The presence of Mg²⁺, Mn²⁺, Ca²⁺, or Zn²⁺ ions did not alter the electrophoretic mobility of Mr_{cp}-20k. Above 0.5 M NaCl, synthetic peptides based on the Mr_{cp}-20 repeats showed self-assembly into fibrils that were hundreds of nanometers long and did not appear to involve β-elements.^[28]

Sea Star and Sea Cucumber Adhesives

The podial adhesive secretion of the sea star *Asterias rubens* is an insoluble matrix that when dry comprises

40% (w/w) inorganic material (presumably sea salts), and contains 2.6 times more protein than carbohydrate. The material has somewhat higher levels of Gly (9.7 mol%), Pro, Ile, and Cys than the average eukaryotic protein.^[29] Immunohistochemistry indicates that a similar adhesive is used by many species of sea star.^[30] In terms of gross composition, the *Asterias rubens* adhesive resembles pedal mucus from the limpet *Patella vulgata*.^[29] The podial discs of sea stars and sea urchins adapt their surface topography to mirror substratum roughness, so the adhesive layer is always just a thin (nm range) film.^[31]

Many holothurians (sea cucumbers) eject tacky tubules as a defense against potential predators. The adhesive is mainly organic and comprises 60% protein and 40% carbohydrate. It is also very insoluble, with urea, SDS, and reducing agents required to achieve partial dissolution. Extracts contain around 10 main proteins (17–220 kDa); these have broadly similar amino acid compositions and are all Gly-rich (16–22 mol%). The proteins visible in isoelectric focusing gels had *pI* values of 3.0–5.5 (denatured).^[32]

Limpet and Periwinkle Mucus

The limpet *Lottia limatula* secretes a mucus that is 93% (w/w) water and contains six times as much protein as carbohydrate.^[33] The mucus of adhered limpets is twice as concentrated as that of mobile ones, and is harder to dissolve. Urea, SDS, and 2-mercaptoethanol cooperate to solubilize the mucus, which contains ~10 proteins ranging from 20 to 220 kDa that are elevated in polar and acidic residues (denatured *pI* typically 4.7–5.3). A 45 kDa protein is Gly-rich (13 mol%), while the only glycoprotein present (140 kDa) has a high Pro content (11 mol%). The mucus proteins have a strong tendency toward noncovalent aggregation. A 118 kDa protein is characteristic of adhesive mucus while a 68 kDa protein is distinctive for the nonadhesive form, but their functions are unclear.^[33]

The mucus of the marsh periwinkle *Littorina irrorata* is also mainly water, with inorganic material accounting for around half of its dry weight. The organic fraction of the trail mucus from mobile periwinkles consists more of large polysaccharides and less of proteins (those present are 59–65 kDa). In contrast, the mucus of tightly adhered snails contains equal amounts of protein and carbohydrate because of the additional (and abundant) presence of acidic proteins (denatured *pI* ~4.8) of 59 and 65 kDa (unreduced) or 36 and 41 kDa (reduced).^[34] Both proteins are lightly glycosylated and have similar amino acid compositions.^[34] It is noteworthy that the periwinkle and the limpet secretions lack the megadalton-sized

glycoproteins typical of mammalian mucus, while in both cases the adhesiveness of the secretion correlates with the presence of particular proteins.^[2]

In the absence of reducing agents, fractions containing the *L. irrorata* 36 and 41 kDa proteins triggered the stiffening or gelling of commercial polysaccharide solutions, especially polyanionic ones, and so did preparations of the proteins elevated in the adhesive forms of mucus from the slug *Arion subfuscus* (61 and 15 kDa) and the land snail *Helix aspersa* (175, 97, and 82 kDa).^[1] It is likely that the glue proteins [which comprise 25–50% (w/w) of the organic fraction of slug, land snail, and periwinkle adhesive mucus] are carbohydrate-binding agents rather than enzymes.^[1] One such protein might bridge several polysaccharide chains in a noncovalent manner.

Stickleback Spiggin

Spiggin is a proteinaceous material that is secreted by the breeding male stickleback and is used as an adhesive thread in the construction of an underwater nest. Although spiggin is encoded by a single gene, it is found as three distinct subunits, which are in fact splice variants.^[35,36] The α , β , and γ subunits are proteins of 103, 70, and 53 kDa, respectively. In kidney tissue, which is the seat of spiggin biosynthesis, the main forms of spiggin appear in Western blots as bands of 130 and 51 kDa; the larger band is thought to represent a glycosylated form of the α -subunit. In contrast, the main form of spiggin detected in bladder urine is a 203 kDa glycoprotein, which is thought to be a dimer of the 130 kDa species. Unfortunately, it is unclear whether the samples used in these gels were reduced or not. Sequence analysis reveals that the three subunits contain different numbers of domains that have high homology to the D-domains of mammalian von Willebrand factor. These are interspersed by Cys-rich regions of comparable size to the D-domains. von Willebrand factor (250 kDa) can multimerize to species >20 MDa, and does so by way of intermolecular disulfide bridges that depend on the presence of two sets of the motif Cys-Gly-Leu-Cys-Gly.^[37] As the same motifs (and/or truncated variants thereof) are present in spiggin, it is possible that the latter multimerizes in a similar way.^[35,36]

Bacterial Adhesives

The extracellular polymeric substances (EPS) secreted by bacteria as an aid to biofilm and floc formation are typically polysaccharides of high molecular mass. They can readily be produced on a commercial scale by fermentation. Xanthan gum, an EPS secreted by the bacterium *Xanthomonas campestris*, is one such

product, and Montana Biotech's C-902 Polymer is another. The latter is noncytotoxic, biodegradable, and, unlike the highly branched Xanthan polysaccharide, does not expand in water.^[38] Although produced in an aquatic environment, bacterial EPS seem to rely on noncovalent interactions and/or polymer chain entanglement for adhesion, and provide the highest bond strengths when dry. Additives and chemical modification have been used to enhance the moisture resistance of C-902 Polymer.^[39]

Pathogenic bacteria use many different cell-surface adhesive proteins (adhesins) to bind specifically to host glycan and protein determinants. Their importance to human health means that many of these molecular recognition systems have been characterized in great detail, but their discussion lies outside the scope of this entry.^[40]

Algal Adhesives

In brown macroalgae (*Fucus distichus*) and green macroalgae (*Caulerpa prolifera*) the elongating rhizoid tips of zygotes, embryos, or cut sections secrete glycoproteins (60–70 kDa) that are recognized by antibodies to vitronectin (65–75 kDa), one of the major cell adhesion proteins of mammalian tissues.^[41,42] These glycoproteins are implicated in rhizoid-substratum adhesion, which for example was inhibited by antivitronection antibodies.^[41] Rhizoid tip adhesion in *Fucus* sp. also requires a sulfated fucan called fucoidan or F2, inviting speculation that the vitronectin-like proteins bind fucoidan in the same way that vitronectin binds heparan sulfate.^[41]

Spores of the marine green alga *Ulva* sp. (formerly *Enteromorpha* sp.) attach to underwater substrata via a glycoprotein adhesive. Western blots reveal a monomer of ~110 kDa, which is thought to become progressively cross-linked after zoospore attachment. The hydrophilic swollen gel cures within 1 hr, becoming less adhesive and more cohesive, but the nature of the cross-links remains unknown.^[43,44]

Like bacteria, microalgae can secrete EPS as an aid to biofilm formation and aggregation. Moreover, the cohesive strength of many algal adhesives may be enhanced by the covalent cross-linking of their polysaccharide chains. Indeed, taxonomically diverse marine algae may share a common mechanism of adhesion in which zygotes (and sometimes eggs and/or embryos) secrete polyphenolic compounds that are activated by extracellular peroxidase enzymes to form covalent cross-links between carbohydrate fibers. For example, marine brown macroalgae use vanadium haloperoxidase to cross-link acidic polysaccharides with polymers of phloroglucinol.^[45,46]

Fungal Adhesives

Like bacteria, fungi can secrete EPS as an aid to biofilm and aggregate formation. Fungal hyphae also secrete small proteins (~100 amino acid residues) called hydrophobins, and to date six or more genes from the hydrophobin gene family have been identified.^[47] At hydrophilic/hydrophobic interfaces, class I hydrophobins self-assemble into thin (5–12 nm) films that present a hydrophobic surface to the nonpolar milieu (oil, plastic, air, etc.) and a hydrophilic surface to the polar milieu (water, hyphal cell wall, etc.). For example, the SC3 hydrophobin allows hyphae of *Schizophyllum commune* to attach firmly to Teflon[®] surfaces when grown in air, while MPG1 of *Magnaporthe grisea* and ABH3 of *Agaricus bisporus* also enable the attachment of submerged hyphae.^[48] Some hydrophobins are decorated with mannose sugars, while others are unglycosylated.^[47]

Macroconidia of the plant pathogen *Nectria haematococca* produce a hydrophobic 90 kDa glycoprotein from the spore tip.^[49] The polypeptide (whose amino acid composition is known) carries N-linked glycans, including mannose residues which seem to be essential to adhesion.^[49] The conidia of another phytopathogen, *Collectrichum graminicola*, adhere to hydrophobic substrata using a glycoprotein (apparent molecular mass ~200 kDa) whose core protein is ~116 kDa and whose dominant sugar is mannose.^[50] Thus, the *N. haematococca* and *C. graminicola* glycoproteins, which are not considered hydrophobins, may exemplify another class of fungal adhesive.^[49,50]

The oral pathogen *Candida albicans* also uses mannoprotein adhesin(s) (25% carbohydrate by weight) to attach to plastic surfaces.^[51] It can attach to host epithelia by a variety of mechanisms, including lectin-like adhesins and hyphal wall proteins that mimic the mammalian substrates of host transglutaminase enzymes.^[52] As with pathogenic bacteria, the cell-surface molecules used by fungal pathogens to recognize and colonize host tissues lie outside the scope of this entry.

Other Aquatic Adhesives

Some parasitic marine monogeneans (flatworms) produce insoluble protein secretions for temporary attachment; this material is Dopa-free and rich in Gly (12–19 mol%) and Ala.^[53] An oyster adhesive features a protein that contains little Cys, some Pro (but no Pro-OH), and a large complement of Gly (25 mol%).^[54] In abalone shell, the insoluble organic adhesive between layers of nacre contains lustrin A, a modular protein that comprises a single domain with a huge Ser content and 10 Cys-rich domains interspersed

by eight Pro-rich domains.^[55] The reef-building polychaete *Phragmatopoma californica* secretes a protein mortar rich in Ser-P (25 mol%), Gly, and Lys. It contains a highly acidic Ser-P protein and two proteins of 10–20 kDa (Pc-1 and Pc-2; calculated $pI \geq 9.7$) that feature repeat motifs rich in Dopa, Gly, and Lys.^[56,57] The aquatic larvae of the blackfly *Simulium ornatum* are anchored by a proteinaceous adhesive secreted from their labial glands. The main proteins are 70, 40, and 20 kDa.^[58] N-terminal sequences have been determined for the two larger proteins, and these contain two- and three-residue repeats of particular residues, such as Tyr.^[58] The blackfly larval adhesive is considered to be a form of silk. Most anuran (amphibian) larvae have a transient cement gland that secretes a mucous adhesive for underwater attachment.^[59]

TERRESTRIAL ADHESIVES

Salamander and Frog Glue

Some adult amphibia secrete tacky exudates that probably form a defense against potential predators.^[60] Salamander skin exudates are proteinaceous but fail to congeal when secreted directly into water.^[61] The adhesive strength of skin secretions from adult salamanders, frogs, and other amphibians has been measured (Table 2).^[60]

When provoked, Australian frogs of the genus *Notaden* secrete a sticky nontoxic exudate.^[62] This sets rapidly into an elastic solid (Fig. 2) that is actually a

Fig. 2 Elasticity of frog glue. A sample of moist glue from *Notaden bennetti* was adhered to plastic test discs (1 cm diameter) and the joint photographed without stress (A) and under tension (B), as described in Ref. [63]. [Photograph courtesy of CSIRO Molecular Science (Australia) and Adelaide Research and Innovation Pty. Ltd. (Australia).]

hydrogel (85–90% water by weight) and functions as a pressure-sensitive adhesive.^[63] It adheres tightly, even in moist conditions, to a wide range of materials including glass, plastic, metal, wood, skin, and Teflon.^[62,64] Dry glue contains little carbohydrate and consists mainly of proteins. The protein complement is rich in Gly (16 mol%), Pro (9 mol%), and Glx (14 mol%), and contains some Hyp (5 mol%) but no Dopa.^[63] Sodium dodecyl sulfate-PAGE reveals a characteristic pattern of proteins spanning 13–400 kDa. The largest protein (apparent molecular mass 350–500 kDa) is also the most abundant, and this protein appears to be the key structural component.^[63] The solid glue can be dissolved in 5% (v/v) acetic acid; raising the ionic strength causes the glue components to self-assemble spontaneously into a solid that resembles the starting material.^[63] The solid glue was shown by scanning electron microscopy to consist of an open, microporous meshwork that—on hydration—would hold a large volume of water. The material's high extensibility may derive from β -turn spiral nanosprings and reflect the relative lack of covalent cross-linking within the material.^[63] The glue may have elements in common with self-assembling amphiphilic peptides, silks, elastin, and other biological adhesives.^[63]

Tick Salivary Cement

Some blood-feeding ectoparasites secure themselves to their hosts using nonimmunogenic adhesives that bind mammalian tissues with great strength. For example, the cement cone of the ixodid tick *Rhipicephalus appendiculatus* consists of two components, a rigid quick-hardening core and a flexible cortex that serves as a hinge or gasket. Some seven structural proteins from the cement cone have been cloned. Generally, the proteins are rich in Gly and Pro or Tyr, and many have repeated motifs.^[65] They have similarities with keratins, collagens, and glutenins; the resemblance to mammalian structural proteins may help the tick evade immune surveillance. Curiously, one protein (*R. appendiculatus* clone 1) is homologous to a reef cement component from the polychaete *Phragmatopoma californica*, seemingly the Pc-1 protein.^[56,65] Cross-linking enzymes may play a role, but this has not been demonstrated. Various regions from a collagen- and keratin-like cement protein named 64P were expressed recombinantly in bacteria, purified, and used to raise antibodies.^[65,66] These and other recombinant cement proteins may be useful for immunizing livestock against tick infestations.

Other researchers have also cloned, sequenced, and expressed tick cement proteins with a view to

producing antitick vaccines.^[67,68] These proteins again resemble collagens and other vertebrate structural proteins, and one of them (RIM36) contains very obvious repeat motifs. A Gly-rich protein (Is9) expressed by feeding *Ixodes scapularis* ticks has homology with both the 64P and RIM36 proteins from *R. appendiculatis*.^[69]

Fruit Fly Larval Glue

The salivary secretions used by the fruit fly *Drosophila melanogaster* to affix its puparium to the substratum contain some five to seven major proteins with apparent sizes of 8–360 kDa, whose polypeptides are encoded by the *sgs* and *ng* gene families.^[70,71] *Drosophila* glue proteins usually have a high Thr content, and many are heavily glycosylated. For example, the proteins derived from the *sgs3* and *sgs4* genes of *D. melanogaster* and the *lgp1* and *lgp3* genes of *D. virilis* comprise tandem repeats of (typically 5- to 12-mer) motifs that are hugely Thr-rich and sometimes also contain Pro.^[72,73] Moreover, while the *sgs4* gene encodes a polypeptide of just 32 kDa, the secreted glycoprotein has an apparent molecular mass of ~100 kDa.^[71] For *lgp1*, the core protein (~138 kDa in SDS-PAGE) is decorated on Thr residues with O-linked hexose-rich glycans to give a glycoprotein (~230 kDa).^[74] The water-binding capacity of the large carbohydrate component in these glycoproteins is thought to account for their stickiness.^[73] *D. nasuta* larvae produce particularly abundant glue glycoproteins that have been characterized to some extent.^[75] However, most work on *Drosophila* larval/salivary glue proteins has focused on the regulation of their expression during development rather than on the proteins themselves.

Insect Mating Plugs

PEB-me is the major protein in the mating plug of *D. melanogaster*.^[76] It is a basic 377-residue protein (calculated $pI \sim 9.7$, 38 kDa) that is rich in Gly (22 mol%) and Pro (17 mol%), and its central region contains tandem Pro-Ser-Pro-Gly-(Gly/Glu) repeats that are somewhat reminiscent of spider flagelliform silk fibroin. PEB-me is autofluorescent.^[76] The excitation/emission filters used to image the protein in vivo (340–360/450–460 nm) can also be used to monitor the formation of dityrosine cross-links (328/410 nm) in proteins, so the presence of a 28-residue segment containing six Tyr residues suggests that the autofluorescence of monomeric PEB-me in SDS-PAGE gels might be caused by intramolecular dityrosine linkages.^[77] However, PEB-me does not seem to engage in covalent intermolecular cross-linking.^[76]

Nonprotein mating plugs are used by some other insects; for example, bumblebees use a sticky mixture of fatty acids.^[78]

Silk Sericins

Silk sericins are polar silkworm proteins with a high Ser content (average 38 mol%) that act as a glue for silk threads in the cocoon. Circular dichroism indicates that renatured sericins have a β -sheet structure.^[79] Transcripts from two sericin genes undergo differential splicing to generate a range of protein sizes up to 400 kDa.^[80] One gene (*Ser 1*) consists of 70 repeats of a 38-residue motif. Synthetic genes expressing up to 20 repeats of the motif were expressed in *E. coli*, but the largest product contained only 12 repeats—a situation reminiscent of bacterial silk production.^[81] All of the recombinant proteins migrated anomalously slowly in denaturing PAGE. Removing urea from the recombinants caused the self-assembly of amyloid fibrils. Natural sericins, which are less repetitive in sequence, are thought to be rich in β -sheet but nonamyloid. A propensity for β -style hydrogen bonding is suggested as the basis for the silk-gluing ability of sericins.

Mantid Oothecal Protein

The fibrous protein found in the ootheca of mantid insects is a coiled-coil protein.^[82] The mantid's left colleterial (i.e., female accessory) gland stores this structural protein in membrane-bound globules as stacked sheets of parallel α -helical fibrils.^[83] On extrusion, the globule membranes coalesce and the contents become a viscous mass. Over 30 min the fibrils change into long flat ribbons, and the final form of the ootheca consists mainly of this ribbon material.^[84] Globule contents can be induced to form ribbons in vitro by adding CaCl_2 .^[83] The ribbons consist of close-packed two-stranded ropes (α -helical coiled coils).^[82,84] Alongside this structural conversion, some covalent cross-linking takes place, as follows. The left colleterial gland secretes a phenoloxidase enzyme along with the precursors of sclerotizing agents, such as 3-*O*- β -glucosides of *N*-acyl-Dopamines (NADAs). The right colleterial gland secretes a β -glucosidase enzyme, which liberates NADAs that are then oxidized by the phenoloxidase to NADA-quinones, which may covalently cross-link proteins directly. In addition, another enzyme isomerizes the NADA-quinones to highly reactive intermediates (possibly quinone methides) that react with nucleophilic groups and thereby covalently cross-link the structural protein in other ways.^[83,85]

Other Terrestrial Adhesives

Silk dope is often used by insects for permanent attachment, and a possible aquatic example has been mentioned above, but a discussion of silk lies outside the scope of this entry.^[58] In several orders of insects, the accessory glands (or sometimes the oviducts) of gravid females produce a glue that attaches the eggs to each other or to the substratum. In some cases, this material takes the form of a protective jelly (if moist) or varnish (if dry) and is called spumaline.^[86] Trichopteran spumaline contains polysaccharide but almost no protein, and the same seems to apply to at least some lepidopteran egg attachment glues.^[86,87] The adhesive mucus of terrestrial slugs and snails has been dealt with above, alongside limpet and periwinkle mucus.^[1] Other organisms use glues to capture prey. Thus, cribellate spiders catch insects using silk threads coated with a sticky aqueous solution that contains glycoproteins (including a major one of ≥ 65 kDa), which appear rich in Gly (22 mol%) and Pro (16 mol%).^[88–90] Likewise, onychophorans (velvet-worms) eject a sticky fluid to immobilize their prey. This material is mainly protein; large collagen-like species (> 600 kDa) were tentatively identified with elastic fibers in the secretion, while small proteins (which, when reduced, were dominated by a 15 kDa species) were presumed to be components of the adhesive fluid.^[91] Last, rove beetles (*Stenus* sp.) capture prey using paraglossae coated with an adhesive secretion that is probably a mixture of protein and lipid.^[92]

APPLICATIONS IN WOUND HEALING AND TISSUE REPAIR

Currently, most of the biological glues used in medicine are based on fibrin, albumin, or gelatin and exhibit low bond strength. Synthetic glues, such as cyanoacrylates, are very strong, but they are somewhat toxic and form rigid nonporous films that can hinder wound healing. In contrast, many of the natural adhesives discussed above are strong and potentially biocompatible. Permanent adhesives from aquatic organisms (and some from terrestrial endo- and ectoparasites) should be able to provide high bond strengths in physiological environments. Bioadhesives with lower bond strengths may still prove useful as sealants and hemostats, while temporary/reversible adhesives from aquatic or terrestrial sources may find niche applications in areas such as wound dressings. In addition to biocompatibility, many natural adhesives possess elasticity and microscopic porosity. Indeed, electron micrographs of mussel plaque, barnacle cement, polychaete cement, monogenean adhesive, sea

star footprints, and solidified frog exudate all reveal a sponge-like ultrastructure that, in a biomedical context, should permit gas and nutrient exchange, and may support the cellular infiltration needed for eventual resorption.^[18,20,29,53,57,64] Some of the steps taken toward adapting natural adhesives for biomedical use are described below.

Mussel Glue

Polyphenolic adhesive proteins are widely reported to be both nontoxic and biodegradable. Moreover, difficulties in raising antibodies against Dopa-containing mussel adhesive proteins suggest that they have low immunogenicity, another desirable property from a biomedical perspective.^[3,7] In some circumstances, however, mussel adhesive proteins seem to induce apoptosis.^[93]

Air-dried films of *M. edulis* adhesive protein have been tested for mucoadhesion and found to be as good or better than polycarbophil, one of the best-known mucoadhesive polymers.^[94] Purified extracts containing mussel adhesive proteins have also been used directly as tissue bonding agents. Chivers and Wolowacz tested the mussel adhesive Cell-Tak in submerged pigskin butt joints without a cross-linking enzyme, and reported a tensile strength of only 0.0003 MPa after 22 hr (Table 2).^[95] Under similar conditions they obtained general tensile strengths of cyanoacrylate (1 MPa) > gelatin/resorcinol/formaldehyde (10^{-1} MPa) > fibrin (10^{-2} MPa). Benedict and Picciano describe formulations in which purified mussel adhesive proteins are mixed with fillers (e.g., collagen), cross-linked using tyrosinase or chemical agents, and tested (over 10–60 min) for the ability to bond meniscal cartilage, vertebrae, lap-jointed skin, and lap-jointed corneal tissue.^[96] The adhesive strength range observed by these investigators (0.002–0.015 MPa) is slightly higher than that reported by Chivers and Wolowacz. In contrast, Ninan et al. claim that the adhesive strength of a mussel extract in butt joints of pigskin reached a maximum of ~ 0.4 MPa (at 40% humidity) or ~ 1 MPa (at 80% humidity) in the absence of cross-linking enzymes, the latter result being similar to the strength of control joints formed using a cyanoacrylate glue.^[97] The bond strengths in this study were generally much higher than those reported by Benedict and Picciano or Chivers and Wolowacz. At the lower humidity, Tisseel[®] fibrin glue was usually twice as strong as the mussel extract, and both glues disimproved beyond 24 hr because of dehydration of the skin. At higher humidity, the mussel extract reached its maximum strength faster (24 hr), and the two glues were at full strength at 48 hr. Inventors continue to file patent specifications directed toward the use of polyphenolic protein

adhesives in medical and other applications, but to date no such product has been approved for use in surgical procedures.

Recent strategies to generate polypeptides based on mussel adhesive protein motifs have included polycondensation of the active esters of synthetic peptides followed by tyrosinase-mediated cross-linking.^[98] Other researchers have focused on more biotechnological approaches. Some have simply opted for the recombinant expression of natural genes that encode mussel adhesive proteins, treating the resulting proteins with tyrosinase to introduce Dopa and promote cross-linking.^[99,100] In this regard, it is worth remembering that ascorbate inhibits the ability of tyrosinase to oxidize Dopa to quinones.^[101] Others have constructed synthetic genes that express artificial proteins containing tandem repeats of the canonical decapeptide repeat of Mefp-1; tyrosinase treatment of such gene products results in cross-linking and insolubilization.^[102,103] Some investigators have suggested the use of plants as expression hosts to encourage posttranslational hydroxylation.^[104] While this may enhance the Hyp content of recombinant Mefp-1 analogs, it is unlikely to introduce Dopa residues as these are not known to occur in plant proteins. Nevertheless, it is interesting to realize that the repetitive proline-rich proteins and nodulins of plants are based on high-order repeats of Pro-Hyp-Val-Tyr-Lys, a sequence that resembles the C-terminal half of the Mefp-1 decapeptide motif.^[105]

Some researchers have focused on multimerizing and cross-linking synthetic peptides that are rich in Tyr and/or Dopa without attempting to mimic the sequences actually found in the mussel proteins. For example, Tatehata et al. synthesized (Xaa-Tyr-Lys)₁₉₋₄₂ and (Tyr-Lys)₁₉₋₄₂ polypeptides, cross-linked them enzymatically using tyrosinase, and measured the resulting adhesive strength in pigskin lap joints. These polydipeptides and polytripeptides provided similar adhesive strength to synthetic polydecapeptides based on the repeat sequences found in mussel adhesive proteins (Table 2).^[106] Subsequently, the same workers found that a formulation of poly(Gly-Tyr-Lys) with tyrosinase was less immunoreactive than Tisseel at closing an incision wound in a live pig.^[107]

Other researchers have avoided the use of polypeptides and focused instead on incorporating Dopa moieties into synthetic polymers. Huang et al. included Dopa residues as end groups in synthetic pluronic acids and found that this led to enhanced mucoadhesion.^[108] The same group has developed a method whereby *N*-methacrylated Dopa monomers mixed with poly(ethylene glycol) (PEG) diacrylate can be copolymerized to form Dopa-containing PEG hydrogels.^[109]

Bacterial, Algal, and Fungal Adhesives

Although most applications of bacterial EPS have been as commodity adhesives, a bacterial EPS from the marine bacterium *Vibrio diabolicus* has proven effective as a coating and void filler in promoting bone repair. Thus, HE 800, a linear exopolysaccharide resembling hyaluronic acid, is reported to restore large bone defects and to be biocompatible, non-immunogenic, and resorbable.^[110,111]

Protein extracts from macroalgae and microalgae have been characterized in terms of amino acid composition and subjected to functional tests, including skin bonding and T-cell adhesion tests.^[112] The resulting patent claims protein-based adhesive preparations from macroalgal holdfasts that fulfill certain criteria, and which potentially include the vitronectin-like proteins discussed previously.^[41,42,112] The European Union FP5 Algal Bioadhesives Consortium (2001–2005) aims to develop materials based on algal bioadhesives for use in wound closure and drug delivery.^[113] Their multidisciplinary approach includes the purification and characterization of algal bioadhesives, as well as gene cloning and recombinant expression. Organisms of interest include *Ulva*, *Caulerpa*, *Fucus*, and *Laminaria*. The consortium also aims to develop new models of human skin and mucosal membranes, which will be used in assessing the adhesive properties of alga-derived materials.^[113] One of the industrial partners in the consortium is Biota Ltd., an Israeli company that was established to develop and commercialize surgical adhesives made from proprietary alga-derived materials.^[114]

Fungal hydrophobins do not elicit cytotoxic or immunogenic responses. These small-protein surfactants can be used to reverse surface wettability or—after chemical or genetic modification—impart specific functionalities to surfaces, such as determinants for mammalian cell attachment.^[47]

Frog Glue

The highly porous nature of the solid glue from *Notaden* sp. seems likely to allow the migration of nutrients, gases, and, perhaps, cells in clinical applications. Initial tests on the compatibility of *N. melanoscaphus* glue with animal tissue preparations showed no adverse effects.^[62,64] In cell culture tests, bovine corneal epithelial cells adhered well to tissue culture plastic that had been coated with dissolved *N. bennetti* glue, and proliferated thereon as if on a hydrophobic surface.^[64] Some initial tests of tissue bonding and wound healing efficacy have also been conducted. In organ culture experiments, dissolved *N. bennetti* glue adhered plastic lenticules to debrided bovine

corneas and permitted epithelial regrowth.^[64] The *N. melanoscaphus* glue was compared to various surgical glues by a tear propagation test on longitudinal bonded tears in excised sheep menisci.^[64,115,116] Meniscal fragments were pressed firmly together for 90 sec with adhesive, and then incubated in moist conditions at room temperature for 24 hr. These data indicated that the frog adhesive was much stronger than the commonly used fibrin or gelatin/resorcinol/formaldehyde adhesives, but not as strong as cyanoacrylate. However, the cyanoacrylate formed a hard, brittle film, while the frog glue remained elastic. A preliminary evaluation of the *in vivo* effectiveness of freshly secreted glue from *N. melanoscaphus* in repairing an artificial meniscal tear was undertaken in a trial involving 16 sheep (10 test, 6 control). After 10 weeks, it was found that the adhesive had successfully held the cut meniscal fragments together. Histology showed new, mainly fibrous, tissue with well-oriented collagen filling the gap.^[62,64]

CONCLUSIONS

There is a significant unmet clinical need for strong, elastic, and biocompatible adhesives that work in moist environments. Many natural glues provide adhesive strengths in or above the 200–700 kPa range considered desirable by the U.S. Department of Defense for an underwater adhesive (Table 2), and can in addition be biologically innocuous. Indeed, parasite adhesives (such as those from worms, ticks, and microbial pathogens) that have evolved to bond tightly to host tissues without causing immune or inflammatory responses seem particularly appropriate for development into surgical glues. The softer hydrogel bioadhesives may prove useful as sealants, void fillers, or reversible glues. In addition, the highly porous nature of many biological adhesives may allow them to function either internally or topically as depots for therapeutic agents. The challenge with all of the natural adhesives is to understand their modes of action sufficiently well that their essential features can be mimicked by simplified systems, such as those consisting of synthetic and/or recombinant components. Early tests of mussel adhesive proteins and their analogs have given mixed results, but—given recent discoveries—the performance of Dopa-based adhesives might improve greatly if Fe³⁺ is provided as a cross-linking agent. The genes encoding the structural proteins of many other types of biological adhesive have been cloned, and it is only a matter of time before their recombinant products are tested as tissue bonding agents. The results of these experiments are eagerly awaited.

Biological Effects of Radiofrequency Electromagnetic Field

Henry Lai

Department of Bioengineering, University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

Radiofrequency electromagnetic field/radiation (RFR) covers a large segment of the electromagnetic spectrum and falls within the nonionizing bands. Its frequency ranges between 3 KHz and 300 GHz. Cellular phones, wireless transmission towers for radio, TV, and telecommunication, radar and many other applications emit RFR. Different frequencies of RFR are used in different applications. For example, the frequency range of 540–1600 KHz is used in AM radio transmission, while 76–108 MHz is used for FM radio. Cell phone technology uses frequencies mainly between 800 MHz and 3 GHz, and RFR of 2450 MHz is used in microwave cooking.

Because of the proliferation of wireless communication in recent years, a large population of people is exposed to RFR constantly. There are two major concerns on the possible biological/health effects of RFR: the effect of RFR absorbed during cell phone use and the exposure to RFR emitted from transmission towers. These two situations represent very different exposure conditions. The close proximity of a cell telephone antenna to the user's head leads to the deposition of a relatively large amount of radiofrequency energy in the head. The relatively fixed position of the antenna relative to the head causes a repeated irradiation of a more or less fixed amount of body tissue. Exposure to RFR from cell phones is of a short-term, repeated nature at a relatively high intensity, whereas exposure to RFR emitted from transmission towers is of long duration but at a very low intensity and, in general, the whole body of a person is exposed.

Biological effects of RFR depend on how energy is deposited in the exposed organism. There are three major physical parameters: frequency, intensity, and duration of exposure. To understand the possible health effects of exposure to RFR, one needs first to understand the effects of these different parameters and how they interact with each other. These are discussed in this entry.

FREQUENCY, INTENSITY, AND PATTERN OF ENERGY ABSORPTION

The frequency of RFR is analogous to the color of a light bulb, and intensity is its wattage. There is a

question of whether the effects of RFR of one frequency are different from those of another frequency. In this case, one is basically asking the question, "Are the effects of red light different from those of green light?" The answer to this is that it depends on the situation. They are different: if one is looking at a traffic light, "red" means "stop" and "green" means "go." But, if one is going to send some information by Morse Code using a light (on and off, etc), it will not matter whether one uses a red or green light, as long as the receiver can see and decode it. We do not know which of these two cases applies to the biological effects of RFR regarding frequency.

It must be pointed out that data are sparse showing either different frequencies producing different effects or an effect observed at one frequency but not at another. An example is the study by Sanders, Joines, and Allis, who observed that RFR at frequencies of 200 and 591 MHz, but not at 2450 MHz, produced effects on energy metabolism in neural tissues.^[1] There are also several studies that showed that different frequencies of RFR produced different effects.^[2–5] However, it is not certain whether these differences were actually due to differences in the pattern of energy absorption in the body of the exposed animal at the various frequencies. In addition, some studies showed frequency-window effects, i.e., effect is only observed at a certain range of frequencies and not at higher or lower ranges.^[6–17] These results may suggest that the frequency of an RFR can be a factor in determining the biological outcome of exposure.

On the other hand, there are more studies showing that different frequencies can produce the same effect. For example, changes in blood-brain barrier have been reported after exposure to RFRs of 915, 1200, 1300, 2450, and 2800 MHz, and effects on calcium metabolism have been reported at 50, 147, 450, and 915 MHz.^[6,8,9,12,13,16–20] If there is any difference in effects among different frequencies, it is a difference in quantity and not in quality.

The intensity of RFR in the environment is the power density measured in units such as milliwatts per square centimeter. However, power density provides little information on the biological consequence unless the amount of energy absorbed by the irradiated object is known. This is generally given as the specific

absorption rate (SAR), which is the rate of energy absorbed by a unit mass of tissue of the object, and usually expressed as watts per kilogram. Thus, to understand the biological effect of RFR, one should know the SAR. It is a more reliable determinant and index of RFR biological effects than power density. Specific absorption rate is used in the setting of exposure standards for RFR.

Biological effects can occur after exposure to high intensity of RFR (high SAR) that can cause general or local heating. In some RFR exposure guidelines, the limits of 0.4 W/kg for occupational exposure and 0.08 W/kg for general public exposure are used based on the experimental results that “disruption of behavior” in animals occurs at 4 W/kg. However, there are many studies that show biological effects at SARs less than 4 W/kg after short-term exposure to RFR. For example, behavioral effects have been observed at SARs less than 4 W/kg: D’Andrea et al., 0.14–0.7 W/kg; DeWitt et al., 0.14 W/kg; Gage, 3 W/kg; King, Justesen, and Clarke, 2.4 W/kg; Lai et al., 0.6 W/kg; Mitchell, Switzer, and Bronaugh, 2.3 W/kg; Navakatikian and Tomashkevskaya, 0.027 W/kg; Schrot, Thomas, and Banvard, 0.7 W/kg; Thomas et al., 1.5–2.7 W/kg; Wang and Lai, 1.2 W/kg.^[21–31] There are also many reports of other biological functions affected by RFR at a SAR less than 4 W/kg. Most of the energy from a cellular telephone antenna is deposited in the skin and the outer portion of the brain. The peak energy output of cell telephones can range from 0.3 to 1 W, although the average output could be much smaller. Relatively high SARs have been determined in various dosimetry studies: Dimbylow and Mann, 2.3 and 4.8 W/kg per watt output at 900 MHz and 1.8 GHz; Anderson and Joyner, 0.12–0.83 W/kg; Gandhi et al., 0.13–5.41 W/kg at 0.6 W output (835 and 1900 MHz); and Van de Kamer and Lagendijk, 1.72–2.55 W/kg at 0.25 W output (915 MHz).^[32–35]

Surprisingly, effects have also been reported in cells and animals after exposure to very low-intensity RFR that apparently cannot cause a physiologically significant change in temperature. Some 40 studies can be listed as low-intensity effects. The following are examples of some of these studies (some studies only give the power density, in mW/cm², of the radiation, whereas others give the SAR, in W/kg, in the exposed objects). Lebedeva et al. showed changes in brain wave activation in human subjects exposed to cellular phone RFR at 0.06 mW/cm².^[36] Magras and Xenos reported a decrease in reproductive function in mice exposed to RFR at power densities of 0.000168–0.001053 mW/cm².^[37] Phillips et al. reported DNA damage in cells exposed to RFR at SAR of 0.0024–0.024 W/kg.^[38] Salford et al. reported nerve cell damage in brain of rats exposed for 2 hr to cell phone signal at 0.02 W/kg.^[39] Tattersall

et al. showed that low-intensity RFR (0.0016–0.0044 W/kg) modulated the function of a part of the brain called the hippocampus, in the absence of gross thermal effects.^[40]

In addition, there are some indications that biological effects may also depend on how energy is deposited in the body. The rate of absorption and the distribution of RFR energy in an organism depend on many factors. These include the dielectric composition of the irradiated tissue, e.g., bones with a lower water content absorb less of the energy than muscles; the size of the object relative to the wavelength of the RFR (thus, the frequency); the shape, geometry, and orientation of the object; and the configuration of the radiation, e.g., how close is the object from the RFR source? These factors make the distribution of energy absorbed in an irradiated organism extremely complex and nonuniform, and also lead to the formation of so called “hot spots” of concentrated energy in the tissue. For example, an experiment reported by Chou et al., measuring local energy absorption rates (SARs) in different areas of the brain in a rat exposed to RFR, has shown that two brain regions less than a millimeter apart can have more than a twofold difference in SAR.^[41] The rat was stationary when it was exposed. The situation is more complicated if an animal is moving in an RF field. Depending on the amount of movement of the animal, the energy absorption pattern in its body could become either more complex and unpredictable or more uniform. Thus, the pattern of energy absorption inside an irradiated body is nonuniform, and biological responses are dependent on distribution of energy and the body part that is affected.^[42,43] Related to this is that we have found that different areas of the brain of the rat have different sensitivities to RFR.^[44] This further indicates that the pattern of energy absorption could be an important determining factor of the nature of the response.

Different propagation characteristics such as “modulation,” or different waveforms and shapes may have different effects on a living system. For example, the same amount of energy can be delivered to tissue “continuously” or “in short pulses.”

Another interesting observation of the research is that modulated and pulsed RFR seem to be more effective in producing an effect. They can also elicit a different effect when compared with continuous-wave radiation of the same frequency.^[16,19,43,45–47] This observation is important because cell phone radiation is modulated at low frequencies. This also raises the question of how much do low-frequency electric and magnetic field components contribute to the biological effects. Biological effects of extremely low-frequency (<100 Hz) electric and magnetic fields are quite well established.

REPEATED EXPOSURE AND DURATION OF EXPOSURE

The majority of the biological studies on RFR have been conducted with short-term exposures, i.e., a few minutes to several hours. Little is known about the effects of long-term exposure. However, in actual human exposure situations, RFR exposure tends to be repetitive and long term. What are the effects of long-term exposure? Does long-term exposure produce different effects from short-term exposure? Do effects accumulate over time?

An important question regarding the biological effects of RFR is whether the effects are cumulative, i.e., after repeated exposure, will a biological system adapt to the perturbation and, with continued exposure, when will homeostasis break down leading to irreparable damage? The question of whether an effect will cumulate over time with repeated exposure is particularly important in considering the possible health effects of cell phone usage, because it involves repeated exposure of short duration over a long period (years) of time. Existing results indicate changes in the response characteristics of a biological system with repeated exposure, suggesting that the effects are not “forgotten” after each episode of exposure. Various biological outcomes have been reported after long-term/repeated exposure to RFR:

1. Effects were observed after prolonged, repeated exposure but not after short-term exposure.^[48,49]
2. Effects that were observed after short-term exposure, disappeared after prolonged, repeated exposure (i.e., habituation) (e.g., Refs. [50–52]).
3. Different effects were observed after different durations of exposure (e.g., Refs. [26,53,54]).
4. There is also an indication that an animal becomes more sensitive to the radiation after long-term exposure (e.g., Refs. [4,21,22,23]). For example, the conclusion from a series of experiments on disruption of behavior in animals after one-time exposure to RFR is that “disruption of behavior occurred when an animal was exposed at a SAR of approximately 4 W/kg.”^[55] However, after long-term exposure (7 hr/day, 7 days/week for 90 days to 14 weeks), the threshold for behavioral and physiological effects of RFR was found to occur between 0.14 and 0.7 W/kg.^[21,22] Thus, RFR can produce an effect at much lower intensities after an animal is repeatedly exposed. This can have very significant implications for people exposed to RFR in the environment.

The conclusion from this body of research is that effects of long-term exposure can be quite different from those of short-term exposure. There is also some

evidence that effects of RFR accumulate over time. Here are some examples: Phillips et al. reported DNA damage in cells after 24 hr of exposure to low-intensity RFR. DNA damage can lead to gene mutation, which accumulates over time.^[38] Magras and Xenos reported that mice exposed to low-intensity RFR became less able to reproduce.^[37] After five generations of exposure, the mice were not able to produce offspring. This shows that the effect of RFR can pass from one generation to another. Persson, Salford, and Brun reported an increase in permeability of the blood–brain barrier in mice when the total energy deposited in the body exceeded 1.5 J/kg, i.e., the effect depends on the amount of energy deposited and not the rate of deposition.^[56] This suggests that, under similar exposure conditions, a short-term/high-intensity exposure can produce the same effect as a long-term/low-intensity exposure. This is an indication that RFR effects can accumulate over time.

Related to this is that various lines of evidence suggest that responses to RFR could be a stress response.^[57,58] Stress effects are well known to cumulate over time and involve first adaptation and then an eventual breakdown of homeostatic processes when the stress persists.

The possibility that effects cumulate over time and that acute effects change with repeated exposure have important implications on the setting of standards of RFR exposure. This suggests that the total amount of energy absorbed, the specific absorption (SA) ($SA = SAR \times \text{time}$) rather than SAR, should be used as the index.

THERMAL AND NONTHERMAL EFFECTS

When RFR energy is absorbed, it is converted into heat. A readily understandable mechanism of effect of RFR is tissue heating (thermal effect). Biological systems alter their functions as a result of change in temperature. However, there is also a question as to whether “nonthermal” effects can occur from RF exposure. There can be two meanings to the term nonthermal effect. It could mean that an effect occurs under the condition of no apparent change in temperature in the exposed animal or tissue, suggesting that physiological or exogenous mechanisms maintain the exposed object at a constant temperature. The second meaning is that somehow RFR can cause biological effects without the involvement of heat energy (i.e., temperature independent). For practical reasons, it may be futile to make these distinctions simply because it is very difficult to rule out thermal effects in biological responses to RFR, and because heat energy is inevitably dissipated when RFR is absorbed.

In some experiments, thermal controls (i.e., samples subjected to direct heating) have been studied. Indeed, there are reports showing that “heating controls” do not produce the same effect of RFR.^[59–62] These were taken as an indication of nonthermal effects. However, as we have discussed earlier, it is difficult to reproduce the same pattern of internal heating of RFR by external heating, as we know that a conventional oven cooks food differently from a microwave oven. And the pattern of energy distribution in the body is important in determining the effect of RFR (e.g., Refs. [19,42,43]). Thus, “heating controls do not produce the same effect of RFR,” does not really support the existence of nonthermal effects.

Furthermore, even though no apparent change in body temperature during RFR exposure occurs, it cannot really rule out a “thermal effect.” In one of our experiments, we have shown that animals exposed to a low SAR of 0.6 W/kg are actively dissipating the energy absorbed, thus, no significant increase in body temperature was observed in these animals.^[42] This suggests that the nervous system involved in body temperature regulation is activated. The physiology of body temperature regulation is complicated and can involve many organ systems. Thus, changes in thermoregulatory activity can indirectly affect biological responses to RFR.

Another difficulty in eliminating the contribution of thermal effects is that it can be “microthermal.” An example of this is the auditory effect of pulsed RFR. We can hear RFR delivered in pulses. One of the explanations for this “hearing” effect is that it is caused by thermoelastic expansion of the head of the “listener.” In a paper by Chou et al., it was stated that “... one hears sound because a miniscule wave of pressure is set up within the head and is detected at the cochlea when the absorbed microwave pulse is converted to thermal energy.”^[63] The threshold of hearing was determined to be approximately 10 μ J/g/pulse, which causes an increment of temperature in the head of one millionth of a degree centigrade. Lebovitz gives another example of the microthermal effect of RFR on the vestibulocochlear apparatus, an organ in the inner ear responsible for keeping the body balance and sense of movement.^[64] He proposed that an uneven distribution of RFR absorption in the head can set up a temperature gradient in the semicircular canals of the vestibulocochlear apparatus, which in turn affects the function of the vestibular system. The semicircular canals are very minute organs in our body.

What about in vitro experiments in which isolated organs or cells are exposed to RFR? Generally, these experiments are conducted with the temperature controlled by various regulatory mechanisms. However, it turns out that the energy distribution in culture disks, test tubes, and flasks used in these studies are often

very uneven.^[65] Hotspots are formed. There is a question of whether the temperature within the exposed samples can be efficiently controlled.

However, the existence of intensity windows, reports of modulated fields producing stronger or different effects than continuous-wave fields, and the presence of effects when exposed to RFR at very low intensity described in the sections above could be indications of nonthermal effects. My argument is that, in the setting of exposure standards, it may not be practical to differentiate these effects owing to the difficulty of eliminating the thermal effects.

OTHER CONSIDERATIONS

It has been repeatedly pointed out that the results reported in RFR research are difficult to replicate or reproduce. Problems in data reproducibility are not uncommon in science. In RFR research, it is further complicated by the complexity of interaction among the various exposure parameters as discussed above. This may make the response more sensitive to experimental procedures. Moderate variations in procedures could lead to different results. Examples are recent attempts to study RFR-induced DNA damage and spatial learning deficit.^[38,66–71] Different results were observed when different experimental procedures were used. However, by comparing them carefully, these differences in results may actually help to reveal the mechanisms of interaction between RFR and biological systems.

An area of research that requires more study is the role played by the physiological conditions of an organism on its response to RFR. For example, The British Stewart Report on “Mobile Phone and Health” recommends caution in the use of cellular phones by young children because of their “developing nervous system.”^[72] Yet, little is known on whether developing biological systems are actually more vulnerable to the effects of RFR. On the other hand, people under certain drug therapies may be more susceptible to RFR. This is suggested by a study by Kues et al. in the early 1990s showing that the ophthalmic drug timolol significantly enhanced corneal endothelial lesion induced by RFR in the monkey.^[73] Little research has been carried out to further investigate this type of interactions.

Another consideration is that the genetics of an organism may affect its response to electromagnetic fields. For example, two groups of researchers reported different effects of magnetic field on 7,12-dimethylbenz[α]anthracene (DMBA)-induced breast tumors in Sprague–Dawley rats.^[74] One team, led by Wolfgang Löscher, later found that two substrains of Sprague–Dawley rats responded differently to the carcinogen

and the magnetic field and that this could account for the different results found by the two research groups.^[75]

CONCLUSIONS

1. It is quite certain that RFR exposure can cause biological effects even at low intensity. However, the potential hazardous health effects of such exposure to humans are not clear. We do not know if these effects occur in humans exposed to RFR, or whether the reported effects are health hazards. Biological effects do not automatically mean adverse health effects. Many biological effects are reversible. However, it is very clear that low-intensity RFR is not biologically inert. Much more needs to be learned, however, before a presumption of safety can be made.
2. Frequency, intensity, exposure duration, and the number of exposure episodes can affect the response to RFR, and these factors can interact with each other and produce different effects. To understand the biological consequence of RFR exposure, one must know whether the effect is cumulative, whether compensatory responses result, and when homeostasis will break down. The response is not likely to be linear with respect to the intensity of the radiation. Other parameters of RFR exposure, such as waveform, frequency and amplitude modulation, etc., are also important determinants of biological responses and affect the shape of the dose–response relationship.
3. Not much is known about the biological effects of long-term exposure. The effects of long-term exposure can be quite different from those of short-term exposure. The effects may accumulate. In that case, the total energy absorbed (i.e., specific absorption) is a more relevant index of biological effect than the rate of energy absorption (SAR).
4. In many RFR exposure guidelines, a limit of 0.4 W/kg is used based on the experimental results that disruption of behavior in animals occurs at 4 W/kg. However, there are many studies that show biological effects at SARs less than 4 W/kg after short-term exposure to RFR. Therefore, the rationale of 4 W/kg should be reconsidered. The guidelines also only consider short-term exposure effect. Effects of long-term exposure, modulation, and other propagation characteristics are not considered. Another omission is that the physiological conditions of the exposed organism are not taken into consideration. Therefore, the present guidelines are questionable in protecting the public from possible harmful effects of RFR exposure.

5. Owing to the uncertainty in science, exposure of the general population to RFR should be kept to a minimum and should follow the ALAR-principle (As Low as Reasonably Achievable).

INTRODUCTION

Materials used in medical applications that necessarily come into intimate contact with the tissues of the body may initiate several and complex defense and healing biological reactions: cell and material contact evokes the release of chemotactic mediators and growth factors that may elicit and sustain inflammatory responses at the implant site.^[1,2] Because biocompatibility has been defined in terms of “the ability of a material to perform with an appropriate host response in a specific application,” it is important to determine the influence of these reactions on biocompatibility because this could influence the length of time in which a biomedical device can remain in the host, as well as the biofunctionality of such a device.^[1,3,4] Because all implanted materials are foreign to the host, the assessment of biocompatibility is an important step to prevent implant failure and includes the determination of the potential host responses to the material.^[4] The implantation of a material (without cells) initiates a sequence of events akin to a foreign body reaction, starting with an acute inflammatory response and leading, in some cases, to a chronic inflammatory response and granulation tissue development, a definitive foreign body reaction, and fibrous capsule formation. The duration and intensity of each of these is dependent upon the extent of injury created in the implantation, biomaterial chemical composition, surface free energy, surface charge, porosity, roughness, and implant size and shape. The extent and duration of the deviation from optimal wound healing conditions and homeostasis determine the biocompatibility of the material.^[5,6]

Vertebrates are provided with an immune system, composed of several lymphoid organs, highly specialized cells, and a circulatory system, that serves to protect the body from damage and disease. These defense mechanisms may be divided into two categories—acquired, also commonly referred as specific, and innate or non-specific.^[7,8] The processes in these categories are quite different, although they may be influenced and mediated by the same agents. Cells such as macrophages play an important role in both specific and non-specific responses.^[9]

The innate immune system is present in all individuals, requires little or no induction period, and does not respond more quickly or more vigorously upon the second encounter with a particular microbe (i.e., it does not exhibit a memory response). It is mediated mostly by neutrophils, eosinophils, basophils, macrophages, and natural killer cells (natural killer cells, also called large granular lymphocytes, are the major population of null lymphocytes, i.e., lymphocytes that are neither B cells nor T cells since they do not carry the markers to be B or T cells, and spontaneously attack and kill infected cells).^[9–11] These cells work by direct antimicrobial action, by killing virus-infected cells or tumor cells, and by secreting cytokines, which orchestrate inflammation and other defense mechanisms.^[9] The acquired immune response requires stimulation or immunization in order to be activated and is mediated by lymphocytes. Each lymphocyte has receptors on its surface that will recognize only a single conformation (antigenic determinant). Upon recognition of a specific antigen, a lymphocyte will proliferate, forming clones. Thus, upon reintroduction of the antigen, the host response is greater and accelerated.^[3] The immune system includes effector mechanisms that are capable of destroying a broad range of microbial cells and particles. A critical aspect of an effective immune response is the ability to avoid unleashing these destructive mechanisms against the host’s own tissues. Avoidance of destruction of self-tissues is referred to as self-tolerance and mechanisms to avoid reactions against self-antigens are expressed in both the innate and the adaptive immune responses.^[8]

MACROPHAGES

Macrophages are quintessentially the central cell in directing host inflammatory and immune processes. As such, determining the macrophage response to materials is extremely important in understanding the material-mediated host response. Several characteristic macrophage functions have been identified as critical events in the material host interaction.^[12] Macrophages are referred to as mononuclear phagocytes, reflecting their important ability to phagocytose

particulate material.^[10] They provide a first line of defense as part of the innate immune response against microorganisms and are therefore essential in the control of some bacterial infections. However, they cannot always eliminate infectious organisms, and there are some pathogens they cannot recognize. The lymphocytes of the adaptive immune system have evolved to provide a more versatile means of defense, which, in addition, provides increased protection against subsequent reinfection by the same pathogen.

Microorganisms such as bacteria that penetrate the epithelial surfaces of the body for the first time are met immediately by cells and molecules that can mount a vigorous, innate immune response. Phagocytic macrophages conduct the defense against bacteria by means of surface receptors that are able to recognize and bind common constituents of many bacterial surfaces. Bacterial molecules binding to these receptors trigger and activate the macrophage to engulf and surround the bacterium and also induce the secretion of biologically active molecules. Activated macrophages secrete cytokines, which are defined as proteins released by cells that affect the behavior of other cells that bear receptors for them. They also release proteins known as chemokines that mobilize cells with chemokine receptors such as neutrophils from the bloodstream along a chemotactic gradient toward a site of infection or injury.

Macrophages recognize pathogens by means of cell surface receptors that can discriminate between the surface molecules displayed by pathogens and those of the host. These receptors include the macrophage mannose receptor, scavenger receptors, which bind many charged ligands, and CD14, a receptor for bacterial lipopolysaccharide.

Upon phagocytosis, macrophages also produce a variety of other toxic products that destroy the engulfed microorganism. The most important of these are hydrogen peroxide (H_2O_2), the superoxide anion (O_2^-), and nitric oxide, which are directly toxic to bacteria.^[13]

In addition to phagocytosis, macrophages play a key role in acquired immunity acting as antigen-presenting cells (APCs). In the initial step of an acquired immune response, antigen processing and presentation by APCs is crucial.^[14] A phagocytic cell may translocate fragments of phagocytosed material to the cell surface in association with major histocompatibility complex (MHC) molecules and engage in binding to a T lymphocyte.^[15,16] It is important to recognize in this context that there are APCs with the capacity to initiate a primary immune response by the presentation of antigen to naive T lymphocytes and also APCs that will stimulate a secondary response by the presentation of antigen to T lymphocytes that have already been exposed to the antigen.^[16,17] Macrophages play an

essential role not only as APCs, but also as a source of cytokines that can manipulate the emerging T-lymphocyte response.^[15] Antigen processing is divided into two pathways that lead to peptide fragments of foreign antigens being presented by MHC class I or class II molecules:

The first pathway is the endogenous pathway: proteins that are derived within the cell (endogenously), such as those produced during viral or intracellular bacterial infections, result in the production of foreign proteins in the cytoplasm of the infected cell. Some of these proteins are cleaved into peptides in the cytosol by a large proteolytic enzyme complex called the proteasome.^[18] These peptides are translocated to the endoplasmic reticulum (ER) and bind to a protein complex called MHC class I. From the ER, the MHC class I–antigen complex is transferred to the cell surface, where it stimulates antigen-specific cytotoxic T lymphocytes (CTLs)—killer cells that seek out and eliminate infected cells.^[19]

The second pathway is the exogenous pathway: proteins that are derived from outside the cell (exogenously) are usually processed differently from endogenous antigens and produce different results.^[18,19] Extracellular pathogens are engulfed by APCs and degraded in phagosomes. This produces peptide fragments but they are not transported to the ER. Instead, they bind directly to a different set of MHC molecules, MHC class II, inside the phagosome and are then transported to the cell surface, where they stimulate a subset of helper T cells. Unlike the CTLs, helper T cells do not kill other cells, but instead produce chemical signals. These trigger the initiation of the humoral response and the production of antigen-specific antibodies by mature B cells (plasma cells), and they elicit an inflammatory response that eliminates the microbial pathogens.^[19]

The rules governing antigen presentation in principle are quite simple—endogenous antigens are presented by MHC class I molecules to stimulate a cell-mediated response, and exogenous antigens are presented by MHC class II molecules to stimulate a helper response. In reality, the situation is not so straightforward. Professional APCs can break these rules and present exogenous antigens on MHC class I molecules in a process known as cross-presentation. The cross-presentation pathway seems to be required for CTL responses to certain exogenous antigens. For example, some viruses do not infect professional APCs, but in order to generate a CTL response that will eliminate virus-infected cells, the APC must present exogenous viral proteins on MHC class I molecules. Cross-presentation might also be important for triggering CTL responses to some cancer cells.^[19]

How do exogenous antigens cross over to the MHC class I pathway? Rodriguez and colleagues^[20] indicated

that exogenous proteins could escape from phagosomes and enter the cytosol, suggesting that cross-presentation might simply involve the transport of exogenous proteins from the phagosome into the cytosol, where they could join the pathway used to process endogenous antigens. This view was supported by data demonstrating that cross-presentation depends on two components of the MHC class I pathway—the proteasome complex and the “transporter associated with antigen presentation” (TAP). The proteasome complex degrades proteins in the cytosol and TAP shuttles the resulting peptide antigens into the ER for loading onto MHC class I molecules.^[19]

LYMPHOCYTES

Lymphocytes are the cells responsible for the acquired immune response. T lymphocytes are responsible for the cell-mediated immune response and B cells are responsible for the humoral immune response, which is mediated by antibodies.^[21] T lymphocytes are derived from pluripotent stem cells in the bone marrow. They undergo differentiation in the thymus, which leads to the expression of their antigen receptor (i.e., T-lymphocyte antigen receptor or TCR).^[18] Each T lymphocyte has a unique receptor generated by recombination of the variable (V: V α and V β), diversity (D: D β), and joining (J: J α and J β) gene segments during thymic maturation.^[18,22,23] This random process generates many non-functional receptors. T lymphocytes bearing these non-functional receptors die by a process called positive selection. Large numbers of the T lymphocytes whose receptors are specific for normal proteins produced by host cells (self-proteins) are also generated. Self-reactive T lymphocytes are eliminated by a process called negative selection. This is one of the mechanisms by which the immune system is made tolerant to a body's own self-cells.^[18]

The immune system has evolved to protect the body from substances and organisms that threaten life.^[7,24] These may be present in extracellular body fluids (e.g., toxins, bacteria) or harbored in the individuals' own cells (e.g., viruses, oncogene products). This distinction is critically important.^[24] Immunity comprises cellular and extracellular components that reflect the diversity of the immune system. B cells produce immunoglobulins that function as extracellular, antigen-specific mediators in the recognition and clearance of foreign or domestic invaders.^[25] T cells carry membrane-associated TCRs that participate in the activation of T cells and recognize antigen that has been “processed” by APCs and presented in association with MHC glycoproteins.^[26–28]

Graft rejection is initiated by host T-cell recognition of alloantigen and activation of major T-cell

subpopulations, such as CD4⁺ and CD8⁺ T cells. Most CD4⁺ T cells function as helper T cells (Th), acting primarily to regulate the cellular and humoral immune response, and most CD8⁺ T cells are cytotoxic, acting primarily to kill cells infected with intracellular microbes.^[7,29,30] In the thymus developing T cells follow a developmental program in which, in the cortex, they at first express neither CD4 nor CD8 (double negative) and then express both CD4 and CD8 (double positive). Double-positive cells are tested by positive selection in the thymic cortex; those that are selected on class I MHC molecules become CD4⁻CD8⁺, and those that are selected on class II MHC molecules become CD4⁺CD8⁻. The cells then move to the thymic medulla for negative selection and export to the periphery. In the blood and secondary lymphoid organs, 60% to 70% of T cells are CD4⁺CD8⁻ (CD4⁺) and 30% to 40% are CD4⁻CD8⁺ (CD8⁺).^[7,31] The role of CD4⁺ and CD8⁺ T cells is well defined in early acute rejection. The chief contribution of CD8⁺ T cells to graft rejection is through direct lysis of target cells, whereas activated CD4⁺ cells contribute to graft rejection by releasing cytokines and recruiting a variety of other effector cells.^[29]

CD4 and CD8 are important in determining which MHC molecule is recognized by the TCR. CD4 binds to MHC class II molecules, helping the TCR to recognize antigens presented by MHC class II molecules. In contrast, CD8 binds to MHC class I molecules and CD8⁺ cells recognize antigens presented by MHC class I molecules.^[10]

CD4⁺ T LYMPHOCYTE SUBSETS

During immune responses, CD4⁺ T lymphocytes differentiate into different functional subsets of Th cells. Initially Th cells were subclassified into two subsets, Th1 and Th2, according to the cytokines secreted. For example, Th1 secrete interleukin 2 (IL-2), interferon- γ (IFN- γ), tumor necrosis factor- α (TNF- α) and TNF- β , whereas Th2 cells produce IL-4, IL-5, IL6, IL-10, and IL-13,^[32–34] among others. The balance between Th1 and Th2 cytokines is the key event that influences the maturation of naive CD4⁺ T cells to differentiate into Th1 and Th2 effectors and is important in the development of inflammatory diseases. Excessive Th1-type cytokines have been associated with the tissue destruction found in autoimmune diseases, whereas overabundant Th2-type cytokines have been implicated in atrophy and allergic asthma.^[33,35] Recently, a third subset was discovered, Th17, that has been associated with major human autoimmune diseases: rheumatoid arthritis, pancreatitis, inflammatory bowel disease, transplant rejection, allergic asthma, or

multiple sclerosis.^[36] The Th17 subset is characterized by the production of IL-17 cytokines, which is a set of six molecules named IL17A, IL17B, IL17C, IL17D, IL17E, and IL17F, which induce the production of proinflammatory cytokines such as TNF- α , IL-1 β , and IL-6 as well as chemokines CXCL1, -2, and -8.^[37-40] IL-17 is produced by activated T cells and mediates its proinflammatory effects via its receptor, IL-17R, which is expressed on all cell types. The IL-17 system appears to be a separate, unique, and potent signaling system involved in the control of the immune responses.^[41]

Different cytokines are involved in the development and proliferation of the Th17 subset from naive CD4⁺ T cells. High levels of transforming growth factor- β and IL-6 are crucial for the differentiation. IL-23, a cytokine produced by APCs, plays an important role in maintaining Th17 effector function.^[40,42]

MAJOR HISTOCOMPATIBILITY COMPLEX

The MHC is a genetic region that contains many genes involved in immune responses.^[43,44] These molecules carry the major histocompatibility antigens, which are tissue cell surface antigens capable of inducing an immune response in a genetically dissimilar (allogeneic) recipient, resulting in the rejection of the tissue or cells bearing those antigens.^[45,46] The immune response to a foreign protein is determined by the expression of specific MHC molecules, designated class I or class II, that bind and present peptide fragments of the protein to T cells. Without these specific recognition elements the immune system would be incapable of responding to a given antigen challenge.^[47-49] The cytosol is predominantly, but not exclusively the source of precursor proteins of peptides bound to MHC class I molecules, whereas peptides bound to MHC class II molecules are mainly derived from the extracellular compartment.^[50]

The complex is divided into three regions on the basis of tissue distribution, structure, and function—class I (HLA-A, -B, -C, -E, -F, and -G genes), class II (HLA-DR, -DP, and -DQ genes), and class III (includes genes encoding complement and TNF). These genes control immune responses to pathogens, graft rejection, and tumor surveillance. The functions of HLA-E, HLA-F, and HLA-G are not completely understood.^[46,51]

The constitutive expression of class I and II molecules is different. MHC class I molecules are cell-surface glycoproteins expressed on most cells of the body, although expression varies widely and is typically highest on hematopoietic cells.^[50,52] Class II molecules are generally restricted to a subset of APCs, such as macrophages, dendritic cells, and B cells. Expression can be induced on other cell types by stimulation with cytokines such as IFN- γ .^[49,53,54] Class I

molecules bind peptides derived from proteins synthesized endogenously by a cell and then display these peptides at the cell surface for recognition by CD8⁺ T cells. Class II molecules are responsible for presenting peptides derived from extracellular pathogens to T cells bearing the CD4⁺ marker.^[54-56]

Determination of the roles played by MHC antigens has focused on the role played by these proteins in the development of tumors, bacterial infections, articular diseases, and organ/tissue transplants. This research led to the development of treatments and vaccinations to combat many of these medical issues. Although there is still a seemingly exponential growth in the widespread use of materials as implanted devices, very little is understood about the immunological response of the body to materials. There is now evidence that some implanted materials may cause acquired immune reactions in a small percentage of the population.^[57] Implanted materials in general have been considered biologically inert; however, there is increasing evidence that no material implanted in living tissues is truly inert and will stimulate an immune response. The wear debris disseminated from these materials is not biologically inert^[58,59] as macrophages phagocytose debris particles. Much research has been focused on their role in the innate immune system; however, studies of periprosthetic tissue suggest that the acquired immune system may also be implicated by these cells and play an important role in the complications of the host response.^[63,64] As APCs, macrophages have the potential to present a biomaterial as an antigen. The material combines with self-proteins becoming antigenic and processed by macrophages for presentation to T cells in combination with MHC.^[62] Understanding the interactions between macrophages and T lymphocytes and the release of proinflammatory cytokines is critical in the development of strategies against current issues like the aseptic loosening of implants.

The immune system modulates many key biological processes in humans; however, the exact role played by the immune system in periprosthetic osteolysis is complex and not completely understood. Human tissue retrieval studies, and in vivo and in vitro experiments suggest that the immune response to polymeric particles is non-specific and macrophage mediated and direct lymphocyte activation by polymer particle protein complexes seems unlikely. On the other hand, metallic products may complex with serum proteins and lead to a T lymphocyte-mediated immune reaction. In predisposed individuals, this reaction may rarely lead to persistent painful joint effusions, necessitating the removal of the bearing surfaces of the prosthesis.^[61]

Hercus et al.^[63] observed T cell infiltration in retrieved periprosthetic tissues from patients with aseptic loosening of prosthetic joints. PCR tests did not show a predominance of Th1/Th2 cytokines. The major

cytokines expressed included IL-2, IL-4, IL-13, and IFN- γ .

Lalor et al.^[64] performed immunohistochemical studies of tissues from patients undergoing revision hip replacement from a previous failed cobalt chrome alloy or titanium alloy implant. All the tissues contained particulate metal debris and T lymphocytes in abundance with no evidence of B lymphocytes. Macrophages surrounding the T lymphocytes expressed HLA-DR and CD11c, indicating that they were antigen presenting cells. These findings suggested that in cases of excessive metal particle production, a T lymphocyte-mediated immune reaction may occur.

Wooley et al.^[65] studied the cellular responses in vitro to particles of polymethylmethacrylate, ultrahigh molecular weight polyethylene, and alloys of cobalt chromium and titanium from patients with underlying osteoarthritis, rheumatoid arthritis, and avascular necrosis. All patients were radiographically diagnosed as having aseptically loosened prostheses. The study confirmed the presence of a positive proliferative response to polymethylmethacrylate, a finding that was not in agreement with the findings by Santavirta et al.^[66] that reported polymethylmethacrylate failed to stimulate proliferation of peripheral blood mononuclear cells, although there was an increase in the expression of the two major markers of immune T cell activation: MCH-II and IL-2R on the cells surface. These different findings can be associated with particle size and culture conditions. The proliferative response to polyethylene was undetectable in vitro. Related to metallic particles neither alloys provoked a significant response.

In the study Arora et al.^[60] the specific roles of T lymphocyte subsets in osteolysis and aseptic loosening of total joint replacements was investigated. Tissue from periprosthetic regions from patients with loose, cemented acetabular components was used to determine the TH1 and TH2 cytokine profile. Immunohistochemistry revealed a significant number of T cells and TH1 (IL-2 and IFN- γ) and TH2 (IL-4 and IL-10) immune cytokines in the periprosthetic tissues. However, no significant differences in the percentage of positive cells expressing cytokines characteristic of the TH1 pathway or TH2 pathway were found when comparing the osteolytic and nonosteolytic groups. It has been suggested that the distinction between TH1 and TH2 cytokines in humans might be obscure.

The less intense reaction around metal-on-metal total hip replacement (THR) compared to metal-on-polyethylene has been reported and might be associated with the differences in the characteristics of metal wear particles. Doorn et al.^[67] characterized metal wear particles extracted from tissues from patients undergoing revision of metal-on-metal total hip replacements with cobalt-chromium-molybdenum bearing couples. It was demonstrated that metal

particles did not cause a more severe local reaction when compared with polymer particles, possibly due to the metal particles being smaller than the polyethylene particles and continuing to degrade further in soft tissues eventually.

Studies of the cement-bone interface of THRs have shown that a synovium-like membrane forms which has the capacity to stimulate the production of prostaglandin E2, collagenase and other osteolytic molecules such as interleukin-1 and tumor necrosis factor. Haddad et al.^[68] investigated a group of patients suffering from early loosening in whom polyethylene debris is unlikely to be responsible. The results indicated that hypersensitivity to DMT (N,N-dimethylparatoluidine, a constituent to bone cement) is the cause of rapid aseptic loosening.

Methe et al.^[69] examined how endothelial immunogenicity was controlled by the interaction with 3-D matrices. Human aortic endothelial cells (HAE) were grown to MHC class II, and integrin, IFN- γ receptor expression, and signaling were analyzed. The matrix architecture is critical for the modulation of endothelial immunogenicity. Embedding HAE within a physiologic 3-D environment affects the activity of intracellular signalling pathways, MHC II expression, and subsequent activation of immune cells. These findings offer insights into understanding endothelial-mediated diseases and may improve the potential for cell-based therapies.

Granchi et al.^[70] evaluated the sensitization status in patients with Co-Cr hip prosthesis in terms of the expression of the CD69 antigens in peripheral blood mononuclear cells collected from and cultured with the metal ions derived from the materials used to produce implanted medical devices. The activation antigens, HLA-DR, were expressed later and required a long incubation time. These data supported the hypothesis that an acquired immune response could contribute to the pathogenesis of hip prosthesis loosening.

Implant localized soft tissue from patients with aseptic loosening of cemented total joint arthroplasties contained more activated T lymphocytes than that of patients without aseptic loosening.^[71] The potential interactions of lymphocytes from peripheral blood and periprosthetic membranes with particulate orthopedic materials was examined in vitro, with the potential interactions between macrophages and lymphocytes in relation to IL-6 and TNF- α release examined further. The results demonstrated that the exposure of macrophages or macrophages cocultured with lymphocytes to particles of all materials tested led to a dose-dependent release of IL-6 and TNF- α . Baldwin et al.^[72] combined histological and molecular biological techniques to build a detailed picture of the cell types present in tissue surrounding failed Accord Knee prostheses and determined the occurrence of

inflammatory cells and cytokines, which may have contributed to implant failure. Tissue samples from patients undergoing revision surgery for aseptic loosening were analyzed to determine the presence and possible significance of inflammatory cells, cytokines, and chemokines present in these prosthesis failures. The research indicated that macrophages produced both the inflammatory cytokines and the chemokines, which may recruit further inflammatory cells to the implant site to perpetuate the cycle. The macrophages sequester a proportion of wear particles but inadequate removal or continued production of wear particles sustained the macrophage-driven response. The results from this immunohistochemical study confirmed the infiltration of macrophages, T cells, granulocytes, and neutrophils to the implant site.

Voggenreiter et al.^[73] analyzed the immunoinflammatory response to titanium and stainless-steel plates in the surrounding soft tissue. The results clearly demonstrated the presence of a marked inflammatory response and tissue reaction in the soft tissue covering stainless-steel and titanium plates used for the internal fixation of the fractures of long bones. Cells localized with metal particles expressed HLA-DR as an indicator of their activation and expression of HLA-DR was observed in the majority of cases, indicating that macrophages that phagocytosed steel or titanium particles were activated as APCs.

In vitro studies by Vallés et al.^[74] indicated that titanium particles in the phagocytosable range induced macrophages to secrete cytokines and initiate an inflammatory response. Rutile particles stimulated the release of TNF- α , IL-6, and IL-1 β to a lesser extent than titanium particles in these cellular models. Luyn et al.^[75] investigated whether repeated subcutaneous application of the same type of material could alter the foreign-body reaction. Two biodegradable (cross-linked collagens) and two non-biodegradable biomaterials (polyurethane and silicone) were tested in a repetitive implantation model. Enhancement of the foreign body reaction was observed by increased ingrowth of cells, increased vascularization, upregulation of MHC class II-positive cells, and the infiltration of plasma cells in the surrounding tissues. Except for the cellular ingrowth, changes occurred with both the biodegradable and the non-biodegradable materials, indicative that alterations were not specifically related to the biodegradation of biomaterials.

CONCLUSION

The immune mechanisms that are triggered when a material is introduced into a body play an important role in determining its biocompatibility. Immediately, cells of the immune system accumulate at the site of

implantation and a sequence of events targeted against the material can take place. Among all the cells of the immune system, macrophages and T lymphocytes are the most abundant or persistent in the material tissue interface or the surrounding tissue. The interaction between these cells results in the secretion of proinflammatory cytokines, soluble molecules involved in the initiation of the inflammatory process that may contribute to material rejection. The implantation of materials has been associated with innate immune inflammatory responses. However, experimental evidence indicates that materials could induce varied and significant expression of MHC molecules that are implicated in acquired immune responses. As cell-based therapies develop and become widespread, the intricacies of the detail of the acquired immunity must be understood. The conventional boundaries between innate and acquired immune responses will be breached, but should ultimately be predictable and therefore controllable. A further characterization of the immunoreactions to implant materials will permit the development of appropriate strategies that could expand the useful life of an implanted material.

Biomaterials: Protein–Surface Interactions

Robert A. Latour, Jr.

Department of Bioengineering, Clemson University, Clemson, South Carolina, U.S.A.

INTRODUCTION

The study of protein–surface interactions represents one of the most important topics in the field of biomaterials, and as such, it has been a focus of intensive study for several decades. The reason for the great interest in this topic is the realization that protein–surface interactions are fundamentally responsible for the biocompatibility of medical devices, or the lack thereof.

When a solid material (e.g., a catheter, stent, hip joint replacement, or tissue engineering substrate) comes in contact with a fluid that contains soluble proteins (e.g., blood, interstitial fluid, cell culture media), proteins rapidly adsorb onto the surface of the material, saturating the surface within a time frame of seconds to minutes. Therefore, when living cells (which are much larger than proteins and thus much more slowly moving) approach the biomaterial surface, they do not actually contact the molecular structure of the material surface itself, but rather they contact and interact with the molecular structure of the adsorbed protein layer. Cells, of course, cannot “see” the adsorbed protein layer, but rather they interrogate their surroundings by way of membrane-bound receptors that can bind to specific bioactive features presented by the adsorbed proteins. Then, through a series of orchestrated molecular mechanisms, these receptor–protein binding events are transduced through the cell membrane in a manner that stimulates specific intracellular processes that then determine a cell’s response. Accordingly, at the most fundamental level the key to controlling cellular response is to control the type of bioactive sites that are presented by the adsorbed layer of proteins. This, in turn, can be controlled by controlling the amounts and the types of proteins that are adsorbed and their orientation, conformation, and packing arrangement on the biomaterial surface. While this is conceptually simple to understand, the numerous types of soluble proteins contained in physiological fluids combined with their structural complexity has made, and continues to make, this an extremely challenging problem.

Many excellent reviews and entire books have been written over the past couple of decades that address the multitude of issues related to the interaction of proteins with surfaces. Several of these reviews and books are referenced in the “Further Readings” section at the

end of this article and the readers interested in this topic are encouraged to seek out these additional sources of information. Given the vast number of studies that have been conducted on this topic, it is of course impossible to provide a complete review of the literature in one article. Instead, the goal here is to provide an overview of the basic understanding that has been achieved over the years regarding how proteins interact with surfaces. This will be accomplished by first providing an overview of protein adsorption processes and then by addressing the special case of the design of surfaces to prevent protein adsorption. Following these topics, attention will be focused on highlighting several of the most interesting relatively recent techniques that have been developed and applied to further our understanding of the sub-molecular-level mechanisms involved in how surface chemistry influences the orientation, conformation, and organization of adsorbed proteins. The continued development of our understanding of these processes is critical if we are to get beyond the current era of surface design largely by trial and error, and move into an era where surfaces are proactively designed to directly control adsorbed protein bioactivity, and thereby control cellular response. This article will then close with a conclusion section that addresses future directions toward the continuing goal of the development of truly biocompatible materials for the design of medical devices for improved patient care.

OVERVIEW OF PROTEIN–SURFACE INTERACTIONS

As introduced in the prior section, the surfaces of synthetic biomaterials (e.g., polymers, metals, and ceramics) are generally not bioactive themselves. Rather, surface bioactivity is provided by the proteins that adsorb to the biomaterial surface following exposure of the surface to biological fluids. The types and the amounts of proteins adsorbed determine the types and surface density of the bioactive sites that may be available for cell interactions, and the orientation, conformation, and packing density of the adsorbed proteins determine whether the available bioactive sites are presented in a manner such that they can be recognized by the membrane-bound receptors of cells as they interrogate the adsorbed protein layer.

Accordingly, to control cellular response, it is important to first understand how surface chemistry and surface topology influence the formation of the adsorbed protein layer and the bioactive sites presented by this layer.

Although the understanding of protein adsorption to biomaterial surfaces is still far from complete, research over the past several decades has led to a general understanding of the complex and multifaceted processes involved in the interactions between proteins and surfaces. In this section, an overview of protein structure is first presented to establish a framework from which protein adsorption behavior can begin to be understood. Following this, an overview of the current understanding of protein adsorption behavior to biomaterial surfaces is presented, initially for the relatively simple case involving protein adsorption from single-component protein solutions, and then for the more complex situation involving competitive adsorption from multicomponent protein solutions. This section will then be completed by addressing the special case of the development of nonfouling surfaces that are highly resistant to protein adsorption.

Protein Structure

Before protein adsorption behavior can be understood, it is first important to understand the basic makeup of protein structure. Proteins are complex copolymers that are made up of four levels of structure, designated as the primary, secondary, tertiary, and quaternary structures.^[1] The primary structure involves the specific sequence of the 20 L-amino acids coded for by the DNA of a cell. As part of a protein, a given amino acid is referred to as a peptide residue. Each amino acid, or residue, has the general backbone structure of $\{-\text{NH}-\text{C}_\alpha\text{HR}-\text{CO}-\}$, with R designating a specific side-group structure that gives the residue its specific functional characteristics. Accordingly, the amino acids are subcategorized into three primary types: nonpolar (i.e., hydrophobic), \pm -charged, and polar. Examples of each type of amino acid are shown in Fig. 1A. The polypeptide chain formed by the primary sequence is then organized into three basic types of secondary structure: α -helices, β -sheets, and loops that connect helix and sheet elements (Fig. 1B). These secondary elements are then organized together

Fig. 1 Protein structure. (A) Primary structure showing examples of four types of residues with designated three-letter and one-letter codes: nonpolar (alanine, Ala, A), positively charged (lysine, Lys, K), negatively charged (aspartic acid, Asp, D), polar (serine, Ser, S). Color code: gray = C, white = H, blue = N, red = O. (B) Secondary structures composed of an alanine sequence: α -helix (views from side and end), β -sheet. Same color code as in (A). (C) Tertiary structure (lysozyme, PDB ID 7LYZ). Color code: yellow = β -sheet, pink = α -helix, blue and white = connecting loops.

to form the tertiary structure (Fig. 1C). Finally, more than one polypeptide chain can be organized together to form quaternary structure, with each individual chain having a separate beginning (N-terminus) and ending (C-terminus), which are typically positively and negatively charged, respectively. The specific functional group character of the peptide residues combined with their spatial organization creates specific bioactive domains in a protein's structure that enable it to perform its specific biological function, whether that is as an enzyme, growth factor, intracellular structure, or extracellular matrix (ECM) assembly, or cell adhesion molecule for cell–cell and cell–ECM interactions.

While the subject of how a polypeptide chain goes about folding into its native structure is still a very active area of research, it is well understood that one of the primary driving forces that causes a protein to fold into its native state, and to be maintained in that state in aqueous solution, is the reduction in free energy due to a decrease in the solvent accessible surface area of the nonpolar residues contained in the protein's structure, i.e., hydrophobic effects.^[1] Accordingly, proteins are generally structured with their hydrophobic residues buried within the core of the protein and their hydrophilic residues (charged and polar) lining the protein's solvent accessible surface. While this generally describes a protein's structural makeup, it is common to have some hydrophobic residues on the surface and hydrophilic residues buried within the protein's core. Thus, a protein's surface is highly amphiphilic, meaning that it displays a myriad of different types of functional groups (nonpolar, \pm -charged, polar) on its surface. As a further feature that can greatly influence protein adsorption behavior, each charged residue on a protein's surface has a designated pK_a value, which defines the residue's protonation state (i.e., whether it is in its charged or neutral state). The overall charged state of a protein is thus sensitive to the pH of the surrounding solution, with the pH value that results in the protein having a net zero value of charge being designated as the isoelectric point (or pI) of the protein. Further details of protein structure are provided in standard biochemistry texts and readers interested in protein adsorption behavior are encouraged to study this material to provide a foundation from which protein adsorption behavior can then be better understood.^[2]

Protein Adsorption Behavior from Single-Component Protein Solutions

The general model used to describe protein adsorption to a surface is illustrated in Fig. 2.^[3] This process

Fig. 2 Illustration of the protein adsorption process. A protein molecule in solution (P) adsorbs to the material surface ($P \cdot S$) in a reversible manner with forward and reverse reaction rate constants, k_f and k_r , respectively. The adsorbed protein then may transition to an irreversibly adsorbed state ($\bar{P} \cdot \bar{S}$) as a result of orientational or conformational changes that further reduce the free energy of the system, which can be described with a reaction rate constant k_i . The release of structured water from the protein and surface back to bulk water represents an important factor that greatly influences these processes. (From Ref. [3].)

can be described by the following chemical reaction equation:

where P is the protein concentration in solution, S is the concentration of available surface area sites for adsorption, $P \cdot S$ is the concentration of reversibly adsorbed protein on the surface with k_f and k_r designating reaction rate constants for the forward and reverse reactions, respectively, and $\bar{P} \cdot \bar{S}$ is the concentration of irreversibly adsorbed protein on the surface with k_i designating the reaction rate constant for the transition of the adsorbed protein from a reversibly bound to an irreversibly bound state. Water is shown complexed to the protein and surface, which is then released to bulk solution during the various stages of adsorption. This is included to emphasize its importance as a molecular constituent in the adsorption process rather than simply being an inert media that the protein and surface happen to be immersed in. Because of the presence of the irreversible step shown at the right-hand side of this equation, a surface that adsorbs a protein in a manner that includes this part of the process will inevitably become saturated with the adsorbed protein if sufficient interaction time is provided. The state of the final adsorbed protein layer will

be determined by the manner in which the proteins are able to organize themselves on the surface, which is influenced by both protein–surface and protein–protein interactions in the presence of the surrounding aqueous solution. The proteins that adsorb to the surface in the latter stages of this process will tend to be increasingly inhibited from the irreversible step of this process by steric restrictions caused by the previously adsorbed proteins. Because of this, the final fraction of the adsorbed protein layer is more likely to be maintained in its native and possibly reversibly adsorbed state.^[4] This behavior, which is illustrated in Fig. 3, explains the frequently observed phenomenon that a fraction of protein is found to desorb from an adsorbed protein layer following exposure of the surface to pure buffer solution while another fraction of the protein layer remains irreversibly adsorbed to the surface. This type of behavior can also be caused by a nonhomogenous surface (e.g., owing to defects in the surface chemistry or phase separation), thus presenting one surface phase that irreversibly adsorbs the protein and another more weakly interacting phase that reversibly adsorbs the protein.

Assuming the conditions of adsorption from a dilute solution and unity activity coefficients of each species, and defining the standard states of the products and reactants of Eq. (1) as being 1.0 M (protein solution) and 1.0 mole fraction (adsorbed protein and surface), the kinetics of protein adsorption for Eq. (1) can be expressed as:^[2,5]

$$\begin{aligned} \frac{d[P \cdot S]}{dt} &= k_f[P][S] - k_r[P \cdot S] - k_i[P \cdot S], \\ \frac{d[\bar{P} \cdot \bar{S}]}{dt} &= k_i[P \cdot S] \end{aligned} \quad (2)$$

where $[S]$, $[P \cdot S]$, and $[\bar{P} \cdot \bar{S}]$ are the mole fraction of surface sites occupied by bare surface and the reversibly and irreversibly adsorbed protein, respectively, and $[P]$ is the molar concentration of the protein in solution. The change in the free energy for the reversible part of the adsorption process can then be expressed as:

$$\Delta G_{\text{ads}} = \Delta G_{\text{ads}}^{\circ} + RT \ln \left(\frac{[P \cdot S]}{[P][S]} \right)$$

Fig. 3 Illustration of the development of an adsorbed protein layer formed when a surface is exposed to a single-component protein solution of constant concentration followed by a rinsing step of pure buffer solution. (A) Proteins initially adsorb to random areas of the surface, possibly in a reversible fashion. (B) The previously adsorbed proteins begin reorienting and spreading out on the surface to become irreversibly adsorbed (black ellipses) while new protein molecules (gray circles) continue to adsorb to open surface areas. (C) This process continues until most of the available surface area is covered with irreversibly adsorbed proteins. The last proteins to adsorb may be sterically prevented from reorienting or spreading on the surface by the previously adsorbed proteins, thus being maintained in a more weakly held, reversibly adsorbed state by the surface (white circles). (D) When the surface is exposed to pure buffer solution, the reversibly adsorbed fraction is able to desorb from the surface with the irreversibly adsorbed fraction remaining.

and at equilibrium:

$$\begin{aligned}\Delta G_{\text{ads}}^{\circ} &= -RT \ln \left(\frac{[P \cdot S]}{[P][S]} \right)_{\text{eq}} = -RT \ln \left(\frac{q}{C_e(Q - q)} \right) \\ &= -RT \ln \left(\frac{\Gamma}{C_e(1 - \Gamma)} \right) = -RT \ln(K) \quad (3)\end{aligned}$$

where ΔG_{ads} and $\Delta G_{\text{ads}}^{\circ}$ are the change in adsorption free energy and change in standard state adsorption free energy, R is the ideal gas constant, T is the absolute temperature, q is the amount of protein per unit area adsorbed in equilibrium with the molar concentration of protein in solution (C_e), Q is the amount of protein per unit area adsorbed at monolayer saturation, Γ is the fraction of surface saturation (or q/Q), and K is the equilibrium constant, which also equals (k_f/k_r).

Eqs. (2) and (3) provide a means to quantitatively describe the reversible part of the protein adsorption process for a given set of conditions. For example, Table 1 provides values for $\Delta G_{\text{ads}}^{\circ}$ and KC_e that correspond to various values of Γ for two different proteins, lysozyme (14.6 kDa) or fibrinogen (340 kDa), reversibly adsorbing to a surface in equilibrium with their respective protein solution concentrations of 1.0 mg/mL (commonly used solution concentration for experimental studies). Here, KC_e , which is derived from Eq. (2) for the reversible part of the adsorption process, expresses the ratio of the initial adsorption rate of protein ($d[P \cdot S]/dt$) onto a completely bare surface compared to the initial desorption rate from a saturated surface into a pure buffer solution over the surface. Taking the energy of a single hydrogen bond to be on the order of -3.5 kcal/mol, which is also on the order of the energy of adsorption of a single hydrophobic peptide residue onto a hydrophobic

surface, the values shown in Table 1 indicate that if the interaction of either of these proteins with a surface involves a decrease in $\Delta G_{\text{ads}}^{\circ}$ of the system no more than that of the formation of about one additional hydrogen bond, or one hydrophobic contact, then the adsorbed amount can be kept to about 0.1% of a monolayer of adsorbed protein.^[6] In contrast to this, a $\Delta G_{\text{ads}}^{\circ}$ value of only -15 kcal/mol (i.e., equivalent to approximately four hydrogen bonds or hydrophobic interactions) will result in essentially 100% monolayer coverage of the surface. Furthermore, considering the ratio of the rates of adsorption to desorption, as indicated by KC_e , an adsorption energy of only -15 kcal/mol results in an adsorption rate that is about one million times faster than desorption. In other words, the number of protein macromolecules adsorbed in 1 sec would take over 10 days to desorb, thus effectively representing an irreversible condition. Therefore, considering the size of many proteins (such as fibrinogen) and the resulting large number of functional group interactions involved when such a protein contacts a surface, it is not surprising that the adsorption of proteins to biomaterial surfaces generally occurs in an effectively irreversible manner, even without considering the actual irreversible stage of protein adsorption indicated in Eq. (1).

Based on the adsorption processes indicated by Eq. (1), when a solid surface is placed in a solution containing a given protein, the protein will generally tend to rapidly adsorb until it saturates the surface. If the surface is hydrophobic, the protein will tend to adsorb by the various hydrophobic patches of residues present on the protein's amphiphilic surface, with the protein then tending to unfold and spread its hydrophobic core over the surface owing to the thermodynamic driving force to reduce the net hydrophobic surface area of the system exposed to the solvent.^[7]

Table 1 Corresponding values of the standard state free energy of adsorption ($\Delta G_{\text{ads}}^{\circ}$) and relative adsorption/desorption rates (KC_e) for a given percent surface saturation

Percent saturation ($\Gamma \times 100$)	Lysozyme (14,600 Da, 1 mg/mL solution)		Fibrinogen (340,000 Da, 1 mg/mL solution)	
	$\Delta G_{\text{ads}}^{\circ}$ (kcal/mol)	KC_e (unitless)	$\Delta G_{\text{ads}}^{\circ}$ (kcal/mol)	KC_e (unitless)
0.10	-1.65	0.001	-3.59	0.001
1.00	-3.08	0.010	-5.02	0.010
10.00	-4.55	0.111	-6.49	0.111
30.00	-5.38	0.429	-7.32	0.429
60.00	-6.16	1.500	-8.10	1.500
90.00	-7.26	9.000	-9.20	9.000
99.00	-8.74	99.00	-10.68	99.00
99.99	-11.58	10,000	-13.52	10,000
99.9999	-14.42	1,000,000	-16.36	1,000,000

Hydrophilic surfaces, on the other hand, tend to interact with the charged and polar functional groups of the protein's surface, thus influencing adsorbed protein orientation, but with a lower tendency to cause the protein to unfold and spread over the surface.^[7] Because proteins generally do not tend to adsorb nonspecifically to themselves (which is why they are soluble in solution in the first place), protein adsorption tends to stop once complete monolayer coverage is achieved. The final organization of the adsorbed protein layer (i.e., the orientation, conformation, and packing arrangement of the adsorbed proteins) depends on the chemical and physical structure of the protein, the surface, and the aqueous solution, and the thermodynamics of the interactions between these system components. It is also strongly influenced by the kinetics of mass transport of the protein to the surface from solution relative to the kinetics of the protein's movement on the surface (i.e., orientational and translational motions), the kinetics of protein spreading on the surface (i.e., conformational changes), and the physical constraints imposed by protein–protein interactions on the surface.^[8]

Because protein adsorption is influenced by so many factors, many of which result in irreversible processes, the final state of an adsorbed protein layer is history dependent, meaning that very different results can be obtained for the same protein–surface system depending on how the adsorption process is carried out. For example, it is generally true that a hydrophobic surface will more strongly adsorb proteins than a neutrally charged hydrophilic surface. Because of this, it is usually believed that a hydrophobic surface will then adsorb a greater amount of protein.^[9] This will tend to be true, however, only if the protein is adsorbed from a solution with high protein concentration such that mass transport to the surface is much faster than the rate of protein spreading/reorientation on the surface. Under this condition, the hydrophobic surface will tend to adsorb more protein than the hydrophilic surface because its stronger attraction for the protein will result in a more densely packed layer of protein at surface saturation. This situation is illustrated in Fig. 4 for adsorption to a hydrophobic surface “a” compared to a hydrophilic surface “b” from a relatively concentrated protein solution. The opposite result can occur, however, if the same protein is adsorbed from a very dilute solution, which will greatly slow down the rate of mass transport of the protein to the surface. If the rate of mass transfer is slow compared to the rate of protein spreading/reorientation on the surface once it adsorbs, then the hydrophilic surface may actually adsorb more protein than the hydrophobic surface. This occurs because spreading tends to occur to a much greater extent on the more hydrophobic surface, thus causing an adsorbed protein

molecule to occupy a greater area of surface, leading to a lower amount of protein that can be adsorbed before the surface is saturated (illustrated in Fig. 4; conditions “c” and “d”). As a further consequence of this concentration effect, a plot of the amount of adsorbed protein vs. solution concentration can erroneously give the appearance of a Langmuir isotherm adsorption plot (see Fig. 4III), which has often mistakenly been taken to imply a reversibly adsorbing system.^[10] In fact, many investigators have wrongly applied Eq. (3) to such isotherms and calculated $\Delta G_{\text{ads}}^{\circ}$ for the adsorption process.^[11,12] As illustrated in Fig. 4, however, a Langmuir-looking isotherm will often occur from an irreversible protein adsorption process simply owing to protein spreading effects. In such cases, the calculation of $\Delta G_{\text{ads}}^{\circ}$ is meaningless; complete reversibility must be established as a necessary (but still not sufficient) requirement for the application of the Langmuir adsorption model for the meaningful calculation of $\Delta G_{\text{ads}}^{\circ}$.

The types of processes described in the preceding paragraph have been clearly demonstrated in experimental studies by Wertz and Santore.^[7] These investigators compared the kinetics and adsorption behavior of albumin and fibrinogen on hydrophobic and hydrophilic surfaces (CH_3 , CF_3 , OH silane-functionalized glass) using total internal reflectance fluorescence spectroscopy. In these studies, the rate of mass transfer of the protein to the surface was controlled by varying both the solution concentration and flow rate over each surface, with the adsorption process being continued until the condition of surface saturation was achieved. The total amount of protein adsorbed to each surface was found to directly correlate with the rate of mass transport provided, with the surface area per adsorbed protein (referred to as the protein's footprint) thus increasing as the mass transport rate was decreased. Their results also indicated that the increase in the size of the adsorbed protein's footprint as the adsorption process was slowed down was associated with the reorientation of the adsorbed protein on the hydrophilic surface and conformational spreading on the hydrophobic surface. Similar events have been demonstrated by Agnihotri and Siedlecki, who used tapping-mode atomic force microscopy (AFM) to observe time-dependent structural differences in fibrinogen adsorbed to a hydrophilic (mica) vs. a hydrophobic (graphite) surface.^[13] In this study, four different orientational states were observed on each surface, with the height of the adsorbed protein on the hydrophobic surface then undergoing a significant reduction over a time period of 2 hr following initial adsorption, while a height increase was actually observed over time on the hydrophilic surface. It was also observed that the AFM tip tended to move the protein around on the hydrophilic surface, but not on

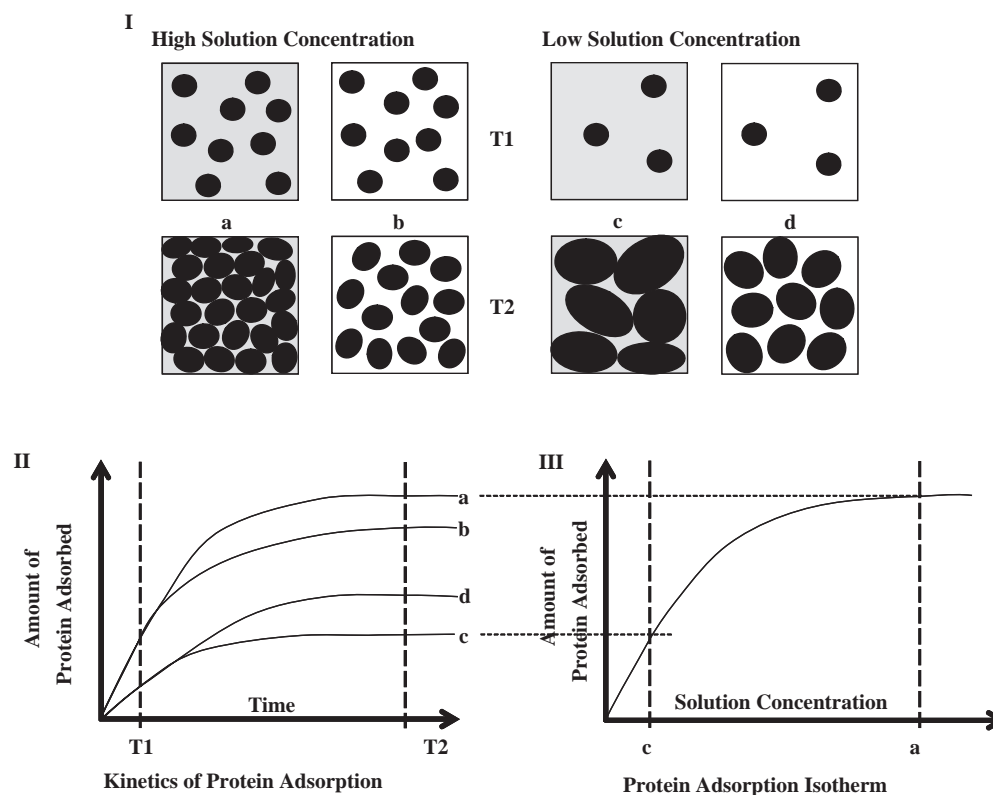

Fig. 4 Illustration of the history dependence of the final state of a protein layer adsorbed from a single-component protein solution. (I) Comparison of the resulting adsorbed protein layers when the same protein is adsorbed from a high vs. low protein concentration solution on hydrophobic (a, c) vs. hydrophilic (b, d) surfaces at time points T1 and T2 ($T1 < T2$), with T2 representing the final condition at surface saturation. (II) The amount of adsorbed protein vs. time for conditions (a)–(d) showing that mass transport controls the kinetics of the initial adsorption process as opposed to surface chemistry, with the final amount adsorbed at surface saturation dependent on both mass transport and surface chemistry. (III) Resulting irreversible adsorption isotherm with reversible Langmuir isotherm-like appearance. The concentration dependence is due to a change in the molecular footprint of the adsorbed protein as opposed to an equilibrium exchange with the protein in solution. Each point on the isotherm plot represents a fully saturated irreversibly adsorbed protein layer. (From Refs. [7,10].)

the hydrophobic surface, thus suggesting a more tightly bound interaction of the protein with the hydrophobic surface. These results are again consistent with the understanding that hydrophobic surfaces tend to more strongly adsorb proteins and induce conformational spreading, while hydrophilic surfaces tend to more weakly adsorb protein and induce orientational changes in the adsorbed protein as a function of time.

Protein Adsorption Behavior from Multicomponent Protein Solutions

When more than one type of protein is present in solution, a competitive process occurs between the different proteins for adsorption to the surface. The first important factor that influences the adsorption of proteins from a multicomponent system is that the mass transfer rate of a given solute molecule to a surface is directly related to its solution concentration

and inversely related to its molecular weight.^[14] Accordingly, when a material is exposed to a solution containing several different soluble proteins, such as blood plasma, the more concentrated and smaller proteins tend to adsorb to the surface first, and then be displaced by larger, more strongly interacting proteins that may arrive at the surface at a later point in time.^[15] This exchange process, known as the Vroman effect, was first recognized by Vroman and Adams in the late 1960s for the case of fibrinogen exchange from various types of surfaces.^[16,17] Although initially believed to be unique for fibrinogen exchange, numerous subsequent studies have indicated that this is actually a general phenomenon that occurs for many other types of proteins, including albumin, IgG, and fibronectin.^[16] Interestingly, this process is observed to occur even for proteins that are otherwise irreversibly adsorbed to a surface. Thus, while an adsorbed protein may not tend to desorb from the surface under the flow of pure buffer solution, it may be displaced from the surface by another more strongly interacting protein

Fig. 5 Illustration of the Vroman effect. Protein “B,” which is initially adsorbed to the surface, is displaced from the surface in an exchange reaction by protein “A” owing to the ability of the residue functional groups presented by “A” to form more stable bonds with the available binding sites on the surface than the residue functional groups of “B.”

that can more successfully compete for the same surface functional groups, thus exchanging itself for the previously adsorbed protein. This process is illustrated in Fig. 5. Many interesting studies have been conducted over the past several decades to investigate the competitive nature of proteins; only a few of which will be highlighted here. Readers are therefore referred to the “Further Readings” section for further references related to this subject.

As an example of the intriguing types of behavior described by Vroman effects, fibrinogen preadsorbed on a negatively charged, hydrophilic glass surface has been observed to be readily displaced following exposure of the surface to various dilutions of blood plasma.^[16] Immunochemistry studies have revealed that fibrinogen is primarily displaced by high molecular weight kininogen (HMWK) under these conditions. In other studies involving the preadsorption of fibrinogen to polyethylene, the behavior is quite different.^[16,18] While fibrinogen is also displaced from a polyethylene surface following exposure to blood plasma solutions, it has been shown that HMWK is not involved in the exchange process. Instead, other proteins, especially high-density lipoproteins, have been shown to be responsible for fibrinogen exchange. Warkentin et al. have conducted studies with multi-component protein solutions that shed some light on why this difference occurs.^[19] Using hydrophobic-gradient surfaces, they found that HMWK exhibited distinctly higher affinity for the hydrophilic end of the gradient-surface compared to other proteins, thus demonstrating that HMWK’s ability to displace fibrinogen from hydrophilic but not hydrophobic surfaces is simply due to HMWK’s inherent ability to bind most strongly to hydrophilic surfaces rather than

due to a specific interaction between HMWK and fibrinogen. More recent studies by Cremer and coworkers have provided insights into some of the actual molecular-level mechanisms that influence Vroman effects with regard to fibrinogen displacement from surfaces.^[20] Their studies showed that at a pH of 8.0, fibrinogen adsorbs to a negatively charged silica surface via the relatively small positively charged α C domains of the protein, while the larger D and E domains of fibrinogen, which are negatively charged, are not adsorbed to the surface because of electrostatic repulsion. This results in the protein being only weakly bound and enables it to be readily displaced from the surface by other, more strongly adsorbing proteins like HMWK. However, at a pH of 3.2, the negative charges of both the protein and this surface are largely neutralized, thus eliminating the electrostatic repulsive effects that previously prevented the D and E domains from adsorbing to the surface. Under these conditions, the D and E domains of fibrinogen are able to participate in the adsorption process via hydrogen bonding and van der Waals interactions with functional groups on the silica, which enables fibrinogen to bind much more strongly to the silica surface. This was observed to reduce the rate of fibrinogen displacement from the silica surface by other plasma proteins by over two orders of magnitude. Other studies have shown that Vroman effects are not only influenced by surface chemistry and solution pH, but also, not surprisingly, by many other variables including solution composition, temperature, and wall shear strain rate.^[16]

Other interesting protein adsorption effects due to protein–protein interactions have been shown by Wertz and Santore. As part of the same study referred

to in the previous section, Wertz and Santore studied the competitive adsorption behavior between fibrinogen and albumin.^[7] In these studies, the surfaces were first saturated with albumin and then aged under an albumin containing solution, following which the surfaces were exposed at various time points to a fibrinogen solution. The amount of fibrinogen adsorption and albumin desorption was then monitored as a function of time by separate radiolabeling studies. The results from these studies indicated that albumin saturated each surface very quickly and then maintained a constant surface density irrespective of aging time. Following exposure to the fibrinogen solution, they found that about the same amount of albumin was displaced by the fibrinogen irrespective of prior albumin exposure time. However, the amount of fibrinogen adsorbed was found to be strongly dependent on the aging time of the adsorbed albumin. This was interpreted to indicate that although the amount of albumin adsorbed did not change with time during the aging phase of the experiment, the pre-adsorbed albumin was able to undergo substantial reorganization during this time period, more effectively covering the surface area, and perhaps strengthen its interaction by interprotein associations, such that less surface area was then available for subsequent fibrinogen adsorption. This effect was observed to occur most strongly on the hydrophobic surfaces, with the implication that surface reorganization on the hydrophilic surface mainly occurred as a result of reorientational effects, while the hydrophobic surfaces induced additional effects due to conformational spreading.

A final study that will be addressed here, reported by Lee et al., compared the competitive binding capabilities on glass for a wild-type T4 lysozyme and two single-residue mutants, one designed to be more conformationally stable and one less conformationally stable than the wild-type lysozyme.^[21] Using binary mixtures of each combination of the proteins, the authors were able to show that in each case, the more stable protein was more easily displaced from the surface by the less stable protein, thus nicely demonstrating that conformation stability plays an important role in the competitive adsorption behavior of proteins.

Surfaces that are Resistant to Protein Adsorption

Surfaces that are resistant to protein adsorption, also referred to as nonfouling surfaces, represent a special case in the study of protein–surface interactions. The development of nonfouling surfaces is of substantial interest for marine, food processing, bioMEMs, and

biosensor applications, in addition to their potential application for the development of medical devices with improved biocompatibility. Of the various types of surface chemistries that have been studied, poly(ethylene glycol) (PEG; $[-(\text{O}-\text{CH}_2-\text{CH}_2)_n-\text{OH}]$) has received the greatest amount of attention because it has been widely demonstrated to be very resistant to the adsorption of proteins from aqueous solution. Many of the earlier attempts to understand and explain the resistance to protein adsorption imparted by PEG-coated surfaces centered on the Alexander-De Gennes theory of polymer interfaces.^[22] This theory essentially presents a “physical view” that supposes that protein resistance is provided by steric repulsion of the protein due to the conformational entropy of the very flexible PEG chains on the surface, which acts as a physical barrier that prevents a protein from approaching the underlying substrate. The development of this theory, however, does not address why the protein does not favorably interact with the PEG molecule itself. In fact, its development is based on the a priori assumption of equal attraction between the PEG chains, water, and protein, thus inherently neglecting any enthalpic contribution to this process. In a relatively recent paper by Morra (22), this deficiency is highlighted and the viewpoint expressed that a more sophisticated theory is needed to explain the non-adsorptive behavior of PEG.^[22] Morra suggests that the physical view be combined with a “chemical view” that includes the strongly favorable enthalpic interactions between the PEG chains and water. This position is supported by a report by Kjellander that addresses the thermodynamics of PEG–water interactions and indicates that PEG apparently interacts with water structure in a very energetically favorable manner that is rather unique among the class of polyether polymers, which are otherwise largely insoluble in water.^[23] While providing an improvement over the relatively simple steric repulsion theory of PEG, this approach still neglects the other side of the issue, which is equally important, namely, why are PEG–protein interactions thermodynamically less favorable than the interactions of PEG with water?

Although a definitive theory regarding how to design molecular structures to provide resistance against protein adsorption has not yet been agreed upon, several attempts have been made to characterize the general qualities necessary for the design of such surfaces. Several studies using oligo(ethylene glycol) (OEG) functionalized alkanethiol self-assembled monolayer (SAM) surfaces have demonstrated that protein adsorption resistance of OEG with either hydroxyl or methoxy end groups ($[-(\text{O}-\text{CH}_2-\text{CH}_2)_n-\text{X}]$; X: OH, O–CH₃) is dependent on the degree of polymerization and chain packing density.^[24–27] Herrwerth et al. have shown that protein resistance requires that

the degree of OEG polymerization be 2 or more (i.e., $n \geq 2$) and suggested that the chains must be sufficiently spaced to enable water to penetrate the OEG layer, especially for the methoxy-terminated surfaces. These findings were summarized by stating that protein resistance requires both internal and external hydrophilicity. Similar findings for hydroxyl- and methoxy-terminated OEG, and other functional groups, have been reported by Whitesides and coworkers.^[27,28] Of particular interest, Ostuni et al. have reported values for the protein resistance provided by 48 different surface functional types covalently linked to SAM surfaces, many of which were very different from OEG, although still providing a high level of resistance to protein adsorption.^[27] In particular, several compounds with dimethyl amine ($-\text{N}(\text{CH}_3)_2$) and methoxy ($-\text{O}-\text{CH}_3$) end groups were shown to adsorb very low levels of protein compared to the other functionalities tested. Based on these findings, these authors stated that four common elements were present in each of the protein-resistance functionalities found in their studies: the functional groups 1) were hydrophilic; 2) included hydrogen bond acceptors; 3) did not include hydrogen bond donors; and 4) were neutrally charged. One immediate problem with this set of four necessary characteristics, however, is that condition (3) is violated by the most protein-resistant molecular structure tested, namely hydroxyl-terminated OEG. Thus, while these studies provide very interesting results, the requirement that protein-resistant functional groups not be hydrogen bond donors obviously cannot be universally applied. Another limitation to the above-described studies is that they again focus on functional group–water interactions and do not address the issue concerning why these interactions are thermodynamically preferred over interactions between the functional groups and the protein.

As indicated from their adsorption/desorption plots, the protein-resistant surfaces reported by Ostuni et al. represent systems exhibiting reversible adsorption behavior with low surface coverage, and thus the results from this study can be considered from a thermodynamic perspective with the approximate determination of the standard state free energy of adsorption ($\Delta G_{\text{ads}}^{\circ}$) calculated from Eq. (3) above.^[27] The data provided by Ostuni et al. are reported as the percent monolayer adsorption of protein (lysozyme and fibrinogen) from 1.0 mg/mL solutions, which, fortuitously, are the same example conditions provided in Table 1 of this entry. Accordingly, the $\Delta G_{\text{ads}}^{\circ}$ values in Table 1 indicate that under equilibrium conditions, to achieve 1% monolayer coverage or less requires that $\Delta G_{\text{ads}}^{\circ} \geq -3.0$ kcal/mol and $\Delta G_{\text{ads}}^{\circ} \geq -5.0$ kcal/mol for the adsorption of lysozyme and fibrinogen, respectively. Considering fibrinogen, which has a side-on molecular footprint of 235 nm^2 ($5.0 \text{ nm} \times 47 \text{ nm}$)

compared to 0.21 nm^2 per OEG surface group on a homogeneously functionalized SAM surface, an adsorbed fibrinogen molecule would potentially interact with over 1000 OEG chains.^[7,29] This thus averages out to $\Delta G_{\text{ads}}^{\circ} \geq -0.005$ kcal/mol per OEG chain, which is approximately stating that $\Delta G_{\text{ads}}^{\circ} \geq 0$ kcal/mol for this interaction. Considering the thermodynamic relationship of $\Delta G_{\text{ads}}^{\circ} = \Delta H_{\text{ads}}^{\circ} - T\Delta S_{\text{ads}}^{\circ}$, it is clear that to provide protein resistance, the interaction of a surface with a protein should thus ideally result in $\Delta H_{\text{ads}}^{\circ} \geq 0$ and $\Delta S_{\text{ads}}^{\circ} \leq 0$; or in other words, the unbound hydrated state of the surface functional group should be lower in enthalpy and higher in entropy than when bound to a protein. Considering enthalpy, this will be provided if the surface functional group is able to bond with water more favorably than with functional groups of the protein. Considering entropy, the functional group must be able to maintain a higher state of system entropy when bonded to water than when bonded to the protein. Of course, the water structure itself must also be considered, with the surface being able to maintain the surrounding water structure in a free-energy state that is equal to or lower than that of bulk water.

With this thermodynamic perspective, it is possible to interpret the results shown by Hernwerth et al. and Ostuni et al. somewhat differently, with a key feature being that water is much smaller and more mobile than the functional groups presented by a protein.^[26,27] Accordingly, if hydrogen bonding groups are presented by the surface molecules in a manner such that water can access the groups much more readily than can the functional groups of a protein, then a lower state of enthalpy will be provided for the hydrated, nonadsorbed state. Similarly, because of the mobility of water, water is able to maintain hydrogen bonding with a flexible surface chain without substantially restricting either the chain's or the water's configurational space, whereas the bonding of the protein to a flexible surface molecule will substantially restrict the motion of the surface chain, thus decreasing the entropy of the system relative to the nonbonded state. Accordingly, the longer the surface chain, the greater the entropic penalty will be for restricting its motion. These arguments are consistent with experimental evidence regarding the types of molecular structure that provide resistance to protein adsorption. Longer OEG chains that are not restricted by too high a packing density are more resistant to protein adsorption (entropic contribution), and chains that have well-hydrated hydrogen bonding groups that are relatively inaccessible to the protein, such as ($-\text{O}-\text{CH}_2-\text{CH}_2-\text{X}$) and ($-\text{N}(\text{CH}_3)_2$), are resistant to protein adsorption (enthalpic contribution). It is interesting to note that similar molecular features are found in phosphatidylcholine molecules presented by cell

membranes and 2-methacryloyloxyethyl phosphor-ylcholine molecules for surface functionalization that have been designed as a biomimetic of the cell surface, both of which provide a very high level of resistance to protein adsorption.^[2,30,31]

PROBING SUBMOLECULAR MECHANISMS OF PROTEIN ADSORPTION BEHAVIOR

While a great deal has been learned from studies focusing on the amount and type of protein that adsorbs to various types of surfaces, if surfaces are to be designed to actually control protein adsorption behavior, it will be necessary to develop a much more detailed understanding of the submolecular mechanisms involved in protein–surface interactions, and how these interactions influence the orientation, conformation, packing, and subsequent bioactivity of adsorbed proteins. Fortunately, several very exciting relatively new technologies are being developed and applied that should greatly advance the understanding of protein–surface interactions. Several of these technologies are highlighted in this section.

Drobny, Stayton, and coworkers are developing solid-state nuclear magnetic resonance (ssNMR) techniques for the study of peptide–surface interactions to enable the distance between isotopically labeled atom types to be measured with subangstrom resolution.^[32,33] By the careful selection of which atoms are labeled in their systems, they have been able to quantitatively determine the secondary structure of adsorbed peptides and to identify the types of peptide residues that specifically interact with functional groups of the surface for several different types of surfaces. This method thus enables specific interactions governing the structure of adsorbed peptides and their associated surface functional groups to be targeted and directly probed.

Circular dichroism spectropolarimetry (CD) has also been demonstrated by several groups to be able to quantitatively determine the secondary structure of adsorbed peptides and proteins, as well as provide information regarding the adsorbed tertiary structure for proteins containing tryptophan residues.^[34–37] In particular, the high sensitivity of this method has enabled its use to be extended to proteins adsorbed onto flat surfaces in addition to particles in solution, thus expanding its versatility to a much broader range of materials while also avoiding issues related to signal noise problems due to light scattering by dispersed solid particles. Recent studies by Hylton et al. have demonstrated that surface chemistry strongly influences the amount of adsorption-induced loss in the α -helix structure of both fibrinogen and albumin and, more importantly, platelet adhesion following protein

adsorption was found to directly correlate to the degree of structural change in the adsorbed layer of each protein.^[36] In another very interesting study, Engel et al. combined CD with stop-flow fluorescence spectroscopy and demonstrated that up to 70% of adsorption-induced unfolding of bovine α -lactalbumin (BLA) on polystyrene nanospheres in aqueous solution occurs within 15 msec of nanoparticle exposure, thus providing direct experimental measurement of the kinetics of the adsorption-induced unfolding process.^[35]

In a very interesting follow-up experimental study by Engel and coworkers, submolecular events related to adsorption-induced BLA unfolding were probed using hydrogen/deuterium (H/D) amide proton exchange and 2D NMR.^[38] This method provides an excellent technique to probe the effect of adsorption on protein structure because H/D exchange is directly related to the degree of solvent accessibility of a given peptide residue. When the H/D exchange behavior for the native BLA in solution was compared to adsorbed BLA, the investigators found distinct differences in H/D exchange before and after adsorption, thus providing direct insights into how BLA unfolds during adsorption by identifying the specific residues that transitioned from a buried to a solvent-exposed state following adsorption. The results of this study support the presence of distinctly different populations of adsorbed protein—one that exhibited substantial unfolding and another, smaller population with near-native-state H/D exchange behavior. This finding was believed to occur because the last fraction of adsorbed proteins was prevented from unfolding because of the physical restrictions provided by the previously adsorbed proteins, which is in agreement with the process illustrated in Fig. 3.

Castner and coworkers are developing a different experimental technique to probe adsorbed protein orientation and conformation using static time-of-flight secondary ion mass spectrometry (ToF-SIMS), which uses an ion beam to release molecular fragments from the top 1.0–1.5 nm of an adsorbed protein layer.^[39,40] Using multivariate analysis techniques, the released fragments are able to be associated with their parent peptide residue types.^[41] Thus, if the adsorbed protein layer is thicker than 1.5 nm (which is smaller than the smallest dimension of most clinically relevant proteins), and if the protein structure has an anisotropic distribution of peptide residues, the specific distribution of peptide residues present in the ToF-SIMS spectrum can be used to provide information relating to the orientation and conformation of the adsorbed protein layer. Castner and coworkers have already demonstrated that differences in both the type and conformational state of adsorbed proteins can be determined with this method, with continued research

Fig. 6 (A) Molecular model of a 30 kDa segment from the C-terminus end of the γ -chain of fibrinogen (γ Fg, PDB ID 1FID) over a SAM surface in 150 mM saline. Water molecules and salt ions surrounding the protein and surface, which were present during the simulation, are not shown for clarity. (B, C) Close-up views of the resulting peptide–surface interactions observed during the 5.0 nsec molecular dynamics simulations for adsorption of γ Fg to a negatively charged COOH-SAM surface (B) and a hydrophobic CH₃-SAM surface (C). Note that positively charged peptide residues (e.g., lysine, arginine) preferentially interacted with the COOH-SAM surface (indicated by * in B) while hydrophobic peptide residues (e.g., alanine, leucine) preferentially interacted with the CH₃-SAM surface (indicated by # in C).

being conducted to further develop and evaluate its potential as a tool for the characterization of adsorbed protein structure.

Advances in biochemistry techniques have also greatly assisted in the study of protein adsorption behavior. As previously noted, extensive peptide residue mutation studies have been conducted with T4 lysozyme.^[42] McGuire and coworkers have used this versatile model protein system to elucidate relationships between protein stability, adsorption behavior, and adsorbed-state bioactivity.^[21,43] García and coworkers have conducted extensive studies with recombinant fragments of fibronectin, which is a clinically relevant ECM cell-adhesion protein with cell-binding domains recognized by various types of integrins displayed by fibroblasts.^[44,45] These studies have clearly demonstrated that surface chemistry substantially influences the adsorption behavior of the cell-binding domains of this protein, with subsequent changes in the integrin expression and adhesion strength of fibroblast cells. In another set of recombinant protein studies, Tang and coworkers have demonstrated that a specific bioactive site located in the C-terminus segment of the D-fragment of fibrinogen, which is not accessible in the soluble state of this protein, becomes exposed when fibrinogen adsorbs to a biomaterial surface, with this bioactive site serving as an important mediator of the inflammatory response.^[46]

In addition to experimental methods, substantial advances in computational hardware, software, and analysis methods have been made over the past few decades. These advances, coupled with the structural determination of thousands of proteins that are now

available via the Protein Data Bank (PDB), have now provided the capability to conduct all-atom molecular simulations to investigate the atomic level behavior of proteins in solution.^[47] While these capabilities have been widely developed and exploited for application to the study of protein folding and ligand–receptor interactions for rational drug design, they represent a largely untapped resource for assisting in the understanding of protein adsorption behavior on biomaterial surfaces.^[48] Latour and colleagues have been working over the past several years to develop the necessary methods to enable molecular modeling to be accurately applied to simulate protein–surface interactions.^[49,50] As an example from this work, Fig. 6 shows the interactions of a 30 kDa segment of fibrinogen with two different SAM surface chemistries.^[49] As illustrated, distinctly different types of peptide residue–surface interactions were predicted for each type of SAM surface, with subsequent hydrophobic, electrostatic, and hydrogen-bonding interactions being observed. In other studies, Jiang and coworkers and Kreuzer and coworkers have applied molecular simulation methods to theoretically investigate protein–surface and OEG–water interactions to gain further insight into the possible submolecular interactions responsible for these types of adsorption systems.^[51–54]

CONCLUSIONS

With the advent of tissue engineering and regenerative medicine, the goals of biomaterial surface design have

shifted from a focus on attempting to minimally disturb the surrounding biological processes to the design of surfaces that are able to direct them to attain a desired response. Although the desired type of response varies widely depending on the specific application, be it the incorporation of an implant without fibrous capsule formation or thrombosis, or the regeneration of a targeted tissue or organ, at the fundamental level the biological response will still largely be governed by the bioactive signals that are provided by the biomaterial surface.

It has now been widely accepted that protein adsorption behavior must be controlled to control the bioactivity of a biomaterial surface.^[55,56] For many applications, the complete prevention of protein adsorption may represent the optimal condition, thus eliminating the presentation of bioactive signals from the surface altogether. Proteins, however, are still the body's natural means of directing biological processes and thus, if properly harnessed, still possess the greatest potential to directly interact with natural cellular processes to direct cellular responses. The central issue still remains: how to control protein adsorption behavior in a manner to realize this potential. It is obvious that there is much more to be discovered and understood. The continued development of experimental methods to probe the submolecular mechanisms that control protein adsorption behavior, combined with the capabilities that can be provided by molecular simulation to theoretically assess and visualize protein–surface interactions at the atomistic level, should provide the means to continue the advancement of our understanding of protein adsorption behavior. Given the widespread recognition of its importance, the study of protein–surface interactions should continue to be of central importance for biomaterials development well into the foreseeable future as the biomaterials community works toward the goal of proactively designing surfaces that are able to directly control biological response.

Biomedical Ethics

Daniel E. Wueste

Robert J. Rutland Center for Ethics, Clemson University, Clemson, South Carolina, U.S.A.

B

INTRODUCTION

The purpose of this article is to survey and discuss the salient features of biomedical ethics in a way that makes its value apparent and its methodology accessible to persons whose interest in it probably arises from involvement in biomedical practice rather than familiarity with ethical theory.

Although biomedical ethics is a relative newcomer to the field of applied or practical ethics, an enormous amount of ink has been put to paper in discussions of issues in the field, alternative ways of approaching them, and even whether any of the alternative approaches is actually viable. The literature is, in a word, vast. Readers are most cordially invited, if they choose, to dive into that literature. Here, however, our focus has to be narrow. Accordingly, after a brief discussion of what brought the newcomer onto the field, we will focus on the principlist approach in biomedical ethics. As it happens, this approach emerged at the start and, although it now has competitors, it remains the standard approach among practitioners and teachers of future healthcare professionals.

The key elements of the principlist approach are the principles of autonomy, nonmaleficence, beneficence, and justice. We will examine each of these principles in some detail to reveal the character of each, how they differ from one another, and how they can be applied in practice. Along the way, we will clarify the notion of applied or practical ethics; distinguish two sorts of ethical standards and explain how they are related to one another; and explain the distinction between absolute and prima facie principles, which is enormously important to the principlist program. We will conclude with an example that brings us back to a point made at the beginning and helps to underscore the necessity for judgment that emerges from systematic, reflective, and responsible engagement with the pressing issues of biomedical ethics.

IN THE BEGINNING

Biomedical ethics is a branch of applied or practical ethics. Like its cousins, engineering ethics, business ethics, and environmental ethics, it focuses on and provides tools for the systematic resolution of ethical

problems that arise in practice. By most accounts, it was born in the 1970s in response to significant and rapid changes in medicine, particularly those tied to advances in research or emerging technologies. Changes in the relationship between physician and patient and the contexts of medical practice and research were also influential. (At that time, the essentially paternalistic character of the doctor/patient relationship came into question and the autonomy of medical professionals began to diminish as the practice of medicine became institutionally entrenched.) However, the most important factor was a medical and scientific scandal revealed in the *Washington Evening Star* on July 25, 1972 under this headline: “Syphilis Patients Died Untreated.” The story, written by Jean Heller of the Associated Press, reported on a US Public Health Service (PHS) study, begun in 1932, “in which human guinea pigs, not given proper treatment, have died of syphilis and its side effects.” Heller reported that the aim of the study, which at that time had been going on for 40 years, was “to determine from autopsies what the disease does to the human body.”^[1] The next day, the story ran on the front page of the *New York Times* with this headline: “Syphilis Victims in US Study Went Untreated for 40 Years,” and the world learned that this study, which has come to be known as The Tuskegee Syphilis Study, was “the longest nontherapeutic experiment on human beings in medical history.”^[2] The PHS study, conducted in Macon County Alabama, involved 600 African-American males, 399 who were syphilitic and 201 who were free of the disease (as control). From the very beginning, the subjects of the experiment were not aware that they were part of a PHS study, let alone what its aim was or what alternatives were open to them.^[3] Like a bacterium subjected to intense heat, the study could not survive for long in the heat and light generated by publicity. It ended on November 16, 1972.

The official name of the study, “Tuskegee Study of Untreated Syphilis in the Negro Male,” reveals a good bit of what was scandalous in it, for although there was no effective treatment for syphilis when the study began, one became available in 1943—penicillin—and it was deliberately withheld from the subjects. In fact, the PHS worked hard to make sure that syphilitic study subjects did not receive treatment. For example, during World War II when these men were subject to

the draft, because draftees with syphilis were required to undergo treatment, the PHS provided the Draft Board of Macon County Alabama with the names of 256 study participants under the age of 45, and formally requested that they be excluded from the required treatment. The Board complied with the request. Similarly, from 1952 until the study ended, local health departments helped the PHS both keep track of study participants who left Macon County and prevent them from receiving treatment.^[3] According to the timeline of the study at the web site of the Centers for Disease Control (CDC), questions about the ethics of the study were raised in 1968.^[4] However, the CDC confirmed the need for the study in 1969; the local chapters of the American Medical Association and the National Medical Association supported its continuation as well. Thus, for 29 years, study participants, *none* of whom had been told that they were infected with syphilis—they had been told that they had “bad blood”—were denied treatment for a disease that could have been effectively treated. Moreover, as a result of the deception and denial of treatment, their wives and lovers were exposed to the disease; when the study ended, 40 wives had been infected and 19 children had congenital syphilis.^[5]

There are many troubling aspects to this sad story. For instance, Alabama law (1927) required reporting and treatment of syphilitic individuals and the Henderson Act (1943) required testing and treatment for venereal disease. In addition, according to the first principle of the Nuremberg Code (1946), voluntary informed consent “is absolutely essential” in experiments with human beings; the Helsinki Declaration of the World Health Organization (1964) makes the same claim. Yet, so far as this study is concerned, such requirements came to nothing. Published articles reporting on the study betray nothing in the way of ethical misgivings. For example, a report in the December 1964 issue of the *Archives of Internal Medicine* marked the 30th year of the study noting 1) that because many of the younger participants had received some treatment, “14 young, untreated syphilitics were added to the study to compensate” and 2) that this “group continues to have higher mortality.”^[6] Indeed, it appears that John Heller, director of the Venereal Diseases Unit of the PHS from 1943 to 1948, summed up the thinking of those involved with the study when, in an interview in 1976, he said that the “men’s status did not warrant ethical debate. They were subjects, not patients; clinical material, not sick people.”^[7]

THE NATIONAL RESEARCH ACT OF 1974

The literature about the Tuskegee study is vast. There is much to ponder and explain in this sad chapter in the

history of biomedicine; there are lessons to be learned and *relearned* as well.^[8] What is most important for the present purpose, however, is the federal legislation enacted in response to the revelation of what, in the name of science, the PHS had been doing in Macon County Alabama for 40 years. The National Research Act of 1974 created the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. Prominent among the tasks undertaken by the Commission was the identification of “basic ethical principles that should underlie the conduct of biomedical and behavioral research involving human subjects” and the development of “guidelines which should be followed to assure that such research is conducted in accordance with those principles.”^[9]

The Commission started its work in December 1974. Its first report, *Research on the Fetus: Report and Recommendations*, was submitted to the Department of Health Education and Welfare (DHEW), Congress and the President in July 1975. The Commission submitted nine more reports. These reports dealt with a variety of issues: 1) research on prisoners (1976); 2) psychosurgery (1977); 3) disclosure of research information under the Freedom of Information Act (1977); and 4) research on children (1977). Five of the reports were submitted in 1978. The topics were: 1) research on those institutionalized as mentally infirm; 2) institutional review boards; 3) ethical guidelines for the delivery of health services by DHEW; 4) the Belmont Report: Ethical Principles and Guidelines for the Protection of Human Subjects of Research; and 5) implications of advances in biomedical and behavioral research.^[10]

The best known in this series of formal reports is the *Belmont Report*. This report differs from the others in not making specific recommendations for administrative action. In this case, the Commission recommended adoption of the report in its entirety, as a statement of policy.^[9] As this report articulates the basic ethical principles and guidelines the Commission had been charged with identifying, its recommendation was, in effect, that these principles and guidelines be an official policy of the federal agencies that fund and oversee research involving human subjects, which is, of course, a rather large portion of the biomedical research undertaken in the U.S.A. What the Commission proposed is, in effect, the case:

Title 45 Code of Federal Regulations, Part 46, Protection of Human Subjects (45 CFR Part 46), embodies the ethical principles of *The Belmont Report*. These regulations apply to all research involving human subjects conducted or supported by the Intramural Research Program (IRP) of the NIH ... The NIH IRP operates under an OHRP [Office for Human

Research Protections] approved Federal Wide Assurance (FWA). The FWA obligates the NIH to conduct all its research activities involving human subjects consistent with the ethical principles of *The Belmont Report*.^[11]

While the Commission was doing its work, Tom L. Beauchamp and James F. Childress were writing a groundbreaking book, *Principles of Biomedical Ethics*. First published in 1979, the book was written “almost coextensively” with the Commission’s work. Indeed, Beauchamp “served as staff philosopher”^[12] for the Commission. Like the Commission in the *Belmont Report*, Beauchamp and Childress present a few basic principles (they offer four principles, the Commission offers three) that can be used by healthcare professionals to work their way through ethical difficulties. It is fairly clear, then, why this is called applied ethics. The approach is also called “principlism;” it has proved to be very popular among healthcare professionals. It is, in fact, the best-known approach in biomedical ethics constituting what can be called, without hesitation, the received or standard approach among practitioners and the teachers of future healthcare professionals. To be sure, as even a cursory survey of the vast literature in biomedical ethics reveals, there are other approaches. For the most part, however, they have emerged in response to perceived weaknesses in the principlist approach and have not (yet) succeeded in usurping the throne of principlism. We will take a look at the principles put forward by the Commission as well the principles championed by Beauchamp and Childress after a few preliminaries about applied ethics.

APPLIED OR PRACTICAL ETHICS

As noted above, biomedical ethics is a branch of applied or practical ethics. Here, as with other varieties of applied ethics, the task is *normative* rather than descriptive; the focus of attention is on how things *ought* to be. In this, we find a sharp contrast with the scientific enterprise as it is commonly understood. For on this conception of science, the scientist’s task is to discover and report the way the world is. Indeed, on some accounts, each scientist is contributing to what will one day be a *complete description* of the way the world is. In any case, the distinction between normative and descriptive is fundamental. When, for example, a social scientist reports that in fact people make promises planning not to keep them, or that, say, studies reveal that 75% of undergraduates cheat on exams or make up data for lab reports, the ethicist is likely to remark that these are *sad* facts; it *ought* to be otherwise. Her response is evaluative and prescriptive.

Of course, in making such judgments, she is applying a standard. Her criterion may be more or less general. It may take the form of a principle or a rule, for example. But either way, and necessarily, a standard is being applied. If it is an ethical standard, then 1) it will be based on impartial considerations favoring neither the interests of an agent/actor nor those of an individual who is making an ethical judgment; 2) it will be general in scope, or put another way, it will be universal in the sense of being applicable in all relevantly similar situations; 3) it will be practicable, which is another way of saying that ought implies can; 4) it will be addressed to serious rather than frivolous matters; and 5) it will be peremptory or overriding, i.e., poised to carry the day in a conflict with another normative standard, for example, a law.

Consider the recent scandals in business—Enron, WorldCom, or Adelphia, for instance. Recognizing the ethical wrongdoing in these cases involves the application of ethical standards. The standards we need are not arcane; what was done in these cases violated basic and familiar ethical standards readily available for application not only in business but also in the professions, government, and the church, for example. It may be that the actors in these cases believed sincerely that they were not doing anything wrong. Indeed, they may have believed, again sincerely, that the relevant standards did not apply to them in their work. Claims of this sort are in fact common in such cases. However, their exculpatory force is illusory. This is so for three reasons. First, concerted efforts to make one’s dealings opaque suggest collusion rather than innocence. (This is true generally.) Second, it is far from clear why the occupations of the actors in these cases would carry a moral exemption; indeed, the idea is so mysterious that such a belief seems explicable only in terms of its convenience. Third, and most important, so far as judging actions is concerned, the sincerity of an actor’s beliefs about their rightness or wrongness cannot itself be decisive, for surely, thinking or believing something is so, however sincerely, does not make it so. A rapist may sincerely believe that what he is doing is perfectly okay; nevertheless, what he believes is false. What he is doing is wrong.

TWO TYPES OF ETHICAL STANDARDS: PRINCIPLES AND RULES

At this juncture we should pause to consider how, if we were challenged to do so, we could make the case for saying that rape is wrong. To be sure, it is illegal, and if the rapist is caught and convicted, he will be punished. But rape is not wrong because it is illegal and carries a heavy sanction. That is the wrong way around—if we say this, we’ve put the cart before the horse. Similarly,

while it is true that customary morality condemns rape, it is not the case that rape is wrong because customary morality condemns it. Again, law and customary morality condemn rape; each includes a rule prohibiting it. However, the rule itself acknowledges or recognizes but does not explain the wrongness of what it prohibits. The challenge we started with is not answered by an appeal to law or customary morality. Rather, it is recast as a question about the rules: Why should we have a rule prohibiting rape? More precisely, what's called for is a principled response to the challenge, which is precisely what will emerge as we articulate the moral considerations that justify this rule (and others as well).

A principle resides at a higher level of abstraction than rules. Rules characteristically require or prohibit actions. Consequently, they have more specificity than principles, which have a different normative function. The relationship between principle and rules is rather like that between a constitution and laws made in the exercise of the powers it bestows. It is, then, a relationship of authorization/justification. Questions about the validity of rules—for instance, about their moral necessity or warrant—are answered by reference to principles. Thus, as we reflect and respond to the question above about the reason(s) for the rule, we will be articulating a relevant principle.

1. Interactions with others should be beneficial, not detrimental. It is obvious that rape entails harm, physical and/or psychological, and this is surely the first thing that comes to mind, if one is asked to defend the judgment that rape is wrong. It is also clearly relevant to the justification of a rule prohibiting rape: Such a rule has the aim of preventing harm. The principle that is in play here is something like this: *It is wrong to willfully harm another person without justification; we ought to make things better for others, not worse; at the very least we have a duty not to harm others.*
2. Another way of making the case for the wrongness of rape, as well as a case in favor of a rule against it, points in a different direction. The rapist treats his victim as a thing, as a mere means to his end of sexual gratification (a rapist may have other ends, for instance, to establish, at least in his own mind, his dominance over women). In treating her this way, he denies her human dignity. He fails to treat her as she *deserves* to be treated; she has a right to be self-governing rather than controlled by another; she has a right to control over her body. Each of us thinks this is true in our case and there is no good reason to suppose that it is any less true of others. The rapist violates this basic right. The principle in play here is something like this: *Persons must be treated as self-governing*

individuals: Their capacity for self-direction must be respected; unlike things, persons are never properly treated as a mere means to an end.

The principles that emerge here speak in terms of consequences and deserved treatment, respectively. The first principle focuses on consequences. It approves of good consequences (i.e., those that are beneficial) and disapproves of bad consequences (i.e., those that are detrimental). Indeed, it speaks of a duty not to harm others, which appears to be where we start. Its concept of positive duty is tied to consequences as well: We ought to help others; the aim is to increase the amount of good in the world. The second principle embraces the idea of human dignity, which is understood in terms of self-governance, and demands respect for persons, in particular, that persons never be treated as if they were things. These principles differ from one another in a fundamental way. One suggests that questions of duty, right and wrong, are to be answered by careful consideration of results, the other focuses on something altogether different. Demanding respect for persons in the name of human dignity, this principle declines the invitation to consider results in judging what is right or wrong. Its claim is not that one should respect persons if or because doing so will have good consequences. Respecting persons is a duty regardless of the consequences. It may be true that respecting persons has good consequences and failing to respect persons has bad consequences. Indeed, the correlation may be very strong. However, an act is not right only because it has good consequences (nor wrong only because it has bad consequences). One acts rightly by respecting persons even when doing so has unhappy consequences. For example, because we have a duty to respect persons, it is necessary to obtain informed consent from research subjects. When research is conducted on human beings without their consent, the research subjects are being treated as a mere means to an end (the successful completion of the study). They are being treated like things rather than persons; their capacity for self-governance is not being respected. This is wrong *even if* the results of the study would be of tremendous value. In fact, so far as this principle is concerned, the results—good or bad—are morally irrelevant; ethically they make no difference at all.

It should be clear that the Tuskegee study violated this principle. It may be less obvious, but it is equally true, that the first principle was violated as well. Because the syphilitic study participants were not told that they had syphilis and because they were denied treatment (and were kept from receiving treatment as inductees during World War II), it was not only foreseeable, it was a virtual certainty that some of the wives and children of the syphilitic study participants would

contract the disease. And as noted earlier, this did in fact happen. Moreover, it strains credulity to the limit to suppose that no one could foresee that if the truth about the study were to become known in the African-American community, the trust essential to effective medical care and public health programs would be seriously eroded. These foreseeable consequences are very bad. Perhaps they are not weighty enough by themselves to justify the claim that the first principle was violated. However, combined with the quite substantial harm to the study participants themselves, the claim that the principle was violated can scarcely be doubted.

PRINCIPLIST PRINCIPLES

Earlier we noted that *The Belmont Report* advances three principles and that in their book, *Principles of Biomedical Ethics*, which was written virtually coextensively with the work of the Commission, Beauchamp and Childress put forward four principles. The first two principles have been the subject of the preceding discussion, though we have not used the names given to them in these two publications and did not arrive at them by the same means. In *The Belmont Report*, the second principle above is called the principle of respect for persons and the first one is called the principle of beneficence. Beauchamp and Childress call the second principle the principle of autonomy and, seeing two distinct aspects in the first principle, they speak of two principles: the principle of beneficence and the principle of nonmaleficence. The remaining principle, discussed below, is called the principle of justice in both places.

CONSEQUENTIALIST PRINCIPLES

Let us take a closer look at the first principle discussed above. The key feature of this principle is that it directs attention to the consequences of actions and indicates that actions are to be morally evaluated on the basis of the overall character of those consequences, that is, the key question is whether the balance of good and bad (benefit and cost) weighs heavier for good or ill. We are to approve of the former and disapprove of the latter. Because it focuses on consequences this principle is aptly categorized as a consequentialist principle. The best-known consequentialist principle is the principle of utility championed by the English utilitarians Jeremy Bentham and John Stuart Mill. The utilitarians taught that one acts rightly when one acts so as to produce the greatest good for the greatest number. Put another way, the criterion for choosing among available courses of action dictates the choice that is likely

to produce the largest benefit with the least in the way of cost for all those who have a stake in the matter (the stakeholders). The utilitarians were realistic. They recognized and in fact emphasized that the choices we make involve a mix of benefit and detriment (i.e., disadvantage or harm). Thus, they were frank in admitting the need to weigh and balance the likely benefits and detriments. However, when one thinks about rape, for example, it seems reasonable to say that the “benefit” the rapist enjoys should not figure in our judgment of his act (so too, *a fortiori*, any benefits that might accrue to his friends or fellow travelers). With this move, one rejects as ludicrous the suggestion that we must weigh all the benefits and all of the costs leaving open the possibility that it could turn out, on balance, that having weighed all of the benefits and costs, the rapist’s action was right. It may be true that we have a duty to maximize benefits—a *duty of beneficence*.^[9] However, we also have a duty not to harm others and this duty takes precedence; it is the first order of business: first, no harm (*primum non nocere*).

The primacy of a duty not to harm seems straightforward to many. For example, H.L.A. Hart observes that “the most common requirements of law and morality” are negative in form, and the most important of these prohibitions “restrict the use of violence in killing or inflicting bodily harm.” Hart suggests that the sense in which a duty not to harm is fundamental emerges with a question: without it, he asks, “what point could there be for beings such as ourselves in having [duties] of *any* other kind?”^[13] Like Hart, Bernard Gert holds that rules that prohibit harming others are quite basic. Indeed, Gert maintains that such rules, which prohibit killing, causing pain, and disabling, as well as depriving others of freedom, opportunity, or pleasure, constitute the core of morality.^[14]

In any case, thinking along lines such as these, one may, as Beauchamp and Childress do, distinguish two consequentialist principles, introducing, in addition to the principle of beneficence, the principle that entails our duty not to harm, namely, the principle of non-maleficence. With this move, it is very clear that consequentialist considerations entail two sorts of moral requirements. One variety is negative: We are duty-bound *not to act* in ways that inflict harm (non-maleficence). The other is positive: We are duty-bound *to act* beneficently; at the end of the day, as it were, as a result of our actions, there ought to be more good in the world. This result might be accomplished by creating value—doing or promoting good. It might also be accomplished by preventing or removing evil or harm (what is bad). As it happens, it is much easier to accept the latter, preventing or removing what is bad, as *duties*. Indeed, it might be said that because

promoting good is not morally incumbent on any and every moral agent independent of social/institutional role, it is not a “duty in the strict sense.”^[15] In any case, should these duties conflict, it is clear that the duty not to harm takes precedence over a duty to benefit others.

TWO POINTS OF SPECIAL INTEREST

Two points of special interest emerge here. First, prominent among the things that do not count as “duties in the strict sense” are the responsibilities individuals have in virtue of roles or relations, for instance, the responsibilities of a physician or a father. While it is probably true there is no duty in the strict sense to benefit others, it is clear that some roles require beneficent acts. For example, in taking the Hippocratic Oath a physician vows that “Into as many houses as I may enter, I will go for the benefit of the ill,” and again, that “I will use regimens for the benefit of the ill in accordance with my ability and my judgment, but from [what is] to their harm or injustice I will keep [them].” (This last, interestingly, captures the thrust of both the principle of beneficence and the principle of nonmaleficence and in the same voice.)^[16]

The second point is that these principles give rise to “prima facie duties.” This is a very important point, for among other things, it holds with respect to all four principles in the principlist approach championed by Beauchamp and Childress. Consider the duty not to lie and the duty not to kill. On one interpretation, the moral point of the claim that we have these duties is that lying and killing are wrong always and everywhere for anyone. Or again, the point is that one must never lie or kill, where “never” means never; under no circumstances is it permissible to lie or kill. Understood in this way, the duties not to lie and not to kill are *absolute* duties. That is to say, they cannot be overridden. Thus, for example, it would be wrong for a doctor to answer a young patient’s question, “Am I going to die?” with anything but the truth, even if the child’s parents had requested that the child not be told or there were good reason to expect that a truthful answer would be injurious. Similarly, it would be morally wrong for a police sniper to kill a terrorist to protect the hostages he was holding. For, as in the lying example, the good achieved makes no difference morally. In either case, thinking otherwise involves the (alleged) mistake of thinking that there are some circumstances in which the duty can be overridden—to achieve some good or prevent some evil, for example. Understanding duties in this way guarantees that they are taken seriously. That is a good thing. But a good thing can be taken too far. The appeal of the notion of prima facie duty is that it allows us to take the notion

of duty seriously without the embarrassment of having to say something that smacks of absurdity, for instance, that the good that could be achieved by overriding a duty makes no difference morally. Where the absolutist conception of duty announces in advance, independent of experience in the situation, that this is so, the prima facie conception of duty says that we cannot know this a priori. To say that one has a prima facie duty not to lie, for example, is to say that there is a presumption in favor of this moral prohibition. That presumption can be overcome—the duty can be overridden—but the justificatory burden for an override is heavy, rather like the burden imposed on a prosecutor by the presumption of innocence in criminal law. That presumption is overcome when, using evidence and argument, a prosecutor eliminates any reasonable doubt on the part of jurors that the defendant is guilty. Similarly here, the case one makes for overriding a prima facie duty has to be strong enough to withstand critical scrutiny by reasonable men and women (e.g., one’s professional peers). Convincing oneself is not enough; the conflict of interest is patent: One ought not be judge in one’s own case.

A DEONTOLOGICAL PRINCIPLE

In *The Belmont Report*, the second principle above is called the principle of respect for persons; Beauchamp and Childress call it the principle of autonomy. The latter is the more common name for the principle. As noted earlier, the key difference between this principle and the first one is that the principle of autonomy does not invite and in fact eschews consideration of consequences. Its demand that human dignity be respected is not based on a forecast of good results, if it occurs. That respecting persons has good consequences is a happy coincidence rather than a reason for judging it right. Thus, in the interest of human dignity, those whose capacity for autonomous action is limited (e.g., children, the infirm) are *entitled* to protection.

This mode of ethical thinking, traditionally called deontological, makes a claim similar to the one made in the American *Declaration of Independence*, which speaks of rights that persons have independent of government, that are, in fact, the reason that governments are established (governments are established to secure and protect them). Rights created or given by government could be as easily destroyed or taken away, presumably on the basis of some calculations about advantage (for the king or the people, for example). The “must” associated with the right/duty relationship here is conditional, i.e., it depends on the advantage generated by its being respected. Deontological thinking denies this contingency; its “must” is

unconditional. Thus, the “must” of respect for persons has nothing to do with efficiency in the pursuit of a goal and the gain it promises. An idea found in the moral philosophy of Immanuel Kant may be helpful. Kant taught that a person has an intrinsic rather than an instrumental value (dignity instead of a price). Accordingly, a person must be treated as an end and never as a mere means to an end. When a person is treated as a mere means to an end, human dignity is denied; the person is treated as a thing. This is a very powerful and appealing idea. Indeed, in the form of a doctrine of natural rights it has inspired men to revolution.

In much the same spirit that the duty not to harm was said to have primacy in consequentialist thinking, it has been argued that the principle of autonomy must carry the day in any conflict with a consequentialist principle (i.e., be regarded as absolute). However, in biomedical ethics, no principle has pride of place; all four are prima facie principles, each one establishes a strong presumption in favor of the duties it entails. In each case, the considerations that argue for the principle are weighty. Yet, in each case, particularly when the principle is brought to bear in context, there are things that make one pause. If these principles were treated as absolute, these difficulties would likely derail any attempt to apply them. For example, in the case of nonmaleficence, does an amputation necessary to save a life constitute prohibited harm? If not, why not? If the answer is that it does not count as prohibited harm because a greater good is achieved by means of it, surely we would be better off to frankly admit that what we are doing is weighing competing principle-based considerations. Practitioners do not have time to engage in a semantic charade aimed at preserving the absolute character of a principle. Similarly, with the principle of autonomy, under what conditions does an individual possess or cease to possess autonomy in the requisite form? It will be granted readily that infants, small children, and adults seriously impaired by Alzheimer’s, for example, do not have it. But what, precisely, are the conditions for recognition or denial? A moment of reflection on the ethical questions about suicide and passive voluntary euthanasia reveal the problems: Does a would-be suicide or a person requesting euthanasia satisfy the conditions of autonomy and thus have a right to deference by healthcare professionals to his/her autonomous decision? Can/should this question be answered without carefully considering the merits of individual cases?

One of the attractions of an absolute principle is that wherever it is applied, it would generate answers in the fashion of an algorithm thereby freeing us from the burdens and responsibilities of judgment. Trouble is, so far, no purportedly absolute moral principle has

emerged from theoretical interrogation intact. Moreover, in light of the stakes and the nuances of human interaction and interdependence, reliance on a set of prima facie principles applied in good faith is clearly to be preferred to “moral algorithms” that are not quite what they purport to be after all.

JUSTICE

The need to rely on judgment exercised in good faith is especially clear when we turn to the fourth principle, justice. Another thing becomes clear as well. The scope of biomedical ethics is such that it is nearly impossible to maintain sharp boundaries between it and other normative disciplines such as social and political philosophy, jurisprudence (legal philosophy), law, and politics. When we ask about the distribution of benefits and burdens in society, for example, when we query whether it is just or fair that the rich and powerful benefit from medical advances that emerge from clinical trials or studies conducted on the weak and the poor, we are in an area where ethical concerns overlap mightily with social, legal, and political concerns. So too when the problem we confront is the allocation of a scarce resource such as organs for transplantation.

What is justice? One answer is that justice consists in treating similar cases similarly and dissimilar cases dissimilarly, the dissimilarity in treatment being proportional to the difference between the cases. This essentially Aristotelian answer is likely to meet with nodding agreement. This is, however, a formal principle. Clearly, we need to know how, that is on what basis, similarity is measured. The relevant similarity might be in need, effort, contribution, or merit, for example. Or we might think that everyone should be treated equally regardless of differences in need and so on. Fig. 1 presents these competing (available) bases for justice in distribution; each gives rise to what is called a material principle of justice. Each of these material principles has some claim on our attention. However, in the context of biomedicine, many find need especially relevant and thus the most compelling of the competing alternatives. It is true, however, as Beauchamp and Childress observe, that there is no obvious obstacle to an embrace of all five as principles that entail prima facie duties.^[12] The key point, as before, is that the moral force of these principles (“their actual weight”) cannot be determined a priori; such an assessment is possible only on the ground, so to speak, in light of the particulars of a situation. Adjudicating among these material principles is a challenge of the first order to be undertaken seriously and in good faith.

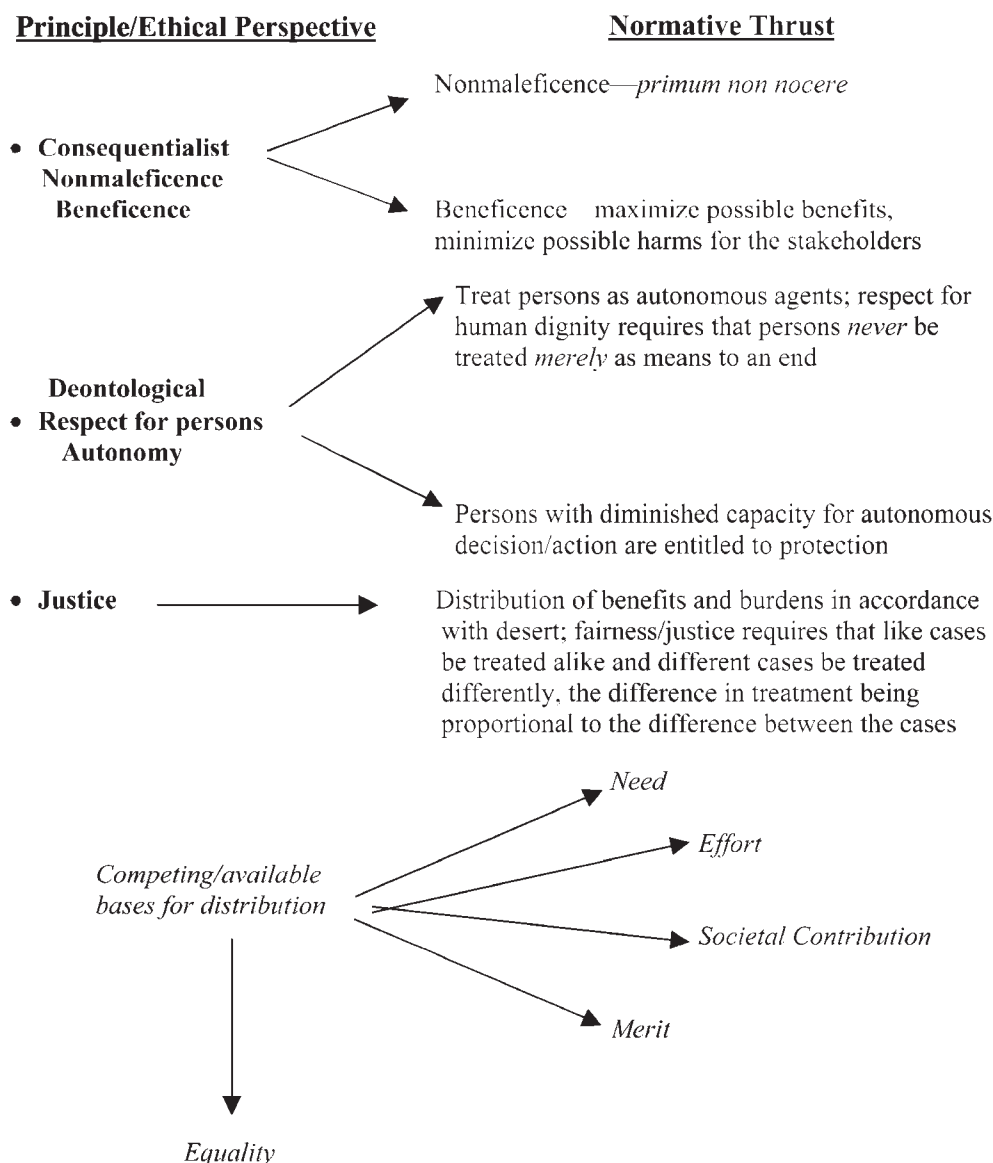

Fig. 1 The prima facie principles of biomedical ethics are tools/instruments of practical ethics. They are not absolute; they do not function algorithmically. Their application in concrete situations requires the exercise of judgement in good faith.

CONCLUSIONS

In closing, it will be well to return to a point about the birth of biomedical ethics. One of the key factors in the beginning was the need to respond to significant and rapid changes in medicine, especially advances resulting from research or emerging technologies. Thus, for example, practitioners faced ethical questions not encountered previously at the end of life (e.g., how to ensure a patient a meaningful measure of control over treatments he or she will receive as life ends; how, in the absence of advance directives, to determine whether further medical intervention is appropriate); at the start of life too, new questions emerged (e.g., whether it is permissible to conduct stem cell research that requires the destruction of human embryos left

over from and slated for destruction after successful in vitro fertilization, which was itself a source of moral controversy when the first “test tube baby” was born).

The need to respond to rapid changes in medicine continues and in fact seems destined to grow. Consider, for example, organ transplantation. There is a shortage of transplantable organs. The shortage is the result of an increase in demand, which, in turn, is the upshot of improvements in the methods for preserving and transporting organs and, most important, the discovery of cyclosporine, which suppresses the immune system so that the recipient’s body does not reject the transplanted organ. Consequently, questions that seemed merely academic 20 yrs ago are quite real and pressing. For example, should there be a market in transplantable organs? Or, alternatively, (a) should

requests to allow transplantation be legally required or (b) should there be a legal presumption that potential donors would agree to their organs being taken for transplant, unless they have opted out? It is essential that these questions and others like them are addressed in a systematic, reflective, and a responsible way. The principles of biomedical ethics discussed above will not provide algorithmic answers to these questions, but they are clearly germane. Moreover, seen as tools/instruments of practical ethics and applied in good faith, they appear well suited to meet this very real need.

Biomimetic Materials

Jun-ichi Kikuchi

Graduate School of Materials Science, Nara Institute of Science and Technology, Nara,
Japan

INTRODUCTION

Although the subdivision of science has given us numerous discoveries and a wealth of knowledge to understand biological systems, the importance of the boundaries between biology and other research fields was pointed out in the middle of the last century. The concept of biomimetic materials was born during the course of studies aimed at mimicking excellent and fascinating biomaterials. Much effort has been devoted to developing biomimetic materials from various points of view. The significance of biomimetic approaches is not only simple mimicry of biomaterials, but also the development of new materials exhibiting unique biomimetic functions. This article discusses biomimetic materials research and its future.

MIMICS OF CELL COMPONENTS

In biochemistry, biomaterials are classified into four main categories depending on each characteristic molecular structure and its consequence in the biochemical function. The categories are proteins, lipid membranes, nucleic acids, and polysaccharides. These biomaterials are macromolecules composed of covalently or noncovalently assembled small molecules, such as amino acids, lipids, nucleotides, and sugars. There are thus two approaches to the design of biomimetic materials: structural and functional mimicking. Major biomimetic materials and their biomaterial building blocks are shown in Fig. 1.

Protein Mimetic Materials

The focus of the early stages of biomimetic materials research was on the mimicking of functional proteins and on catalysis (or enzymes), because studies on enzyme models were useful in unveiling the reaction mechanism of enzymes.^[1–3] In general, enzymatic reactions proceed through formation of an enzyme-substrate (ES) complex. The process of forming this complex is intrinsic to the catalytic performance of enzymes, including high reactivity and strict substrate

specificity. Three types of enzyme mimicry capable of forming the ES complex—macrocyclic compounds, micelles, and polymers—have been proposed.^[4]

Macrocyclic compounds having an inner cavity as the substrate-binding site are simplified structural models of the enzyme active site (Fig. 2). Cyclodextrins (cyclic oligomers of glucose) are typical examples of the macrocyclic enzyme models.^[5] They are called α -, β -, and γ -cyclodextrins depending on whether the number of the glucopyranose units is 6, 7, or 8, respectively. The cyclodextrins bind hydrophobic substrates into their cavities in aqueous solution, and have two rims of hydroxyl groups that can either react with substrates themselves or be used to attach to other catalytic and functional groups. The introduction of multiple functional groups into cyclodextrins is essential to the design of more sophisticated artificial enzymes. For example, a β -cyclodextrin bearing two imidazolyl groups acts as an excellent artificial ribonuclease showing turnover behavior (possibly through the bifunctional catalytic assistance of the imidazolyl groups). On the other hand, a compound carrying both a pyridoxamine and an ethylenediamine unit attached to a β -cyclodextrin on the neighboring primary methylene groups has behaved as a potent artificial aminotransferase. Aromatic L- α -amino acids such as phenylalanine, tryptophan, and phenylglycine have been generated with high enantiomeric excess through transamination reaction.

Cyclophanes—synthetic macrocycles with aromatic ring(s)—have also proved to be useful as attractive components of artificial enzymes.^[6] Whereas a relatively limited range of structural modifications is possible with cyclodextrins, a wide synthetic variation of cyclophanes can be achieved so that, with regard to size, shape, and microenvironment, an appropriate recognition site can be provided for a target substrate molecule. Crown ethers, discovered by Pedersen in 1967 (for which discovery Pedersen, Cram, and Lehn were awarded the Nobel Prize in Chemistry in 1987), can act not only as ionophores but also as key components of artificial enzymes in organic solutions.^[7] Calixarenes, developed by Gutsche, belong

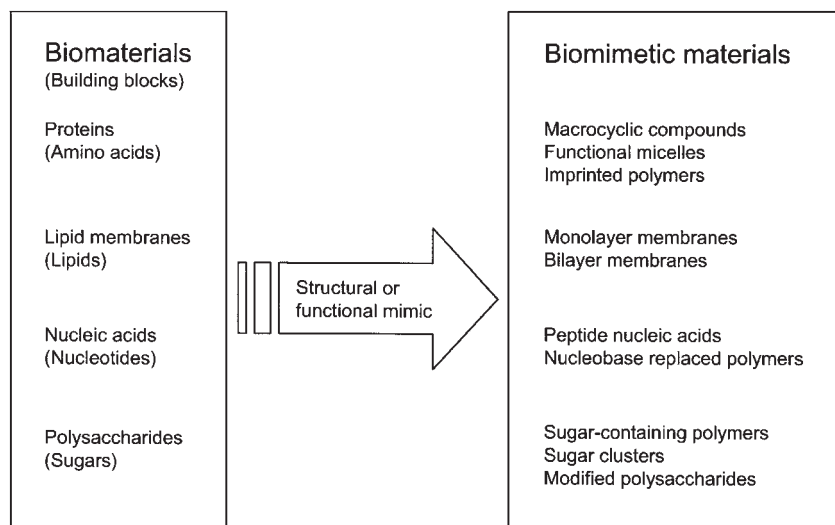

Fig. 1 Classification of biomimetic materials.

by definition to a family of cyclophanes; much attention has been focused on their catalytic functions as artificial enzymes based on their versatile molecular recognition abilities.^[8] Other macrocyclic compounds such as cryptands, spherands, and cucurbiturils seem to be feasible as equally promising enzyme mimics.

Another type of enzyme mimic provides a substrate-binding site as a result of the self-aggregation of functional elements through noncovalent intermolecular interactions in solutions.^[4] These are the surfactant

micelles, which, in aqueous media, have been widely employed as enzyme models. Reverse micelles formed with various surfactants in apolar solvents in the presence of small amounts of water have also been extensively studied for the characteristic features of their cores in enzyme-mimetic reactions.

On the basis of their structural resemblance to enzymes, various kinds of biomimetic polymers have been developed as artificial enzymes. These polymers are mainly classified into modified biopolymers and

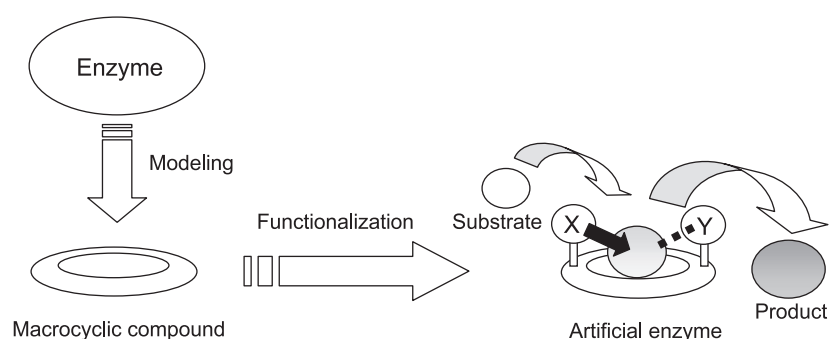

Fig. 2 Examples of biomimetic materials employing macrocyclic compounds.

totally synthetic functional polymers. The design of artificial enzymes through site-directed mutagenesis (an example of the former classification) has been well established.^[9] By single or multiple replacement of amino acid residue placed in the enzyme protein, enzymatic functions such as reactivity, substrate specificity, and reaction selectivity can be altered. Incorporation of unnatural amino acids and nonamino acids into proteins has also been made possible by employing site-directed mutagenesis, expanding the genetic code.^[10] Development of catalytic antibodies or abzymes is another fascinating approach to artificial enzymes.^[11] The concept of catalytic antibodies is that, if a putative transition state analogue of a reaction for which a selective and efficient catalyst is desired is used to elicit antibodies, they are likely to catalyze the reaction of a parent substrate. Although the site-directed mutagenesis and the catalytic antibody technique are useful genetic methods, the chemical modification of enzymes remains a valuable tool for protein engineering. The latter approaches are divided into direct modification of an enzyme protein and modification of a cofactor bound to the enzyme.^[12,13]

As regards enzyme mimics formed with totally synthetic polymers, relatively simple water-soluble polymers with catalytic functionalities were employed in early studies.^[4] Although the simulation of enzymatic behavior was successful to a degree by employing such prototype models, recent interest has focused on more intelligent synthetic polymers, such as imprinted polymers^[14] and dendrimers.^[15] When a polymer is prepared in the presence of print molecules as the transition state or intermediate analogue (extracted after polymerization), the remaining polymer may contain catalytic cavities capable of recognizing the print molecules. On the other hand, because dendrimers are structurally regulated polymers with an inner core like an active enzyme site, the characteristics that make them enzyme mimics have also been attracting attention recently.

The basic concepts of artificial enzymes can be applied to the design of artificial receptors, which recognize a signaling ligand to respond.

Membrane Mimetic Materials

Lipids are major constituents of biomembranes. As regards membrane-forming lipids such as phospholipids and glycolipids, their important functions generally derive from their formation of molecular self-assemblies that provide internal phases with defined sizes, shapes, and microenvironments for the incorporation of various biomolecules into their fluid matrices. Biomembranes exercise recognition and response to signal molecules, material separation and

transport, fusion, endocytosis, and exocytosis as cellular functions. Spontaneous formation of the lipid bilayer membranes was first reported by Bangham and Horne in 1964 for aqueous dispersions of naturally occurring phospholipids. In 1977 Kunitake and Okahata demonstrated that a totally synthetic bilayer membrane can be formed by a simple lipid, didodecyl-dimethylammonium bromide. These topics led to extensive research on lipid assemblies as biomembrane mimics.^[16]

There are several types of lipid assemblies as biomembrane models. The spreading of a lipid at an air-water interface leads to formation of monolayer membranes. Because they present one-half of the biomembrane's lipid bilayer, the lipid monolayer often utilized to understand the physicochemical characteristics of biomembranes.^[17] Investigations of the monolayer membranes supply precise information about the molecular packing and orientation of lipids that cannot be obtained from the bilayer membranes. Highly ordered, ultrathin Langmuir-Blodgett (LB) films, which are obtained by transferring lipid monolayers onto solid substrates,^[4] and self-assembled monolayers (SAMs) of thiolate lipids covalently bound on metal surfaces^[18] are expected to be useful as functional elements for biomimetic materials, especially for molecular devices. Liposomes are spherically closed lipid bilayer vesicles with an aqueous inner compartment formed in aqueous media. Vesicles prepared by various methods differ in diameter as well as in number of bilayers. For example, the sonication of lipid suspensions in water leads to small unilamellar vesicles whose diameter range is 20–100 nm. The swelling of lipid films with water under appropriate conditions, however, affords to uni- or multilamellar giant vesicles with the size of a cell. Planar lipid bilayers are another type of biomembrane model. They can be prepared either as freestanding black lipid membranes^[4] or as supported planar bilayer membranes.^[19] Various kinds of biomembrane processes have been simulated by employing these membrane mimetic materials.

In focusing on lipid bilayer membranes, relationships between the molecular structures of lipids and their consequence on assembling behavior have been systematically investigated up to the present. Thus it is relatively easy to design synthetic lipids showing expected aggregate morphology and physicochemical characteristics. As one such example, synthetic peptide lipids bearing amino acid residue, interposed between a polar head moiety and a hydrophobic double-chain segment through peptide bonds, have been developed.^[20] The peptide lipids that have an ionic head generally form stable bilayer membranes in aqueous media. Morphological stability of the unilamellar vesicles is greatly enhanced through formation

of the hydrogen-belt domain in the membrane. Owing to such strong hydrogen bonding interactions among amino acid residues of the lipid, phase transition parameters for the membrane from gel to liquid-crystalline phase are predictable from the molecular structure. In addition, the nonlamellar aggregates adopting inverted cubic or inverted hexagonal phase (suggested to participate in the membrane fusion process) can be systematically created by adjusting the critical packing parameters of the peptide lipids in the aggregate. Whereas the peptide lipids are effective biomembrane models, the bilayer vesicles act as artificial enzymes upon incorporation of the hydrophobized coenzyme moiety such as vitamin B₆ and B₁₂.^[6]

Morphological stabilization of lipid membranes is an important requirement for biomimetic materials. Numerous methods to stabilize the lipid assemblies have been developed, mainly by using polymeric systems.^[21] The polymerization of lipids before or after their orientation in membranes has been studied most intensively. Other possibilities to stabilize lipid assemblies are based on the noncovalent binding of polymers to the membrane surface. Morphological stabilization of the bilayer vesicles has been achieved by introducing the concept of the organic-inorganic hybrid into the liposome chemistry. Thus bilayer-forming lipids with a trialkoxysilyl head moiety form the cerasome, a liposomal membrane with ceramic surface, in aqueous media.^[22] Hierarchical assembly formed with the cerasome is expected to apply to the biomimetic multicellular systems or artificial organs.

Nucleic Acid Mimetic Materials

Nucleotides serve as building blocks in the construction of nucleic acids, in which nucleotide subunits are covalently linked by the formation of a phosphodiester bond between the phosphate group attached to the sugar of one nucleotide and a hydroxyl group attached to the sugar of the next nucleotide. The fundamental role of nucleic acids in the cell is in the storage and retrieval of biological information. To elucidate and mimic the versatile functions of deoxyribonucleic acid (DNA) as genetic material and ribonucleic acid (RNA) as its transcribed messenger molecule, a wide variety of nucleic acid model compounds have been designed, which show sequence-specific recognition of messenger RNA and double-stranded DNA.

Peptide nucleic acids (PNAs), defined as oligomers of nucleobase amino acids, were originally designed as mimics of DNA-recognizing, major-groove-binding, triplex-forming oligonucleotides.^[23] The PNA is constructed of three basic parts: an α -amino acid, a nucleobase attached via an amide linker, and an

ethylene spacer. The pseudopeptide backbone of a PNA-containing glycine unit has proven to be a good structural mimic of the ribose-phosphate backbone of nucleic acids. Thus, PNA has attracted wide attention in medicinal chemistry for development of therapeutic gene (antisense and antigene) drugs, and in genetic diagnostics.

DNA is not only a carrier of genetic information, but is also a versatile supramolecular scaffold, arranging smaller organic structures into predesigned geometries. Replacement of the nucleobases in DNA with designer molecules (such as fluorophores, ligands for metals, helix stabilizers, and DNA shape mimics) has thus been reported.^[24]

Sugar (Polysaccharide) Mimetic Materials

Polysaccharides and glycoproteins participate in a number of biochemical reactions and cell-to-cell recognition processes. Synthetic carbohydrate-based polymers are increasingly being explored as biodegradable, biocompatible, and biorenewable materials for use as water absorbents, chromatographic supports, and medical devices. Moreover, synthetic polymers bearing sugar residues also offer a good surface for cell attachment and might thus be applied to cell recognition events in antimicrobial/viral and tissue engineering.

Various types of synthetic polymers bearing sugar residues have been developed.^[25] These polymers are classified into four major categories: linear polymers, comb polymers, dendrimers, and hydrogels. Linear polymers are usually linked through the anomeric position with other hydroxyl groups in the adjacent sugar residue. Comb polymers are prepared from polymerizable sugar derivatives. Dendrimers are synthesized in stepwise fashion from simple branched monomer units, and are considered one of the prime nanometer-scale building blocks in the construction of nanoscale objects, molecular devices, and advanced drug delivery systems. To design intelligent sugar mimetic materials, the introduction of a cluster glycoside effect (or the enhancement of valence-corrected binding activities of saccharide ligands) are of great importance.^[26] Cross-linked polymers and hydrophobized polysaccharides have been developed as sugar-based hydrogels. Cholesterol-bearing pullulan forms self-assembled hydrogel, which assembly acts as an artificial molecular chaperone that selectively traps heat-denatured proteins and intermediates in refolding to prevent irreversible aggregation.^[27]

HOW TO MIMIC BIOMATERIALS

Although the foregoing presents a wide variety of approaches to the mimicking of biomaterials, one

guidepost in the creation of intelligent biomimetic materials is the hybridization of the functional building blocks of biological and artificial molecules. Typical examples of biomimetic materials prepared through the hybridization of functional building blocks are listed in Table 1.

As regards amino acids, their hybrids with sugars through covalent bonds have been present as biomaterials (glycoproteins). Hybrids of a polypeptide with a naturally occurring functional small molecule (such as coenzyme and cofactor) act as biocatalysts, (holoenzymes) for the reactions that cannot be catalyzed by the apoprotein alone. Thus, hybrid materials of amino acids with lipids, nucleotides, and artificial building blocks are candidates for biomimetic materials. Peptide lipids^[20] and peptide nucleic acids^[23] that have been designed according to this concept are excellent biomimetic materials, combining characteristics of each building block. Functional fusion of the catalytic group of amino acids with various artificial building blocks (such as cyclodextrins, cyclophanes, and crown ethers) produces catalytic macrocycles as artificial enzymes.^[5,6]

Several kinds of biomimetic hybrid materials that use lipids as building blocks have been developed. In addition to peptide lipids, hydrophobized polysaccharides, and cerasomes, nucleolipids^[28] form a hybrid with nucleotides, and octopus cyclophanes^[6] form a hybrid with cyclophanes. Nucleolipids (with a nucleobase as a polar head moiety of the lipid molecule) have been developed to clarify complementary interactions at the interface of the lipid assemblies. Octopus cyclophanes are unique amphiphilic macrocycles, capable of performing induced-fit molecular recognition and utilized as artificial enzymes and receptors.

Because of the diversity of molecular design in artificial building blocks and connection modes with

other counterparts, a large number of biomimetic hybrid materials (in addition to the examples in Table 1) have been reported.

MIMICS OF BIOLOGICAL SYSTEMS

An examination of biological systems highlights the existence of various functionally connected supramolecular systems, including metabolic and energy conversion systems and information networks. The second stage of biomimetic materials science should thus aim at construction of the supramolecular systems or molecular devices in which the functional connection of biomimetic materials with each other or with biomaterials can be achieved. A molecular platform capable of arranging individual functional elements is required for this purpose. The layer-by-layer assembling technique through multiple electrostatic interactions is a powerful tool to construct such nanoarchitectures on solid substrate.^[29] In the biomimetic sense, however, lipid membranes as biomembrane mimic are a fascinating platform for molecular organization; much effort has been devoted to constructing membrane mimetic supramolecular systems.^[6,22] Typical examples of such systems constructed in lipid bilayer membranes are shown in Fig. 3.

Setting up multienzyme systems in combination with natural and artificial enzymes is fascinating. An artificial multienzyme system has been developed that combines a catalytic bilayer membrane as artificial aminotransferase with a natural lactate dehydrogenase (Fig. 3a). The artificial aminotransferase is composed of a peptide lipid bilayer as apoenzyme model, a hydrophobized pyridoxal derivative as potent coenzyme derivative, and metal ions as cofactor. The multienzyme complex is formed with the lactate

dehydrogenase and the artificial enzyme, primarily through multiple electrostatic interactions. This hybrid system enhances catalytic activity if the artificial enzyme promotes the sequential transformation of α -amino acids to the corresponding α -hydroxy acids via formation of α -keto acids, showing marked substrate specificity. A multicomponent vesicular system has also been developed in which electrons derived from the enzymatic decarboxylation of pyruvate serves to reduce a synthetic, membrane-spanning steroidal

Mn(III) porphyrin and to mediate subsequent oxygen activation and transfer.

As an energy conversion system, an artificial photosynthetic membrane can be constituted that combines a liposomal bilayer, an artificial proton-pumping photocycle, and F-type ATP synthase (Fig. 3b). The proton pump is driven by vectorial photo-induced electron transfer in a synthetic carotene-porphyrin-naphthoquinone molecular triad. On accumulation of efficient proton motive force, proton flow through the coupling factor in thermodynamically allowed, with the concomitant formation of ATP from ADP and inorganic phosphate.

Detection of an external signal on the cell surface is accomplished by a specific receptor, and the signal recognition of the receptor molecule then stimulates the required intracellular response. Such signal transduction behavior mediated by cell-surface receptors presents various examples of supramolecular systems. In relation to the ion channel-linked receptor, a bio-sensing system has been developed, in which the conductance of a population of molecular ion channels is switched by the molecular recognition event. This approach mimics biological sensory functions and can be used with many types of receptors, including antibodies and nucleotides. An artificial signaling system inspired by biological signal transduction and mediated by the G-protein-linked receptor is another example. Because the G-protein is regarded as a signal transmitter between a cell-surface receptor and an enzyme, a strategy can be adopted that replace the G-protein in an artificial system by a simple mediator species capable of affecting both receptor and enzyme functions. Thus, a supramolecular system has been designed, based on an artificial receptor, a signal mediator, and a natural enzyme, placed on the lipid bilayer membrane (Fig. 3c). In this system, information of an external signal binding to the receptor molecule is transferred to the effector via a signal transmitter, followed by amplified signal output as enzymatic reaction.

CONCLUSION

Extensive studies of biomimetic materials have unveiled structural and functional mysteries in biological systems and have advanced synthetic and analytical procedures in materials science. At present, we have a wide variety of biomimetic materials exist that are not simple mimics of biomaterials, but are new materials and molecular devices that exceed biological functions. Further conceptual fusion of the biological and materials sciences may lead to a new field of science—bioinspired materials science.

Biopotential Amplifiers

Albert Lozano-Nieto

Engineering Technology and Commonwealth Engineering, The Pennsylvania State University, Lehman, Pennsylvania, U.S.A.

B

INTRODUCTION

The vast majority of biomedical amplifiers have been specifically designed to detect, measure, and record biopotentials, i.e., voltages and electrical fields generated by nerves and muscles. The measurement of these biopotentials is not a trivial task as their level is low (around 1 mV although they can be as low as 1 μ V) and is also immersed in noisy environments including internal and external interference.

This article starts with a short description of the different types of biopotential signals, followed by the requirements for amplifiers to detect biopotential signals and their design. After discussing the different interference sources for biopotential amplifiers, the entry analyzes the methods to mitigate their effects. The final section in this article describes how the generic biopotential amplifier described earlier is used for the measurement and detection of the different types of biopotential signals described at the beginning of this article.

BIOPOTENTIALS—ORIGIN AND NATURE

Biopotentials are produced as the result of some electrochemical activities in excitable cells. The voltage that can be measured across the membrane of these cells presents two very distinct periods: *action potential* when they are properly stimulated and *resting potential* without stimuli. During the resting potential phase, the voltage across the membrane of the cell is kept constant at a value that can range from 50 to 400 mV, with the exterior of the cell being more positive than the interior of the cell. This is also referred as the cell membrane being *polarized*. In the presence of an adequate excitation, the cell becomes *depolarized* acquiring an opposite voltage up to 60 mV that is independent of the amount of stimuli applied to the cell. This period of change in voltage polarity is called the action potential. After the action potential has been triggered, the ability of the cell to respond to another stimulus is extremely restricted. During the initial period of the action potential, the cell is not able to respond to any stimulus no matter how intense. This period is called *absolute refractory period*. It is followed

by the *relative refractory period* in which another action potential can be triggered by a stimulus of much higher value.^[1,2]

Biopotentials can then be viewed as the additive contribution of all the several action potentials propagating through the conductive tissue. Therefore, biopotentials can be classified depending on the type of cells and tissue, thus yielding the traditional biopotential signals. Furthermore, it is also important to note that because of the travel and propagation of these signals, the shape, amplitude, and other characteristics of biopotentials detected on the surface of the body will be very different from those detected inside the specific tissue that one wants to measure.

TYPES OF BIOPOTENTIALS

The following are some of the most common types of biopotentials. This is not an exhaustive list however. A more complete and detailed list of biopotentials can be found for example in Ref. [3].

Electrocardiogram

The electrocardiogram (ECG or EKG) is probably the most and best characterized biopotential and therefore is the one used mostly in the clinical practice. The cells that form the different tissues in the heart (sinoatrial and atrioventricular nodal tissues, atrial, Purkinje, and ventricular tissues) have very differentiated action potentials that in turn originate the composite signal known as ECG. The detailed explanation of the sequence of events for the electrical activation of the heart chambers as well as the interpretation of the resulting signal is beyond the scope of this section and can be found elsewhere.

The electrical activity of the heart as recorded on the surface of the body is the signal known as ECG. However, when it is necessary to record signals of higher magnitude to evaluate the significance of very small fluctuations, or when it is necessary to acquire the high-frequency components of the action potentials in the heart, the traditional ECG has several problems. These are mainly owing to the attenuation that the

electrical signals suffer as they travel through the different tissues of the body surface, the low-pass filtering associated to the same condition and the problems associated with the electrode-to-skin interface.^[3] In these situations, there are several alternatives for measuring the biopotentials of the heart with a higher degree of accuracy: In the *esophageal* ECG, the detection electrodes are placed inside a pill that is ingested by the patient and is stopped when it reaches the esophagus.^[4] Because of the closer proximity of the electrodes to heart and the absence of the electrode-to-skin interface and of motion artifacts, the signal obtained is much clearer and with more details, being especially useful to analyze the lower voltage amplitudes of the P-wave. By means of a cardiac catheterization—most of times done for other medical reasons—it is then possible to detect and record the action potentials inside the heart.^[5] This technique allows recording these signals with the highest bandwidth possible.

Electroencephalogram

The term “electroencephalogram” (EEG) is referred to the diverse techniques that are used to record the fluctuations in potential owing to the activity of the brain. Different types of electrodes are used depending on their location, giving rise to different types of signals.^[6]

1. Electrodes on the scalp surface that are small silver pads or cups for the standard EEG.
2. Sphenoidal EEG, using alternate insulated silver and bare wire and chloride tip inserted through muscle tissue by a needle.
3. Nasopharyngeal EEG, by means of silver rods with silver balls at their tips inserted through the nostrils.
4. Electroencephalographic signal, using cotton wicks soaked in saline solution that rests on the brain surface.
5. Intracerebral signal using sheaves of Teflon-coated gold wires, used to electrically stimulate the brain.

However, the most common type of EEG is performed with electrodes placed on the scalp, after the area has been cleaned with alcohol to remove skin oils. In this case, 20 small surface electrodes are placed on the patient’s scalp according to a normalized location map. The resulting signal for all these three cases is the superposition of the signals generated by a wide variety of neuronal current generators. In contrast to the ECG in which each part of the signal is clearly differentiated and the point of the heart where it originated is known, the EEG signal is made of a series of irregular waves,

without a general pattern. The clinical analysis of the EEG signal is based on the frequency classification of the waves and their amplitude.^[7]

Electromyogram

The electromyogram (EMG) is the combined result of action potentials from skeletal muscle tissue called the *motor unit*. The EMG can be recorded using surface electrodes, although they can only be used with superficial muscles. The EMG signal recorded this way is sensitive over a wide area, thus originating from an unpredictable signal in which only its amplitude may be relevant. To avoid these problems, the EMG can also be recorded using several types of insertion-type electrodes that are useful to detect signals from deep muscles or from small regions within a muscle.^[8]

Electroretinogram

The electroretinogram (ERG) uses two electrodes: one electrode known as the exploring electrode attached to the cornea in a manner similar to a contact lens, and a reference electrode placed elsewhere on the body surface. When the retina is stimulated with a brief flash of light, it is possible to record a very specific sequence of action potential changes known as ERG.

Electrooculogram

The electrooculogram (EOG) is a technique used to record the movement of the eyes, normally for sleep and dream research, although it has also been used to measure levels of alertness. In an EOG, two electrodes are placed to the left and right of the eye, in the nose and temple. When the eye moves in one direction, the voltage increases in the electrode closer to the eye movement. By placing the electrodes above and beyond the eye, it is also possible to measure vertical eye movements.

REQUIREMENTS FOR BIOPOTENTIAL AMPLIFIERS

Given the characteristics of bioelectrical signals discussed previously, the general requirements for biopotential amplifiers can be summarized as:

1. Have high input impedance to not distort the biopotential signal that needs to be measured.
2. Provide electrical isolation to not influence or modify the physiological parameter to be measured.
3. Have a bandwidth adequate to the biopotential signal to measure, normally including DC-rejection

and limited enough to not increase the noise level.

4. Provide enough gain within its bandwidth to have an output level compatible with the rest of the measurement system.
5. Reject, as much as possible, the noise in the system as well as the other interfering signals.
6. Have low output impedance and be able to supply the amount of current necessary to the load.
7. Have the means or provisions for calibration to guarantee the accuracy of the processed signals.

In addition to these generic requirements, each application will demand additional requirements to meet the specific requirements demanded by a specific biopotential signal.

DESIGN OF BIOPOTENTIAL AMPLIFIERS

A typical configuration of an amplifier for biopotentials is shown in Fig. 1. It consists of two input electrodes that are used to measure the biopotential (*measuring electrodes*) and a third electrode used as reference (*reference electrode*), normally connected away from the other two. The two measuring electrodes are connected to the input stage of a differential amplifier. The mission of the differential amplifier is to amplify the signal between the measuring electrodes while rejecting any unwanted signals, either other biopotentials or external sources of interference.

In Fig. 1, V_d represents biopotential to be measured that with these configurations appear as a differential voltage, while V_{cm} represents the voltage that appears in both inputs, known as *common-mode voltage*. This voltage is normally produced as interference

Fig. 1 Typical configuration of an amplifier for biopotentials. For simplification purposes, this figure does not include electrode impedance.

by the power lines surrounding the measurement system as well as interference from nearby instruments and even interference from other biopotential signals.

Ideally, the output of the biopotential amplifier could be represented as

$$V_o = A_d V_d \quad (1)$$

where V_o is the output of the amplifier, V_d is the differential voltage, that is, the biopotential to be measured and A_d is the differential gain of the biopotential amplifier.

From Eq. (1) it can be seen that for an ideal biopotential (differential) amplifier, the output is totally independent of the interfering voltage and only responds to the biopotential to be measured as differential input. It is necessary to mention that strictly speaking, not any differential amplifier can be used as a biopotential amplifier. Only those differential amplifiers that meet the requirements specified in the previous section—and in particular the requirement of high input impedance—can be used as biopotential amplifiers. These differential amplifiers are commonly known as *Instrumentation Amplifiers*.

With real electronic devices, however, this ideal situation is never achieved.^[9] Eq. (2) shows more realistic representation of the voltage at the output of the differential biopotential amplifier

$$V_o = A_d V_d + A_{cm} V_{cm} \quad (2)$$

where V_{cm} is the common-mode voltage at the input of the differential amplifier, and A_{cm} is the common-mode gain for the amplifier.

An additional problem arises when considering the relative magnitude values of the biopotentials to detect the interference signals. While biopotentials—differential signal—do not normally exceed 1 mV, the common-mode interfering signals can very easily have values around 30 V. With these circumstances it is then imperative that $A_{cm} \ll A_d$ in order for the output voltage to be meaningful by having a low value of error.

To give a figure of merit or quality to a differential amplifier, the parameter *common-mode rejection ratio* (CMRR) is generally used. The CMRR of an amplifier is defined as the ratio of differential gain to common-mode gain:^[10]

$$\text{CMRR} = A_d / A_{cm} \quad (3)$$

and is normally expressed in logarithmic units (decibels).

$$\text{CMRR}(\text{dB}) = 20 \log\{A_d / A_{cm}\} \quad (4)$$

We can then find the error term as follows

$$V_o = A_d\{V_d + V_{cm}/CMRR\} \quad (5)$$

Eq. (5) clearly shows that the error term ($V_{cm}/CMRR$) can be minimized by increasing the value of CMRR as much as possible. However, there are some factors that limit the increase of CMRR from a design and construction point of view. The previous calculations have been derived from an overidealistic case in which we have assumed that the input impedances to the differential amplifier, both in common-mode and in differential modes were infinity. In a realistic situation, the finite values of these impedances as well as their unbalances will contribute to degrade the value of CMRR, thus increasing the error in the output measurement. The CMRR decreases as the frequency of the signal increases. The study of how CMRR is affected by design parameters, design topologies, and type of semiconductors used is beyond the scope of this entry. However, it is generally accepted that the CMRR for a biopotential amplifier should be higher than 100 dB, preferably in the range of 120–140 dB.^[11] It is also accepted that the minimum values of the input impedances to be at $10^9 \Omega$.

The bandwidth requirements for the biopotential amplifier are carried out with a low-pass filter (LPF) and a high-pass filter (HPF). The HPF is placed as close to the front-end of the system as possible. The goal of this filter is to eliminate the DC voltages (*offset voltage*) that appear as a consequence of the electrode-to-skin interface. This offset voltage does not show a constant value, making it necessary to eliminate its drift. The LPF is designed with a cut off frequency high enough so it does not distort the biopotential signal, but low enough so it does not add unnecessary noise to the system. Given the small magnitude of

biopotential signals, it is essential to preserve the signal-to-noise ratio in the measurement system. As mentioned earlier, a biopotential amplifier needs to incorporate galvanic isolation to prevent the possibility of inducing a macroshock or a microshock on the organism that is measuring. Although there are several methods to create electrical isolation, one of the most common methods is to use an isolation amplifier. This isolation amplifier will create galvanic isolation as well as will introduce additional gain in the measurement gain. In any case, it is necessary to keep in mind that if there are active components in the patient side of the system, these need to be powered by an isolated power supply. Some isolation amplifiers incorporate an isolated power supply to solve this problem, while in using other isolation amplifiers or other methods for isolation, it is necessary to specifically introduce this isolated power supply. Moreover, international standards specify the maximum amount of leakage that is permissible on the patient side for different applications. Fig. 2 shows a typical disposition of the different systems and components for a biopotential amplifier, although as it has been mentioned earlier, some of the systems or components can be placed at different locations.

INTERFERENCE IN BIOPOTENTIAL AMPLIFIERS

Any biopotential amplifier has two main requirements that are in principle opposite: Provide electrical safety to the organism under study and have the highest degree of protection against interferences, therefore having to reach a compromise between them. This happens because the most obvious approach and solution to eliminate interferences in a measurement system such as grounding the object under

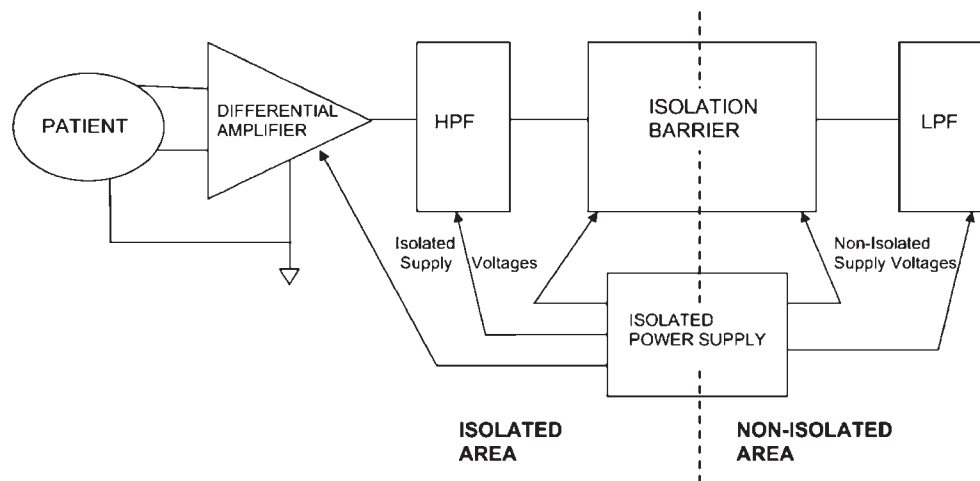

Fig. 2 Typical configuration for a biopotential amplifier. Depending on the specific type of biopotentials to detect, the HPF and LPF may be interchanged.

measurement cannot be applied here because it would result in a high risk of electrical shock. In fact, the degree of electrical isolation required for using biopotential amplifiers in human beings is a requirement that forces the need for a very careful design of the whole system to minimize the effect of interferences.

Interferences in biopotential amplifiers can be classified attending to their origin as

1. Other biopotential signals that occur simultaneously to the signal to be measured, such as the EMG signal when interested in measuring the EEG for example.
2. The voltage known as contact potential that appears in the electrode-to-skin interface owing to the chemical reactions. This signal can be eliminated by using a HPF, although the biopotential to detect may have energy components at a very low frequency, the design of this filter is not a trivial task.
3. Motion artifacts owing to electrode movements. The elimination of these interfering signals that can saturate the amplifiers requires the use of electrolytic gel to lower the contact impedance of the electrode, the selection of a front-end with a very high input impedance (above $1\text{ G}\Omega$) as well as choosing the front-end active devices with input offset currents as low as possible, ideally below 50 pA .
4. Respiratory movements that change the electrical characteristics of the thorax.
5. Triboelectric charges that may result in an increase of the patient-to-ground voltage owing to the accumulation of charges.
6. Interference from nearby high-power electrical signals such as electrosurgery units or even nearby high power radio, television, or radar facilities. In these situations, the patient leads act like an antenna. Other sources of similarly related electromagnetic interference are x-ray machines or switches and relays on heavy-duty electrical equipment.
7. Interference from the mains electrical distribution network.

From the enumerative list above, it is easy to see how the last item, the interference resulting from the main line distribution network can be the most harmful one, because it is the most difficult to eliminate and will always be present in a measurement system. Furthermore, the frequency of the mains line usually falls within the bandwidth of the biopotential amplifier, thus increasing the difficulties for its elimination. There are three paths for the energy from the mains electrical distribution network to enter the biopotential amplifier system and therefore become an interference signal.

These are capacitive coupling, inductive coupling, and resistive coupling.^[12]

Fig. 3 shows the basis for capacitive coupling: as the patient—that is acting as a conductor—is not grounded owing to safety reasons, it is possible to distinguish two stray capacitances, C_1 and C_2 , that are charged by the stray current I_s . I_s is generated by the voltage difference created by the mains generator and has typical values from 0.01 to $10\text{ }\mu\text{A}$. This originates a patient-to-ground voltage in the range from 100 mV to 1 V at 60 Hz depending on the values of C_1 and C_2 . It is important to note that the current I_s does not flow through the amplifier because of its high input impedance. Instead, it flows through the much lower skin-electrode resistance and stray capacitance to ground, thus closing the path. Although the patient voltage may seem low, it is indeed several orders of magnitude higher than the biopotentials to be measured. In addition to the patient voltage generated by the stray patient capacitances C_1 and C_2 , additional stray capacitances appear owing to the chassis of the amplifier not being grounded, thus increasing the amount of stray current and therefore the patient voltage with respect to ground.

Inductive coupling is owing to the current induction on wires and conductors generated by a variable magnetic field. These magnetic fields are generated by the power lines as well as by the transformers and ballasts in fluorescent lights. The main entry for this type of interference is through the cables that connect the amplifier to the electrodes. Inductive coupling can be greatly reduced by twisting the cables as much as possible and by avoiding cable loops of larger areas, as the value of the interfering voltage is proportional to the area of the effective loop.

Resistive coupling arises as a consequence of the resistance in the measuring wires, in particular the wires that connect the distant and proximal points in a measurement system. Because the return path is used by leakage currents to be drained to ground, they

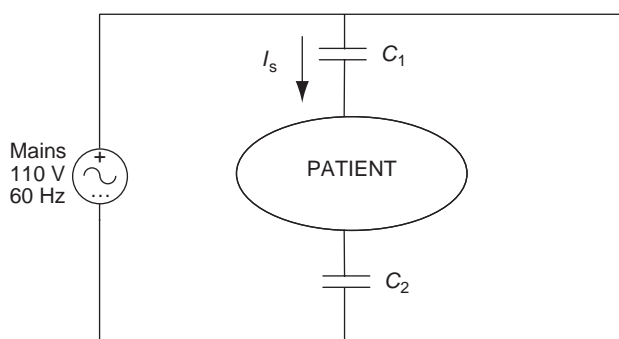

Fig. 3 Principle of capacitive coupling in which stray current flows through stray capacitances C_1 and C_2 .

generate an additional voltage that is not negligible and is present as a common-mode voltage superposed to the biopotential signals to be measured.

INTERFERENCE REDUCTION TECHNIQUES FOR BIOPOTENTIAL AMPLIFIERS

As seen earlier, much of the interfering signals are present as common-mode voltages. This is another reason why a differential amplifier with a high CMRR is absolutely necessary in the measurement of biopotential signals. A complementary approach for interference reduction is the elimination of the cause that originates the interfering signal when possible.

Electrostatic shielding is a technique useful to eliminate interference generated by electrical field, mostly through capacitive coupling.^[13] Shielding is accomplished by placing a grounded conducting plane between the source of electrical current and the measurement system as shown in Fig. 4. In this case, the interference current I_s is drained to ground as the impedance of the shield is much lower than the impedance presented by the stray capacitances inside the shield. Many hospitals have shielded rooms to measure EEG and other low-level signals. It is necessary to note, however, that the traditional electrostatic shielding is ineffective against magnetic fields. For shielding to be effective against magnetic fields, the shielding has to be made from a material that is a good electric and magnetic conductor, making its cost to increase for several orders of magnitude.^[14]

The elimination of ground loops is a technique useful to eliminate both inductive and resistive interference. As the magnetic interference is proportional to the area of the effective loop, by eliminating all ground loops, the number of areas that can pick up magnetic fields is drastically reduced. Furthermore, by designing grounding circuits so that there is a single unique path between each component and ground as well as a single

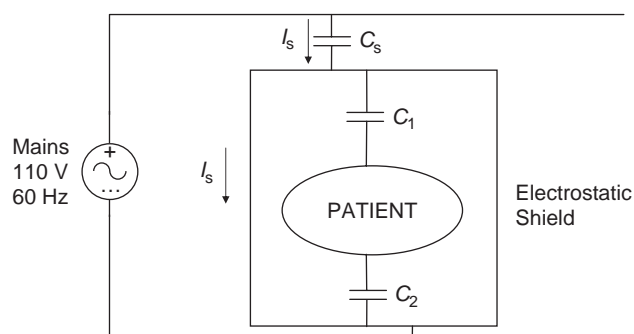

Fig. 4 Principle for electrostatic shielding, making the stray current I_s not to modify the voltage of the patient referred to ground.

unique path between the ground circuit of one component and that of any other component of the system, the interfering voltages generated by resistive coupling are eliminated.

Finally, a very common technique for interference reduction is the so-called *driven-right-leg* approach. In this technique, the right leg of a patient is connected to the output of an auxiliary amplifier whose voltage follows the inverted common-mode voltage in the patient. This approach keeps the patient ideally at 0 V, becoming a virtual ground without the risks associated to directly connecting the patient to ground. In reality, the characteristics of the amplifier used to reinject the common-mode voltage into the patient will determine the patient voltage, although in any case it will be greatly reduced.

TYPES OF BIOPOTENTIAL AMPLIFIERS

Amplifiers for Electrocardiographic Signals

A single electrocardiographic signal requires three electrodes as described earlier: two measuring electrodes and a reference electrode. The combination of how the measuring electrodes are placed on the body is called a *lead*. In the clinical practice, it is necessary to record more than one lead to fully characterize the electrical activity of the heart. There are a total of three basic leads (differential measurements between measuring electrodes), three augmented leads (unipolar measurements between one measuring electrode and a reference electrode denominated *Wilson's central terminal*), and six precordial leads. The detailed characteristics of all these leads can be found elsewhere in this volume.

An amplifier for electrocardiographic signals needs to accept and process the electrical signals originated by each one of these possible leads that have very different characteristics in terms of their amplitude and frequency components. For this reason, the first stage on an electrocardiograph is a lead selector that will choose the appropriate combination of the biopotentials on the patient for the lead or leads that need to be recorded.

Commercial amplifiers for ECG signals also incorporate a calibration signal for the operator or technician to verify the accuracy of the gain. The calibration signal is a 1 mV signal that produces a specific displacement of the needle on paper or on the output screen. The overall frequency response for an amplifier for ECG signals that has a flat bandwidth ranges from 0.14 to 25 Hz. The traditional method of recording ECG signals has been on a paper chart by using thermal-sensitive paper to avoid the friction of a writing instrument with the paper. However, with the advent of computers and networks of computers, ECG signals are increasingly displayed on a computer screen

and recorded on magnetic or solid-state media. However, when ECG is displayed on a computer screen, they still follow the traditional protocol of using a speed of 25 mm/sec as the clinical community is used to observing them.

Amplifiers for ECG signals also need to be protected against large signals generated by systems other than the amplifier itself. This happens, for example, in patients undergoing electrosurgery or being defibrillated while having an ECG amplifier attached to them. Ideally, an amplifier for ECG signals should be designed to be completely unaffected by these signals and continue functioning normally even after encountering these large signals. However, in practice this is not possible and designers need to settle for limiting the effects of these transient signals on the ECG signal to measure as well as to protect the equipment. This is achieved by connecting a voltage-protection device between ground and each one of the inputs from an electrode. These voltage-protection devices do not respond to the small-level signals generated by the cardiac biopotentials. However, when a certain threshold is exceeded—this threshold can be chosen by selecting the type of voltage-protection device to be used, normally in the range of 300–600 mV—they become active and drain all the signal to ground, thus protecting the ECG amplifier. It is also common to use different types of voltage-protection devices to ensure the protection of the biopotential amplifier against a wide range of harmful voltages. In addition to protecting the ECG amplifier, these voltage-protection devices also need to have a short recovery period because while they are active, blocking all the signals at the input of the amplifier, there is no recording of the patient's ECG. Another source of blocking the ECG signal in the presence of an over-voltage is the transient time required to discharge the HPF once it is saturated. Because the low-frequency response of the filter is at 0.25 Hz, the ECG signal may be blocked for several seconds after the offending signal has been eliminated.

Amplifiers for Electroencephalographic Signals

The clinical use of EEG signals requires the recording of more than one EEG channel, normally 8, 16, or 32 different channels chosen from the different combinations possible with the 20-scalp electrodes that are used following the standardized electrode placement. Therefore, the first stage is a matrix-like set of switches that routes and combines the appropriate signals that have been selected. The output of the switching system will contain 8, 16, or 32 signals—depending on the type of EEG system used—that are connected to the input of a set of amplifiers acting as preamplifiers.

These preamplifiers have differential inputs and have a constant gain of 1000. Given the very small amplitude of the EEG signals recorded on the scalp (approximately $5\ \mu\text{V}$), all the front-end is extremely susceptible to interference from the power-supply lines as well as noise from other physiological signals, mostly from muscle contractions. For this reason, it is very important that the front-end preamplifiers are powered with a power-supply as clear as possible. Other requirements for these preamplifiers are: low internal noise, CMMR in excess of 100 dB at the mains frequency, a low-pass cut-off frequency of 0.1 Hz or below, very low DC drift, and input impedance higher than $10\ \text{M}\Omega$. The outputs of the array of differential preamplifiers are now unipolar signals that are sent to an array of adjustable gain amplifiers. These amplifiers are used to condition the signals to the gain selected by the operator to a level that allows them to be digitized for computer storing and display, or drive power amplifiers for chart recording. We need to note once again, that the very low cut-off frequency of the amplifiers will increase the desaturation time if the amplifiers become saturated, normally owing to the presence of noise artifacts. In addition to the preamplifiers and amplifiers, it is necessary to introduce one adjustment for the sensitivity of the whole system and a set of adjustments for the sensitivity of each one of the unipolar amplifiers. These adjustments need the presence of a known and stable calibration signal that ranges from 5 to $1000\ \mu\text{V}$, injected into the differential preamplifiers.

The technique known as *averaging repetitive EEG* allows for detection and separation of the very small amplitude-evoked potentials from the background EEG. These evoked potentials or *cortical potentials* can be evoked from sensory stimuli, although their amplitude on the scalp is too small to be recorded by typical EEG amplifiers, thus requiring the averaging repetitive approach. The averaging technique has two effects: it enhances the evoked potentials signal while at the same time it reduces the ongoing EEG signals because of its random nature. The number of averages needs to be selected carefully as some information is lost in the process. A typical number of averages are approximately 100. The approach to detect evoked potentials is similar to the EEG, although in this case there is only one differential channel. After the signal is amplified, it is fed to a system for averaging. This system also synchronizes the stimuli that produce the evoked potential, either visual or auditory.

Amplifiers of other Bioelectrical Signals

Amplifiers used to detect and record the other bioelectric signals described earlier follow a similar

structure, mostly differing in the frequency bandwidth and the amplification level, thus placing different constraints in the design of the amplifiers. Additionally, the electrodes that are used to detect the signals may also have a strong influence. While the impedance of the interface between skin and ECG or EEG electrodes is generally low, other type of measurements may be affected by higher impedance at the interface as well as by the effects of more abundant drifts and presence of noise artifacts.

As mentioned earlier, the EMG signal has energy in the frequency range from 25 Hz to several kHz, with amplitudes that can range from 100 to 100 mV. This makes an EMG to have a much wider bandwidth than ECG or EEG amplifiers, but liberates them from the strong constraints of a low frequency as low as these amplifiers. This originates, in turn, that EMG amplifiers will have faster response times when saturated owing to motion artifacts. Furthermore, these low-frequency signals created by noise and electrode artifacts can be filtered to eliminate them. When using surface electrodes for the EMG detection, the amplifier will have to accommodate a bioelectrical signal in the range from 0.1 to 1 mV, with an electrode impedance generally low, below 1 kHz. These requirements are not very different from the specifications for an ECG amplifier. However, when using intramuscular needle electrodes for EMG detection, the amplitude of the bioelectrical signal increases in about one order of magnitude, thus requiring less gain. The electrode impedance also increases considerably owing to the reduction of the contact area, therefore forcing to use amplifiers with much higher input impedance values than those used for ECG or EEG.

The use of very small electrodes is necessary when we want to measure the potential across the membrane of a cell that is in the range from 50 to 100 mV. This is achieved with the use of intracellular electrodes or microelectrodes that can penetrate a single cell. The problem associated to the use of these electrodes resides in the fact that the small size and small effective contact area of these electrodes give them a very high source impedance, needing an amplifier with a value of input impedance higher than several G Ω . Moreover, the high shunting capacitance of the electrode itself affects the frequency characteristics of the system, reducing the effective bandwidth to values lower than desired. The cell has information of physiological value as low as DC and as high as 10 kHz. To compensate for this high capacitance, the detecting amplifier must use positive-feedback approaches, even with the risks of instability and oscillation associated to positive feedback. Another problem linked to the use of positive feedback is the increase in the noise level, although

this problem is diminished by the high value of cellular potentials. All this makes the design of amplifiers for microelectrodes to be a nontrivial task, more complicated than the design of amplifiers for any other biopotential signal.

CONCLUSIONS

Biopotential amplifiers are electrical voltage amplifiers that have been specifically designed to detect the electrical voltage signals generated in the human body due to several physiological processes. The detection of biopotential signals is difficult due to biopotential having voltages several orders of magnitude below the other signals present in the measurement system that become sources of interference. Biopotential amplifiers are therefore required to have very critical requirements in order to be able to provide an accurate representation of the biopotential signal they have been designed to measure.

Bioreactors

Lito C. Mejia

EnduraTEC Systems Corporation, Minnetonka, Minnesota, U.S.A.

Kent S. Vilendrer

Tissue Growth Technologies, Inc., Minnetonka, Minnesota, U.S.A.

INTRODUCTION

Bioreactors play a significant role in the ever-expanding world of functional tissue engineering. A new generation of bioreactors that are increasingly comprehensive in capability is emerging. These bioreactors do more than just culture cells; they apply multi-axial physiological pressure/loading conditions to scaffolds and the growth environment, they analyze mechanical properties during the growth stages, and they can optimize the stimulation protocol to intelligently achieve the desired properties of functional tissue-engineered medical products.

As of this writing, the primary role of the bioreactor has been basic tissue research. These devices have often been home built, lacking the design and experimental discipline to be readily comparable to other home built systems and their respective results. The authors of this paper have proposed a technology platform for bioreactor design that can provide flexibility for both cardiovascular and orthopedic applications, and thus advance the uniformity of inter-laboratory comparisons, leading to improved development of functional tissue engineering processes. Commonality of design also provides a scalability factor and allows multiple constructs to be evaluated under a varying array of parameters. Bioreactor technologies that have scalability with faster evaluation and established testing protocols will become extremely important as functional tissue engineering moves from the research world to the production world.

TISSUE ENGINEERING

Tissue engineering is a promising field that offers a potentially unlimited source for transplantable tissues to replace damaged human ligaments, repair cartilage, or be an outright replacement of bone. It is not limited to tissues in the musculoskeletal system; there is also significant research and commercial activity in the cardiovascular arena for such tissues as pericardium, heart valves, arteries, and supporting blood vessels and organs.

Tissue Engineered Medical Products (TEMP) are expected to play a major role in the future of heart valve replacement, cardiovascular bypass surgery, venous

valve repair, and other intravascular surgeries. Research in this area has been focused on creating a three-dimensional construct from porous matrices (collagen, elastin, poly(glycolic acid), etc.) and seeding it with cells. For example, arterial construct development requires the appropriate biochemical and mechanical environments so that endothelial cells, smooth muscle cells, and fibroblasts proliferate to create an extracellular matrix. Mechanical stimulation of a seeded scaffold plays a significant role in inducing cell differentiation. Applying pulsatile pressure and media flow has shown that the applied stresses help promote faster cell growth, orientation, and mechanical strength.^[1-8]

Functional tissue engineering aims to develop biological substitutes for the repair, reconstruction, regeneration, or replacement of tissues. Its long-term goal is to construct biomaterials that are biocompatible, biodegradable, and capable of integrating molecules (e.g., growth factors) or cells.^[1,8] Currently, many different materials such as ceramics, polymers of lactic and glycolic acid, collagen gels, and other polymers have been tested in vitro and in vivo.^[1]

An important aspect of functional tissue engineering is that the discipline provides the basis for quantitative in-vitro studies of tissue development by culturing cells on 3-D constructs that are then exposed to physical and biochemical factors. It is here that bioreactors play their part. The bioreactor can be designed to provide cells capable of differentiating into desired lineages, seeding those cells onto a scaffold or other structural matrix, exposing the cultured cells to specific stimuli, and providing the necessary biochemical and growth factors that direct the cells to differentiate and develop. Bone and cartilage are the tissues in which most tissue engineering techniques have been applied, and the need for more research is substantial.

BACKGROUND

Cells communicate with each other chemically and respond to cues from their environment. The cues important to tissue engineers are those that tell cells to divide, migrate, and differentiate into different types of tissue. Mesenchymal stem cells, for example, have the

ability to become bone, cartilage, tendon, teeth, fat, or skin. Within the bioreactor there must exist a sterile environment of natural substances, such as growth factors, hormones, and other regulatory molecules, that guide these cells to differentiate along specific lineages (e.g., ligament lineage). It has been demonstrated that mechanical stimulation of the environment or mechanical stress (particularly multidimensional strain) of the seeded scaffold plays a significant role in inducing cell differentiation.^[9] Altman et al. documented that mechanical stimulation of ligaments based on human or bone marrow-derived cells induced elongated, ligamentlike cell morphology and cell alignment in the direction of loading. This was contrasted to round and randomly distributed cells with nonstimulated controls.

Why mechanical stimulation enhances cell differentiation is not clearly understood. It has been speculated that the mechanical forces signal or trigger cells to respond in some biological manner to produce ligament extracellular matrix components.^[9,10] Natural chemical environments also assist growth, making for challenging research in order to determine the optimal factors. Also, it is not known if the influence of mechanical stimuli on the differentiation process is transient or permanent. Ratcliffe and Niklason^[8] have noted that, under conditions of periodic compressive strain, the properties of engineered cartilage are significantly improved. Mol et al.^[11] note that straining resulted in more pronounced and organized tissue formation. Overall tissue properties improved with increasing levels of strain.

CLINICAL SIGNIFICANCE

According to the American Heart Association (2002 Heart and Stroke Statistical Update), approximately 1 million people suffered a myocardial infarction in 1999. Forty-five percent (45%) of these cases were fatal. Other statistics for 1999 include

- Cause of death was cardiovascular related in 41% of all deaths.
- 571,000 cardiac bypass surgeries were performed.
- Valvular heart disease claimed 19,612 lives.
- 96,000 valve replacement surgeries were performed.
- About 40,000 babies are born each year with cardiovascular defects.

The replacement or repair of diseased vessels with natural synthetic vascular grafts has become a routine treatment for certain types of intravascular disease. For coronary bypass surgery, the autologous saphenous vein remains the graft of choice for its nonthrombogenic flow surface, and its ability to be healed by the host as well for its strength and elasticity. However, efforts to

create a suitable synthetic small-diameter vascular graft have been largely unsuccessful.^[1]

Likewise, man-made medical devices have been used to replace heart valves and repair other intravascular complications. These devices are typically made from metals (stainless steel, nickel titanium alloys, carbon, fiber) and fabric (e-PTFE, Dacron, carbon fiber) that are foreign to the body. Their use often requires special blood-thinning medication that can lead to further health complications. Additionally, the devices are fixed form and do not conform to the body as the patient grows from childhood to adulthood, thus necessitating multiple surgeries. There are some areas (i.e., venous valves) where medical device designs offer low patency and the only means of repair is through reconstructive surgery or transplantation.

Knee ligament damage, in particular the anterior cruciate (ACL), is a frequently sustained knee injury. More than 100,000 ruptures of the ACL are estimated to occur every year in the United States,^[12,13] and, with the low healing capacity of the ACL, surgical reconstruction of some sort is necessary in order to restore normal knee function. A tissue-engineered ligament can address the shortcomings of traditional ACL therapies.

Knee meniscal tears due to twisting or compression forces are also common sports injuries. Nearly a million are estimated candidates for tissue-engineered meniscus. Traumatic meniscus tears accompany half of all anterior cruciate ligaments tears.

Damage to knee articular cartilage is a common problem following sports injuries. It leads to premature arthritis, causes a considerable decrease in quality of life, and has enormous long-term healthcare costs.^[12,14] Regeneration of damaged articular cartilage is very limited because adult cartilage lacks blood supply, lymphatic drainage, and innervation. Furthermore, chondrocytes are sheltered from synovial fluid nourishment and reparative recognition by their large extracellular matrix.^[15]

Arthritis, which can occur as either an inflammatory or degenerative joint disorder, affects tens of millions of people worldwide. Osteoarthritis is a form of arthritis that involves degeneration of the joint, with the most common being osteoarthritis of the knee. With the aging population, and the expectations for more active lifestyles, it is expected these numbers will increase dramatically in the coming years. With increasing obesity in younger, more inactive people, osteoarthritis is expected to become more prevalent in the young and middle age groups as well.^[16,17]

THE ROLE OF INTELLIGENT BIOREACTORS

Using intelligent bioreactors, a researcher can seed the construct and then apply pressure/flow waveforms of

varying shapes and frequencies to stimulate cell proliferation and matrix deposition leading to constructs with properties suitable for use in humans. The waveforms are generated using a computer-controlled dynamic pumping system that allows experimentation with different pressure/flow conditions. Godbey and Atala^[18] have reported that pulsatile fluid flow has been used to develop tissue-engineered heart valves, with the assumption that mimicking in-vivo conditions will yield a stronger tissue. Hoerstrup et al.^[19] and Sodian et al.^[20] describe bioreactors that utilize a respirator for driving pulsatile flow through heart valves and blood vessels.

Hoerstrup et al. as well as Dumont and Demarteau^[19-27] reported an increase in material properties for tissue-engineered heart valves, pulmonary artery conduits, and small-caliber vascular grafts stimulated for several weeks in a bioreactor that had pulsed flow. Jockenhoovel et al.^[28] describes a laminar flow chamber for in-vitro improvement of mechanical tissue properties. Ratcliffe and Niklason^[8] have noted that, under conditions of periodic compressive strain, the properties of engineered cartilage are significantly improved.

The intelligent bioreactor can also provide a non-destructive means for evaluating the strength of the developing tissue construct during its growth cycle. The loading system is capable of pausing the normal stimulation and introducing dynamic pressure or mechanical loading to the tissue construct to measure the construct's response. With special software, the complex modulus of the tissue can be estimated. This information may be stored for comparison of different constructs and for monitoring tissue construct development.

A bioreactor can culture in-vitro ligament tissues by seeding anterior cruciate or medial collateral ligament cells (fibroblasts) on porous scaffolds (synthetic biodegradable polymer or collagen-based matrices). Similarly, a bioreactor can culture in-vitro cartilage tissues by seeding cartilage cells (chondrocytes) on porous scaffolds (also of synthetic biodegradable polymer or collagen-based matrices). In time, the new tissue will develop its own supportive matrix and no longer need the scaffolding; therefore, biodegradable scaffolds are essential. Another approach involves the direct use of autologous tissues, which can differentiate within the host tissues (bone, meniscus, ligament, muscle) and can then be cultured in a bioreactor.

A six-station intelligent bioreactor represents an advancement in bioreactor technology in that several constructs can be developed simultaneously, allowing for more thorough and quantitative analysis of how a bioreactor environment enhances functional tissue growth. In addition, the ability to culture multiple constructs simultaneously allows the researcher to address important bioprocess engineering issues such

as scale-up and tissue uniformity. These criteria will become important as tissue engineering moves from the research laboratory to a production environment.

With the commercially available ITEMS (Intelligent Tissue Engineering via Mechanical Stimulation) BioReactor, the researcher can evaluate various combinations of culture techniques, scaling parameters, monitoring technologies, and control strategies to produce differentiated tissues with suitable biomolecular and mechanical properties. Until now, the production of one or a small number of constructs has been the norm, with little attention given to inter- or intrabatch variability for key tissue markers. Clearly, process development for production of tissue-engineered medical products will require knowledge of the variability of tissue characteristics, and definition of acceptable ranges for key cellular and molecular components and processing technologies.

CONSIDERATIONS FOR DEFINING CELLULAR CHARACTERISTICS

Experiments to test the effect of the appropriate conditions (hydrodynamic loading, oxygen tension, growth factors, etc.) on construct development can be performed. Constructs can be harvested periodically to provide kinetic data, and morphological analysis can be performed to include immunohistochemical staining and fluorescence microscopy to characterize cell and matrix distribution in growing constructs. Morphometric techniques to quantify construct matrix architecture for different bioreactor conditions will need to be developed. Quantitative morphometric analysis can include the use of confocal laser scanning microscopy (CLSM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM).

CLSM can be used to provide spatial relationship information between cells, matrix proteins, undegraded polymer, and voids, and to allow for three-dimensional reconstruction of the construct. For example, CLSM can quantify tissue heterogeneity,^[29,30] including identification of secretory cells and degenerating cells,^[31] and structural organization of native tissue.^[31-33] These techniques have been proposed for the development of the quantitative ultrastructural detail of tissue-engineered medical products. SEM can provide high-detail matrix composition and allow visualization of collagen fibers^[34] in the matrix.^[29] Observations can then be confirmed using TEM. Relating tissue mechanical properties as a function of matrix organization, especially collagen and elastin, to the quantification of collagen and elastin fiber diameter, length, and branching in tissue sections will allow comparison of tissue structure to function (mechanical properties) and bioreactor growth conditions.

BIOREACTORS: A LITERATURE AND PATENT BRIEF

Various bioreactor designs exist, and most are single-purpose home-built designs. These include simple spinner flasks and rotating-wall vessels such as slow-turn-lateral and high-aspect-ratio vessels. Rotating-wall perfused vessels (such as hollow fiber bioreactors), along with perfused column and perfused chambers, complete the mix of bioreactor designs.^[34–37] These systems provide basic medium and gas exchange with mixing mechanisms combined with fluid flow to provide mass transfer in the bulk medium. Although they are initially used to attain uniform seeding of three-dimensional scaffolds, rotating bioreactors have been used to study effects of turbulent and laminar flow (mass transfer rates or direct hydrodynamic effects) on tissue development via continuous recirculation. Effects of microgravity have also been studied in these bioreactors and have included the use of magnetic resonance imaging (MRI) as a nondestructive means to monitor the development of engineered cartilage. In certain cases, local measurements of the velocity field made using particle-image velocimetry (PIV) permit the determination of local shear stresses (cartilage applications).^[38]

Biodynamic bioreactors attempt to maintain the spatial uniformity of cells during the seeding process as well as expose the (vascular) cells to pulsatile physical forces during vasculogenesis and throughout its life.^[4,5,39,40] Although chemical regulators mediate tissue morphogenesis, tissue-engineering researchers critically emphasize that the signals that are responsible for tissue pattern are often mechanical in nature.^[41] Examples include the pattern-generation effects of compression on bone, shear on blood vessels, and tension on muscles. Mechanical stresses also play a role at the cellular level (cell-generated forces) during tissue morphogenesis.^[41]

Mechanical testing and in-vivo implantation studies ultimately assess the functioning engineered tissue's (vascular graft) ability to withstand long-term exposure to systemic pressures and hemodynamic forces. Stress-strain analysis to provide elastic modulus and compliance data can help predict the graft's resistance to dilation and aneurysm formation in vivo.^[39] While in-vivo implantation is the definitive means for evaluating the performance of the engineered tissue, a literature search, reveals that current bioreactors lack the capability of multi-axis pressure/physiological loading, as well as the means to provide real-time mechanical properties assessment to allow for more intelligent functional tissue engineering.

There is a critical need for more advanced bioreactors that can provide 1) complete mechanical stimulation to enhance tissue growth with simultaneous

mechanical properties analysis, 2) real dynamic mechanical analysis (DMA) for viscoelastic characterization of the tissue, and 3) elastic modulus and compliance information attained during and after the growth process.

A new generation of more sophisticated bioreactors is emerging that can provide larger three-dimensional tissue-engineered constructs. Altman et al.'s^[8] tissue engineering of ligaments uses multiple bioreactor vessels housed in a mechanical device that can stimulate translationally and rotationally the collagen gel suspended between two bone anchors (see Fig. 1). Sodian et al.^[20] have designed a new pulsatile bioreactor for the fabrication of tissue-engineered patches. The closed-loop perfused bioreactor design combines continuous pulsatile perfusion and mechanical stimulation by periodically stretching the autologous tissue-engineered patch construct. This approach is aimed at providing optimal biomechanical and biodynamic stimuli for controlled tissue development. Dumont et al.^[21] describe their bioreactor pulsatile capability for aortic heart valves as able to perform hydrodynamic studies over a wide physiological range with controllable resistance, compliance, stroke volume, and frequency. Demartean et al.^[22] have designed multiple-chamber bioreactors for cartilage applications using computer-controlled stepper motors to provide compressive loading while the bioreactor chamber provides different mixing velocities and different polymer scaffolds.

Vorp et al. at the University of Pittsburgh have designed a single-specimen apparatus that can apply cyclic twist and extension of perfused vascular segments.^[42] Fig. 2 is a detailed sketch of the specimen-housing chamber. Perfusion tees enter into the chamber while allowing desired stretching and twisting motion. The chamber allows access for a video camera for

Fig. 1 This bioreactor design by Altman et al. (Tufts University) shows multiple chambers in a mechanical assembly that provides both translation and torsional stimulation. Collagen gel supported by bone anchors is shown.

Fig. 2 This schematic details the specimen-housing chamber of a single-station bioreactor. Stretching and twisting of the vascular scaffold is accomplished inside the assembly. (Courtesy of D. A. Vorp: University of Pittsburgh.)

strain measurement. Ports allow for physiological sampling and oxygenation of the bath medium. Bioreactors employing nonperfusion, biaxial stretching techniques (e.g., Banes et al.), via a rubber membrane (via vacuum) are also available.^[43] This biaxial stretching technique, however, is more difficult for programming a specific physiological pressure or loading and strain profile to the gel matrix.

Enhanced techniques were used by Kasra et al.^[44] to determine the effect of hydrostatic pressure on rabbit intervertebral disc cells. Short-term application of high loading amplitudes and frequencies (to 20 Hz) was found to be beneficial in the stimulation of protein synthesis and the reduction of protein degradation. Bioreactor designs of the future can provide these higher levels of performance. Latterman at the University of Pittsburgh Hospital has designed a complete ligament bioreactor using a highly responsive dynamic linear motor; the complete system can be placed inside an incubator, as shown in Fig. 3.

Notable patents have surfaced within the past several years. Many are in the cardiovascular area. Vilendrer et al., in “Bioreactor with Plurality of Chambers for Conditioning Intravascular Tissue Engineered Medical Products,” provides a complete scalable bioreactor platform that incorporates multiple chambers and attempts to combine pressure, axial loading, torsional or lateral shearing, and bending of a seeded scaffold (see Fig. 4).^[45] Others are more specific to culturing tissues as a primary goal without any further conditioning of the construct.

Macallister et al. focus on a tissue-engineered blood vessel that is made from a cultured fibroblast sheet rolled into a multilayer vessel (via a rolling mandrel) to achieve sufficient burst strength to withstand physiological blood pressure without the use of a synthetic scaffold.^[46] One often finds variations of rotary bioreactors with enhanced features such as a two-chamber perfusion bioreactor (Dimitrijevič et al.) to counteract

Fig. 3 This first-generation bioreactor shown inside an incubator uses a voice coil actuator as the actuation method and provides only axial loading. The three ligament chambers share a common load cell. The next design will feature independent load measurement and incorporate a moving magnet motor instead of the voice coil. (Photo courtesy of C. Latterman of University of Pittsburgh Hospital.)

significant shear stresses while allowing high nutrient transfer and removal.^[47]

INTELLIGENT BIOREACTOR DESIGN CONSIDERATIONS FOR CARDIOVASCULAR APPLICATIONS

The following sections describe a scalable biodynamic environmental system that provides a complete closed-loop, nutrient-flow subsystem capable of introducing mechanical stresses and strains to a tissue-engineered construct during its growth cycle. In addition to mechanical stimulation, the researcher can query the tissue construct to evaluate its mechanical condition. This procedure allows adjustment of the stimulation profile to best meet the desired growth plan for the chosen tissue-engineered construct.

The ITEMS (Intelligent Tissue Engineering via Mechanical Stimulation) BioReactor is based on the design of the EnduraTEC 9100 Series of Stent Graft Testers, and it includes several important design features for the tissue-engineering researcher. Additionally, experience with the single-specimen ITEMS BioReactor configuration in collaboration with a major research institute has provided insight into its functionality and usability. Several of the significant capabilities of this second-generation, commercial system are summarized below.

Servocontrolled Bioreactor

Fig. 4 Patents such as those described by Vilendrer et al. attempt to incorporate almost every facet of mechanical motion to apply to the construct/manifold. These include pressure, axial loading (stretching), torsion (twisting), lateral shearing, and bending.

Moving Magnet Motor

A central element of the ITEMS BioReactor is the moving magnet linear motor, which provides the cyclic motion that in turn provides cyclic pressure or cyclic loading (see Fig. 5). The ITEMS unit (with the linear motor) fits into a tissue culture incubator and is not affected by moisture.

The moving magnet motor is composed of three basic elements: the magnet, the coils, and the core. The magnet moves up and down while the coils and core remain stationary. The core and coil combination may be viewed as an electromagnet producing a north and south pole as a function of current. When the current is applied, the appropriate poles of the magnet are either attracted or repelled, producing the force and thus moving the actuator up or down. The stronger the current, the stronger is the force.

Magnetically, the magnet is charged, or magnetized, with two polarities. The function of the coil and core assembly is to carry and modulate the flux across the gap where the magnet resides. The flux generated by the coils interacts with the flux generated by the magnet, causing the magnet to react with a force either up or down depending on the polarity of the coil flux. The

implemented structure will produce a force that is directly proportional to the current in the coils. Maximum force is limited only by the thermal performance of the overall system design.

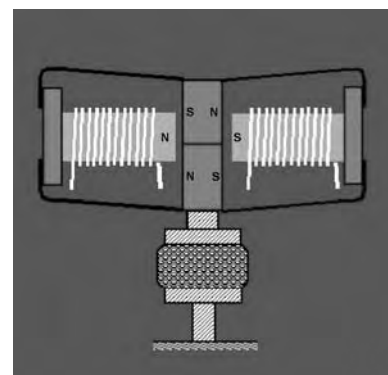

Fig. 5 This schematic details the moving magnet as part of a simple electromagnet principle. Its simplicity and clean design make it ideal for bioreactor applications. The magnet/flexure assembly offers low magnet mass and a frictionless-flexure-suspension design and can be controlled to provide both high-frequency performance and step-loading capability that is highly suited for characterizing soft tissue.

The moving magnet linear motor system is inherently a high-fidelity device due to its low magnet-mass and frictionless-flexure-suspension design. The capability of high-acceleration and high-frequency performance for cyclic/step load and displacement profiles makes it ideal for tissue stimulation and characterization. Naturally quiet in operation, and with very few moving components (only the magnet/flexure assembly is moving), the super-clean, efficient design (no seals or pneumatics/hydraulic residue) is highly desirable for use within an incubator system. Also noteworthy is the infinite fatigue life of the frictionless-flexure-suspension design, which provides a durability factor into tens of billions of cycles with literally no maintenance.

Ergonomic Features for a Laboratory Setting

The ITEMS BioReactor is a compact design; it can be completely placed within medium-sized incubation systems that control temperature, humidity, and the environment (see Figs. 6–9). A typical single-station bioreactor configuration is 305 mm (12 in) wide by 381 mm (15 in) deep and 560 mm (22 in) high, with the multistation only slightly wider and taller. The weight ranges from 14 to 20.4 kg (31–45 lb). The BioReactor

Fig. 6 Single-station BioReactor showing the moving magnet motor to provide dynamic pressure pulsing.

Fig. 7 Close-up of BioReactor showing components, transducers, and feed-throughs. The typical bioreactor chamber utilizes stainless (or titanium), plastic, and glass components. Each chamber can be readily disassembled for ETO or autoclave sterilization.

chambers and dynamic pumps are fabricated from titanium, stainless steel, delrin, and glass for long life and durability. The stand-alone device is designed to minimize contamination and allow experimentation in a nutrient environment. The biochamber is a modular design that allows rotational cellular seeding of the scaffold independent of the stimulation system. In addition, the chamber is a high-visibility design that allows optical monitoring of the construct, and it is ported to provide independent internal and external flow of nutrient solution to the intravascular construct (Fig. 10).

Pulsatile Pressure Control

Mean flow and superimposed dynamic flow can be varied independently to provide a full range of hydrodynamic loading conditions. The combination of dynamic and mean flow pumps allows the researcher to create almost any flow waveform, and an example of the achievable waveforms can be found in Fig. 11a.

Fig. 8 Six-station BioReactor configuration showing individual chambers and mean pressure pumps.

For growing tissue-engineered medical products such as arteries, combined dynamic and mean flows can be utilized to deliver the wall shear stress that duplicates the average wall shear stress deemed suitable for stimulation. The mean flow can be adjusted from 5 to 25 L/min while pulse rate and dynamic bellows pump displacements can be varied to characterize the effect of varying flow conditions on construct morphology and function. Typical dynamic displacement and pressure range are 6.4 mL/pulse and 0–300 mm Hg respectively. The integrated mean flow pump is a commercial gear variety, and it features a DC brushless motor and reusable gear head pump.

Integrated Control Electronics

The ITEMS BioReactor system uses a controller that is implemented on a Windows-based personal computer and provides great flexibility for exploring different stimulating conditions, transducer measurement, and algorithm development. The mechanical stimulation parameters that can be controlled open up new possibilities to understand their effects on the formation of tissue with improved quality.

Measurement of Material Properties

In addition to reduced cell-growth time periods, a major desired outcome of mechanical stimulation is to create enhanced material properties. These might include resistance-to-burst characteristics and a more

Fig. 9 Overview of the six-station BioReactor within an incubator showing the compact design of the BioReactor.

suitable modulus of elasticity. The ITEMS BioReactor has the capability to measure the differential pressure between the inside and outside of the construct using catheter pressure transducers. The resistance to burst is easily determined using these two readings. In addition, combining this pressure information with the applied flow pulse information allows a pseudo determination of the relative stiffness (modulus) can be made. This provides some feedback to the researcher about how the stimulation may be affecting the modulus; see Fig. 11b. The BioReactor can display these measurements automatically, which will allow rapid progress in understanding which stimulation parameters have the greatest impact on tissue strength.

Use of Material Properties As Input to Algorithms That Can Automatically Adjust Applied Conditions

Once the pseudo determination of relative stiffness is understood, the researcher can develop control algorithms for optimizing the applied conditions. The computerized monitoring and control system enables the researcher to program these algorithms into the BioReactor's stimulating system so that the computer can make changes to the conditioning sequence based on the pseudo stiffness measurements on a real-time basis. The ability to adjust parameters and conditioning sequences is a dramatic improvement to existing practices. With this innovation, it is possible to optimize the stimulation input to the condition of the

Fig. 10 Functional schematic of the multiple-chamber BioReactor. The movement of the bellows provides the pulsatile pressures. Each chamber has its own, independently controlled mean flow pumps.

construct, leading to significantly improved tissue. A potential added benefit is that the tissue may also be produced in a shorter amount of time because of the optimization algorithms. The adjustment of more

than one material measurement may also accelerate the tissue development, saving additional time. The ITEMS BioReactor has the capability to measure and control multiple factors.

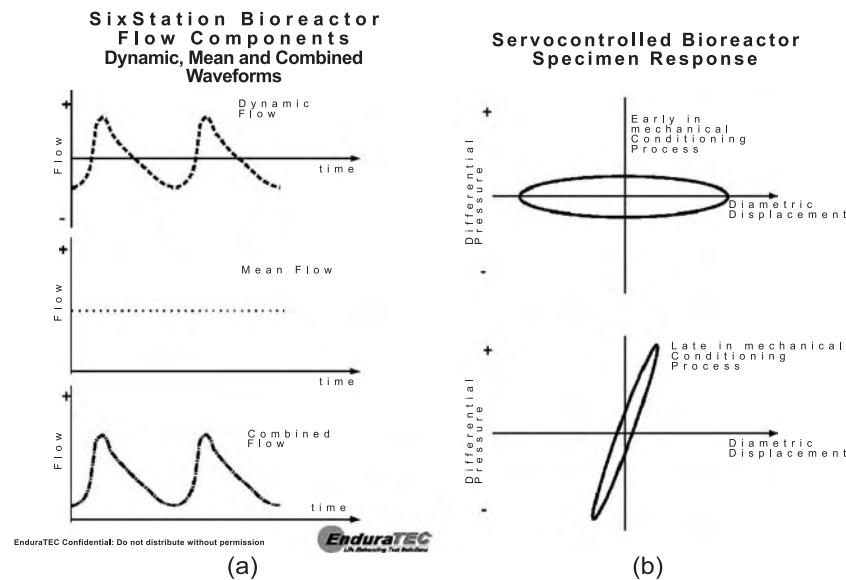

Fig. 11 (a) The dynamic, mean, and combined flow profiles that are used for stimulating the vascular construct. (b) The early and late mechanical conditioning process. The hysteresis loops for the late conditioning process will exhibit one to several orders of magnitude in stiffness as compared to the original construct properties.

Pressure/Flow Measurement Instrumentation

The ITEMS BioReactor system features catheter-based pressure and flow measurement transducers. This means the researcher is able to accurately measure the mechanical stimulating conditions that are applied to the construct, and with this capability quantitative studies can be performed to understand the impact of these factors. The measurement of internal conduit conditions is critical to understanding the tissue growth process, and as a result, more detailed discussion of the measurement approaches are presented.

The ITEMS BioReactor utilizes internal and external pressure transducers to measure differential pressure conditions across a vascular conduit. These are shown in Figs. 7 and 10. The fluid flow velocities are measured using the mean flow pump input voltage, then differentiating the dynamic pump motion multiplied by the pump area, and then summing these two components.

Measurement of the flow conditions at the input and output of the construct's inner lumen will provide better flow information, and these two readings could be used to measure pseudo material properties. For example, if the construct has a high radial compliance, there will be a substantial phase and amplitude difference between the dynamic velocity readings at these two locations. This is equivalent to a fluid bulge working its way down a soft hose.

Methods for measuring the internal pressure conditions from outside the BioReactor chamber using a laser- or ultrasonic-based method are also being investigated. Transducers that could measure the diameter change of the construct with each pulse would provide a direct measurement of the radial compliance of the construct. These measurements would be useful in more accurately ascertaining the construct's material properties.

The approach of measuring radial strains directly is used in the EnduraTEC 9100 Series Stent Graft Test Instruments. Although these Stent Graft systems use a

Fig. 12 This figure details the functional design for ligaments. Single or independent mean flow pumps can be provided. Manual length adjustment is required to properly insert each ligament. Axial motion and torsion motion are accomplished via the lower unit assembly, which utilizes either two linear motors or a linear motor and rotary motor.

Fig. 13 This drawing describes the individual components along with overall dimensions of the ligament BioReactor.

laser micrometer to make the diametral measurements, and the same micrometer could be used in the ITEMS BioReactor, the use of ultrasonic sensors as the means for this measurement is a more attractive possibility. EnduraTEC believes that ultrasonic transducers can be made more robust and could be fabricated for hundreds of dollars versus thousands of dollars for a laser system. These measurement options are important considerations for researchers depending on their specific requirements.

Multistation Configuration—Multiple BioReactor Chambers

A multiple-chamber BioReactor configuration is available so that multiple experiments can be performed simultaneously. In an effort to minimize the expense associated with the linear pump motor and controls, the multistation BioReactor has six chambers with dynamic pumps that are driven from a common linear motor. Each chamber has its own mean flow pump,

which enables the researcher to vary that parameter if desired.

BIOREACTOR DESIGN CONSIDERATIONS FOR ORTHOPEDIC (LIGAMENT AND CARTILAGE) APPLICATIONS

The ITEMS BioReactor can be configured for ligament and cartilage applications and has several important features for these types of tissues. Concept drawings of the ligament accessories are shown in Figs. 12–15. The moving magnet linear motor design remains as the heart of the system for both ligament and cartilage applications. However, higher forces for the multispecimen configuration requires dual linear motors. Additionally, cartilage stimulation requires shearing motion (either simple lateral or pure torsional shearing) as part of the design. A third motor is needed to provide this shearing motion. For vascular tissue and ligaments, torsional loading is an option that is easily incorporated.

Multi Station Cartilage Bioreactor Functional Drawing

EnduraTEC Confidential: Do not distribute without permission

Fig. 14 This drawing details chamber modifications to accommodate small cartilage samples. The chamber is shorter in length, and the bellows arrangement provides for both axial loading and lateral motion (simple shear). As in the ligament, a common reservoir with a single or independent mean flow pumps can be provided.

Mechanical Stimulation Subassembly

The axial-loading subassembly utilizes dual linear motors to provide a maximum of 450 newtons of force. The total load is distributed to the six stations through a spider load distribution subassembly so that each specimen can be subjected to as much as 75 newtons. Each specimen station will have its own dedicated load cell for measurement of the exact applied force (see Figs. 12 and 13).

For cartilage, shear loading is provided by another linear motor that rotates the spider assembly to provide an effective linear displacement of ± 3 mm of the bottom compression platen in each of the chambers. This motion provides shear forces of up to 58 newtons per sample (see Figs. 14 and 15).

The flexible bellows design allows both vertical and lateral displacement. There is a chamber through-hole that has sufficient clearance to allow lateral displacement (shear) of the bottom piston when the spider assembly is programmed for rotational motion.

The piston assembly is designed with the appropriate stiffness to minimize any lateral displacement error.

Modified BioReactor Chambers

Each transparent chamber will house gripping and piston assemblies for dynamic loading of the ligament or cartilage scaffold as shown in Figs. 12–15. The chambers will incorporate commercially available seals that are best rated for low pressure, short dynamic strokes, low friction, and biocompatibility to the nutrient matrix.

For ligaments, each pull/push rod is attached to a load cell below the chamber to measure load. The top push rod will have a manual slack adjustment to accommodate the length of the scaffold. Manual locking mechanisms for the push/pull rods are provided to facilitate moving/transfer of the BioReactor chamber after assembly, seeding (if seeding is done remotely),

B

Multi Station Cartilage Bioreactor Assembly

EnduraTEC Confidential: Do not distribute without permission.

Fig. 15 This Solidworks™ drawing details the main components of the cartilage BioReactor configuration. The lower unit assembly that houses the linear and rotary motors makes the unit taller but maintains overall functionality to be used within an incubator as the cardiovascular and ligament configuration.

and placement into the loading spider carousel of the BioReactor. These locking mechanisms are similar for both ligament and cartilage applications.

It is intended that the whole chamber assembly can be easily removed so that a chamber and scaffold that has been seeded at a separate processing station can be

quickly inserted into the ITEMS BioReactor. In the case where the chambers are routinely moved between incubator and into the BioReactor, the locking mechanisms can act as “zero” start positions and prevent looking for the zero electronically.

Each chamber is serially connected to a mean flow pump (for nutrient/environment media), which enables the researcher to vary that parameter if desired. The chambers could also be connected in parallel to the mean flow pump. For those applications where independent pumps are required, this capability can be provided as an option. This could be desirable to minimize any contamination between chambers, or if different fluid media are required for each chamber.

It is intended that the multiple-chamber configuration may be removed as a unit. The intent, in this case, is that mechanical stimulation could be set up as a scheduled periodic activity. The six-chamber subassembly could reside in another incubator and then be placed on the ITEMS BioReactor for a stimulation routine. This feature allows the use of multiple six-chamber assemblies, thus providing cost-effective/productive tissue-engineering practices.

Gripping and Attachment Considerations

The attachment of the ligament scaffold or construct to the stimulation mechanism is an area that requires significant collaboration with the researcher. EnduraTEC has created several mechanical designs that have been successful; however, each application may require some variation. Some situations may entail allowing the tissue to grow directly onto the gripping mechanism; in other cases, either attaching to or mechanically gripping the ends of the scaffold may be appropriate. For cartilage, simple compression platens (10–15 mm in diameter) with detent for scaffold positioning are provided.

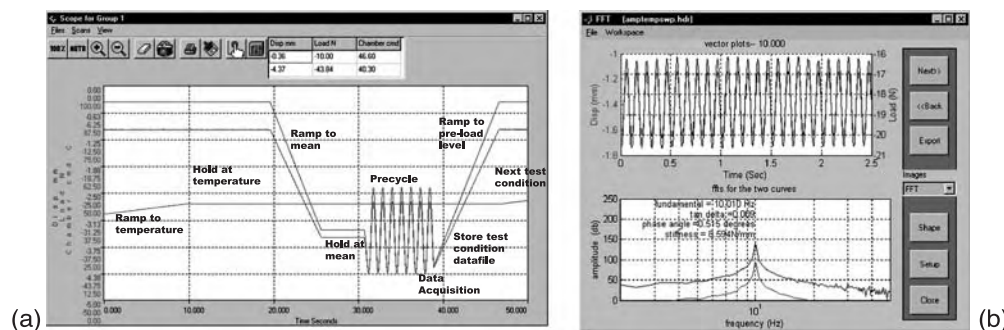

Fig. 16 (a) Graph showing how DMA, or dynamic mechanical analysis, frequency, dynamic amplitude, mean level, and the control mode can be defined. (b) A typical DMA plot showing results at a particular fundamental frequency.

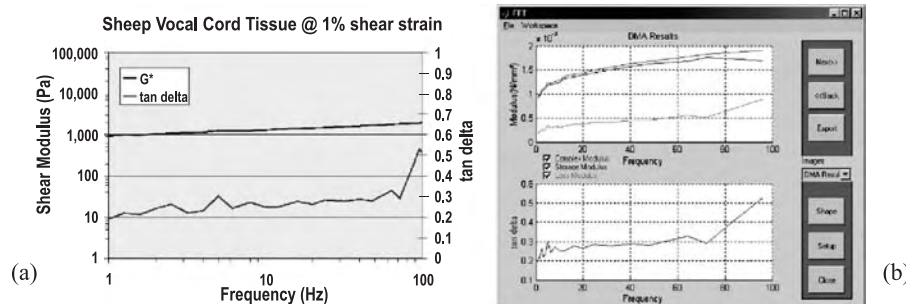

Fig. 17 These figures show DMA results for sheep vocal cord tissue. (a) A 50-gram cell was used to measure forces in the shear direction. This testing was performed on the same linear motor technology described by the BioReactor so that it could be compared to potential tissue-engineered cord tissue. (b) Compression DMA testing on porcine fold was also performed during this exercise. Compression modulus is higher than existing data in shear or tension due primarily to the pre-compressive stress required to maintain contact during testing. A 45-N cell was used for these compression tests.

B

Measurement Instrumentation

The ITEMS BioReactor for ligaments and cartilage utilizes a mean flow internal pressure transducer to measure pressure conditions of the nutrient environment. The fluid flow velocity is measured using the mean flow pump input voltage. In addition, the loading mechanism for each chamber will have a load cell for measuring dynamic loading imposed to the ligament specimen. For overall operation, the six sensors will be averaged to get the control command desired. Lateral or torsional shear measurements are possible.

Material/Construct Properties

Unlike cardiovascular applications, Dynamic Characterization Analysis (DMA) applications software is available. It uses load, displacement, or strain information to evaluate how the scaffold and scaffold/tissue construct is performing during its growth/stimulation stages. By performing this material characterization exercise, the constructs' viscoelastic properties such as dynamic modulus, storage modulus, and tan delta can be readily calculated. With DMA software, the researcher can define frequency, dynamic amplitude, mean level, and the control modes that are most

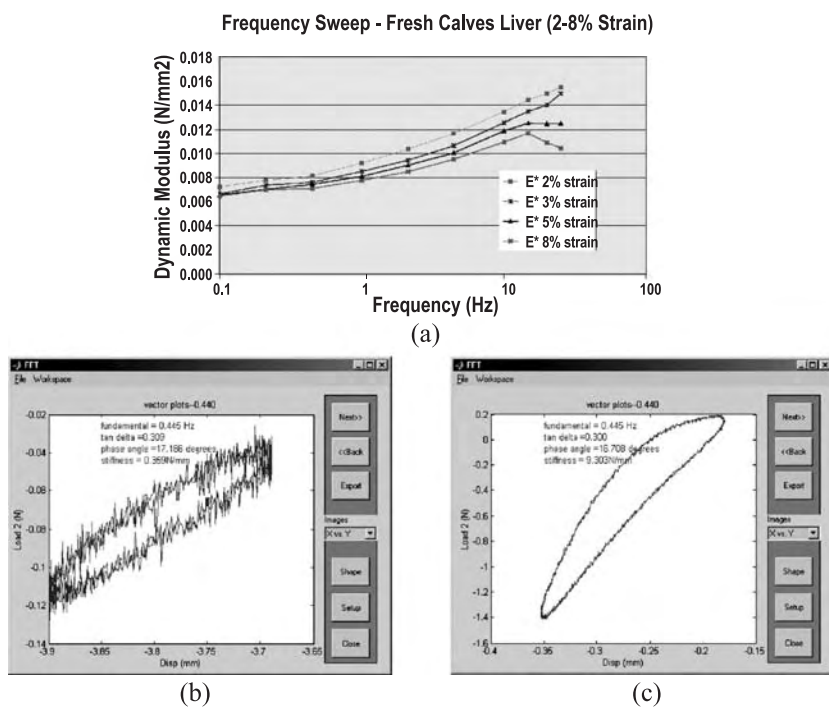

Fig. 18 These graphs show another example of soft tissue (liver) DMA results. Programming both frequency and strain sweeps is relatively easy to perform once the test protocol is established. Typical loads at 1% strain were about 0.2 N (200 g). Figures (b) and (c) show the hysteresis curves for the same sample as (a). In (c), the liver was ablated (radio frequency) to correlate viscoelastic properties derived from DMA to sonoelastography measurements. There are two order-of-magnitude differences in the stiffness between the two curves. (b) shows a relatively flat hysteresis curve due to its very low stiffness and shows more “noise” in the measured feedback to extremely low loads, as would be seen in the initial stages of tissue growth. As the tissue/scaffold gets stronger/stiffer, hysteresis curves as dramatic as the ablated example may be measured.

applicable to characterize the tissue. The graphs in Fig. 16 describe typical data presented after DMA analysis (via FFT) is performed. Figs. 17 and 18 show viscoelastic data on sheep vocal cord material and calf liver. The linear motor is ideal for characterizing such soft tissue. This data would be the baseline information (reference curves) that one would compare the properties of tissue-engineered liver and tissue-engineered vocal cord. Ideally, by using these reference curves and querying the tissue-engineered medical product during the growth cycle, and then making comparisons, optimized growth via manual or automatic adjustments to the stimulation process can be realized.

SUMMARY

A flexible tool such as the ITEMS BioReactor provides well-defined mechanical forces during construct development to enhance the biomolecular composition and mechanical function of tissue-engineered medical products such as arteries, ligaments, and cartilage. It can be utilized in fundamental studies to develop precise quantitative relationships between chemical and mechanical environments and construct growth. In addition, with this second-generation BioReactor, researchers can begin to address some of the concerns regarding the production of large numbers of uniform constructs suitable for human implantation.

A bioreactor with the ability to grow multiple constructs independently under well-defined hydrodynamic conditions represents an important advancement for functional tissue engineering. Since each chamber is independent, cells, scaffold, nutrients, and mechanical loading can be varied between constructs, providing the development of quantitative relationships between hydrodynamic or mechanical loading on cell proliferation and matrix deposition.

The use of a scalable, intelligent bioreactor that is commercially produced and supported will allow tissue-engineering researchers to devote more time and resources to rapidly move forward with their functional tissue engineering research programs. With a highly functional platform that can be easily configured for either vascular or orthopedic constructs, the uniform design attributes of the ITEMS BioReactor will allow researchers to readily compare their tissue engineering results in the hope that functional tissue engineering milestones can be greatly expedited.

The major design elements of the ITEMS BioReactor are 1) a simple geometry to allow for accurate modeling and visualization of the internal (luminal) and external flow fields and mass transfer, 2) compact and easy-to-use biochamber designs for different applications, and 3) advanced control and measurement capabilities to evaluate material properties and adjust

the conditioning parameters in order to optimize the stimulation input to the construct, leading to significantly improved tissue.

B

INTRODUCTION

Biodegradable polymers have significant potential in biotechnology and bioengineering. However, for some applications, they are limited by their mechanical properties' mismatch and unsatisfactory compatibility with cells and tissues. A strong, biodegradable, biocompatible elastomer could be useful in fields such as tissue engineering, drug delivery, and medical devices. Poly(glycerol sebacate) (PGS) is a tough biodegradable elastomer designed and synthesized from biocompatible monomers. PGS forms a covalently cross-linked three-dimensional network of random coils with hydroxyl groups attached to its backbone. Both cross-linking and the hydrogen bonding interactions between the hydroxyl groups likely contribute to the unique properties of the elastomer. *In vitro* and *in vivo* studies show the polymer has good biocompatibility. *In vivo* degradation shows a near linear loss of mass with time, and a gradual decrease of mechanical strength with very limited water uptake. Polymer implants under animal skin are absorbed completely within 60 days, followed by restoration of the implantation sites to their normal architectures. PGS supports the growth of many cell types, and may be useful in tissue engineering, medical devices, and other fields in biomedical engineering.

BACKGROUND

Advances in biomaterials have significantly impacted many fields in life sciences and technology, and improved the quality of life of tens of millions of individuals.^[1–3] Annual sale of medical systems using biomaterials in the United States alone exceeds \$100 billion.^[4] An increasingly important category of biomaterials is biodegradable polymers, which have been used widely in fields such as tissue engineering, drug delivery, and medical devices. Many biomedical devices are placed in a mechanically dynamic environment in the body, which requires the implants to sustain and recover from various deformations without mechanical irritations to the surrounding tissues. In many cases, the matrices and scaffolds of these implants would ideally be made of biodegradable

polymers whose properties resemble those of extracellular matrices (ECM)—soft, tough, and elastomeric in order to provide mechanical stability and structural integrity to tissues and organs. Hence a soft biodegradable elastomer that readily recovers from relatively large deformations is advantageous for maintaining the implant's proper function without mechanical irritation to the host. One such material is a series of biodegradable elastomers based on glycerol and sebacic acid, hence the name poly(glycerol sebacate).

These elastomers are biodegradable, biocompatible, tough, and inexpensive. Upon degradation *in vivo*, PGS loses mass almost linearly with time, and its mechanical strength decreases gradually with very limited water uptake. Unmodified PGS supports the growth of many different cell types, including endothelial and smooth muscle cells, Schwann cells, hepatocytes, cardiomyocytes, and chondrocytes. PGS has been fabricated into different physical forms such as flat sheets, foams, and tubes. Microfabricated PGS has also been used as a scaffolding material to make patent endothelialized branching capillary networks that may serve as artificial microvasculature for engineering vital organs. As one of the few biodegradable and biocompatible elastomers, PGS may be useful in soft tissue engineering, medical devices, and other fields in biomedical engineering.

DESIGN OF PGS

PGS is analogous to vulcanized rubber in that it forms a cross-linked three-dimensional network of random coils. Such a strategy to achieve tough and elastomeric materials is also found in nature; collagen and elastin, the major fibrous protein components of ECM, are both cross-linked. In addition to covalent cross-linking, hydrogen bonding interactions through hydroxyproline hydroxyl groups also contribute to the mechanical strength of collagen. The design of our polymer is based on two hypotheses: 1) good mechanical properties can be obtained through covalent cross-linking and hydrogen bonding interactions; and 2) rubberlike elasticity can be obtained by building a three-dimensional network of random coils through copolymerization whereby at least one monomer is

Scheme 1

trifunctional. To realize this design, the following criteria were considered: 1) degradation mechanism—hydrolysis was preferred to minimize individual differences in degradation characteristics caused by enzymes;^[2] 2) hydrolyzable chemical bond—ester was chosen for its established and versatile synthetic methods; 3) cross-link density—low density was preferred, as a high degree of cross-linking usually leads to rigid and brittle polymers; 4) cross-link chemical bonds were chosen to be hydrolyzable and identical to those in the backbone to minimize the possibility of heterogeneous degradation; and 5) specific monomers—they should be nontoxic, at least one should be trifunctional, and at least one should provide hydroxyl groups for hydrogen bonding. Glycerol [CH₂(OH)-CH(OH)CH₂OH], the basic building block for lipids, satisfies all three requirements and was chosen as the alcohol monomer. From the same toxicological and polymer chemistry standpoints, sebacic acid [HOOC(CH₂)₈COOH] was chosen as the acid monomer. Sebacic acid is the natural metabolic intermediate in ω -oxidation of medium- to long-chain fatty acids,^[5,6] and has been shown to be safe in vivo.^[7] Both monomers are inexpensive, an advantage for large-scale applications. This approach was likely to yield biodegradable polymers with improved mechanical properties and biocompatibility.

SYNTHESIS OF PGS

The polymer was synthesized by melt polycondensation of an equimolar amount of glycerol and sebacic acid at 120°C under argon for 24 h (Scheme 1). The pressure was then reduced from 1 Torr to 40 mTorr over 5 h. The polymer at this stage is a highly viscous liquid above 80°C, and is soluble in organic solvents such as tetrahydrofuran (THF), *N,N*-dimethylformamide, and ethanol. The polymer was cured at 40 mTorr and 120°C for 48 h. The resultant polymer is a transparent, almost colorless elastomer.^a The resulting polymer features a small amount of cross-links and

^aRigid, totally crosslinked polymer has been synthesized from glycerol and sebacic acid (glycerol/sebacic acid molar ratio: 2/3) under different conditions. See Ref. [8].

hydroxyl groups directly attached to the backbone. PGS is insoluble in water and swells only $2.1 \pm 0.33\%$ after soaking in water for 24 h. As is the case for other hydrolyzable polymers, PGS should be kept in an anhydrous environment for long-term storage.

CHARACTERIZATION OF PGS

The chemical and physical properties of PGS were characterized by various instrumental methods. Fourier transformed infrared spectroscopy (FTIR) on a newly prepared KBr pellet of PGS showed an intense C=O stretch at 1740 cm^{-1} , which confirmed the formation of ester bonds. The absence of C=O stretches corresponding to carboxylic acids suggested a high conversion rate to the polymer. FTIR also showed a broad intense OH stretch at 3448 cm^{-1} , indicating the hydroxyl groups were hydrogen-bonded (Fig. 1).

Differential scanning calorimetry (DSC) measurement showed two crystallization temperatures, -52.14°C and -18.50°C , and two melting temperatures, 5.23°C and 37.62°C , respectively. No glass transition temperature was observed above -80°C , the lower detection limit of the instrument. The DSC results indicate that the polymer was totally amorphous at 37°C .

Elemental analysis on vacuum-dried PGS samples confirmed the composition of the polymer as approximately 1 glycerol:1 sebacic acid. Water-in-air

Fig. 1 FTIR spectrum of PGS. Note the intense C=O, and O-H stretches at 1740 cm^{-1} and 3440 cm^{-1} , respectively.

contact angle was measured at room temperature using the sessile drop method and an image analysis of the drop profile on slabs of polymer fixed on glass slides. The polymer surface is very hydrophilic due to the hydroxyl groups attached to its backbone. Its water-in-air contact angle was 32.0° , almost identical to that of a flat 2.7 nm thick type I collagen film (31.9°).^[9] The cross-linking density is expressed by n , moles of active network chains per unit volume, which was $38.3 \pm 3.40 \text{ mol/m}^3$, and M_c , the molecular weight between cross-links, which was $18,300 \pm 1620$, calculated from equation:^[10]

$$n = E_0/3RT = \rho/M_c$$

where E_0 is Young's modulus, R is the universal gas constant, T is the temperature, and ρ is the density. The low M_c value confirms that the cross-linking density is low in PGS. Depending on the monomer ratio and process parameters, the modulus of PGS can be controlled within at least an order of magnitude. On the low modulus (soft) limit, tensile tests on thin strips of PGS revealed a stress-strain curve characteristic of an elastomeric and tough material (Fig. 2). The nonlinear shape of the tensile stress-strain curve is typical for elastomers, and resembled those of ligament^[11-13] and vulcanized rubber.^[14] PGS can be elongated repeatedly to at least three times its original length without rupture. The total elongation is unknown, as grip breaks occurred at $267 \pm 59.4\%$ strain. The tensile Young's modulus of the polymer was $0.282 \pm 0.0250 \text{ MPa}$ with an ultimate tensile strength greater than 0.5 MPa (grip break). The value of the Young's modulus of PGS is

Fig. 2 Stress strain curves of two extremes of PGS, the soft (-----) and the stiffer one (.....), and vulcanized rubber (—). Both soft PGS and vulcanized rubber are marked by low modulus and large elongation ratio, indicating elastomeric and tough materials. The modulus of the stiffer PGS is 10 times higher than that of the soft one. Grip break for both PGS.

between those of ligaments (kPa scale),^[11-13] which contain a large amount of elastin in addition to collagen, and tendon (GPa scale),^[15-17] which is mainly made of collagen. The strain to failure of PGS is similar to that of arteries and veins (up to 260%),^[18] and much larger than that of tendons (up to 18%).^[19] On the high modulus limit, PGS can be stretched to about 20%, still much higher than stiff biodegradable polymers such as poly(lactide-co-glycolide) (PLG). Once cross-linked, PGS is insoluble in water or organic solvents. After soaking 24 h in water, the weight of PGS barely changed and the mechanical properties were virtually the same as for dry polymer.

DEGRADATION OF PGS

The degradation characteristics of PGS were examined both in vitro and in vivo. Agitation for 60 days in phosphate buffered saline solution (PBS) at 37°C caused the polymer to degrade $17 \pm 6\%$ as measured by change of dry sample weight. In contrast, subcutaneous (SC) implants in rats were totally absorbed in 60 days. For the in vivo experiment, enzymes, and perhaps macrophages as well, may have caused differences in degradation rate. In vivo degradation thinned the polymer implants, with the explants maintaining their square shape and relatively sharp edges up to at least 35 days. Both the mechanical strength and the mass decreased almost linearly as the polymer degraded. Both results suggest PGS predominantly degrades through surface erosion. The preservation of integrity during the degradation process can be important for certain types of tissue-engineered implants, drug delivery devices, and medical devices.

In Vivo Degradation

Appropriate degradation properties of biodegradable polymers are critical for the success of their clinical applications. The in vivo degradation characteristics of PGS were evaluated using a subcutaneous model in Sprague-Dawley (SD) rats with PLG as the control material. Carboxyl-terminated PLG (50:50, carboxyl-ended, MW 15,000) powder was pressed into round disks. The surface area/volume ratio was the same for PGS and PLG samples. PGS samples were autoclaved, and PLG samples were sterilized by ethylene oxide (4 h sterilization, 48 h ventilation) before implantation. All samples were implanted subcutaneously in the backs of SD rats. The animals were randomly divided into five groups. At days 7, 14, 21, 28, and 35, implants were explanted from one group of animals under general anesthesia. The implants were carefully retrieved and rinsed sequentially with PBS solution and deionized (DI) water. The geometry and surface

Fig. 3 Photographs and scanning electron micrographs ($1000\times$) of PGS (top) and PLG (bottom) explants at various time points of degradation. PGS implants preserve their geometry and surface integrity throughout the degradation period, whereas PLG implants deform severely. PGS, A–D; PLG, E–H. A: new PGS slab; B: 21 days implantation; C: surface of autoclavated PGS slab—new; D: surface of PGS slab implanted for 21 days. E: new PLG disk implantation; G: surface of ethylene oxide sterilized PLG disk—new; H: surface of PLG disk implanted for 21 days.

properties of the explants were examined, and the change of mass, water content, and mechanical strength with time were also monitored. All these parameters are important indications for the mechanism of degradation, and are crucial for the integrity and proper function of an implant. Macroscopically, the PGS explants maintained their geometry throughout the time period tested (Fig. 3). In contrast, the geometry of PLG explants was distorted significantly within 14 days, most likely because of bulk degradation and swelling. They were deformed considerably from transparent disks to white opaque irregular lumps (Fig. 3). No PLG implants were retrieved successfully beyond three weeks due to excessive swelling and the fragile nature of the implants.

The surface integrity of the explants was observed by scanning electron microscopy (SEM). Both pristine sterilized samples and cleaned and dried explants were mounted on aluminum stubs, and their surface morphologies were observed. SEM observation showed that the PGS explant surface maintained its integrity well. Contoured features developed on the surface after autoclaving. Such features remained throughout the course of the experiment; however, no crack formation was observed (Fig. 3). In case of PLG implants (Fig. 3), $20\ \mu\text{m}$ holes developed on the surface 7 days postimplantation; cracks about $20\ \mu\text{m}$ wide formed within 14 days, and by 21 days, networks of both larger cracks wider than $40\ \mu\text{m}$ and smaller cracks could be seen throughout the PLG surface.

The degree of swelling of degradable polymers in vivo is a key parameter for proper implant materials. Excessive swelling is usually undesirable for an implant, as it distorts the shape of the implant and softens the polymer.^[20,21] The degree of swelling was estimated by measuring the explant weight differences

before and after drying. The explants were cleaned and the surface water removed with a Kimwipe before weighing. Each explant was thoroughly dried at 40°C under vacuum ($85\ \text{mTorr}$) for 48 h. Each explant was weighed again before any subsequent testing. The swelling ratio was calculated from explant weight difference before and after drying: $(W_w - W_d)/W_d$, where W_w is the wet sample weight and W_d is the dry sample weight. The water content of PGS implants rose linearly and reached 15% in 35 days, at which time the polymer had degraded $> 70\%$ (Fig. 4A). In contrast, water uptake of PLG implants showed a time lag followed by a surge of water content, in a pattern similar to its mass loss (Fig. 4B). The water content of PLG implants increased gradually to 11% within 14 days, then increased abruptly, and reached 49% within the next 7 days. One of the key functions of a degradable polymer in an implant is to provide mechanical support. Hence it's critical to know how the mechanical strength changes with degradation. The PGS implants lost mechanical strength gradually and slowly after implantation, about 8% each week. At day 35, when $< 30\%$ of the PGS implant's mass was left, the modulus was $> 50\%$ (Fig. 4A). In contrast, PLG implants lost their mechanical strength shortly after implantation ($> 98\%$ within 7 days). At 14 days, PLG implants' moduli were reduced to 0.25%. At 21 days, with 42% of the mass left, their moduli were reduced to 0.023% (Fig. 4B). This demonstrates that PGS implants maintained their mechanical strength much better than PLG implants. The explants were tested according to ASTM standard D575-91. Briefly, the explants were compressed at a fixed ramp speed of $2\ \text{mm/min}$. PGS explants were compressed to 50% strain, whereas PLG explants were compressed to failure. Pristine samples and PGS explants had regular

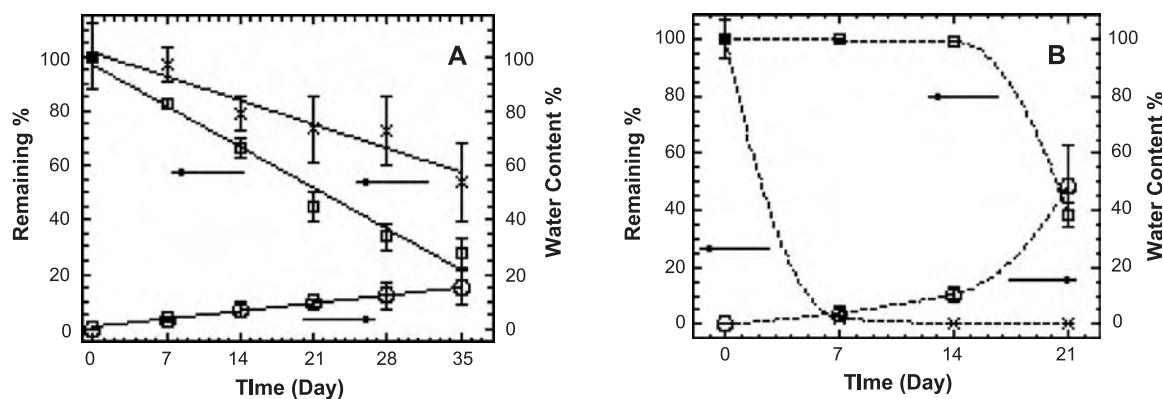

Fig. 4 Comparison of the changes in mass (\square), mechanical strength (\times), and water content (\circ) of PGS (solid line) and PLG (dashed line) implants upon degradation. A) Steady, almost linear changes of PGS implants' properties upon degradation. B) Abrupt, nonlinear changes of PLG implants' properties upon degradation. Data were plotted as mean with standard deviation. (Adapted from Ref. [22].)

geometry and were measured with a digital caliper. PLG explants deformed upon degradation, and their dimensions were measured to the best approximation. The rate of mass loss is of fundamental importance in studying the degradation characteristics of a biodegradable polymer. PGS implants lost their weight steadily and linearly over the test period of 35 days, at which time they had lost $> 70\%$ of their mass (Fig. 4A).^[22] The mass loss of PLG was negligible ($< 1\%$) within 14 days, then surged abruptly, and reached 61% in the next 7 days (Fig. 4B). The dramatic mass loss after the initial lag for PLG upon degradation was similar to what has been reported in the literature.^[23-25] The differences in degradation characteristics between PGS and PLG under identical conditions indicate they probably degrade by different mechanisms. Unlike PLG, which degrades mostly by bulk degradation, in vivo degradation of PGS is dominated by surface erosion, as indicated by linear mass loss with time, preservation of implant geometry, better retention of mechanical strength, absence of surface cracks, and minimal water uptake. Upon degradation, PGS implants keep their integrity better than PLG implants, and may prove useful in biomedical applications where other such polymers are unsuccessful.

BIOCOMPATIBILITY OF PGS

PGS appears to be biocompatible both in vitro and in vivo. Under identical conditions, cultured fibroblasts grew faster on PGS surfaces than on PLG surfaces. Subcutaneous implantation experiments showed that PGS induced only acute inflammation, whereas PLG implantation sites presented signs of chronic inflammation such as fibrous capsule formation and foreign body giant cells.

In Vitro Biocompatibility

The in vitro biocompatibility of PGS was evaluated in comparison with PLG, both in morphology and in cell growth rate. Glass Petri dishes were coated with PGS and PLG, respectively. The coated dishes were sterilized by UV radiation for 15 min. Each dish was soaked in growth medium for 4 h; the medium was replaced with fresh medium and the dishes soaked for another 4 h to remove any unreacted monomers or residual solvents before cell seeding. NIH 3T3 fibroblast cells were seeded homogeneously on these coated dishes. The cells in PGS sample wells were viable and showed normal morphology with higher growth rate than the control, as tested by methyl thiazol tetrazolium (MTT) assay.^[26] Cells in PLG wells tended to form clusters, and the number of floating cells was higher; furthermore, most of the attached cells adopted a long thin threadlike morphology. These experiments suggested that PGS is at least as biocompatible as PLG in vitro.

In Vivo Biocompatibility

Subcutaneous implantation in SD rats was used to compare the in vivo biocompatibility of PGS and PLG. The surface area/volume ratio was kept the same for both PGS and PLG implants. Autoclaved PGS slabs of approximately $6 \times 6 \times 3$ mm, and ethylene oxide-sterilized PLG (50:50, carboxyl-ended, MW 15,000, Boehringer Ingelheim, Inc., Germany) disks were implanted SC in female SD rats by blunt dissection under general anesthesia. Two implants each of PGS and PLG were implanted symmetrically on the upper and lower back of the same animal. Every implantation site was marked by tattoo marks. The animals were randomly divided into five groups. At each predetermined time point (7, 14, 21, 28, 35 days),

one group of rats was sacrificed, and tissue samples surrounding the implants were harvested. The samples were fixed and embedded in paraffin after dehydration. The slides were stained with hematoxylin and eosin (H&E) and Masson's trichrome stain (MTS). The thickness of the inflammatory zone (H&E) and collagen deposition (MTS) for each polymer implant is expressed as the average value of three readings per slide for six slides at each time point.

The inflammatory responses subsided with time for both PGS and PLG implants. In the first three weeks, the inflammatory response of PLG implantation sites was about 16% thinner than that of PGS (Fig. 5). The thickness of the inflammatory zone in both implantation sites was approximately the same at weeks 4 and 5. Fibrous capsules surrounding PLG implants

developed within 14 days, and their thickness hovered around 140 μm . Collagen deposition did not appear around PGS implants until 35 days. The collagen layer was highly vascularized and was only about 45 μm thick. Foreign body giant cells were present in the PLG implantation sites 35 days postimplantation. However, no foreign body giant cells were observed around PGS implants. The inflammatory response and fibrous capsule formation observed for PLG is similar to those reported in the literature.^[27,28] Thick fibrous capsules may block mass transfer between the implants and surrounding tissues, which can impair implant functions. In an *in vivo* study with PGS alone, the SC implantation sites were undetectable despite repeated sectioning of the specimens at multiple levels in 60 days (two implantation sites each in three animals).

Fig. 5 Photomicrographs of rat skin; comparisons of lumen wall characteristics (H&E, 10 \times) and fibrous capsule thickness (insets, MTS, 5 \times) at implantation sites across time. A, C, E: PGS; B, D, F: PLGA. A, B: 7 days postimplantation (pi)—lumenal wall was markedly thickened by a zone of dense vascular proliferation and mild inflammation without detectable collagen deposition. C, D: 21 days pi—lumenal wall was significantly thinner with a modest degenerative inflammatory infiltrate immediately adjacent to the polymer. PLGA implantation site (D) was marked by a significant collagen fibrous capsule, which was absent in PGS. E, F: 35 days pi—lumenal wall was reduced to a thin zone of cell debris with no vascular proliferation. Collagen deposition in PGS implantation site was much thinner than that surrounding the fragmented PLGA implant. Top: skin, implantation site: *, scale bar = 200 μ . (Adapted from Ref. [26].)

The implants were completely absorbed without granulation or scar tissues, and the implantation site was restored to its normal histological architecture. Overall, the acute inflammatory response of PGS is similar to that of PLG. However, unlike PLG, PGS barely induces any significant fibrous capsule formation, and the implantation site is free of foreign body giant cells, suggesting the absence of chronic inflammation.

APPLICATIONS OF PGS

Similar to vulcanized rubber, this PGS elastomer is a thermoset polymer. However, the uncross-linked prepolymer can be processed into various shapes, because it can be melted into a liquid and is soluble in common organic solvents. In a typical procedure, a mixture of NaCl particles of appropriate size and an anhydrous THF solution of the prepolymer is poured into a Teflon mold. The polymer is cured in the mold in a vacuum oven at 120°C and 100 mTorr. A porous scaffold that conforms to the shape of the mold is obtained after salt leaching in DI water. So far, the applications of PGS are focused on soft-tissue engineering. The material supports the growth of a wide range of cell types such as endothelial and smooth muscle cells, Schwann cells, cardiomyocytes, hepatocytes, chondrocytes, and fibroblasts.

Artificial Microvasculature

Vital organs maintain dense microvasculatures to sustain the proper function of their cells. For tissue-engineered organs to function properly, artificial capillary networks have to be developed. Due to its elastomeric properties, PGS might be a good candidate for fabricating microvasculature. Standard MicroElectroMechanical Systems (MEMS) techniques were used to etch capillary network patterns onto silicon wafers. The resultant silicon wafers served as micromolds for the devices. The patterned PGS film was bonded with a flat one to create capillary networks. The devices were perfused with a syringe pump at a physiological flow rate, and became endothelialized to near confluence within 7 days. These endothelialized capillary networks could be used in tissue engineering of vital organs.

Cardiac Patch

To evaluate the performance of PGS as a scaffolding material for cardiac tissue engineering, neonatal rat cardiomyocytes were seeded in PGS, collagen, and PLG scaffolds. The PGS constructs beat spontaneously for 3 days after seeding, and they beat

synchronously with a DC pulse of 1 Hz until at least 14 days. The collagen constructs behaved similarly up to 6 days. After 6 days, the constructs collapsed, because the collagen matrix was degraded or absorbed so much that it had little mechanical strength to hold the construct in proper shape. PLG scaffolds were also used to build cardiac patches. The construct failed to show any beating at macroscopic level, most likely because of the stiffness of the PLG scaffolds. Compared with collagen foams and PLG, PGS appears to be as good, if not better suited, for tissue engineering of cardiac muscles.

Liver Tissue Engineering

One challenge in liver tissue engineering is to keep the liver-specific functions of the hepatocytes in the constructs. PGS and PLG scaffolds of the same porosity and pore sizes were treated under identical conditions, and seeded with hepatocytes. Hepatocytes on PGS scaffolds showed approximately four times higher ammonia metabolism rate and 40% higher albumin secretion rate than those on PLG.

CONCLUSION

Compared with conventional biodegradable polymers, PGS appears to be tougher, less expensive, and more flexible. In the models tested, the material is biocompatible both in vitro and in vivo. The degradation of PGS is mostly through surface erosion, which gives a more linear decrease in mass and gradual change in mechanical properties. In addition, the polymer doesn't swell in aqueous media conditions when fresh, and has limited swelling upon degradation. Thus, the geometry and surface integrity of PGS implants are maintained very well. These properties of PGS may be desirable in many applications in biomedical engineering beyond those discussed previously. The polymer's properties—such as hydrophilicity, degradation rate, and pattern—can potentially be tailored by grafting hydrophobic moieties onto the hydroxyl groups. To further control or regulate polymer interaction with cells, biomolecules could be coupled to the hydroxyl groups or integrated into the polymer backbone.

Biosensors

Jerome S. Schultz

Center for Bioengineering Research, University of California, Riverside, California, U.S.A.

B

INTRODUCTION

Biosensors are small devices that utilize biological components such as enzymes, membranes, or antibodies for detecting specific analytes. These devices intimately couple a biological recognition element that interacts with an analyte with a physical transducer that converts the biorecognition event into a useful electric signal. Common transducing elements include optical, electrochemical, mass-sensitive, or thermal devices that generate light, current, frequency, or temperature signals, respectively.

OVERVIEW

The earliest chemical sensor, which was in the form of a probe that could be placed in a solution, was the glass pH electrode for the measurement of hydrogen ion concentration. Because of the relative inertness of glass to most chemicals and ions, the pH electrode—which was developed in the 1920s—was one of the first devices that could be used directly in biological media such as blood. One can distinguish two categories of biosensors by the nature of the recognition event. Bioaffinity devices rely on selective and sometimes reversible binding of the target analyte to a surface-bound ligand. No net consumption of analyte or other reagent takes place. In contrast, biosensors that use biocatalytic components such as an immobilized enzyme to recognize target substrate incur loss of some component(s) of the assay mixture. These two types of biosensor systems have different operational characteristics. In the latter case, because of the consumption of reagents, the diffusion of the analyte to the sensor can become a limiting factor in sensor response or sensitivity. For example, if the biosensor is placed in a sample that is not well stirred, then variations in the rate at which the analyte can reach the sensor can affect the magnitude of the signal generated and slow down the response of the system. For the former (bioaffinity) type, the rate at which the sensor reaches a steady reading may be affected by sample mixing, but the calibration will not be affected.

With the increasing interest in miniaturized sensing systems, the distinction between a biosensor and a portable bioassay is becoming blurred. Portable

bioassays were introduced in 1965 with the paper strip assay system for glucose called Dextrostix, which was manufactured by Miles Laboratories (now Bayer). This “dry chemistry” technology consisted of a glucose oxidase enzyme impregnated into a paper strip with associated chemicals that produced a color change when a drop containing glucose was applied to the strip. The method was used for monitoring blood glucose.

In that case, the chemical reactions were

Hydrogen peroxide + Orthotodine

→ Oxidized orthotodine (colored)

The amount of color produced was quantitated either by comparing to a standard color chart or by measurement in a reflectometer device called the Ames Reflectance Meter.

These types of assays have expanded greatly with the introduction of immunoassay cartridge units that have been devised for a variety of purposes from pregnancy tests to tests for drugs of abuse. When the readout of these bioassays has been coupled to an instrument such as a colorimeter or an electrode system, the device is sometimes called a biosensor. While the original use of the term “biosensor” implied a handheld probe of some type that could be placed in a sample to obtain a continuous measurement of a specific analyte, today the term biosensor is used so broadly that the only remaining feature of the original meaning relates to a miniature bioanalytic system that incorporates a numerical readout device.

The history of biosensors goes back to 1956 when Leland Clark described an oxygen electrode^[1] and 1962 when he coupled an enzyme to the oxygen electrode to make a glucose electrode.^[2] The problem that prompted this invention was the need to continuously measure metabolites in biological tissues. As is still true, most methods required sampling of tissue, blood, or other fluids and processing the material separately through various laboratory procedures in order to obtain accurate estimates of various biochemicals. The lack of suitable sensor systems limited

the understanding of the dynamics of biological systems, and in certain applications such as diabetes and chemotherapy, the clinical benefit of invoking control algorithms by feedback techniques was not possible.

The critical new concept introduced by Clark in 1956 was the use of permeable membranes to form separate but intercommunicating regions within the device. In a polarographic cell, he interposed a membrane between the platinum working electrode and the external media to protect the electrode from deleterious components in the sample solution. Clark's oxygen electrode, shown as the upper component in Fig. 1, is an amperometric polarographic device. A constant voltage is applied to a platinum electrode versus the reference silver/silver chloride that places the electrode in the diffusion-limited regime, i.e., the oxygen concentration at the electrode surface is reduced to zero. Thus, the amount of current developed at the electrode is directly proportional to the rate of oxygen diffusion to the electrode. Clark's invention was to place a plastic membrane that provided a constant diffusion resistance to oxygen between the electrode and the test solution, ensuring that the current was proportional to the oxygen. The other function of the

plastic membrane was to prevent other electroactive substances in the test solution from reaching the platinum electrode. (Gases can diffuse through plastic but ions cannot.) Because of the success of Clark's glucose electrode (Fig. 1), much of the early work on biosensors also utilized electrochemical detection devices.

The emergence of alternative measurement methods that utilized spectrophotometric techniques was initiated in 1976 by Lubbers and Optiz,^[3] who coined the term "optodes" as a methodology coupling optical systems to miniaturized analytical methods for sensors. (The word "optode" was meant to convey a similarity of this technique to electrodes, where the interaction occurs at the surface of the device.) This opened doors to transforming many of the analytical colorimetric, spectrophotometric, and fluorometric methods used for many years in analytical chemistry to sensor formats. Lubbers showed that these approaches could be miniaturized by placing appropriate chemistries at the end of an optic fiber, thereby producing probes that could be used in a variety of environments and solutions. One of the very first probes of this sort was produced by Peterson and colleagues at NIH,^[4] who developed a fiber-optic pH probe. This device was

Fig. 1 Structure of Clark sensors. The upper section of this composite sensor is the "oxygen electrode." This portion consists of an amperometric polarographic cell that is separated from the environment by a silicone rubber membrane. The lower "biorecognition section" contains the enzyme glucose oxidase that converts glucose to gluconic acid. Together, the two sections compose Clark's "glucose biosensor."

based on the changes in the absorption spectra of pH-sensitive dyes placed at the end of a fiber-optic catheter. Peterson also developed a fluorescent probe for oxygen by using a dye that exhibits quenching in the presence of oxygen (first described and utilized in this fashion by Lubbers).

This concept was elaborated further by David Walt and colleagues,^[5] who made enzyme optodes by placing enzymes at the end of optical fibers and using chemical reagents that produced an optical change (either absorption or fluorescence) when presented with the analyte.

A key advantage of most biosensors is the ability these probes can provide for reliably measuring specific analytes when inserted into diverse samples consisting of complex mixtures of chemical and biochemical entities. This capability makes biosensors particularly attractive for research and consumer use. Since Clark's invention, hundreds, if not thousands, of biosensors have been described in the literature. A few sensor devices have reached commercialization with applications still primarily in the biomedical area, such as for blood glucose. However, as these devices are proven to be reliable, robust, and portable, their applications to other fields, such as the food industry (for freshness) and environmental/toxic monitoring, is expanding rapidly.

There are two major components of biosensors, as shown in Fig. 1. These consist of the biochemical component that provides the recognition of the analyte of interest, and a detector that responds to a physical/chemical change in the local environment that is the result of the interaction of the analyte with the biochemical component. Often membranes are used to separate regions of the sensor for various reasons—e.g., to prevent the leakage reagents from touching the

sensor, to protect the detector from deleterious interactions with materials in the sample, to allow only certain types of chemical species to enter the sensor.

Although there are many sensors that could be used as a detector in a biosensor, the choice is somewhat limited to the type of chemical interaction that occurs between the analyte and recognition element. Fig. 2 illustrates some of the schemes that have been tried for a glucose biosensor. The sensitivity of the final biosensor system is strongly related to the characteristics of the physical sensor used as the detector element.

The biological recognition element is the component that gives biosensors their unique qualities of selectivity. These molecules are a gift of millions of years of biochemical evolution. During the eons that living systems evolved, several unique structures were evolving at the molecular level as well. For example, antibodies (Fig. 3) are an essential component of the immune system that only came into existence when mammals made their appearance on earth. The immune system is the most powerful molecular identification system yet discovered. A typical animal has the ability to generate about 100,000 different antibodies that have binding selectivities for an equal number of analytes. In addition, a typical cell has hundreds of different enzymes, each of which could serve as the recognition element in a biosensor. Also, the enormous diversity of receptors for signaling species such as G proteins just becoming documented are another potential resource for biosensors.

Some appreciation of the discriminatory capability of biosensors can be obtained from the data in Table 1 (from YSI) that gives the relative response of their glucose biosensor to various compounds that might be found in blood or other biological samples. As can be seen, the potential interference of a glucose measurement

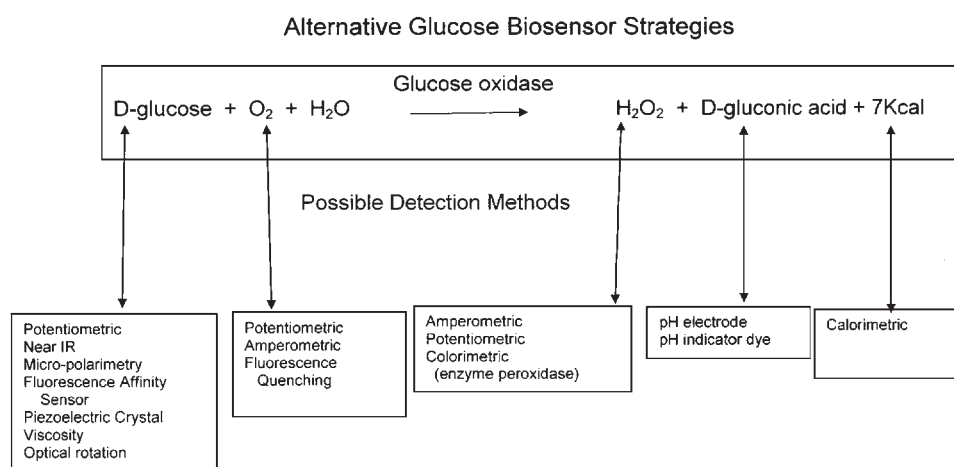

Fig. 2 Examples of the wide variety of strategies for the measurement of glucose primarily based on the biorecognition afforded by glucose oxidase. Biosensors corresponding to each of these strategies have been described in the literature. (Adapted from Ref. [6].)

Fig. 3 General structural features of IgG antibodies, molecular weight about 180,000. The binding sites are located at the terminal ends of the arms of the molecule. The molecule can be cleaved near the hinged region to result in active mono-binding fragments known as Fabs.

by other compounds in these samples can be quite high (e.g., acetaminophen). This illustrates the need to evaluate the response of biosensors in the type of samples of interest, since there might be unknown components that may affect the calibration of the biosensor.

GENERAL FEATURES OF A BIOSENSOR

The components of a commercial model of a Clark-type glucose sensor produced by YSI are shown in a more expanded view in Fig. 4. The primary component is the enzyme glucose oxidase that provides the selectivity to the sensor. As mentioned earlier, glucose oxidase had been used in the Miles Dextrostix glucose assay strip.

The reaction steps for the glucose electrode are shown below:

The net reaction is

For every mole of glucose that reaches the enzyme and is consumed, $1/2$ mole of oxygen is also consumed. Since the detector, an oxygen electrode, measures

oxygen concentration, the net result of the presence of glucose is a reduced oxygen reading from the oxygen electrode. Thus for the sensor to work satisfactorily, the oxygen concentration in the solution presented to the glucose electrode should be the same from sample to sample. This condition is easy to achieve if the solutions presented are saturated with air, but difficult to achieve if the sensor is placed in tissue where the oxygen concentration can vary widely.

This illustrates that there are special design considerations and compromises that are required in most sensor designs. For example, one solution to deal with the variation in oxygen concentration in vivo was developed by David Gough, who fashioned a dual-electrode system consisting of a glucose electrode and a separate oxygen electrode in the same catheter. Thus variations in blood oxygen could be accounted for. In one series of animal tests, Gough's glucose sensor gave reliable measurements for more than six months when implanted in a blood vessel in a dog.^[7]

Although there is ongoing very active research on new biosensor technologies, translating these new concepts into practical products for commercial use has been difficult. Issues to be resolved are stability (such as storage life), reliability, and accuracy. Since many of these sensors contain complex biomolecules such as antibodies and enzymes, long-term stability is an important issue. One solution is to manufacture the biosensor in a manner so that various elements can be replaced easily. YSI markets a biosensor platform that can be disassembled to replace sensitive components while preserving the configuration of the various elements as shown in Fig. 4.

Membrane matrices are available with a variety of different immobilized oxidase enzymes to allow the measurement of a variety of analytes such as choline, D-glucose, dextrose, ethanol, galactose, hydrogen peroxide, lactose, L-glutamate, L-glutamine, L-lactic acid, methanol,

Table 1 Inhibitors of glucose oxidase-based biosensor

Analyte	Response relative to glucose ^a (percent)
Fructose	0.1
Sorbitol	0.3
Xylose	1.0
Galactose	1.5
Ascorbic acid	2.0
Mannose	3.0
Acetaminophen	300

^aResponse relative to glucose is calculated as follows: If we assume that the instrument reading for glucose at some concentration (A) is 50 and the instrument reading for another analyte at the same concentration (A) is x, then the response relative to glucose is $(x/50) \times 100$.

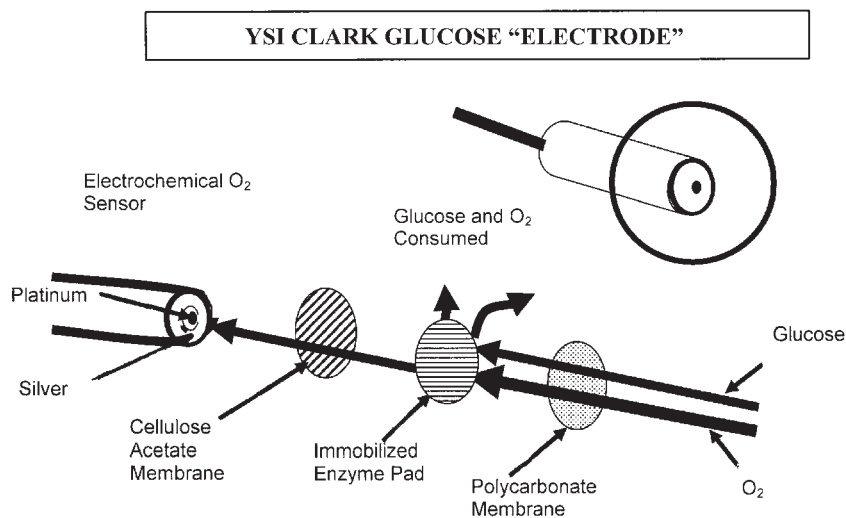

Fig. 4 Exploded view of a commercial biosensor (manufactured by YSI). The sensor is designed to provide a platform for several analytes. The section titled “Enzyme Pad” can be substituted with membranes containing different enzymes so that the biosensor can be used to measure several analytes.

and sucrose. Typical sample volume for these commercial biosensors is on the order of 10–25 microliters.

Another example of a commercial biosensor is the handheld glucose analyzer that is sold to diabetics for daily monitoring of blood glucose (Fig. 5). In this device, a drop of blood is placed on a disposable strip that contains the reagents, including glucose oxidase. The monitoring device may have a data storage unit that allows the review of blood glucose values over a period of time.

BIOLOGICAL RECOGNITION ELEMENTS

Enzymes have been the most frequently selected biorecognition element in biosensors for a number of

Fig. 5 Photo of a commercial biosensor used by diabetics. First, one draws a drop of blood by pricking a finger. The drop is placed on a treated paper strip that is then placed inside the sensor to obtain a measure of the glucose concentration in the blood. Most of the commercial glucose sensors to date use glucose oxidase as the active reagent.

reasons. The technology for producing enzymes for commercial purposes is very well developed, and a number of enzymes are commonly used in conventional bioassays such as ELISAs (enzyme-linked immunoassays). Technologies to isolate, purify, and immobilize these reagents makes them a very practical resource for biosensor applications. In addition, the reaction kinetics and substrate specificities of many enzymes have been well documented and reported in compendiums of enzyme literature. Some of the enzymes that have been used in biosensors are listed in Table 2. In some cases, the role of the enzyme is not for biorecognition but rather as a biochemical amplifier to enhance the measurement of a binding event with the selective bioreceptor. This strategy was first used in immunoassays—for example, using horseradish peroxidase with the substrate *o*-phenylenediamine to produce a highly colored product—resulting in a well-established technology that is useful for developing biosensors.

Another principle that has been evaluated for the construction of optically based sensors is the use of chemiluminescence. In these cases, an enzyme system specific for the analyte is coupled to reactions that produce light through chemiluminescence. In principle, systems of this type could be very sensitive, first of all due to the amplification factor of enzyme reactions, and secondarily because fluorescence measurements are among the most sensitive of optical techniques.

At nearly every level of biological behavior, there are recognition events that direct biological function. Doubled-stranded DNA holds together due to the complementary structure of the two strands, proteins are synthesized through a series of steps involving transfer RNA and ribosomes, some proteins become enzymes and have specific binding characteristics for certain substrates, and so on, including membrane

Table 2 Enzymes that have been used in commercial biosensors

Enzyme	K_M (mol l ⁻¹)	Substrate
Alcohol dehydrogenase	1×10^{-2}	Ethanol
Catalase	1	Sucrose, glucose
Choline dehydrogenase	7×10^{-3}	Phospholipids
Lactate dehydrogenase	2×10^{-3}	Lactate
Galactose oxidase	2×10^{-1}	Galactose
Glycerol kinase	1×10^{-6}	Glycerol
Glucose oxidase	1×10^{-2}	Glucose
Lactate dehydrogenase	2×10^{-2}	Lactate
Lactate oxidase	2×10^{-2}	Lactate
Mutarotase	3×10^{-2}	Glucose
Sulfite oxidase	3×10^{-5}	Sulfite
Urate oxidase	2×10^{-5}	Uric acid

(From Ref. [8].)

proteins that have specific transport properties. Each of these biological elements can in principle be used as a recognition element in a biosensor. Recently there has been a great deal of research to understand and predict the binding characteristics of various proteins that control essential physiological functions. These studies use computer programs to simulate the binding (or docking) of reagents to the “active site” of proteins. Interest in these programs (available from companies such as Tripos and Accelrys) derives primarily from the pharmaceutical industry to obtain some educated guesses for potential drug candidates. But these programs can also benefit groups working on sensor development. One may wonder why such complex molecules evolved to carrying our signal transduction in biological systems. The likely explanation is that the macrostructure is needed to stabilize the three-dimensional configuration of the binding site.

One class of bioreceptors that has made a considerable impact on bioassays is antibodies. The use of antibodies as an analytical reagent was pioneered by Berson and Yalow,^[9] who devised the type of assay known as immunoassays. Their technique is illustrated in Fig. 6. It depends first on finding an antibody to the analyte of interest and synthesizing an analogue to the analyte, denoted by the symbol (*), with some type of signaling agent as part of its structure (such as a radioisotope or a fluorochrome). (In the immunology literature, the analyte is called the antigen.) In one mode of operation, the antibody is immobilized on the surface of the test vessel. Then, the test solution with a known amount of the analogue analyte is introduced into the test vessel. After a period of incubation, the test solution is removed, and the amount of analogue analyte remaining in the tube is measured. This

amount will be inversely related to the amount of analyte in the test solution. The sensitivity of the immunoassay is related to the affinity of the analyte to the antibody. As shown in Fig. 7, depending on the method of preparation, antibodies can be prepared with affinities that range over six orders of magnitude. However, as also shown in this figure, the higher the affinity the slower the rate of dissociation of the antibody–analyte complex.

Today hundreds of immunoassay kits are produced commercially for use in hospitals and clinical laboratories, and thousands of these tests are performed daily. This assay is widely used because of the high specificity of antibody–analyte binding in the presence of many other biochemicals. For example, the test sample can be from blood plasma and can be used in an immunoassay without further purification. This

Fig. 6 Illustration of the immunoassay method developed by Berson and Yalow. An antibody (denoted by the symbol Y) for the analyte of interest (denoted by the symbol O) is immobilized on the surface of a well of a multiwell plastic analysis plate (1). A sample containing an unknown amount of the analyte (O) and a known amount of an analogue analyte (*) is pipetted into the well (2). Both the analyte and analogue compete for antibody binding sites. The more analyte in the unknown sample, the less of the analogue will bind. The well is rinsed with buffer to remove unbound analyte and analogue (3). The remaining amount of analogue analyte is measured by a fluorescent photonic device (4).

Fig. 7 The range in binding constants that can be prepared from animals. The greater the affinity of an antibody for the analyte, the more sensitive the immunoassay (or biosensor) will be for the analyte. (Data reported in Ph.D. thesis of Ref. [10].)

selective characteristic of antibodies has found many applications in the production of biosensors.

Schultz and Mansouri^[11] were one of the first to apply the immunoassay technique to make a biosensor. First, they placed the reagents in a porous microdialysis “test tube” at the end of an optical fiber. Since an antibody for glucose was not known at the time, they used the protein Concanavalin-A, a lectin well known for its affinity for glucose, as a surrogate for the antibody. They thus demonstrated that any protein that shows specific binding behavior could be used in a biosensor, and termed the technique “affinity biosensors.” A typical calibration curve, Fig. 8, shows the saturation behavior at high analyte concentrations for this type of biosensor.

More recently, Ballerstadt and Schultz^[12] have developed a minimally invasive biosensor that is designed to be placed just under the skin. The implanted capsule is illuminated by an external light source, and fluorescence emitted by the biosensor is measured with an external photodetector. The structure of the sensor is illustrated in Fig. 9a. The hollow dialysis microcapsule is loaded with Sephadex microbeads and fluorescein-labeled Concanavalin-A. The dialysis membrane allows glucose to freely exchange between tissue fluid and the inside of the capsule. The polymer composing the microbeads has many pendant glucose residues, and when the glucose concentration in the microporous capsule is low, most of the Concanavalin-A will reside inside the microbeads because of its affinity for the pendant glucose residues inside the bead. The microbeads are treated with dyes so that light cannot enter the beads and does not elicit emission from the fluorescein/Concanavalin-A within the beads. Whenever the glucose concentration within the capsule

increases, glucose competes for Con-A binding sites, releasing some Con-A from within the beads. The fluorescein/Concanavalin-A now is exposed to the external light, and emission occurs. Thus the magnitude of emission is directly related to the concentration of glucose in the tissue outside of the microdialysis tube. This sensor is designed to be placed subdermally and operated with an external light source and detector as shown in Fig. 9b.

With the recent sequencing of entire genes, the measurement of DNA fragments has become an essential clinical tool for tracking diseases. Biosensor approaches for DNA detection use the hybridization property of complementary DNA sequences as a molecular recognition event. One example is the synthesis of molecular beacons (Tyagi and colleagues^[13]) that are small nucleotide strands designed to self-hybridize by incorporating complementary DNA sequences at each end of the linear strand. At the two terminals of the strand, fluorescent dyes are attached. These dyes are selected to show fluorescence quenching when in close proximity. This is shown diagrammatically in Fig. 10a, the so-called stem-and-loop configuration. There are 5–8 bases at each of the two ends of the beacon that are complementary to each other. When the molecular beacon is exposed to a DNA fragment that is complementary to its sequence, it will bind and the structure will open up, separating the terminal dyes (Fig. 10b). When separated the dyes will fluoresce, and this signal can be used to identify the unknown DNA fragment in the sample.

S. Fodor^[14] introduced the concept of developing array technologies for massive analysis in biotechnology research in 1991. The group at Affymax

Fig. 8 Typical calibration curve for an affinity biosensor. This glucose biosensor data from the work of Schultz and Mansouri shows saturation behavior at high glucose levels corresponding to complete saturation of Concanavalin-A with glucose.

Fig. 9 Concept for a subdermal optical biosensor for various metabolites or drugs. A) The biosensor “capsule” consists of a microporous tube containing the sensor reagents. B) The glucose biosensor components consist of porous Sephadex beads coated by appropriate dyes to prevent fluorescence from fluorescein/Con-A adsorbed inside the beads. When the biosensor is exposed to glucose, glucose enters the capsule and competes with Sephadex for Con-A binding sites, resulting in the displacement of the fluorescent Con-A from the beads into the void space where they are excited by light and emit light at a longer wavelength. The emitted light is measured by a photonic device placed on the surface of the skin.

showed that gene sequencing and gene discovery could be accomplished by immobilizing thousands of polynucleotide fragments of known characteristics as a matrix of micron-sized spots on microscope-like slides. The array chip is then exposed to fluorescent-labeled gene fragments from a sample under study. Hybridization is allowed to occur, and then by the pattern of fluorescent spots on the chip, the DNA sequence of the unknown sample can be deduced. Array technology has been expanded to be useful in identifying genetic defects and in drug discovery.

For DNA chip technologies, the DNA fragments are bound to the surface. A variety of methods have been used to attach the DNA probes, but they usually involve a carboxyimide coupling using the five prime amino-modified nucleotides placed directly on the surface with a mechanical micropipette. Current commercial versions of these chips hold 20,000–40,000 probes in approximately a one-square-centimeter chip area. Another approach for putting the DNA on the chip is by using microjet dispensing systems. The protocol for using a DNA microarray chip usually is as follows. DNA is extracted from the sample of interest, and the DNA is amplified by a PCR technique. At some point during this process, fluorescent tags are incorporated into the DNA strands. The DNA is

separated into individual strands and then exposed or put on the microarray plate. DNA fragments will associate with immobilized DNA on the microarray plate wherever there is a match between the unknown DNA in the sample and a known fragment on the plate, resulting in a spot at that location. These spots where there is a combination between the DNA sample and the DNA on the plate will give rise to a fluorescent spot, and this can be measured with a reader. Since the DNA on the chip is known, the corresponding sequence on the DNA in the unknown is determined.

Another type of biosensor that uses artificial ion channels has been reported by Cornell et al.^[15] (Fig. 11). The basic mechanism for this type of device depends on the use of artificial bilayer membranes that have pore-forming materials in the surface, such as the antibiotic gramicidin, that are cross-linked to an affinity ligand. Gramicidin has a doughnut-type structure and randomly floats in each surface of the bilayer. Normally the different floating doughnuts do not coincide and there isn't an aqueous channel across the bilayer membrane through them. However, if due to binding events with the affinity ligand these doughnut-like molecules are aligned, aqueous pores are formed through the membrane, allowing a high flux of ions to pass through. Along with this ion flux is a large change

Fig. 10 “Molecular beacon” sensor mechanism. A DNA loop structure is synthesized containing the mating sequence to a DNA fragment to be identified. In the loop configuration (a), the terminal ends of the strand are in close proximity, causing fluorescence from the pendant dye molecule to be quenched. When the sensor with the molecular beacon on its surface is exposed to a sample containing the corresponding DNA fragment, the molecule opens up, separating the ends and resulting in an increase in emitted fluorescence (b).

in conductivity that can be quantified by impedance measurements. Thus the change in impedance due to the binding of the analyte to the affinity ligand composes this biosensor.

CELL-BASED SENSORS

One of the first applications of cells as biosensors has been in the field of pollutants (reviewed by Pancrazio et al.^[16]). Some pollutants may affect the metabolism of bacteria or microorganisms, and the change in the metabolism of these microorganisms to produce more

acid or decrease oxygen consumption is an indication of the concentrations of the pollutants. Typically cells are placed near a sensor that measures a change in the local environment—for example, either the pH or the oxygen concentration. In the presence of the pollutant, if the cells’ metabolism is changed, there will be a change in the concentration of one of these environmental components. By measuring the change in pH, for example, one can estimate the amount of the pollutant. A commercial device called a Cytosensor, once manufactured by Molecular Devices, used whole cells as biosensors. Essentially this instrument was a microphysiometer that consisted of very small wells in

Fig. 11 Concept for a biosensor based on the conductivity through a bilayer (Cornell and coworkers). A membranelike bilayer is deposited on a conductive surface (e.g., gold). The bilayer is seeded with a molecule that has an aqueous core (e.g., gramicidin). In the lower bilayer, the gramicidin is anchored to the metal surface. The upper bilayer is seeded with gramicidin that is tethered to an analogue analyte whose motion is hindered because it is bound to a bioreceptor for the analyte. When the biosensor is exposed to free analyte, the upper gramicidin is released and moves freely in the upper bilayer. Occasionally (right panel) it intersects with a gramicidin molecule in the lower bilayer, creating an aqueous channel that allows the passage of ions and resulting in a measurable current.

a culture dish where the organisms were placed. An optical system to measure pH changes was used to measure changes in the metabolism of cells. In addition to toxicology studies, this type of device is useful for pharmacokinetic studies and drug screening and has been used with a variety of cellular types including neurons, hepatocytes, T-cells, etc.

Alternatively, instead of measuring the metabolic response of cells to various analytes, another sensitive indicator that reflects cell "well being" is the impedance of cells to electric fields. Cells have dielectric properties that are a function of the status of the cell membrane. Since intact living cells are very good insulators at low frequencies, slight changes in membrane properties can be measured accurately. By culturing cells over electrode arrays, changes in the electrode impedance allows a noninvasive method of following cell behavior such as adhesion, spreading, and motility. Impedance measurements have been used to monitor behavior of nonexcitable cell types including macrophages, endothelial cells, and fibroblasts.

Excitable cells such as neurons and myocardiocytes provide a very sensitive resource for monitoring certain analytes, particularly toxic agents such as drugs of abuse and nerve agents. Typically the cells are cultured on chips consisting of microarrays of electrodes. This type of biosensor is especially useful when one wants to establish whether the sample contains substances that may be harmful to cells, rather than to identify a particular material or its concentration. Also with these devices, signal propagation through synaptic transmission or gap junction connectivity can give a measure of cell coupling which is inaccessible under other techniques. Unfortunately, excitable cells are typically quite unstable, making this technique difficult to use routinely.

Another approach using microorganisms has been to use a genetically engineered protein that causes bioluminescence in the presence of the pollutant. Typically a hybrid plasmid is introduced into the organism with dual functionality. One section is activated by a particular analyte (e.g., a pollutant such as mercury), and the second section codes for an enzyme that produces an easily detected product. An example is the construct reported by Selifonova et al.^[17] The pollutant turns on the gene; in the same gene, coding for bioluminescent proteins is activated to give a visible signal.

DETECTOR ELEMENTS

Optical biosensors often rely on changes in color or fluorescence resulting from the biorecognition event and commonly use flexible fiber-optic wave guides to illuminate the sensor constituents that are placed at the distal end of the optical fiber.

The use of optical methods became popularized after the work of Lubbers and Opitz, who developed technology that they termed "optrodes." These are fiber-optic devices in which a chemically sensitive material such as pyrene butric acid that shows fluorescence quenching by oxygen is placed at the terminal end of a fiber-optic system. Light is transmitted along the optical fiber, and when it interacts with the material at the terminal end, a change in the characteristics of the light occurs, e.g., absorption, fluorescence, scattering, and polarization. Some of this light energy is captured and retransmitted back through the same or an alternative fiber to a photodetector device. The change in optical characteristics can then be related to the concentration of material at the end of the optical fiber.

Optical fiber detectors are typically utilized as either miniature spectrophotometers or fluorimeters and employ indicator dyes that can be detected by absorbance or fluorescence methods. For example, by measuring the absorption of solutions of phenol red at two wavelengths, the isobestic point at 490 millimicrons where absorption is virtually independent of pH and at 600 millimicrons where the intensity of absorption is very pH sensitive, one can estimate the pH of a solution or region optically. Thus, in the glucose biosensor systems shown in Fig. 2, such a fiber-optic pH sensor could be used to estimate the amount of gluconic acid formed.

Many different chromophores have been developed for use in bioassays. These compounds either change color as a result of some change in the environment such as a pH shift or change their fluorescent properties as a result of some chemical environmental change. Fluorescence methods tend to be more sensitive for analytical purposes if in the absence of the analyte light emission is minimal, resulting in a desirable high signal-to-noise ratio.

Another method uses a phenomenon known as surface plasmon resonance. This effect occurs at a surface that is coated with a thin layer of metal (e.g., gold). The critical angle of total internal reflection is then a function of the thickness of an adsorbed film on the metal surface. Lundstrom and colleagues^[18] showed that if the metal surface is first coated with a biorecognition component, such as an antibody, the subsequent binding of an analyte will cause a change in the angle of maximum reflection as shown in Fig. 12. Instruments using this technology are manufactured by Biacore and Thermo Lab Systems.

In situ label-free (i.e., without the use of chromophores) optical detection can be achieved through changes in other optical properties designed into the biorecognition event. For example, an array of nanoparticles changes its color as a function of spacing or aggregation. Asher^[19] showed that these particles can be coated with antibodies for a specific analyte and

Fig. 12 An optical biosensor technique based on surface plasmon resonance. When the gold film is on the order of 50 nanometers in thickness, the angle of total internal reflection at a gold-quartz interface is directly proportional to the thickness of protein adsorbed on that surface. To make a biosensor, the surface is coated with a biorecognition species such as an antibody (Ab). When the surface is exposed to a solution containing the corresponding antigen (Ag), a thicker protein layer (Ab + Ag) forms, and the angle of maximum reflection changes as shown in the lower panel.

fabricated in a membrane form. When exposed to a sample containing the analyte, the analyte binds to the antibody, causing a change in the electric field around the particles. The particles will disperse and a change in color of the film will result.

Some other techniques include quartz crystal microbalance transducers. These are very sensitive mass-measuring devices that allow the dynamic monitoring of binding events. These devices consist of an oscillating crystal where the material is immobilized on the surface. When the analyte binds, the increase in mass associated with the binding events causes a decrease in oscillation frequency.

MICROFABRICATION

Miniaturization of devices and mass-production manufacturing techniques are some of the key reasons for commercial interest in biosensors at this time. Manufacturing technologies developed for completely

different applications, such as micromachining for integrated circuits and fiber optics components for telecommunications, have allowed rather novel designs to be contemplated and developed for biosensors. Another key feature of these technologies is the miniaturization of devices that one is able to achieve. Usually a microsized analytical system has components for the following functions: sample injection, preparation, separation, and detection. While current techniques for computer devices can make features at the nanometer level, for microfabricated analytical devices the usual feature dimensions are more likely at the micron level. This capability leads to the potential for very small, sensitive, and very stable devices that allow the development of portable and perhaps disposable biosensors. This will permit bringing the analysis system very close to the source of the analyte rather than the current mode of bringing samples of the analyte to centralized analysis laboratories. For example, if the application is environmental, one could put the sensor in remote locations to monitor many sites simultaneously. For medical uses, one can put the sensor in a catheter to be inserted into a blood vessel, or an individual could have a portable analyzer and periodically place a drop of blood in contact with the sensor.

An example of a commercial microanalysis system that utilizes microfabrication and incorporated fluidic circuits and biosensors is the product produced by i-STAT for point-of-care monitoring of blood chemistries. An exploded view of their device is shown in Fig. 13 with an explanation for the operation of this device.

SENSOR DYNAMICS

The response time of sensors to changes in concentration of an analyte depends on the response rate of the various components of a sensor. Usually, diffusional processes are the limiting factor; these include diffusion of the analyte to the surface of the sensor (dependent on external mixing), diffusion through membranes, and diffusion through the various regions of the sensor structure. Since diffusion lag times increase with the square of distance, it is imperative to maintain the active layers of the sensor to dimensions on the order of tenths of a millimeter or less. Enzyme reactions can usually be made nonlimiting if necessary by increasing the amount of enzyme in the system. In general terms, this behavior can be understood by considering the two processes involved that influence the behavior of biosensors. Diffusion of the analyte, such as glucose, into the sensor usually involves transport through a permeable membrane.

The i-STAT sensor arrays insure the integrity of the overall analytical process. The solid-state chips contain biosensors configured to perform specific tests with chemically sensitive membranes and films containing reagent chemicals. Sensors perform other functions such as monitoring the quality of the sample being tested. Silicon-type microfabrication utilizing high quality materials that exhibit exceptional stability allows consistent reproducibility in a high-volume manufacturing environment. This well accepted technology ensures that each cartridge offers a high level of accuracy and reliability.

When blood samples contact the sensors, they are measured electrochemically as follows:

Sodium, Potassium, Chloride, Ionized Calcium, pH and PCO₂ are measured by ion-selective electrode potentiometry. Concentrations are calculated from the measured potential through the Nernst equation.

Urea is first hydrolyzed to ammonium ions in a reaction catalyzed by the enzyme urease. The ammonium ions are measured by an ion-selective electrode and concentration is calculated from the measured potential through the Nernst equation.

Glucose is measured amperometrically. Oxidation of glucose, catalyzed by the enzyme glucose oxidase, produces hydrogen peroxide. The liberated hydrogen peroxide is oxidized at an electrode to produce an electric current which is proportional to the glucose concentration.

PO₂ is measured amperometrically. The oxygen sensor is similar to a conventional Clark electrode. Oxygen permeates through a gas permeable membrane from the blood sample into an internal electrolyte solution where it is reduced at the cathode. The oxygen reduction current is proportional to the dissolved oxygen concentration.

Hematocrit is determined conductometrically. The measured conductivity, after correction for electrolyte concentration, is related to the hematocrit.

A variety of calculated results are available that include HCO₃, TCO₂, BE, sO₂, Anion Gap and Hemoglobin.

Fig. 13 Exploded view of a commercial biosensor for six different analytes manufactured by i-STAT.

$$N = PA (S_e - S_i) \quad (1)$$

where

N = rate of substrate transfer (moles/s)

P = permeability of membrane (cm/s)

A = area of membrane (cm²)

S_e = external concentration of substrate (mole/cm³)

S_i = internal concentration of substrate (mole/cm³)

The rate of consumption (e.g., conversion of glucose to gluconic acid) is given by the following equation:

$$r_c = \frac{kVES_i}{K_M + S_i} \quad (2)$$

where

r_c = rate of substrate consumption (mole/s)

k, K_M = kinetic constants

V = internal volume of biosensor (cm³)

E = enzyme concentration (mole/cm³)

At steady state

$$N = r_c$$

Or

$$PA (S_e - S_i) = \frac{kVES_i}{K_M + S_i}$$

From this relationship, it can be shown that increasing the enzyme concentration (E) results in a lowering of the internal substrate concentration (S_i), eventually

resulting in the condition $S_e \gg S_i$. Under these conditions, by Eq. 1, the rate of substrate diffusion into the biosensor (and thus the magnitude of response of the biosensor) will be nearly proportional to the external concentration of the analyte, S_e .

Some of the considerations that are important in determining the structure of sensors for use in analytical assays are discussed in the following sections.

Sensitivity

Sensitivity relates to the lowest concentration that the system can reliably detect. The biochemicals in blood can have average concentration ranges from milligrams per cubic centimeter to nanograms per cubic centimeter. The wide range of concentration of different biochemicals that are present in blood presents a technical challenge to the measurement of several analytes simultaneously in the same detection system. For example, colorimetric methods can provide reliable estimates of concentrations in the millimeter range, but fluorescence techniques often are required if the analyte is in the micromolar range of concentration.

However, the rate of dissociation of antibody–analyte complexes decreases directly with increasing binding affinity. For high levels of sensitivity, high binding constants are needed. For example, to measure an analyte at a concentration of nanomoles, a binding constant on the order of nanomoles is required. The dissociation rate for such antibodies is on the order of tens of minutes.

Dynamic Range

In addition to sensitivity of an assay system, the range of sensitivity of the device is another important consideration. The dynamic range is usually defined as the ratio of highest concentration to the lowest concentration that a particular technique can reliably measure. For many analytical methods based on biosensors, the dynamic range is rarely more than a factor of about 10. Thus for any particular application, the system needs to be engineered to achieve a dynamic range that covers the normal variation in concentration for that analyte. For example, for the measurement of blood glucose, the normal level is about 100 milligrams/deciliter and the dynamic range should be between 50 and 200 milligrams/deciliter and somewhat higher for diabetics. For systems that use biological materials such as enzymes or antibodies, this means that one has to select the appropriate protein with the correct binding characteristics or reactive characteristics for the molecule that is to be measured. Fortunately, with the advent of modern molecular biology, one can either select or modify the protein's

active site to change its selectivity to fulfill the analytical requirements.

An equation that depicts the interaction of an antibody with a ligand is

The affinity constant for these antibodies is the concentration at which the protein is half saturated with the ligand.

$$K_a = K_f / K_r$$

where

K_f = forward rate constant

K_r = reverse rate constant

K_a = equilibrium constant

As can be seen by Eq. 2, enzymes have kinetic characteristics that show saturation behavior. That is, when the numerical value of the substrate concentration (S_i) is much larger than the kinetic constant K_M , the right-hand side increases to a constant asymptotic value of kVE .

The parameter for enzymes that characterizes the sensitivity level for sensors based on them is the kinetic parameter known as the Michaelis Menton constant (K_M). Again looking at the behavior of Eq. 2, when the substrate concentration is numerically equal to K_M (i.e., $S_i = K_M$) or smaller, the reaction rate is approximately linearly proportional to substrate concentrations. Enzymes can be found in nature or readily genetically modified to have K_M that vary over five orders of magnitude. Table 2 lists K_M values for some enzymes that have been used in biosensors.

Response Time

The response behavior of sensor-based analytical devices is affected by a number of parameters. With respect to the sensor component, response characteristics are usually determined by a combination of diffusional and reaction kinetic processes. The usual configuration for a biosensor includes a membrane that protects the sensor element. Thus, in the Clark glucose sensor shown in Fig. 7, the diffusion processes include the passage of glucose and oxygen from the external fluid through the dialysis membrane into the enzyme compartment and the subsequent passage of oxygen through the silicone rubber membrane into the electrode compartment.

The approximate lag time introduced by diffusion layers (either membranes or liquid layers) around or

within biosensors is related to the thickness (L) and analyte diffusivity (D) through the layer.

$$\text{Lag time (s)} = 0.2L^2/D$$

where

D = diffusivity of solute in the layer (cm^2/s)

L = thickness of layer (cm)

If the biological element is an enzyme then the kinetics of the reaction of analyte will be governed by an equation similar to that given in Eq. 2 and the overall rate of reaction will be determined by the enzyme concentration in the preparation (E) and the inherent substrate turnover of the enzyme characterized by V_m .

If the biological element is an antibody or a bioreceptor, the kinetics will be related to the magnitude of the affinity constant K_a . The affinity constant is essentially the equilibrium constant for the reversible association and dissociation of the ligand for the antibody. Kinetic studies of these reactions have shown that an increase in binding constants is directly correlated with a reduction in the inherent dissociation rates of these reactions. The implication of this behavior is that the response rate of sensors based on antibodies becomes slower with higher affinities.

An approximate value for the association rate constant (K_f) for ligands with antibodies is $10^8 \text{ M}^{-1} \text{ s}^{-1}$. Thus, an approximation for the lag time for dissociation of antibody–ligand complexes is

$$\text{Lag time (s)} = 10^{-8}/K_a$$

where

K_a = ligand–antibody association equilibrium constant (M^{-1})

Biosynthesis and Applications of Alginates

Bernd H. A. Rehm

Institute of Molecular BioSciences, Massey University, Palmerston North, New Zealand

INTRODUCTION

Alginate is a nonrepeating copolymer of β -D-mannuronic acid (M) and α -L-guluronic acid (G), linked by 1–4 linkages. Alginates adopt in nature various material properties ranging from slimy and viscous solutions to pseudoplastic materials when cross-linked with divalent cations. The comonomers are arranged in blocks of continuous M-residues (M-blocks), G-residues (G-blocks), or alternating residues (MG-blocks) (Fig. 1). Alginates are produced by bacteria and brown seaweeds. The M-residues of only the bacterial alginates are acetylated to a variable extent at positions O-2 and/or O-3. The variability in comonomer blocks and the acetylation degree strongly affect the material properties of the polymer. To understand how biological systems control this variability is of scientific and applied importance. Moreover, the analysis and understanding of the structure–function relationships of alginates would provide the basis for the production of tailor-made polymers with particular material properties for a certain application.

Since the early 20th century, alginate is an industrial product obtained commercially by harvesting of brown seaweeds from coastal regions. Only bacteria belonging to the genera *Pseudomonas* and *Azotobacter* are capable of producing significant quantities of this polymer as an exopolysaccharide. In both genera, the genetics, gene regulation, and biochemistry of alginate biosynthesis have been well characterized and only differences with respect to the alginate modifying enzymes called epimerases were obtained. In contrast to *Pseudomonas*, *Azotobacter vinelandii* produces various extracellular epimerases that enable enhanced control of epimerization of nascent alginate. Nevertheless, the polymerization process and the export of the alginate are still not known. The direct precursor of polymerization is GDP-mannuronic acid, which is polymerized to polymannuronate. This homopolymer can be further modified by acetylation at positions O-2 and/or O-3 and by epimerization, leading to a variable content of acetyl groups and G-residues, respectively. The G-residue content and distribution strongly affect the gel-forming capacity of alginates. Thus, the epimerization process is of great interest from an applied point of view. Alginate is currently used for a variety of industrial purposes, and the production is hitherto exclusively based on brown seaweeds. This entry provides

an overview of the state of art in alginate biosynthesis and the biotechnological potential of the production of tailor-made alginates focusing on medical application. Alginates have been considered as valuable biomaterials because of their interesting material property range as well as their biocompatibility. The use of highly purified alginates in medical application is already targeted by strong research and development activities as well as by steadily increasing market shares. Highly purified alginates can serve for immunoisolation of allogenic and xenogenic cells as well as tissues enabling long-term and functional implantation into the human body, as shown for allogenic parathyroid tissue implanted into patients with severe hypoparathyroidism. Further examples comprise treatment of Parkinson's disease with neuroblastic cells and diabetes mellitus using encapsulated porcine Langerhans islets.

Biomaterials play already an important role in medicine. Natural and synthetic polymers are used as biomaterials implementing a multidisciplinary approach including wound dressings, dental implants, tissue engineering, and microencapsulation of drugs, peptides, and cells as controlled drug delivery systems. The current crucial problems in purity, biocompatibility, and batch-to-batch reproducibility, especially in the case of naturally occurring polymers, must be addressed in future to enable application in medicine. The main commercial sources are species of *Ascophyllum* and *Laminaria* (Europe), *Lessonia* (South America), *Ecklonia* (South Africa), *Durvillaea* (Australia and Chile), and *Macrocystis* (California). Polyphenolic compounds and proteins, which are difficult to remove, contaminate alginates derived from harvested seaweeds and result in bioincompatibility. Hence, further thorough purification of alginates from seaweeds is required for implantation and other medical applications. These circumstances do certainly attract more interest in biotechnological production of alginates using bacteria in defined production processes.

ALGINATE BIOSYNTHESIS

Biosynthesis of the Alginate Precursor, GDP-Mannuronic Acid

The GDP-mannuronic acid is the activated precursor for alginate polymerization. Early biochemical

Fig. 1 Secondary structures of polymannuronate (M-blocks) and polyguluronate (G-blocks).

analysis of brown algae indicated enzyme activities related to alginate biosynthesis. The phosphomannose isomerase–guanosine diphosphomannose pyrophosphorylase (PMI–GMP) is a bifunctional protein catalyzing the initial and third steps of alginate synthesis. The PMI catalyzed reaction channels fructose-6-phosphate into alginate synthesis via formation of mannose-6-phosphate. Mannose-6-phosphate is converted to mannose-1-phosphate catalyzed by phosphomannomutase. The GMP activity of the PMI–GMP catalyzes conversion of mannose-1-phosphate to GDP-mannose while hydrolyzing GTP. Although the enzyme favors the reverse reaction, the efficient subsequent removal of GDP-mannose in the next step enables efficient channeling toward alginate synthesis. GDP-mannose is oxidized to GDP-mannuronic acid catalyzed by the enzyme guanosine diphosphomannose dehydrogenase (GMD). These first biosynthesis steps were confirmed in bacteria and brown algae (Fig. 2).^[1,2] Because the intracellular enzyme activities are rather low, it has been assumed that the enzymes PMI–GMP and PMM form an enzyme complex (“metabolon”).

Genes Involved in Alginate Biosynthesis

The alginate biosynthesis genes involved in the synthesis of the precursor GDP-mannuronic acid have all been identified and characterized in bacteria, and they have been designated *algA* (encoding PMI–GMP), *algC* (encoding phosphomannomutase), and *algD* (encoding GMD). With the exception of *algC* (encoding phosphomannomutase), the other two genes and all other known structural genes involved in alginate biosynthesis in *bacteria* are clustered (Table 1). So far, the respective genes were not identified in eukaryotic alginate producers such as brown algae. Several bacterial gene products putatively involved in

the polymerization process are functionally not understood. This is due to a lack of biochemical characterization of the respective proteins and to a lack of an *in vitro* alginate synthesis assay. The gene products of *alg8*, *alg44*, *algK*, and *algX* are candidates for being subunits of the alginate polymerase. The deduced amino acid sequences of these proteins contain hydrophobic regions, indicating a localization in the cytoplasmic membrane.^[4,5] Because the *algK* deletion led to the formation of uronic acids, a role in polymerization had been suggested.^[6] Recent biochemical characterization of AlgX showed that this protein is localized in the periplasm and required for alginate formation.^[7,8] Because no undecaprenol-linked intermediate has been identified in *Pseudomonas*

Fig. 2 Alginate biosynthesis pathway. PMI, phosphomannose isomerase; PMM, phosphomannose mutase; GMP, GDP-mannose pyrophosphorylase; GMD, GDP-mannose dehydrogenase.

Table 1 Bacterial alginate biosynthesis genes

Gene	Gene product/function
<i>AlgD</i>	GDP-mannose dehydrogenase
<i>alg8</i>	Polymerase/export function
<i>alg44</i>	Polymerase/export function
<i>AlgK</i>	Polymerase/export function
<i>AlgE</i>	Outer-membrane porin/export
<i>AlgG</i>	Mannuronan C-5-epimerase/biosynthesis
<i>AlgX</i>	Putative polymerase/export function and high-sequence similarity to <i>algJ</i>
<i>AlgL</i>	Alginate lyase/biosynthesis
<i>algI</i>	O-Acetylation
<i>AlgJ</i>	O-Acetylation
<i>AlgF</i>	O-Acetylation
<i>Alga</i>	PMI/GDP-mannose yrophosphorylase
<i>AlgB</i>	Member of <i>ntrC</i> subclass of two-component transcriptional regulators
<i>AlgC</i>	Phosphomannomutase
<i>AlgH</i>	Unknown function
<i>algR1</i>	Regulatory component of two-component signal transduction system
<i>algR2 (algQ)</i>	Protein kinase or kinase regulator
<i>algR3 (algP)</i>	Histone-like transcription regulator
<i>AlgZ</i>	AlgR cognate sensor
<i>AlgU (algT)</i>	Homologous to <i>E. coli</i> σ^E global stress response factor
<i>algS (mucA)</i>	Anti- σ factor
<i>algN (mucB)</i>	Anti- σ factor
<i>AlgM (mucC)</i>	Regulator
<i>algW (mucD)</i>	Homologous to serine protease (HtrA)

(Adapted from Ref. [3].)

aeruginosa or *A. vinelandii*, the polymerase, presumably localized as a protein complex in the cytoplasmic membrane, could catalyze alginate formation via an undecaprenol-independent mechanism.^[2] Thus, alginate synthesis might be similar to bacterial cellulose synthesis. In *Acetobacter xylinum* the cellulose synthase, a protein complex of 420 kDa, is localized in the cytoplasmic membrane, and catalyzes the processive polymerization of glucose residues.^[9] Accordingly, the alginate polymerase in the cytoplasmic membrane might bind the GDP-mannuronic acid at the cytosol site leading to polymerization and simultaneous translocation of nascent alginate.^[3]

In the alginate biosynthesis cluster of bacteria a gene encoding an outer membrane protein has been identified.^[10–13] Biochemical and biophysical characterization of the outer membrane protein indicated an anion-selective pore function.^[12] Topological models of these outer membrane proteins were developed showing these proteins as β -barrels consisting of 18 β -strands. Since these channel proteins could be partially blocked by GDP-mannuronic acid, these proteins

might form alginate-specific pores, which enable export of the nascent alginate chain through the outer membrane. Genes encoding the three alginate modifying enzymes (lyase, transacetylase, and C5-mannuronan epimerase) were identified and characterized in bacteria.^[3] Recently, a family of C5-epimerase genes has also been identified in the brown algae *Laminaria digitata*.^[14] Modifications of bacterial alginate are introduced after polymerization and presumably in the periplasm. The bacterial proteins involved in transacetylation (AlgI, AlgJ, AlgF), the epimerase (AlgG), and the lyase (AlgL) have been characterized.^[15–17] O-2 and/or O-3 positions of the mannuronic acid residue are targeted by the transacetylase. Acetylated residues are protected against epimerization to guluronic residues by the epimerase AlgG. Thus, the degree of epimerization is controlled by the transacetylase activity. Increasing acetylation degree results in changes of the physicochemical properties of alginate impacting on its role in biofilm formation.^[18] Thus, acetylation might be particularly relevant under dehydrating conditions, e.g., during infection and

colonization of the lungs from cystic fibrosis patients. The alginate lyase might function by controlling the molecular weight of the alginate and/or provides primer for the polymerase. However, this biosynthesis lyase does not play a role in utilizing alginate as a carbon source.

In the bacterium *A. vinelandii*, it has been found that the genome encodes a seven-member family (AlgE1-7) of Ca²⁺-dependent mannuronan C-5 epimerases, which are secreted to the surface and extracellular environment.^[19-21] Interestingly, after production in *Escherichia coli*, each epimerase has been found to introduce its characteristic sequence distribution of G residues in the substrate, explaining the extensive variability in the monomer sequences of the alginates produced by *A. vinelandii*.^[20] It is probable that this ability is biologically significant for the formation of a particular resting stage, called cyst.^[22,23] These enzymes, therefore, potentially explain the monomer sequence differences observed in *P. aeruginosa* and *A. vinelandii* alginates. Further aspects of these discoveries are discussed in the paragraph below dealing with the potential applications of bacterial alginates.

Surprisingly, the *A. vinelandii* genome also encodes a biosynthesis mannuronan C5-epimerase (AlgG) that belongs to another class than AlgE1-E7, and this epimerase seems to represent the equivalent of AlgG in *P. aeruginosa*.^[24] In contrast to the extracellular epimerases (AlgE1-E7), the biosynthesis epimerases were found to be required for alginate production.^[25,26]

Regulation of Alginate Synthesis

All the information about regulation of alginate biosynthesis has been derived from bacteria. The regulatory genes, genotypic switch genes, and biosynthesis genes are not colocalized in bacteria. The alginate structural genes are controlled via the positively regulated *algD* promoter.^[27] In *A. vinelandii*, on the other hand, there seems to exist an additional *algD*-independent promoter, from which at least *algL* (the lyase gene) and *algA* (encoding PMI-GMP) are transcribed.

Regulation of alginate biosynthesis is becoming increasingly complex and involves various specific and globally acting gene products (Figs. 3 and 4).^[28] Alginate biosynthesis is regulated based on environmental stimuli and/or by a genotypic switch comprising a mutation inactivating the antisigma factor MucA.^[29]

Alginate production is regulated by a number of transcriptional factors.^[30] The genotypic switch region comprising *algU*, *mucA*, *mucB*, *mucC*, and *mucD* is found in bacteria, and the corresponding gene sequences are highly homologous (see Ref. [3] for a

review). Regulation of alginate biosynthesis by the sigma factor AlgU (AlgT) via the Muc proteins has been extensively investigated.^[29,31-37] All the known *alg* genes and their corresponding proteins are listed in Table 1.

Mutations in *mucA* prevent MucA, an anti-sigma factor, from interaction with AlgU, leading to AlgU-mediated transcriptional activation of the alginate biosynthesis operon. Additionally, the periplasmic protein MucB is required for alginate regulation because mutations in *mucB* also cause the conversion of *P. aeruginosa* from a nonmucoid to a mucoid phenotype. Mutations in MucD were also found to enhance transcription of the alginate biosynthesis operon.^[38] For MucC a negative regulatory role in alginate production had been suggested, too.^[39]

The two-component transcriptional regulator AlgR is required for alginate production in response to environmental stimuli.^[40-42] Environmental conditions such as high osmolarity, N- and P-starvation, dehydration, and the presence of phosphorylcholine activates a cascade of regulatory proteins involved in activation of *algD* promoter-dependent transcription. The regulator AlgR binds to three sites within the *algD* promoter and thereby activates transcription of the alginate operon. Furthermore, AlgR regulates alginate production through *algC* by binding to its promoter.^[43] AlgR binds to three positions within the *algC* promoter region, but the orientation and positioning of the AlgR binding sites differ in the *algC* and *algD* promoters. AlgR exerts a more global function by regulating additional genes besides those required for alginate production. AlgR has been shown to be required for twitching motility.^[43-46] AlgR overexpression was recently used in *P. aeruginosa* to identify genes regulated by AlgR using DNA-microarray analysis. These data suggested an even more global role of AlgR.^[44,46,47]

The entire alginate biosynthesis gene cluster of *P. aeruginosa* is transcribed under control of the *algD* promoter and the region (*algD*-*algA*) comprises an operon.^[48] In *A. vinelandii* two additional *algD*-independent promoters were identified as being involved in the transcription of *alg8*-*algJ* and *algG*-*algA*.^[49,50]

MEDICAL APPLICATIONS OF ALGINATES

Besides traditional applications of algal alginates as food additives, alginates have been increasingly applied in the medical field particularly as dressings in surgery and wound management.^[51] Large quantities of alginate dressings are used each year to treat exuding wounds, such as leg ulcers, pressure sores, as well as infected surgical wounds. These dressings are

made of Ca^{2+} -alginate fibers to form a product with increased fabric strength when it is soaked with exudate or blood. Some products contain a proportion of sodium alginate to enhance the gelling properties of the applied dressing. Other dressings have been produced from freeze-dried alginate. Upon contact with an exuding wound, the calcium ions in the dressing are exchanged by the sodium ions in serum or wound fluid. Replacement by sodium causes the fibers to swell and partially dissolve, resulting in an amorphous gel. This also makes it easy to remove these dressings from large open wounds or burns because they do not adhere to the wound. Removal can be assisted by applying saline solutions to the dressing to ensure its conversion to soluble sodium alginate. The degree of swelling is strongly dependent on the chemical composition of the alginate, which varies between algal species. However, some evidence was provided that alginates may influence wound healing in an unknown way. Recently, the consumer division of a multinational pharmaceutical company launched a new line of adhesive bandages and gauze pads based on calcium alginate fibers. They are being promoted as helping blood to clot faster—twice as fast as their older, well-established product.

The alginic acid powder swells when in contact with water. This property was used for the application as disintegrant in certain tablets. The swelling property was also used in dietary foods to provide a “full” feeling, and in tablets taken to relieve heartburn and acid indigestion. The swollen alginic acid reduces reflux irritating the lining of the esophagus.

Alginate is also used in controlled release of medical drugs and other chemicals. The active ingredient is entrapped in calcium alginate beads and slowly released upon exposure to certain environmental conditions. Recently, alginate microspheres, sometimes coated with chitosan to enhance the mechanical strength, have been developed and tested as oral controlled-release systems for drug delivery.

NONMEDICAL APPLICATIONS

Paper: Alginate is used in the paper industry for surface sizing and high-performance printability.

Welding rods: Alginate is applied in coatings to welding rods or electrodes. The quantities of alginates used are very dependent on the type of welding rod being coated and the extrusion equipment being used.

Binders for fish feed: Crude alginate is used as a binder in fish feeds. Bound alginate can lower the consumption by up to 40% and culture ponds are less polluted.

Release agents: Alginates are used as mold release agents for the formation of fiberglass plastics.

POTENTIAL APPLICATIONS OF BACTERIAL ALGINATES

Because the prices of algal alginates are low, the establishment of a competitive bacterial production process appears to be rather difficult unless high-value applications are targeted. The following two strategies are currently pursued: 1) optimization of the bacterial production process to reduce prices and 2) bioengineering of alginates with high-value applications justifying high production costs. However, it is increasingly more likely that bacterial alginates may become commercial products because environmental concerns related to the traditional seaweed harvesting and processing are increasing as well as the demand for higher-quality alginates. Because the past decades provided extensive insight into the molecular processes of alginate biosynthesis in bacteria, this knowledge is an important foundation for manipulation and exploitation of the microbial production process. Strategies for the production of high-quality and/or tailor-made bacterial alginates with improved qualities will be discussed on the basis of recent advances in alginate research.

Bioengineering of Bacterial Alginates

The material properties of alginates are determined by their molecular weight, degree of acetylation, and monomer composition and sequence. Based on the current knowledge it seems likely that all these three parameters can be controlled in the bacterial alginates. In contrast, seaweeds harvested from the ocean will not enable this degree of control and therefore the product range will be limited by the potential of fractionation of polymer mixtures and upgrading using alginate modifying enzymes.

The degree of polymerization impacts on viscosity properties of alginates. It might be possible to control this parameter in bacteria by controlling both the fermentation conditions and the alginate lyase activity. Bacterial production could provide alginates with a given viscosity by means of reduced molecular weight. However, very high viscosities will impair oxygen transfer in fermentors and sophisticated aeration techniques will have to be developed and applied. Whether this will be feasible is currently unclear.

The most interesting potential provided by bacterial alginates is based on the possibility of controlling their monomer composition as well as sequential structures. The mannuronan C-5-epimerases catalyze the conversion of mannuronic acid residues into guluronic residues in the polymer chain without breaking the glycosidic bonds. This reaction is similar to the conversion of β -D-GlcA into α -L-IdoA in the biosynthesis

of heparin, heparan sulfate, and dermatan sulfate.^[52] According to the current knowledge it appears that *Pseudomonas* species have only one mannuronan C-5-epimerase, encoded by the *algG* gene, and this enzyme is able to introduce only single G residues in the polymannuronate chain. These alginates are strongly impaired in their gel-forming capacity. Divalent cation-dependent (typically Ca^{2+}) gels are formed by alginates containing G-blocks. Thus, the in vivo manipulations of monomer composition in *Pseudomonas* alginates is rather limited. However, inactivation of the *algG* gene should enable production of pure mannuronan, and supporting evidence for this has been obtained by Franklin et al.^[15] Polymannuronate is known to be a strong immunostimulant and could have a commercial potential in applications where this property is of interest.

In *A. vinelandii* the epimerization system is much more complicated. This bacterium encodes seven secreted Ca^{2+} -dependent epimerases, which have been sequenced, cloned, and produced recombinantly in *E. coli*.^[53,54] Each of these recombinant enzymes generates specific nonrandom epimerization patterns when acting upon mannuronan or alginate as substrate. The AlgE4 epimerase catalyzes predominantly an alternating residue sequence, whereas the action of AlgE1, AlgE2, and AlgE6 generates long G blocks.^[24,53–57] It therefore seems clear that the monomer sequence variability observed in alginates isolated from natural sources may originate from the action of a set of different epimerases, each representing a particular specificity with respect to the final reaction product.

Insight into enzymes involved in sequence variability provides a potential for applications. Tailor-made alginates could be made by initially producing deacetylated poly-mannuronic acid using *Pseudomonas* mutants, which are deficient in acetylation and thus enable epimerization.^[16,18] Alternatively, the acetyl groups could be removed from the purified polymer by standard chemical deacetylation procedures. Such polymannuronates could be epimerized by one particular recombinantly produced epimerase, an engineered enzyme or a combination of such enzymes. It is also conceivable to fractionate and purify commercially produced seaweed alginates employing these recombinant epimerases. It is now likely that almost any alginate structure could be produced by such processes aiming at particular material properties of applied interest.^[19,58–60]

Besides the bioengineering of alginates, an enormous design space is provided by the combination of other biopolymers with alginate. Recent studies indicate a promising potential of composites for future applications, particularly in the medical field.^[61,62]

Bacterial alginates might be first applied as immunostimulants or for immobilization of cells. Cells

immobilized in gel-forming alginates might be used for various biotechnological production processes or in medical transplantation technologies.^[63–66] The reversal of Type I diabetes by immobilizing insulin-producing cells in alginate capsules has been already achieved. These capsules have been implanted into the body of whole animals and even humans, and long-term biological efficacy was found.^[67,68]

CONCLUSIONS

Currently, pharmaceutical and medical uses of alginates are about 20% of the market value with 2–4% annual growth rates, which are maintained by continuous developments in controlled release technologies and the use of alginates in wound care applications. Food applications are worth about 20% of the market value and the annual growth of 1–2% is rather low. The best profitability is related to high-value applications, such as pharmaceutical and medical applications. This has already justified research and development activities implementing bacterial alginates using bioengineering approaches, grafting, and blending to obtain high-performance materials for medical applications.

INTRODUCTION

Albee, in 1920, reported the first successful application of a calcium phosphate (CaP) reagent for the repair of bone defect in human.^[1] More than 50 yr later, Nery et al.^[2] reported successful clinical use of a porous “tricalcium phosphate (TCP)” in surgically created periodontal defects in dogs and Denissen^[3] reported the use of dense hydroxyapatite (HA) as immediate tooth root replacements. In the early 1980s, synthetic HA and β -TCP became commercially available as bone-substitute materials for dental and medical applications largely through the efforts of Jarcho, de Groot, and Aoki.^[4–8]

The term “biphasic calcium phosphate (BCP)” was first used by Nery et al.^[9] to describe the bioceramic that consisted of a mixture of HA and β -TCP, after the x-ray diffraction analysis by LeGeros^[8] in 1986 showed that the porous TCP preparation material used in their early publications^[2] was, in fact, a mixture of 20% HA and 80% β -TCP. The first studies on BCP with varying HA/ β -TCP reported by LeGeros, Nery, Daculsi et al.^[10–13] demonstrated that the bioactivity of these ceramics may be controlled by manipulating the HA/ β -TCP ratios. Subsequently, focussed and intensive studies on macroporous BCP (MBCP) by Daculsi and coworkers^[14–18] led to the development and commercialization of MBCP as bone-substitute biomaterial for orthopedic and dental applications.^[19–26] BCP bioceramics consist of a mixture of HA, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ and β -TCP, $\text{Ca}_3(\text{PO}_4)_2$ of varying HA/ β -TCP ratio. The BCP ceramics concept is based on the combination of the more stable phase of HA and more soluble phase, β -TCP. The more soluble β -TCP gradually dissolves in vivo, seeding new bone formation as it releases calcium and phosphate ions into the biological medium.^[10–12,26]

At present, BCP is commercially available in Europe, U.S.A., Brazil, Japan, Korea, Taiwan, and China as a bone-graft or bone-substitute materials for orthopedic and dental applications under various trade marks (e.g., BCP[®], MBCP[®], Triosite[®], Zimmer,

Europe, Hatric[®], Tribone 80[®], TricOs[®], Eurocer[®], and Biceram[®]). Macroporous BCP is available in blocks, particulates, and customized design (Fig. 1) and as an injectable material in a polymer carrier (MBCP Gel[®]). The main attractive feature of bioactive bone-graft materials such as CaP (HA, β -TCP, and BCP), ceramics, and bioactive glasses is their ability to form a strong direct bond with the host bone resulting in a strong interface compared to bioinert or biotolerant materials that form a fibrous interface.^[3–5,15,27–31] The formation of this dynamic interface is believed to result from a sequence of events involving interaction with cells and formation of carbonate HA (CHA) (similar to bone mineral) by dissolution/precipitation processes.^[10–12,26,32–34] This review briefly describes preparation of BCP bioceramics, their in vitro properties, cellular events after implantation, and subsequent biodegradation and biodissolution including the significance of the biological apatite precipitation.

PREPARATION OF BCP BIOCERAMICS

Calcium-Deficient Apatites

The BCP or mixtures of HA and β -TCP are obtained when biologic or synthetic calcium-deficient apatites (CDAs) are sintered above 700°C^[26,28,35] according to the following reaction

The apatite is considered calcium deficient when the Ca/P ratio is lower than the stoichiometric value

Fig. 1 MBCP[®] block, granules, cylinders, wedges, and customized design available for bone reconstruction.

of 1.67 for pure calcium HA, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$. The CDAs may be represented by the formula, $\text{Ca}_{10-x}\text{M}_x(\text{PO}_4)_{6-y}(\text{HPO}_4)_y(\text{OH})_2$, where M represents other ions (e.g., sodium and magnesium) that can substitute for calcium (Ca) ions.

The Ca deficiency of the apatites depends on the synthesis conditions (precipitation or hydrolysis methods), reaction pH, and/or temperature.^[26,28,35,36] The CDAs may be obtained by precipitation method under different conditions of pH and temperature; the lower the pH, the higher the temperature required for the precipitation of apatite.^[26,28] For example, CDA is obtained by precipitation at 80°C to 100°C even at low pH (pH 4–6). At lower temperatures and low pH, nonapatitic CaPs, e.g., dicalcium phosphate dihydrate (DCPD), $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ or octacalcium phosphate (OCP), $\text{Ca}_8\text{H}_2(\text{PO}_4)_6 \cdot 5\text{H}_2\text{O}$, is obtained.^[28]

Another method of CDA preparation is by hydrolysis of nonapatitic CaPs including amorphous CaP, $\text{Ca}_x(\text{PO}_4, \text{HPO}_4)_y$; DCPD; dicalcium phosphate anhydrous, CaHPO_4 ; OCP; or β -TCP, $\text{Ca}_3(\text{PO}_4)_2$.^[26,28,35,36] In the hydrolysis of DCPD in NaOH solutions, the Ca deficiency of the unsintered apatite and, subsequently, the HA/ β -TCP ratio of the BCP obtained after sintering can be controlled by two variables: the concentration of the NaOH solution and the ratio of the weight of the DCPD to the volume of the NaOH solution.^[36]

Variation in HA/ β -TCP Ratio in BCP

The BCP composition (HA/ β -TCP ratio) obtained after sintering depends on the Ca deficiency of the unsintered biologic or synthetic apatite and on the sintering temperature.^[26,28]

Sintering commercial CaP reagents (labelled as “HA” or “calcium phosphate, tribasic” or “TCP” (e.g., Baker or Fisher or Mallinckrodt, U.S.A.; or Merck, Darmstadt) above 900°C was shown to result in pure HA, pure β -TCP, or BCP.^[28,37] The BCP

ceramic may also be prepared by mechanically mixing two types of synthetic apatites or commercial CaP reagents.^[26,38]

Introduction of Macroporosity and Microporosity

Two physical properties of bioceramics are believed to be very important for optimum biological performance, including bioceramic–cell interaction, bioceramic resorption, bioceramic–tissue interface, and new bone formation. These fundamental physical properties are interconnecting macroporosity and appropriate microporosity.

Macroporosity in the BCP ceramic is introduced by incorporating volatile materials (e.g., naphthalene, hydrogen peroxide, or other porogens), heating at temperature below 200°C, and subsequent sintering at higher temperatures.^[39–41] Macroporosity results from the release of the volatile materials (Fig. 2).

Microporosity is a consequence of the temperature and duration of sintering.^[26] The higher the temperature, the lower the microporosity content and the lower the specific surface area (Figs. 3A and B).

Presently, commercial BCP products of different or similar HA/ β -TCP ratios are manufactured in many parts of the world and their successful use in medicine and dentistry has been reported.^[14,16,21–24] The total porosity (macroporosity plus microporosity) of these products is reported to be about 70% of the bioceramic volume. The current BCP products used by the surgeons (with 60/40–75/25 HA/TCP ratio) present similar percent macroporosity (50–60%), but the additional microporosity was very different among them, varying from 3% to 25%. Low percent microporosity and low surface area can result in lower

Fig. 2 Scanning electron microscopy blocs showing macroporous structure.

Fig. 3 The MBCP sintered at (A) 1050°C and (B) at 1200°C.

bioactivity and lower dissolution property. A microporosity of at least 20% with specific surface area higher than $2 \text{ m}^2/\text{g}$ is suggested for optimal BCP efficacy.

The ideal pore size for a bioceramic approximates that of bone. It has been demonstrated that microporosity (diameter $< 10 \mu\text{m}$) allows body fluid circulation whereas macroporosity (diameter $> 100 \mu\text{m}$) provides a scaffold for bone-cell colonization. It was reported that BCP ceramic with an average pore size diameter of $565 \mu\text{m}$ (compared to those with average pore size diameter of $300 \mu\text{m}$) and 40% macroporosity (compared to 50% macroporosity) had greater bone ingrowth.^[17]

IN VITRO PROPERTIES OF BCP CERAMICS

Crystal Properties

Hydroxyapatite crystals are not distinguishable from the β -TCP crystals in the BCP sintered above 900°C

using scanning electron microscopy (SEM). However, using transmission electron microscopy (TEM), electron diffraction is able to distinguish between HA and β -TCP crystals in the BCP.^[42] The crystallinity (reflecting crystal size and perfection) of the HA and β -TCP phases in BCP depends on the sintering temperature of CDA: The higher the sintering temperature, the higher the crystallinity.^[26]

Mechanical Properties

It is expected that the pore size and percent macroporosity of the BCP ceramic will affect the mechanical properties.^[17,38] The preparation method also was found to have a significant influence on the compressive strength. The BCP ceramic prepared from a single CDA phase was reported to exhibit higher compressive strength compared to BCP ceramic prepared by mixing two unsintered CaP preparations, one which, after sintering at 1200°C , resulted in only HA or only β -TCP.^[43] The initial mechanical property is not the best criterion for assessing the efficacy of bone ingrowth. For example, BCP with high mechanical property owing to low microporosity (resulting from high sintering temperature) may exhibit reduced bioresorption and bioactivity. On the contrary, it was demonstrated that the initial mechanical property of BCP increased two or three times in a few weeks after implantation owing to physicochemical events of dissolution and biological precipitation into the micropores.^[17]

Dissolution Properties

The extent of dissolution in acidic buffer in vitro is much higher for the β -TCP ceramic compared to that for the HA ceramic.^[26,28,44] Thus, the extent of dissolution of BCP ceramic of comparable macroporosity and particle size will depend on the HA/ β -TCP ratio: The higher the ratio, the lower the extent of dissolution.^[10,27,44] The dissolution properties are also affected by the methods of obtaining BCP: whether from a single calcium-deficient apatite phase (BCP1) or from a mechanical mixture of two unsintered CaP preparations (BCP2): BCP2 exhibited higher extent of dissolution compared to BCP1.^[38] In some cases, BCP ceramic with similar HA/ β -TCP ratios could present different dissolution rates.^[26] This phenomenon may be caused by processing variables (sintering time and temperature) that could affect the total macroporosity and microporosity: The greater the macroporosity and microporosity, the greater the extent of dissolution. In vivo, dissolution of BCP ceramics is manifested by a decrease in crystal size and increase in macroporosity and microporosity.^[10,12,15]

B

In Vitro Cell–BCP Ceramic Interaction

BCP ceramics, such as HA or β -TCP ceramics, present hospitable surfaces for spreading of monocytes^[45,46] or osteoclasts.^[29,47] In vitro studies using commercial BCP ceramic with an HA/ β -TCP ratio of 60/40 (Triosite) showed less resorption pits on the BCP discs compared to those in dentin.^[46] Yamada et al.^[47] reported that osteoclastic resorption was highest for the BCP ceramic with HA/ β -TCP ratio of 25/75 compared to those with higher ratios. This observation seemed to indicate that osteoclastic resorption is a function of the solubility of the BCP, which in turn, is a function of the HA/ β -TCP ratio: The lower the ratio, the higher the solubility. However, the same study also demonstrated that the BCP (HA/ β -TCP ratio, 25/75) had a higher osteoclastic resorption than pure β -TCP in spite of the higher solubility of the latter. This may be related to the observation that the amount of calcium and phosphate ions released in the environment is critical to cellular activities.^[48]

CELLULAR EVENTS AND TISSUE RESPONSE AFTER IMPLANTATION OF BCP

The BCP materials elicit responses from bone cells and related cells in vitro and in vivo, which are similar to those elicited by bone.^[49] These materials allow cell attachment, proliferation, and phenotypic expression. The first biological events after BCP ceramics implantation are biological fluid diffusion, followed by cell colonization into the macropores of the implanted BCP (Fig. 4).

Fig. 4 Newly formed bone into the macropores of MBCP implanted in rabbit femoral epiphysis after 14 days of implantation showing osteoclasts and osteoblasts. Decalcified section stained with Masson's trichrome staining.

Fig. 5 Tartrate-resistant acid phosphatase staining of osteoclast associated with MBCP implanted in rabbit femoral epiphysis after 14 days of implantation.

These cells are macrophages in early steps, followed by mesenchymal stem cells, osteoblasts, and osteoclasts. The resorbing cells forming both on the surface of the newly formed bone and on the bioceramic surface look like osteoclast and are tartrate-resistant acid phosphatase (TRAP)-positive^[25] as shown in Fig. 5.

In human spine arthrodesis, we observed that after two months, bone remodelling occurs with secondary osteoclast resorption of the BCP and bone ingrowth at the expense of the implanted BCP (Fig. 6).

Generally, when granules are used in osteoarticular surgery, some grains are released in the cartilage or nonosseous sites. No foreign body reaction or material rejection was observed. Resorption or tissue incorporation was demonstrated. For example, in human spine arthrodesis after 3.5 months of implantation, granules

Fig. 6 Human spine arthrodesis using Triosite blocks after 3.5 months of implantation showing bone ingrowth at the expense of the Triosite (Tr) with osteoclast (arrow) near vascular channel (V).

Fig. 7 MBCP[®] granules implanted for two weeks in muscular area of rabbit. Undecalcified section with Movat staining.

of Tr (BCP with a 60/40 HA/ β -TCP ratio) appeared surrounded by newly formed cartilage without fibrous encapsulation.^[30] Moreover, after implantation in nonosseous site (in subcutaneous area), osteoid formation into some MBCP macropores was observed (Fig. 7).^[24]

These observations suggest that BCP with appropriate interconnecting macroporosity present suitable chemical environment associated with efficient architecture that allows the capture of mesenchymal STEM cells and induce their phenotype to osteogenic cell lines. These observations have been also described by other groups.^[50–53] This property can be used for artificial bone in irradiated implantation site. Irradiation produces irreversible effects on normal tissues, involving damages on their repair properties. Nevertheless quality of life of patients who undergo radiotherapy could be improved by bone reconstructions. A preclinical study performed in irradiated dogs demonstrated bone ingrowth at the expense of structured implants of micro MBCP filled with autologous bone marrow after implantation in irradiated soft and bone tissue,^[24] shown in Fig. 8.

We have conducted a comparative study^[54] on cell interaction with three biomaterials: 0.5 to 1 mm granules of unsintered bovine bone mineral (BioOss[™], Geistlich, Switzerland, 60% porosity) sintered bovine bone mineral (“BonAp,” 60% porosity, prepared by LeGeros, New York University), and synthetic BCP (MBCP[™], 70% total porosity and 60/40 HA/ β -TCP ratio) implanted in epiphysis of rat femur. The three biomaterials allowed cell attachment, proliferation, and osteogenic expression. Light microscopy and SEM examinations showed bone ingrowth with osteoblasts, and osteoid or bony formation between and on the surfaces of the residual granules. However, the amount of resorption was very limited for the bovine bone-derived biomaterials, sintered and unsintered, in spite

Fig. 8 Bone reconstruction into MBCP implant mixed with autologous bone marrow and implanted in irradiated (65 grays) femoral canine bone defects.

of an evidence of higher amount of macrophagous cells associated with BioOss. On the contrary, the biodegradation of the MBCP[™] was associated with bone ingrowth with numerous bone trabeculae between the granules and on the surface of the residual materials. Microscanner revealed bone architecture of physiological bone ingrowth on MBCP samples. However, it was more difficult to distinguish the host bone from the bone implant (BioOss). These results suggested that all the bone-substitute material tested had osseointegrative properties; however, the kinetics of bone ingrowth was higher for synthetic micro and macroporous MBCP. The sintered bovine bone (“BonAP”) showed low amount of bone formation perhaps owing to the larger apatite crystal size caused by high sintering temperature. For the unsintered bovine bone (BioOss), resorption was limited and bone ingrowth appeared delayed compared to synthetic MBCP, in spite of the microcrystalline nature of BioOss.

BIODEGRADATION, BIODISSOLUTION, AND SIGNIFICANCE OF BIOLOGICAL APATITE PRECIPITATION

The processes of biodegradation and bioresorption of bone-substitute biomaterials are the main factors for promoting bioactivity and for providing the space for bone ingrowth.

The biodegradation of BCP include the dissolution of the individual HA or β -TCP crystals.^[41] The HA/ β -TCP ratio in the BCP appeared greater after implantation,^[42] confirming the greater solubility of the β -TCP compared to the HA phase in the BCP.^[44]

Formation of microcrystals with Ca/P ratios similar to those of bone apatite crystals was also observed after implantation of the MBCP. The abundance of

Fig. 9 Biological apatite precipitation at the surface of residual crystals in BCP, observed in high-resolution TEM.

Fig. 10 Spongy bone formed at the expense of Tr blocks in human spine arthrodesis.

these crystals was directly related to the initial β -TCP/HA ratio in the BCP: The higher the ratio the greater the abundance of the microcrystals associated with the BCP crystals. According to these data it is possible to control the kinetics of dissolution and precipitation, and subsequently the bioactivity.^[10–12] Using high-resolution TEM, we have demonstrated for the first time that the formation of these bone apatite-like microcrystals (Fig. 9) after implantation of CaPs (HA, BCP) were nonspecific, i.e., not related to implantation site (osseous or nonosseous sites), subjects of implantation, and types of CaP ceramics.^[10–12,32–34]

The coalescing interfacial zone of biological apatite and residual BCP ceramic crystals (mostly HA), provide a scaffold for further bone-cell adhesion and further bone ingrowth. The bone repair or bone regeneration process involves dissolution of CaP crystals and then a precipitation of CHA needle-like crystallites in micropores close to the dissolving crystals (Fig. 9). The coalescing zone constitutes the new biomaterial–bone interface, which includes the participation of proteins and CHA crystals originating from the BCP ceramic crystals, but does not include the biomaterial surface. The ensuing events of bone ingrowth and formation of new bone progressively replace the initially formed CHA from the CaP biomaterials.^[11,12,34]

The processes of cell colonization, adhesion, phagocytosis and osteoclastic resorption, extracellular matrix elaboration and mineralization, bone ingrowth, and bone remodelling associated with the biological apatite precipitation during CaP ceramics dissolution are continuously in progress. Consequently, the interface is not static but dynamic and in constant evolution, taking into account bone physiopathology, biomechanical factors, and bone maturation. The processes involved a well-organized and mineralized bone ingrowth at the expense of the bone-substitute biomaterial (Fig. 10).

BIOACTIVE, OSTEOCONDUCTIVE, AND OSTEOINDUCTIVE PROPERTIES

The bioactive concept of BCP has been applied to a new composite consisting of water-soluble polymer and MBCP granules in an injectable form.^[55–57] We have elaborated on such an injectable bone substitute (IBS) (MBCP Gel™ Biomatlante, France) that is ready to use, biocompatible, able to conform to the shape of any bone defect, and bioresorbable. The IBS (MBCP Gel) cannot have mechanical properties like the self-setting hydraulic CaP bone cements.^[58,59] However, bone cells are able to invade the spaces released by the disappearance of the polymer and bone ingrowth take place at the expense of the resorption of the BCP grains (Fig. 11).

In time, mechanical property increases owing to increasing new bone formation.

Fig. 11 The SEM using backscattered electron imaging of polished section of IBS after three weeks of implantation in rabbit showing bone growth closely associated with the residual grain of CaP.

Osteoconductive and Osteoinductive Properties

The CaP biomaterials, including BCP, have been described as osteoconductive but not osteoinductive.^[60] Osteoconductive materials serve as scaffold or template, allowing “vascular ingress, cellular infiltration and attachment, cartilage formation, and calcified tissue deposition.” Osteoinductive materials [(e.g., bone morphogenetic proteins (BMPs))] “stimulate uncommitted cells (e.g., mesenchymal stem cells) to convert phenotypically to chondroprogenitor and osteoprogenitor cells.”^[61] Ripamonti, Crooks, and Kirbride.^[51–53] and Kuboki, Takita, and Kobayashi^[50] demonstrated that some CaP materials with appropriate geometry can have osteoinductive properties. Osteoinductive properties have been reported for other CaP biomaterials including BCP.^[62–68]

Reddi^[61] attributed the phenomenon of osteoinductive properties associated with specific (but undefined) biomaterial geometry to the binding of an optimum amount of endogenous BMPs in circulation to the CaP biomaterial allowing the biomaterial to be osteoinductive. Ripamonti, Crooks, and Kirbride^[53] and Kuboki, Takita, and Kobayashi^[50] have postulated that the geometry of the material is a critical parameter in bone induction. Kuboki, Takita, and Kobayashi^[50] concluded that the geometry of the BMP carrier is one of the important factors controlling the efficacy of the phenotype induction. Daculsi et al. have shown that micropores combined with the high solubility of β -TCP and stability of HA induce the precipitation of biological apatite crystals on to BCP ceramics.^[10–12,25,66] The osteoprogenitor cells might in turn recognize the bone-like apatite layer formed by dissolution–reprecipitation on the material^[10–12,34] and produce bone. Others have thought that low oxygen tension in the central region of the implants might provoke a dedifferentiation of pericytes from blood microvessels into osteoblasts.^[68,69]

CONCLUSIONS

The BCP bioceramic is an intimate mixture of HA and β -TCP, obtained by sintering CDA. The BCP has the advantage of controlled bioactivity by manipulation of the HA/ β -TCP ratio owing to the preferential dissolution of the more soluble β -TCP component. The BCPs like other bioactive materials have the ability to form carbonateapatite on the surface by the process of dissolution and precipitation. Biphasic calcium phosphates, like other CaP biomaterials, are osteoconductive but can be made osteoinductive by appropriate geometry, specifically, macroporosity and microporosity. Besides its current application in orthopedics and dentistry, BCP can also be used as scaffolds for

tissue engineering using stem cells, delivery system for drugs, antibiotics, and hormones, and carriers for growth factors.

Blood-Material Interactions

Stephen R. Hanson

Dept. of Biomedical Engineering, Emory University, Atlanta, Georgia, and Department of Biomedical Engineering, Oregon Health & Science University, Beaverton, Oregon, U.S.A.

B

INTRODUCTION

In general terms, blood-material interactions are the interactions occurring reversibly and irreversibly between surfaces and blood components, including small solute molecules, proteins, and cells. The types of interactions include adsorption, absorption, adhesion, denaturation, activation, cellular spreading, and cell-cell interactions, all of which occur dynamically under variable conditions of exposure time, blood composition, and blood flow. Following contact with blood, most—if not all—artificial surfaces quickly acquire a layer of adsorbed blood proteins whose composition may vary with time in a complex manner, which depends in part on the physicochemical properties of the substrate surface. Plasma contains more than 100 identified proteins with specific functions and varying biologic properties. Unfortunately, the relationships between material surface properties, the initially deposited protein layer, cell-surface interactions, and later events, which could be of clinical consequence for the evaluation of biocompatibility and the design of blood-contacting cardiovascular devices, are not well understood. This is because the dynamics of protein-cell-surface interactions under flow are extraordinary complex and therefore difficult to study. Accordingly, the following discussion will consider primarily those blood proteins, cellular elements, biochemical pathways, and physical factors that contribute most directly to adverse blood-material interactions, e.g., thrombosis and thromboembolism, which currently limit the usefulness and more widespread application of devices used in contact with blood.

HEMOSTASIS

Mechanisms of physiological hemostasis are designed to maintain the integrity of the vascular system by quickly causing the arrest of bleeding from injured blood vessels, which thereby facilitates later vessel repair through normal healing mechanisms. These usually advantageous processes may also produce adverse reactions when the synthetic artificial surfaces comprising most prosthetic cardiovascular devices are placed in contact with blood. Primary hemostasis

involves a complex set of interdependent biochemical and cellular reactions between: 1) the material or device surface; 2) circulating blood platelets, with less direct or later interactions involving erythrocytes and leukocytes; 3) blood proteins, especially coagulation enzymes that may trigger the formation of a blood clot or thrombus that may obstruct blood flow or detach (embolize) to occlude distal microcirculatory beds; and 4) the fibrinolytic mechanism, which ultimately lyses the residual thrombus mass. The process is localized to the surface of a device or injured blood vessel by a balance between activation and inhibition mechanisms, which thereby maintains the fluidity of blood in the circulation. Although a great deal is known regarding blood responses to injured arteries and blood-contacting devices, the interrelationships are complex and not fully defined in many instances and particularly regarding the physicochemical properties of synthetic materials that are exposed to blood. Accordingly, thrombosis and thromboembolism complicate to some extent the use of all blood-contacting devices, whether intended for short-term or long-term applications and despite the general use of anticoagulants. These topics will be reviewed briefly. A more detailed discussion has been given in other reports.^[1–3]

Blood Coagulation

At least 12 plasma proteins interact in a series of enzymatic and cofactor reactions leading to blood clotting. The coagulation factors are identified by Roman numerals and were named in order of their discovery while the clotting scheme was being elucidated experimentally. The biochemical properties of the coagulation factors are summarized in Table 1. Initiation of clotting occurs either intrinsically through surface-mediated reactions or extrinsically through activation of factor X by the tissue factor:factor VIIa complex. The two systems converge upon a final common pathway, which leads to the formation of the key procoagulant enzyme thrombin. Thrombin acts enzymatically on fibrinogen, which then polymerizes to form an insoluble fibrin gel that stabilizes the thrombus mass.

Table 1 Properties of human clotting factors

Clotting factor	Apparent molecular weight (number of chains)	Approximate normal plasma concentration ($\mu\text{g/ml}$)	Active form
Intrinsic clotting system			
Prekallikrein	100,000 (1)	50	Serine protease
High molecular weight kininogen	120,000 (1)	80	Cofactor
Factor XII	80,000 (1)	30	Serine protease
Factor XI	160,000 (2)	3–6	Serine protease
Factor IX	57,000 (1)	3–5	Serine protease
Factor VIII ^a	330,000 (1)	0.2	Cofactor
Von Willebrand factor ^a	250,000 (1)	10	Cofactor for platelet adhesion
Extrinsic clotting system			
Tissue factor	44,000 (1)	0 ^b	Cofactor
Factor VII	50,000 (1)	1	Serine protease
Common pathway			
Factor X	59,000 (2)	5	Serine protease
Factor V	330,000 (1)	5–12	Cofactor
Prothrombin	72,000 (1)	140	Serine protease
Fibrinogen	340,000 (6)	2500	Fibrin polymer
Factor XIII	320,000 (4)	10	Transglutaminase

^aIn plasma, Factor VIII is complexed with von Willebrand factor, which circulates as a series of multimers ranging in molecular weight from about 600,000 to 2×10^6 .

^bThe tissue factor concentration in cell-free plasma is minimal because tissue factor is an integral cell membrane-associated protein expressed by vascular and inflammatory cells, although a soluble form of tissue factor has recently been described.^[4]

Coagulation proceeds through a cascade of reactions whereby normally inactive factors, e.g., proenzymes, become activated after surface contact or proteolytic cleavage by precursor enzymes, e.g., factor XIIa activates factor XI to factor XIa. These enzymes, in turn, activate other precursor molecules, e.g., factor XIa converts factor IX to factor IXa. Because this sequence involves a series of steps and one enzyme's molecule can act upon many substrate molecules, the reactions are quickly amplified, which result in the generation of significant amounts of thrombin. Thrombin potently activates circulating platelets, which further amplify coagulation reactions by localizing clotting factors to platelet membrane phospholipids that act as a surface catalyst, i.e., several clotting reaction steps proceed at an effective rate only on the surface of activated platelets. The accumulation of platelets and the formation of fibrin at sites of vessel injury result in the arrest of bleeding. The process is further localized, i.e., widespread or systemic clotting does not occur, due to the dilution of activated factors by blood flow and the actions of coagulation enzyme

inhibitors that are present in circulating blood or are generated within clotting blood.

Fig. 1 presents a diagram of the classical clotting factor cascade for both the intrinsic and extrinsic systems and the common pathway that begins with the activation of factor X. Except for the contact phase, calcium (Ca^{++}) is required for most clotting reactions. Accordingly, chelators of calcium such as sodium citrate and ethylenediamine tetra-acetic acid (EDTA) are commonly used as anticoagulants for in-vitro blood studies. It should be recognized that the in-vitro interactions of clotting factors, clotting, is not identical with coagulation in living systems due to the presence in vivo of complex blood flow phenomena, the proximity of vascular tissues that also modulate coagulation reactions, and normal physiological mechanisms of blood recirculation, inactivation, and dilution. There are also interrelationships between the intrinsic and extrinsic systems such that crossover or reciprocal activation reactions may be important, such as the activation of factor IX by either extrinsic pathway factor VIIa and tissue factor or intrinsic pathway

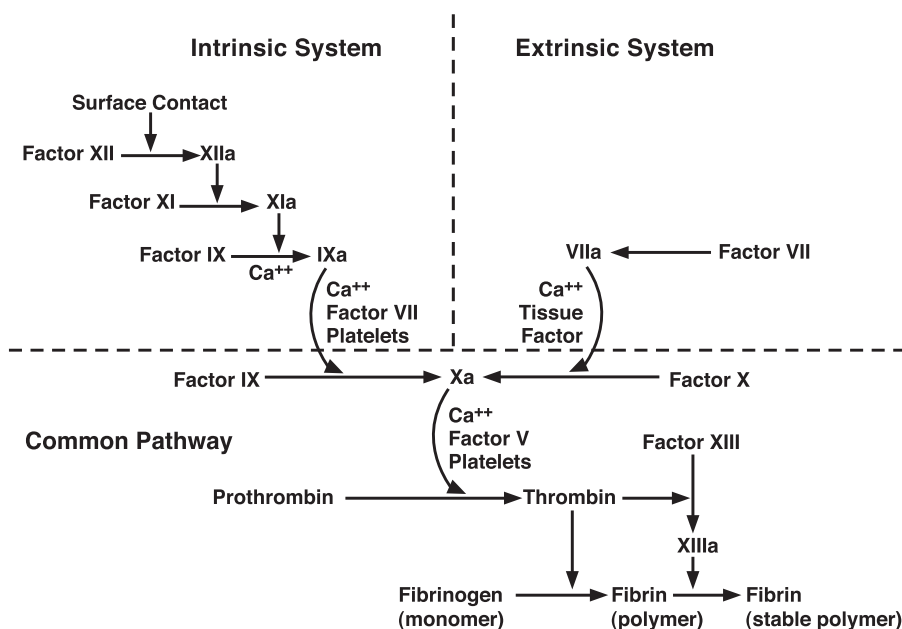

Fig. 1 Blood coagulation. Clotting factors (proenzymes), identified by Roman numerals, interact in a sequential series of enzymatic activation reactions (coagulation cascade) leading to the amplified production of the enzyme thrombin, which in turn activates fibrogen to form a fibrin polymer that stabilizes the clot or thrombus.

factor XIa.^[1-5] Due to the complexity of the hemostatic system and the difficulty of studying hemostasis *in vivo*, many aspects of coagulation, thrombus formation, and adverse blood-material interactions remain to be elucidated.

In the intrinsic system, contact factor activation refers to reactions following adsorption to surfaces of a group of proteins known as contact factors. The most potent artificial surfaces for activating blood are negatively charged, e.g., glass. Although the contact reactions have been well studied *in vitro*, their pathologic significance remains uncertain. In hereditary disorders, only very low levels of factor XI are associated with abnormal bleeding although normal levels of factor XI may contribute to the growth and propagation of thrombus. Contact factors include factors XII, XI, prekallikrein, and high molecular weight kininogen (HMWK). All contact reactions take place in the absence of calcium. Kallikrein is also involved in the fibrinolytic system and inflammation.^[5]

A middle phase of intrinsic clotting begins with the first calcium-dependent step, the activation of factor IX by factor XIa. Factor IXa subsequently activates factor X. Factor VIII is an essential cofactor for the intrinsic pathway activation of factor X. To exhibit cofactor activity, factor VIII first requires modification by an enzyme such as thrombin. In the presence of calcium, factors IXa and VIIIa form a complex on phospholipid surfaces, e.g., on the surface of activated platelets, that then activates factor X. This reaction proceeds slowly in the absence of an appropriate phospholipid surface that serves to localize these biochemical events to the surface (versus bulk fluid) phase of blood.

The extrinsic system of blood clotting is initiated by the activation of factor VII. When factor VIIa interacts with tissue factor, which is expressed by many cell types, the tissue factor:factor VIIa complex becomes an active enzyme that is the extrinsic pathway activator of factor X. Tissue factor becomes available when underlying vascular structures (the subendothelium) are exposed to flowing blood upon vessel injury, or tissue factor may be expressed by activated white cells that are involved in inflammatory reactions.

The common pathway begins when factor X is activated by either factor VIIa:tissue factor or the factor IXa-VIIIa complex. After the formation of factor Xa the next step involves factor V, a cofactor, e.g., factor VIII, which has activity only after modification by another enzyme such as thrombin. Factor Xa-Va, in the presence of calcium and platelet phospholipids, is then capable of converting prothrombin (factor II) to thrombin. Like the conversion of factor X by phospholipid-VIIIa-IXa (tenase complex), prothrombin activation is similarly catalyzed by phospholipid-Va-Xa (prothrombinase complex). The higher plasma concentration of prothrombin (Table 1), as well as the biologic amplification capacity of the clotting cascade, allows for a few molecules of an activated initiator to generate a large amount of thrombin activity. Thrombin, in addition to its ability to modify factors V, factor VIII, factor XI, and activate platelets, acts enzymatically upon two other important substrates: fibrinogen and factor XIII. The action of thrombin on fibrinogen releases small peptides from fibrinogen, e.g., fibrinopeptide A, that can be assayed in plasma as evidence of thrombin activity. After thrombin cleavage, the fibrin monomers then polymerize to form an

insoluble fibrin gel. Factor XIII is either trapped within the clot or provided by platelets and is activated directly by thrombin. A tough, cross-linked fibrin polymer is formed by interaction of the fibrin polymer with factor XIIIa.

Control Mechanisms

Obviously, the body has mechanisms for avoiding explosive coagulation and thrombus formation once coagulation is initiated. At least four types of mechanisms may be considered. First, blood flow may reduce the localized concentration of precursors and removes activated materials by hemodilution into the circulating blood pool. Filtration and rapid removal of inactivated factors is accomplished by passage through the liver. Second, the rate of several clotting reactions is fast only when the reaction is catalyzed by a surface. These reactions include the contact reactions, the activation of factor X by factor VII-tissue factor at sites of tissue injury, and reactions that are accelerated by deposited platelet phospholipids (activation of factor X and prothrombin). Third, there are naturally occurring inhibitors of coagulation enzymes, including serine protease inhibitors such as antithrombin III, which potently inactivate thrombin and other coagulation enzymes. Consequently, plasma levels of thrombin:antithrombin III complex can also be assayed as a measure of thrombin production *in vivo*. Fourth, during the process of coagulation, enzymes are generated that not only activate coagulation factors but also degrade cofactors. For example, the fibrinolytic enzyme plasmin degrades fibrinogen and fibrin monomers and can inactivate cofactors V and VIII. Of particular importance is the thrombin:thrombomodulin pathway. Thrombin is ultimately removed from the circulation after it binds to thrombomodulin, a protein found on the surface of blood vessel endothelial cells. Thrombin interaction with endothelial cell thrombomodulin also results in a complex that activates circulating protein C to form activated protein C. Activated protein C, a key physiologic anticoagulant protein, in turn inactivates coagulation factors V and VIII, which thereby down regulates thrombin production. While thrombin produced locally upon vessel injury or in association with the use of cardiovascular devices is a potent trigger for thrombosis, circulating thrombin, paradoxically, may produce a systematic anticoagulant state through activation of protein C.^[6] A number of other physiologic inhibitory systems have also been described.^[1] In summary, the platelet, coagulation, and endothelial systems interact in a number of ways that serve to promote localized hemostasis while preventing generalized blood clotting and thrombosis.

PLATELETS

Introduction

Platelets are nonnucleated, disk-shaped cells having a diameter of 3–4 μm and an average volume of $10 \times 10^{-9} \text{ mm}^3$. Platelets are produced by the fragmentation of bone marrow megakaryocytes and circulate at an average concentration of about 250,000 cells per μl of blood. Platelets occupy approximately only about 0.23% of the total blood volume. In contrast, red cells typically circulate at 5×10^6 cells per μl and may compose 40–45% of the total blood volume. A comparison of the types, concentrations, and sizes of primary blood cellular elements is given in Table 2. Platelets are of particular interest since they markedly accelerate coagulation reactions and play a key role in thrombus formation in arteries—processes that can lead to heart attacks and strokes. As described subsequently, platelet functions are designed to initially arrest bleeding through formation of platelet plugs and stabilize platelet plugs by catalyzing coagulation reactions leading to the formation of fibrin.

Platelet structure provides a basis for understanding platelet function. In the normal (nonstimulated) state, the platelet discoid shape is maintained by a circumferential bundle (cytoskeleton) of microtubules. The external surface coat of the platelet exposes membrane bound receptors, e.g., glycoproteins Ib and IIb/IIIa, that mediate the platelet functions of adhesion (platelet-surface) and platelet aggregation (platelet-platelet). The membrane of activated platelets also contains negatively charged phospholipids, e.g., phosphatidyl serine, upon which coagulation reactions efficiently proceed. The platelet membrane forms a spongy, canal-like (canalicular) open network that represents an expanded reactive surface to which plasma factors are selectively adsorbed and activated. Thus, when platelets aggregate, platelet coagulant activity is produced, including expression of membrane phospholipids that accelerate two critical steps of the blood coagulation sequence, factor X activation and the conversion of prothrombin to thrombin. Platelets also promote the proteolytic activation of factors XII and XI. Thus, the surface of the aggregated platelets serves as a site

Table 2 Blood cell parameters

	Concentration (per μl)	Average size (fl)	Volume (% of blood)
Red cells	5,000,000	87	43
Platelets	250,000	9	0.23
White cells	7,000	383	0.27

Fig. 2 Platelet reaction at artificial surfaces. Following protein adsorption, platelets adhere and release their α -granule contents, including ADP. Thrombin production is catalyzed locally by platelet membrane phospholipids. Thromboxane A₂ (TxA₂) is synthesized. ADP, TxA₂ and thrombin then recruit additional circulating platelets into an enlarging platelet mass that is stabilized by fibrin.

where thrombin can form rapidly and locally in excess of the capacity of the anticoagulant mechanisms of blood.

Platelets also contain substantial quantities of muscle proteins, e.g., actin and myosin, which allow for internal contraction when platelets are activated. Platelets also contain three types of cytoplasmic storage granules: 1) α -granules, which are numerous and contain the platelet-specific proteins platelet factor 4 (PF-4) and β -thromboglobulin (β -TG) as well as other proteins that are found in plasma (fibrinogen, albumin, fibronectin, and coagulation factors V and VIII); 2) dense granules that contain adenosine diphosphate (ADP), calcium ions (Ca^{++}), and serotonin; and 3) lysosomal granules containing enzymes (acid hydrolases). Platelets are extremely sensitive cells that may respond to stimulation by a variety of agonists, such as thrombin and epinephrine, as well as other agonists which are released by platelets themselves, e.g., ADP and serotonin. Activation causes platelets to become adhesive and change in shape to irregular spheres with multiple spiny pseudopods, which facilitate platelet adhesive encounters, accompanied by internal contraction and extrusion of storage granule contents into the extracellular environment. These secreted platelet products stimulate ambient circulating platelets and cause irreversible platelet aggregation, which leads to the formation of a fused platelet thrombus (Fig. 2).

Platelet Adhesion

In the process of hemostasis, platelets initially adhere to artificial surfaces and injured blood vessels. At sites of vessel injury, platelet adhesion involves the

interaction of platelet glycoprotein Ib (GP Ib) and connective tissue elements that become exposed, e.g., collagen, and requires plasma von Willebrand factor (vWF) as an essential cofactor. GP Ib (about 15,000 molecules per platelet) acts as the surface receptor for vWF. The hereditary absence of GP Ib or vWF results in defective platelet adhesion and a serious bleeding tendency. Platelet adhesion to artificial surfaces may be mediated by other plasma adhesive glycoproteins, such as fibrinogen, which bind to the integrin receptor platelet glycoprotein IIb/IIIa. GP IIb/IIIa (about 40,000 copies per platelet) is the platelet receptor for adhesive plasma proteins that support cell attachment and spreading, including fibrinogen, vWF, fibronectin, and vitronectin. Resting platelets do not bind these proteins, which normally occurs only after platelet activation causes a conformational change in GP IIb/IIIa that renders it competent to bind ligands. Platelets activated near surfaces, e.g., by exposure to factors released from thrombus such as thrombin and ADP, could adhere through this mechanism, e.g., to surface-adsorbed fibrinogen. Also, normally unactivated GP IIb/IIIa receptors could react with surface proteins that have undergone conformational changes or denaturation as a result of their adsorption to surfaces. Supporting this view is the enhanced adhesiveness of platelets towards surfaces preadsorbed with fibrinogen that has been commonly observed in in-vitro studies. Following adhesion, activation, and release reactions, the expression of functionally competent GP IIb/IIIa receptors may also support tight binding and platelet spreading through multiple focal contacts with fibrinogen and other surface-adsorbed adhesive proteins.

Platelet Aggregation

Following platelet adhesion, a complex series of reactions is initiated involving: 1) the release of dense granule contents such as ADP; 2) the formation of small amounts of thrombin at the platelet surface; and 3) the activation of platelet biochemical processes to generate other platelet-activating species such as thromboxane A₂. The release of ADP, thrombin formation, and thromboxane A₂ generation act in concert to recruit platelets into an enlarging platelet aggregate (Fig. 2). Platelet stimulation by these agonists causes the increased expression on the platelet surface of GP IIb/IIIa, mobilized from platelet granular stores, which then binds plasma proteins that support platelet aggregation. Under normal circumstances, fibrinogen, due to its relatively high concentration in blood (Table 1), is probably the most important protein-supporting platelet aggregation. The platelet-platelet interaction is calcium-dependent and involves bridging of adjacent

platelets by fibrinogen molecules, e.g., platelets aggregate poorly or not at all in the absence of fibrinogen, GP IIb/IIIa, and calcium. Thrombin binds directly to platelet-associated thrombin receptors (PARs) which, following cleavage by thrombin, cause platelet activation.^[7] Thus, thrombin plays a key role in platelet aggregation and thrombus formation by activating platelets that then catalyze the production of more thrombin; stimulating the release of ADP, thromboxane A₂ and other platelet agonists; and enzymatically cleaving fibrinogen to form fibrin that stabilizes the growing platelet mass.

Platelet Release Reaction

The release reaction is the secretory process whereby substances stored in platelet granules are extruded from the platelet into its external environment. ADP, collagen, epinephrine, and thrombin are physiologically important release-inducing agents and interact with the platelet through specific receptors for these agonists on the platelet surface membrane. The alpha-granule contents (PF-4, β -TG, and other proteins) are readily released by relatively weak agonists such as ADP. Release of the dense granule contents (ADP, calcium, and serotonin) requires platelet stimulation by a stronger agonist such as thrombin. Agonist binding to platelets also initiates the formation of intermediates that cause activation of the contractile-secretory apparatus, production of thromboxane A₂, and mobilization of calcium from intracellular storage sites. Elevated cytoplasmic calcium is probably the final mediator of platelet aggregation and release. As noted previously, substances that are released (ADP), synthesized (TxA₂), and generated (thrombin) by platelets affect other platelets and actively promote their recruitment into growing platelet aggregates and thrombi. Measurements of plasma levels of platelet-specific proteins, such as PF-4 and β -TG, have been widely used as indirect markers of platelet activation and release that may occur in various disease in vivo.

Platelet Consumption

The turnover or rate of destruction of platelets has also been used as a diagnostic test for thrombosis. In man, platelets are cleared from circulating blood in an approximately linear fashion over time with an apparent lifespan of approximately 10 days. With ongoing thrombosis that may be produced by cardiovascular devices, platelets may be removed from circulating blood at a more rapid rate. Thus, steady-state elevations in the rate of platelet destruction, as reflected in a shortening of platelet lifespan, have been used as a

measure of the thrombogenicity of artificial surfaces and prosthetic devices.^[8,9]

Fibrinolysis

The fibrinolytic system removes unwanted fibrin deposits and thrombus in order to improve blood flow through injured vessels after the arrest of bleeding and facilitate the healing process after injury and inflammation. The fibrinolytic mechanism is a multi-component system composed of precursors, activators, cofactors, and inhibitors and has been studied extensively.^[1-3] In brief, the fibrinolytic system interacts with the coagulation system at the level of contact activation.^[5] The most well-studied fibrinolytic enzyme is plasmin, which circulates in blood as the precursor plasminogen. Plasminogen adheres to a fibrin clot and is incorporated into the fibrin mesh during polymerization. Plasminogen is activated to plasmin by the actions of plasminogen activators that may be present in blood or released from tissues or may be administered therapeutically. Important plasminogen activators occurring naturally in man include tissue plasminogen activator (tPA) and urokinase, which are also given therapeutically in patients having heart attacks, strokes, and other thromboembolic disorders. Following activation, plasmin digests the fibrin clot by releasing soluble fibrin/fibrinogen digestion products (FDP) into circulating blood that may be assayed as markers of in-vivo fibrinolysis, e.g., D-D dimer fragment of fibrin. In a manner analogous to the regulation of coagulation, the activity of the fibrinolytic system is modulated by naturally circulating inhibitors of plasmin, e.g., antiplasmins such as α -2-antiplasmin, or plasminogen activator inhibitors, e.g., plasminogen activator inhibitor 1 or PAI-1.

COMPLEMENT

The complement system is primarily designed to effect a biologic response to antigen-antibody reactions. In a manner similar to coagulation and fibrinolytic reactions, complement proteins are activated enzymatically through a complex series of reaction steps.^[5] Several proteins in the complement cascade exhibit activity as inflammatory mediators. Ultimately, activation of the complement system results in the generation of an enzymatic complex that causes irreversible damage by lytic mechanisms to the membranes of antigen-presenting cells, e.g., bacteria.

There are multiple interactions between the complement, coagulation, and fibrinolytic systems that have been reviewed elsewhere.^[5] In recent years, there has been considerable interest in the problem of

complement activation by artificial surface, which has been prompted by observation that devices having large surface areas, e.g., hemodialyzers, may cause reciprocal activation reactions between complement enzymes and white cells and complement activation that may mediate both white cell and platelet adhesion to artificial surfaces.^[3,5]

ERYTHROCYTES

Red cells (erythrocytes) are usually considered as passive participants in processes of hemostasis and thrombosis. Although, under some conditions, e.g., low shear or venous flows, red cells may comprise a large proportion of total thrombus mass. The concentration and motions of red cells under flow have important mechanical effects on the diffusive transport of blood elements.^[10] Specifically, blood flow phenomena control the rate of transport by diffusion and convection of cells and proteins in the vicinity of artificial surfaces and thrombi. While physiologically encountered blood shear forces probably do not damage or activate platelets or red cells directly, such forces can dislodge platelet aggregates and thrombi that may attach farther downstream or are carried away (embolize) to distal circulatory beds. Platelet diffusion in flowing blood and early platelet attachment to surfaces may be increased 100-fold by the presence of red blood cells that greatly enhance movement of platelets across parallel streamlines and hence increase the rate at which platelets can participate in thrombus development. As a consequence of red cell motions under laminar flow, platelets may become more concentrated at the periphery of the blood vessel while red cells may have a reduced concentration in the near-wall region. Under some conditions, red cells may also contribute chemical factors that influence platelet reactivity.^[11] The process of direct attachment of red cells to artificial surfaces has been considered to be of minor importance and has therefore received little attention in studies of blood-material interactions.

LEUKOCYTES

The various classes of white cells perform many functions in inflammation, infection, wound healing, and blood response to foreign materials. The reactions of white cells to artificial surfaces may depend upon both the properties of the biomaterial surface as well as local flow conditions, i.e., these reactions may be sensitive to shear stress.^[12,13] White cell adhesive interactions with artificial surfaces may proceed through mechanisms related to activation of the complement, coagulation, fibrinolytic, and other enzyme systems, which result in

the expression by white cells of procoagulant, fibrinolytic, and inflammatory activities. For example, stimulated monocytes express tissue factor that can initiate extrinsic coagulation. Neutrophils may contribute to clot dissolution by releasing potent fibrinolytic enzymes, e.g., neutrophil elastase. White cell interactions with devices having large surface areas may be extensive, especially with surfaces that activate complement, which result in their marked depletion from circulating blood. Activated white cells, through their enzymatic and other activities, may produce organ dysfunction in other parts of the body. The relative importance of many of these reactions for outcomes following the contact of biomaterials with blood remains to be defined.

ARTIFICIAL SURFACES AND CARDIOVASCULAR DEVICES

Introduction

Thousands of devices made from synthetic materials are commonly used in settings that involve their exposure to blood. Since cardiovascular devices as well as the biological environment are complex, even though the materials comprising a device may be considered to be blood compatible, i.e., no adverse events are expected that could compromise device function or host well-being, an implanted device that is fabricated from combinations of those materials will not necessarily be blood compatible. Such devices may be used short-term or implanted permanently and include the extracorporeal pump-oxygenator (heart-lung machine) used in many surgical procedures; catheters for blood access and blood vessel manipulation, e.g., angioplasty and stenting; heart ventricular assist devices; hollow fiber and other types of hemodialyzers for treatment of renal failure; and devices for replacement or repair of diseased heart valves, e.g., prosthetic heart valves, and arteries, e.g., vascular grafts and endovascular stents. Since these and many other blood-contacting devices have been successfully used in patients for many years, they are judged to be therapeutically beneficial. Nonetheless, the performance of many existing devices is also less than optimal.^[14] For example, prolonged cardiopulmonary bypass and membrane oxygenation can produce platelet dysfunction and a severe bleeding tendency. Mechanical heart valves can accumulate thrombus and occasionally shed emboli to the brain, which produce neurological dysfunction. Synthetic vascular grafts perform less well than grafts derived from natural arteries or veins. Graft failure due to thrombosis can lead to ischemia, i.e., lack of oxygen, and injury in downstream tissue beds. At the present time, there are no acceptable synthetic substitutes for

the replacement of small diameter arteries, e.g., less than 6 mm in diameter, which might be used to replace diseased coronary arteries and other blood vessels. Due to the pressing need for blood vessel substitutes, this area remains one of intensive investigation. Thus, while the performance characteristics of many devices is acceptable, i.e., the benefit/risk ratio is high, many existing devices could be improved to extend their period of safe operation, e.g., oxygenators; reduce adverse long-term events, e.g., heart valves; and eliminate or reduce the need for anticoagulating drugs that are required in many instances, e.g., oxygenators, heart valves, and hemodialyzers, and pose a significant risk of increasing bleeding. Device improvements in these areas could result in enormous medical and economic benefits.

Evaluation of Blood-Material Interactions

Despite intensive efforts, the blood responses to specific materials or devices for particular applications are not well-established or predictable because the devices used may be complex in terms of geometry and material composition; the blood flow phenomena associated with device use may be poorly understood regarding the mass transport phenomena that control the rate of blood-material interactions; the possible blood responses are numerous, complex, and dynamic; and it is difficult to measure device thrombogenicity in a manner that is clinically relevant (i.e., predictive of outcomes in man) in either experimental animals or man. Thus, the assessment and interpretation of blood compatibility testing remains uncertain. Most tests purported to measure blood compatibility really evaluate only certain blood-material interactions that are specific to the experimental configuration used and cannot be extrapolated to other conditions involving changes in blood exposure time; blood chemistry, e.g., native versus anticoagulated blood; flow geometry; or species, e.g., animals versus humans. In general, materials and devices that perform well across a wide range of test conditions and, in several animal species, are more likely to perform acceptably in humans as well although this conclusion is not assured until clinical testing has actually been performed. Nonetheless, such tests have provided insights into the mechanisms of thrombus formation and the role of device properties and have permitted some general guidelines for device development. Further improvement of approaches for the rational design of materials and devices that contact blood will require a greater understanding of the physical and biological mechanisms of blood-material interactions.

BLOOD-CONTACTING MATERIALS

Introduction

As a result of the above considerations, it is still not possible to simply rank or classify materials with respect to their suitability for use in particular blood-contacting devices. Nor is it possible to predict in any general way, based on the properties of devices and their blood-contacting surfaces, the behavior of blood in contact with materials or the propensity of devices to produce clinically adverse events. Despite many attempts to correlate biologic responses with device physicochemical property measurements, our success has been largely empirical. These findings suggest that no material may be simply blood-compatible or nonthrombogenic since this assessment will strongly depend on details of the test system or usage configuration. Indeed, under conditions of sluggish (low-shear) blood flow or stasis, most—if not all—synthetic materials may become associated with localized blood clotting and thus be considered thrombogenic. This is because synthetic materials, unlike the endothelium that lines all blood vessels, cannot actively inhibit thrombosis and clotting by directly producing and releasing inhibitors or inactivating procoagulant substances. The development of vascular tissue constructs that possess such favorable biologic activities is one goal of tissue engineering.

Conventional Polymers

Conventional polymers such as poly(ethylene), poly(vinyl chloride), poly(tetrafluoroethylene), and poly(dimethyl siloxane), and certain poly(urethanes) have been used for many decades in short-term blood contact applications, including catheters, cannulas, arteriovenous shunts for hemodialysis, and tubing components of extracorporeal circuits.^[8,14] When used in patients with systemic anticoagulation, the performance of such materials has usually been acceptable. For example, although thrombus on angiographic catheters can be demonstrated in about half of all cases, most thromboembolic or occlusive events are clinically silent and produce significant complications in less than about 1% of procedures. With the use of catheters for venous sampling or drug administration, even the total occlusion of peripheral veins is usually inconsequential. However, longer-term indwelling catheters in a variety of configurations and polymer compositions, particularly in infants and children, are now recognized to involve a significant risk of thrombosis that can ultimately lead to organ or limb damage and even death. Poly(urethanes), due in part to their flexibility and toughness, are perhaps the polymer of

choice for ventricular assist devices, blood pumps, and the next generation of prosthetic heart valves. While all conventional polymers are at risk of eventual degradation and failure due to hydrolysis, calcification, and absorption of lipids, considerable effort is being directed towards overcoming these challenges.

Hydrophilic Polymers

These materials, which preferentially adsorb or absorb water (hydrogels), were initially postulated to be blood-compatible based on the view that many naturally occurring phospholipids comprising the cell membranes of blood contacting tissues are also hydrophilic. Thus, water, as a biomaterial, was expected to have minimal interaction with blood proteins and cells. Interestingly, in animal studies, highly hydrophilic polymers based on acrylic and methacrylic polymers and copolymers as well as poly(vinyl alcohol) were all found to consume platelets, i.e., shorten the circulating platelet lifespan, when implanted for periods up to several weeks although these polymers accumulated little visible thrombus.^[8] While the rates of platelet destruction were variable between materials, the hydrophilic polymers had little capacity to retain adherent thrombus, i.e., they shed deposited blood elements as microemboli. Thus, while hydrogels, which are mechanically weak, are currently used to improve catheter lubricity and serve as reservoirs for drug delivery, they have not received widespread application for improving blood-compatibility. Another hydrophilic polymer that has received considerable attention is poly(ethylene oxide). While poly(ethylene oxide) surfaces have been shown, e.g., hydrogels, to reduce interactions with blood proteins and cells *in vitro*, their use for clinical device applications has not been established.

Metals

Metals tend to be thrombogenic in experimental test systems and are most commonly applied in situations requiring considerable mechanical strength, e.g., the struts of mechanical heart valves and as endovascular stents. Stents are metallic mesh devices mechanically placed within blood vessels to expand the vessel lumen diameter, e.g., after balloon angioplasty, in order to preserve vessel patency and improve blood flow. Metals most commonly employed are stainless steel and tantalum. Guidewire thrombogenicity, although readily documented, has been less of a problem clinically because of the usually short period of blood exposure. Theoretically, reduced thrombogenicity of metallic stents and heart valve components might be achieved by thin film polymer coatings although the

clinical effectiveness of this strategy has not been demonstrated. Thus, systemic anticoagulation or long-term platelet inhibitor therapy, e.g., aspirin, is generally employed in patients with prosthetic heart valves and stents.

Carbons

Cardiac valves fabricated from low temperature isotropic carbons, e.g., pyrolytic carbon, are successfully used clinically. These materials are appropriate for such applications as mechanical valves that require long-term chemical inertness, smoothness, and wear-resistance. The reasons for the marked improvement in the performance, e.g., reduced thrombosis and thromboembolic stroke rates, of these newer versus older style heart valves are not entirely understood, but they are undoubtedly multifactorial and relate to improved patient management and valve design with respect to flow phenomena as well as to the nature of the carbon surface. Clearly, these carbons confer specific benefits with respect to blood cell and protein interactions, which result in a very low frequency of clinical complications, although their development has been largely empirical and dictated by the mechanical requirements of prolonged implantation. The use of carbon coatings has been proposed for other devices, e.g., vascular grafts, and such devices are gaining acceptance clinically.

Biological Surfaces

The use of biological and bioactive molecules as device surface coatings dates back many years to the use of coatings containing albumin, phospholipids, and the anticoagulant heparin. These coatings may confer significant thromboresistance. Phospholipids such as phosphorylcholine, a normal constituent of cell membranes, may orient polar head groups towards the aqueous phase and locally organize water molecules—much like hydrogel surfaces. These surfaces may minimize protein and complement interactions.^[15] In preliminary animal studies, phosphorylcholine-coated stents, guidewires, and vascular grafts have shown improved thromboresistance. This approach is being actively developed for clinical applications. Heparin, a naturally occurring anticoagulant glycosaminoglycan, has been considered an attractive surface coating based on its ability to directly catalyze the inactivation of procoagulant enzymes. Recently, the reduced thrombogenicity and improved biocompatibility of heparinized stents and vascular grafts has been demonstrated in animals. This method has also been widely used clinically for the heparin coating of catheters and other devices, and it is clear that the improved

Fig. 3 Integrated hemostatic reactions between a foreign surfaces and platelets, coagulation factors, the vessel endothelium, and the fibrinolytic system.

biocompatibility is a function of heparin's anticoagulant activity as opposed to heparin's nonspecific physicochemical properties. Finally, coatings based on hyaluronic acid have also shown promise for reducing the thrombogenicity of metallic endovascular stents.^[16] In general, biomolecule coatings have shown considerable promise as blood-contacting materials.

CONCLUSION

Interrelated blood systems respond to tissue injury in order to quickly minimize blood loss and remove unneeded deposits after healing has occurred. For purposes of illustration, Fig. 3 depicts several of these relationships and inhibitory pathways that apply to blood reactions following contact with both natural and artificial surfaces. When artificial surfaces are exposed to blood, an imbalance between processes of activation and inhibition of these systems can lead to excessive thrombus formation and an exaggerated inflammatory response. While certainly the key blood cells, proteins, and reaction steps have been identified, many aspects of their biological interrelationships remain poorly understood. Because the variables affecting cardiovascular device responses are sufficiently numerous and complex, including the effects of flow phenomena, those properties of blood-contacting surfaces that would be desirable to minimize adverse reactions cannot, in most instances, be predicted with confidence. The choice of material is often constrained by mechanical property considerations and variable requirements for material durability and chemical stability. Newer materials, including biomolecule coatings, and newer devices, including tissue-engineered constructs having beneficial biological properties

that are found in normal vascular tissue, hold considerable promise for improving the performance of blood-contacting materials that are used in the diagnosis and treatment of vascular disease.

Houston, Texas, U.S.A.

INTRODUCTION

Currently, approximately one million patients are kept alive with the help of hemodialysis. If there were no dialyzers today, all these patients would have died within two weeks of kidney failure. Some hemodialysis patients have lived for longer than 30 years. However, in order to avoid chronic hemodialysis syndrome, which is produced by the insufficient removal of renal toxins, hemodiafiltration or plasmapheresis should be effectively employed. These new technologies should be useful in the treatment of not only metabolic diseases but also immunologically induced diseases.

Plasmapheresis involves the nonspecific or specific removal of plasma factors and cellular removal or modulation, reducing their circulating concentrations and thereby improving the clinical state of the patient.

It is estimated that approximately half a million therapeutic plasma treatment procedures are currently carried out in the world per year, and that this number will increase yearly. Growth is related to the cost-effectiveness of the procedure compared with conventional treatments. Plasma treatment has been employed in a wide variety of disease states that may be generally categorized as metabolic or immunologic. The original procedure of plasma exchange has been expanded to plasma fractionation by membrane, adsorbents, or cytapheresis. The physical characteristics of membrane filters in plasmapheresis will be summarized. While many studies have been anecdotal in nature, plasmapheresis is highly recommended in certain diseases. Through further investigation the role of plasma treatment will be more scientifically understood.

These blood purification technologies are described in detail in *Manual on Artificial Organs: The Artificial Kidney*,^[1] and *Blood Purification—Artificial Kidney and Plasmapheresis*,^[2] together with two issues of *Therapeutic Apheresis*.^[3,4]

HEMODIALYSIS: THE DIALYSIS OF BLOOD

Blood returned to the body from the artificial kidney has a lower concentration of chemicals than the surrounding body tissues. These chemicals will diffuse out

of the tissues into the blood. Blood is returned to the dialyzer many times. This repeated return of the dialyzed blood to the body provides for a continuous diffusion of excess body chemicals from the body cells (Fig. 1).

Routine dialysis procedures take three to five hours and are performed three times a week in chronic patients. Hemodialysis is routinely done in outpatient dialysis centers or in the home. Twelve liters of blood are processed per hour. Blood access is normally made via an internal fistula. An anticoagulant such as heparin is required to prevent blood clotting in the circuit during treatment. Hemodialysis is performed to remove small molecules in blood, physiologically removable by the kidney, based on the principle of osmosis.

Principles of Hemodialysis

The hemodialyzer, or artificial kidney, can perform some but not all of the functions of a natural kidney. The artificial kidney removes waste metabolites and water and maintains chemical equilibrium sufficiently to return the patient to a nearly normal condition for several days. Dialyzers operate outside the patient's body to cleanse the blood. One important issue is that hemodialysis does not fully reproduce the natural kidney function. Thus, after several years of hemodialysis treatment, new diseases emerge due to the insufficient restoration of kidney function. However, the current blood purification technologies will help hemodialysis patients maintain a healthy condition. The blood is usually drawn from a tube in an artery and, after passing through the dialyzer, is returned through a tube inserted into a vein.

What makes it possible to use only the blood to restore the patient to a nearly normal condition? As it flows through the body, the blood collects waste materials and excess water that are discharged when the blood reaches the kidney. The kidneys act as a regulating mechanism by determining how much of the various waste materials, chemicals, and water to remove. By effectively removing these various materials from the blood, the dialyzer temporarily performs the function of the natural kidney and is able to keep the patient in

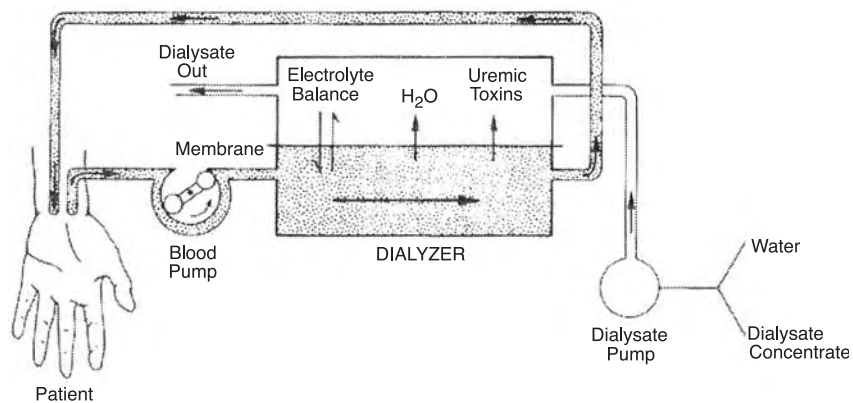

Fig. 1 Hemodialysis circuitry. (From Ref. [2].)

close to a normal condition. Deficiencies in the removal of these waste products can be compensated for by hemodiafiltration or apheresis (described in a later section) (Fig. 2).

Just how the dialyzer performs each of its separate functions is described in the following paragraphs.

Waste Product Removal

Waste products are defined as the unusable end products of metabolism. Metabolism is the process by which food is converted to energy and structural components for the body. The waste products from metabolism accumulate in the bloodstream, and during normal renal function are removed when the blood passes through the kidneys. As a partial substitute for disabled kidneys, these waste products are removed by the process of dialysis.

Dialysis Membrane

Dialysis involves the use of a thin, porous membrane that keeps the blood separated from another fluid, the dialysate. The membrane can be compared to a metal netting. The membrane has perforations, but they are so small that they are invisible to the naked eye. Waste products in the blood are able to pass through these minute perforations into the dialysate fluid, where they are immediately washed away. The perforations in the

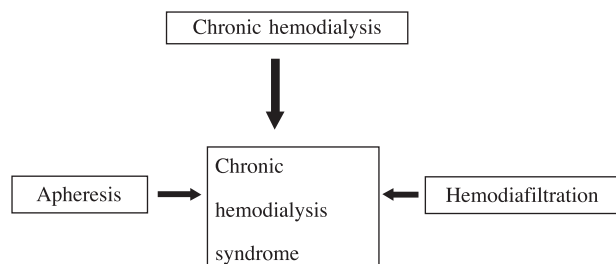

Fig. 2 Hemodialysis and blood purification.

dialysis membrane have an average diameter of 50 Å, with an estimated range of 30 to 90 Å. The original cellulose membrane utilized for hemodialysis was manufactured primarily for sausage casing.

Concentration Gradient

The waste products (as molecules) pass through the membrane by action of a concentration gradient (Fig. 3). Molecules move in a random manner when they occupy a given volume, and in so doing they tend to distribute themselves evenly throughout the entire

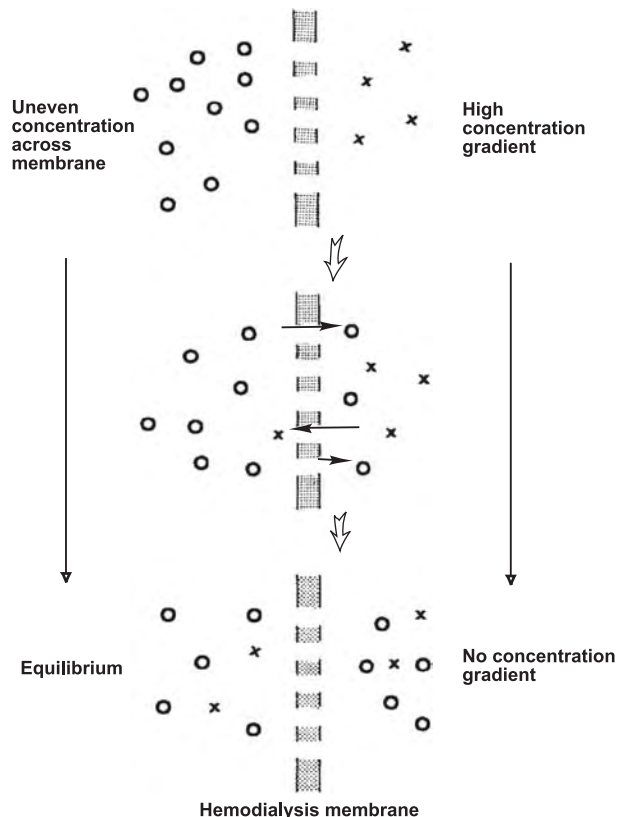

Fig. 3 Concentration gradient. (From Ref. [1].)

volume. The number of molecules in a specific volume represents the concentration. In the artificial kidney, the dialysis fluid is free of waste product molecules; consequently, those in the blood are able to pass through the membrane and tend to distribute themselves evenly throughout the blood and the dialysate. Thus, there is a net movement of waste product molecules from a region of high concentration (the blood) to a region of low concentration (the dialysate). This difference in concentration between the blood and the dialysate, which is the cause of the movement of molecules, is known as the concentration gradient.

Selective Permeability of Molecules in the Blood

There are many different types, as well as sizes, of particles (molecules) in the blood (Table 1). These molecules include waste products such as urea, creatinine, and uric acid; ions (small particles that have an electrical charge), and many other, larger molecules. In addition to the proteins, there are even larger particles (such as erythrocytes and leukocytes) that are the formed elements of the blood. These blood cells, along with the majority of proteins, do not pass through the membrane during dialysis; they are just too large for the perforations (Fig. 4). This selective quality of the membrane—allowing small molecules to pass through

Fig. 4 Permeable smaller molecules and non-permeable larger molecules.

but retarding the passage of progressively larger molecules and particles—represents the real advantage of dialysis. Proteins, erythrocytes, and leukocytes are invaluable to the body, and their loss would have fatal consequences for the patient. Because the membrane can effectively retain these larger substances and at the same time eliminate unwanted waste materials from the blood, dialysis has become an effective agent in the treatment of renal diseases. Furthermore, no bacteria or viruses can be introduced into the blood compartment because they are too large to pass through the perforations in the dialysis membrane.

Maintenance of Balance of Body Chemistry

Many chemicals are present in all parts of the human body. These chemicals appear in several forms—compounds, ions, and aggregates. The relative amounts of these chemicals are critically important to normal body function. For example, potassium is present both in the body cells and in extracellular fluid such as blood. There is a definite relationship between the amount of potassium in the blood and the corresponding amount in the body cells. In blood, the ionic form of potassium is minute and can easily pass through the dialysis membrane into the dialysate fluid. If dialysis were performed with dialysate that contained no potassium, the amount of potassium in the blood would steadily decrease. The ratio between the amount of potassium in the body cells and in the blood would consequently be upset, and the effects could be dangerous. In actual practice, potassium-free baths are used for hemodialysis on uremic patients without any danger. Imbalances are avoided by the addition of chemicals to the dialysate fluid to make their concentration the same as the concentration in the blood. With no concentration

Table 1 Molecules in the blood

Molecules	Molecular weight
Electrolytes	
Sodium	22.989
Chloride	35.453
Potassium	39.102
Calcium	40.08
Magnesium	24.312
Urea	60.06
Creatine	113.14
Uric acid	168.11
Dextrose	180.16
Bilirubin	584.67
Amino acids	
Glycine (smallest)	75.07
Tryptophane (largest)	204.22
Proteins	
Albumin	68,000
γ -globulin	150,000
Hemoglobin	68,000
Fibrinogen	400,000

Source: Ref. [1].

gradient, there is no net movement of these critically important chemicals through the pores of the dialysis membrane. Thus, valuable chemicals small enough to pass through the pores of the dialysis membrane are retained in the blood. Conversely, when the body balance of some vital chemical is upset as a result of disease, it may be restored by properly adjusting the concentration of the chemical in the dialysate fluid. When it is desirable to remove an excess of a chemical from the blood, that chemical is not added to the dialysate fluid. This will result in a large concentration gradient, favoring net movement of the chemical from the blood to the dialysate. To add a given chemical to the blood, the procedure is reversed.

Water Removal

Water molecules are extremely small and pass easily through the pores of the dialysis membrane. The water

concentration is the percentage of water molecules in a specific volume containing many different molecules. All other molecules and particles dispersed among the water molecules are known as solutes, and the water is called the solvent. The two together are referred to as a solution. If the number of solutes is significantly increased, then the water concentration is decreased. In practice this principle is one basis for removing excess water from the blood during dialysis. There are two methods of water removal: the addition of a substance to the dialysate fluid and ultrafiltration.

A large amount of some harmless substance such as dextrose is added to the dialysate fluid to decrease the water concentration. Because the water concentration in the blood is higher than that in the dialysate fluid, a concentration gradient is set up that results in a net movement of water out of the blood into the dialysate fluid. This phenomenon is commonly referred to as osmosis (Fig. 5).

Fig. 5 Water removal. (From Ref. [1].)

Table 2 Conditions for an effective dialyzer (optimal metabolic clearance)

Large surface area of membrane
Good dialysis membrane
Small, constant priming volume
Thin channel for blood
Even distribution of blood
Short channel of blood
Effective mixing of blood
High blood pressure (if a blood pump is not used)
High blood flow
Fresh dialysate and effective dialysate flow
Countercurrent flow of dialysate and blood
High flow rate of dialysate
Effective exposure of the dialysis membrane to the dialysate
High temperature of dialysate

Source: Ref. [1].

Excess water is usually removed from the blood by another process known as ultrafiltration. This process is more effective than the addition of dextrose to the dialysate. Ultrafiltration of water through a dialysis membrane works on the principle of pressure difference. In order to make water flow through a pipe or other

**Fig. 6** Differences of dialysis, hemofiltration, and plasma separation.

conduit, the pressure applied to the fluid at the upstream end of the pipe must be greater than the pressure at the downstream end. One can imagine an analogous situation in the artificial kidney during dialysis. Blood and dialysate flow through compartments separated from each other by the dialysis membrane. Since the water molecules in both the blood and the dialysate fluid can easily pass through the membrane, the direction of flow will be primarily determined by the pressure difference (Fig. 5). At points along the membrane length where the pressure on the blood is greater than the pressure on the dialysate fluid, the water flows from the blood into the dialysate. When the situation is reversed, water flows from the dialysate into the blood.

Since ultrafiltration is a much more effective means of removing excess water than osmosis, it is usually favored if practical. The pressure difference in the dialyzer can be adjusted to remove variable amounts of excess water. Hemofiltration and hemodiafiltration (the combination of dialysis and filtration) are very efficient for removing smaller molecules (smaller than albumin) and low-concentration molecules. On the other hand, hemodialysis is very efficient for removing smaller (than albumin) molecules with a higher concentration.

Dialyzer Effectiveness

Several points should be made in regard to the optimal performance of various types of dialyzers.

Metabolite clearance (MC) is a measure of the removal rate of waste products. The mathematical equation

$$MC = \frac{C_1 - C_2}{C_1} Q_B$$

**Fig. 7** Monsanto hollow-fiber device evaluated as an experimental plasma separator in 1972. Separated plasma is seen at the bottom of the hollow-fiber column. (From Nosé, Y.; Malchesky, P.S. Therapeutic Membrane Plasmapheresis. In *Therapeutic Plasmapheresis*; Oda, T., Ed.; F.K. Schattauer Verlag: Stuttgart, 1981; 3.)

where C_1 = blood inlet concentration of waste product to the dialyzer, C_2 = blood outlet concentration of waste product from the dialyzer, and Q_B = blood flow rate (ml/min), shows that waste product removal depends on, or is a function of, the blood flow and the fractional change in waste product concentration as the blood passes through the dialyzer. The magnitude of these quantities depends on such physiological factors as blood pressure and blood vessel patency, as well as on physical factors such as blood film thickness and resistance, dialysate flow rate, and membrane form and permeability. Optimizing the metabolite clearance of any dialyzer requires manipulation of these factors

until a satisfactory waste removal rate is established (Table 2).

Another commonly used indicator of the efficiency of dialysis is dialysance. This is the molecular exchange ratio between the blood and dialysate. Dialysance increases when blood flow increases:

$$D = \frac{C_1 - C_2}{C_1 - C_D} Q_B$$

where D = dialysance (ml/min) and C_D = concentration in the dialysate. The difference between clearance and dialysance is evident when the dialysate is recirculated.

Fig. 8 Membrane plasma exchange. (From Ref. [2].)

Fig. 9 Plasma filtration. (From Ref. [2].)

However, when the dialysate is used in only a single pass, these two values are the same.

In many cases, the variables themselves depend on other variables, and often compromises have to be made between opposing factors to achieve optimal efficiency of the dialyzer. Ultrafiltration (ml/hr) is just as important in many patients as waste product removal. Often, however, conditions for good ultrafiltration are in opposition to those for adequate waste product removal. For example, in a continuous-flow dialyzer, when a patient requires little or no water removal, the dialysate is generally pumped through the dialyzer. If more water removal is necessary, the dialysate is sucked through the dialyzer. Sucking creates a negative pressure in the dialysate ("negative pressure" refers to a pressure that is less than normal atmospheric pressure). The effect of this negative pressure is to increase the pressure difference between the blood and the dialysate, thereby increasing the rate of water removal. However, the same increase in pressure difference that increases ultrafiltration also increases the priming volume and blood film thickness and consequently reduces the waste metabolite removal. It is important to recognize that many of the physiological and physical variables affecting dialysis (waste removal) also affect ultrafiltration and vice versa. A dialyzer capable of a urea clearance of over 80 or 90 ml/min at a flow rate of 150 ml/min and ultrafiltration rate of over 150 ml/hr is clinically acceptable.

HEMOFILTRATION

Hemofiltration is a process for removing water and small molecules in the blood by the ultrafiltration principle (Fig. 5). The sizes of molecules removable by hemofiltration are dictated by the pore size of the membrane. Typically, hemofiltration is utilized to remove molecules smaller than albumin (and occasionally the same size as albumin) whose concentration in the blood is very small. Osmosis is not an effective removal method when the concentration of the molecules is very low. Typically, approximately 20 liters of filtrate are removed from the patient's blood while 17 liters of pyrogen-free sterile dialysate are infused at one session of the treatment. Then the low-concentration toxic substances are effectively removed. Hemodiafiltration is the combination of hemodialysis and hemofiltration. This combination therapy can take advantage of osmosis (dialysis) for the removal of molecules of higher concentration and filtration for the removal of molecules of lower concentration.

PLASMAPHERESIS

Separation of plasma from the cellular components of the blood is achieved by either the plasma separator

membrane or the centrifugal method. In this chapter, only membrane separation is described. A membrane with much larger pore size than is used for hemofiltration should be used for this purpose. For the effective removal of plasma, the transmembrane pressure should be kept as low as possible. The differences between dialysis, hemofiltration, and plasma separation are summarized in Fig. 6.

Membrane Plasma Separation and Plasma Treatments

By 1972, the development of membrane technology was such that hydrophobic membranes with a porosity of 0.2 to 0.5 μm were available and used initially for membrane oxygenators. I. O. Slayer together with Y. Nosé had developed the Monsanto hollow-fiber membrane oxygenator (Fig. 7). Nosé discovered that the polymeric hollow-fiber device showed reasonable gas exchange characteristics but also produced a large amount of plasma by leakage through the membrane walls.^[3] The membrane was not hydrophilic enough to be practical for oxygenators.

But Nosé thought that this type of hydrophilic membrane would be effective for plasma separation. Thus, the Cleveland Clinic group lead by Nosé and P. S. Malchesky devoted their efforts to the development of a membrane for plasma separator and plasma fractionator systems.^[3] Initially a plate-type plasma separator was utilized. In 1977, a hollow-fiber plasma separator became available from Asahi Medical Inc. in Japan. Z. Yamazaki and N. Inoue in Tokyo performed the first clinical application of this filter for hepatic failure patients. The CCF group initiated its clinical application using this filter the next year.^[3]

Fig. 11 Plasma adsorption. (From Asanuma, Y.; Malchesky, P.S.; Zawicki, I.; Smith, J.W.; Carey, W.D.; Ferguson, D.R.; Hermann, R.E.; Nosé, Y. Clinical hepatic support by on-line plasma treatment with multiple sorbents—Evaluation of system performance. *Trans. Am. Soc. Artif. Intern. Organs* 1980, 26, 400.)

The following plasma treatment methods were developed using these microporous membrane filters (Table 3).

Plasma exchange

Utilizing a plasma separator (either membrane or centrifuge) (Fig. 8), the diseased patient's plasma is separated on-line. At the same time, the healthy patient's plasma or albumin solution replaces the lost plasma volume.

Plasma filtration

After plasma is separated with a plasma separator, the diseased plasma is filtered through a second filter called

a plasma filter or plasma fractionator (Fig. 9). The molecules of unwanted size are removed by the secondary plasma fractionator module (Fig. 10). LDL cholesterol is a much larger molecule than HDL cholesterol; it is very easily removed by the proper plasma fractionator (Kuraray 5A) while HDL cholesterol is retained. To enhance the efficiency of plasma filtration, cryofiltration and thermofiltration (described in a later section) were introduced.

The plasma filter or plasma fractionator separates unwanted larger-size molecules inside the second filter and retains these larger molecules (Table 4). Filtered plasma without the unwanted molecules is returned to the patient.

Plasma adsorption

Specific adsorption columns can remove unwanted macromolecules in plasma (Fig. 11). This procedure is called plasma adsorption (Table 5). To enhance its efficiency, multiple adsorption columns are often necessary.

On-line membrane filtration with plasma treatment

Membrane plasma separators are very similar to capillary hemodialyzers in terms of results. Their basic operational constraints, however, are completely different. Membrane plasma separators are designed to separate the cellular components of the blood from the non-cellular components (Fig. 12). After separation, plasma can either be discarded (Fig. 8), or processed by sorbents (Fig. 11), secondary membranes (Fig. 9), or

Table 5 Adsorbents for therapeutic apheresis

Material	Target substance or disease

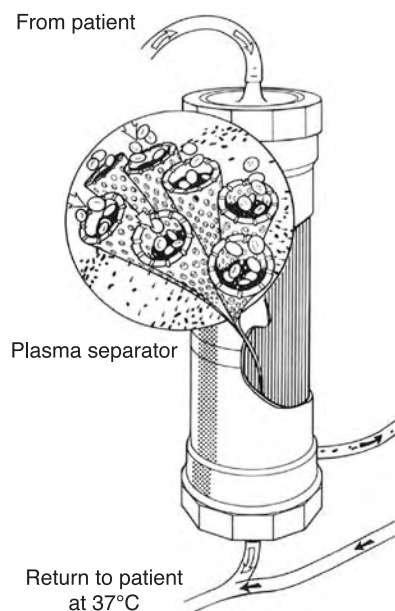

Fig. 12 Membrane plasma separators for plasma treatment. Blood is perfused through the lumens of the hollow fiber. Under a low hydraulic transmembrane pressure gradient, plasma is freed through the membrane wall, collected, and thrown away (in the discarded plasma treatment scheme). Blood cells are retained in the lumen and are not allowed to pass through the wall before being returned to the patient. (From Nosé, Y.; Horiuchi, T.; Malchesky, P.S.; Smith, J.W.; Matsubara, S.; Abe, Y. Therapeutic Cryogel Removal in Autoimmune Disease: What is Cryogel? In *Therapeutic Plasmapheresis (II)*; Oda, T., Ed.; F.K. Schattauer Verlag: New York, 1982; 15.)

cryofiltration. With on-line plasma treatment systems, we not only discard a large variety of macromolecules, which has metabolic or immunological consequences for the body, but also eliminate the need for infusion of foreign macromolecules from plasma products, which are potentially incompatible with the recipient.

On-line plasmapheresis is a treatment modality consisting of

1. Removal of whole blood from the patient
2. Separation of plasma from the cellular blood components via a porous membrane or a centrifugal process
3. Subjecting the separated plasma to specific procedures, such as cooling, filtration, and perfusion through columns
4. Reunion of the treated plasma with the cellular blood components and its return to the patient

Cascade membrane technology

If it is known that certain macromolecules should be removed, cascade membrane technology can be used

Fig. 13 Cascade membrane technology for selective removal of macromolecules. The general objective of this technology is selection of filter membranes of various porosities suitable for selective removal of macromolecules from blood. (From Nosé, Y.; Malchesky, P.S.; Smith, J.W. Hybrid artificial organs: Are they really necessary? *Artif. Organs* **1980**, 4(4), 285.)

(Fig. 13). Using this principle we can selectively separate molecules of a few million daltons molecular weight (e.g., immune complexes), of a few hundred thousand daltons molecular weight (e.g., gamma globulin fractions), or below 100,000 daltons molecular weight (e.g., albumin fractions). Aiming for the separation of these various types of macromolecules, several industrial firms have developed macromolecular filters of various porosities.

Cryofiltration

Selective separation of globulin fractions or larger molecules from albumin or smaller molecules is theoretically possible, but the molecular sizes of albumin and globulin are quite similar, and it is rather difficult to separate them effectively using simple membrane filtration systems. Because cryoprotein is very often present in the autoimmune disease state treated by plasmapheresis, an attempt was made to utilize temperature as a variable in the membrane separation of pathological macromolecules in the plasma (Fig. 14A). Cryoproteins

Fig. 14 (A) Cryoprecipitates formed from the serum of patients by cooling at 4°C for 72 hours. From the left: control, rapidly progressive glomerulonephritis, rheumatoid arthritis, myasthenia gravis, and Sezary syndrome. These cryoprecipitates are different from cryogel, which is formed in heparinized plasma. (B) Heparinized plasma (right) is cooled to below 35°C (typically near 0 degrees). Then the plasma changes to a milkylike solution, indicating the formation of cryogel (left). (C) After the cooled heparinized plasma is cryofiltered, the cryogel is formed inside the filter and removed from the plasma. When the cryogel is heated above 35°C, this gel changes its appearance to a liquid form. (From Nosé, Y.; Malchesky, P.S.; Smith, J.W. Problems of Current Technology for the Selective Removal of Pathological Macromolecules. In *Therapeutic Plasmapheresis III*, Oda, T., Ed.; Schattauer Verlag: Stuttgart, 1984; 3.)

Fig. 15 The cryofiltration circuit. Cryogel is primarily formed as fibrinogen-heparin-fibronectin complexes. Antibodies, cryoprotein, immunocomplexes, pathological albumin, endotoxin, and other forms are also included. (From Malchesky, P.S.; Asanuma, Y.; Zawicki, I.; Blumenstein, M.; Calabrese, L.; Kyo, A.; Krakauer, R.; Nosé, Y. On-Line Separation of Macromolecules by Membrane Filtration with Cryogelation. In *Plasma Exchange*; Sieberth, H.G., Ed.; F.K. Schattauer-Verlag: Stuttgart, 1980; 133.)

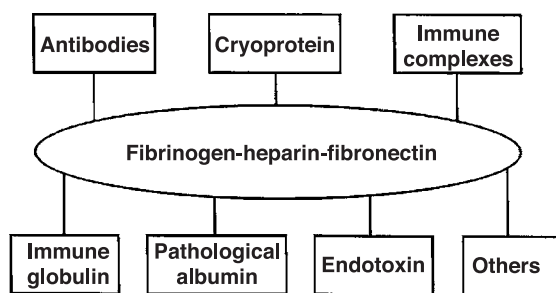

Fig. 16 Composition of cryogel. (From Nosé, Y. Congress presidential address: 5th WAA congress, therapeutic artificial organs, 10 years after. *Artif. Organs* **1995**, *19*(3), 204.)

are serum proteins that precipitate and gel spontaneously at a low temperature (near 4°C for three to five days) and return to a soluble form on elevation of the temperature. Cryoprecipitates also occur in heparinized plasma more dominantly and represent a homogeneous mixture of proteins, immunoglobulins, immune complexes, certain complements, lipids, and fibrinogen fractions. Particularly at a temperature below 35°C, heparin used as an anticoagulant for the extracorporeal circulation establishes fibrinogen–heparin–fibronectin complexes and attracts antibodies, immunocomplexes, and other forms inside of these complexes. This gel-type residual inside the secondary filter was coined “cryogel” by Y. Nosé^[3] (Fig. 14B,C). While normal values exist in nondisease states, concentrations of cryogel over 10 times higher are not uncommon in the autoimmune-diseased patient.

Cryofiltration was introduced by P. S. Malchesky and Y. Nosé, taking advantage of cryogel formation. Cryofiltration is the technique of cooling (possibly to near freezing) and filtering plasma on-line. Cryogel is formed and retained in the membrane filter. While distinctly different from cryoglobulins as measured by

Fig. 17 Kinetics of cryogel in aged and diseased individuals. (From Nosé, Y. Congress presidential address: 5th WAA congress, therapeutic artificial organs, 10 years after. *Artif. Organs* **1995**, *19*(3), 204.)

B

classical assays, cryogel removal has been shown to be beneficial in the treatment of rheumatoid arthritis and other autoimmune diseases. A cryofiltration circuit is shown in Fig. 15. Blood is pumped from the patient into a plasma separator, which separates the plasma from the cellular components of the blood. The plasma is then pumped into a cooling module, where it is cooled and filtered on-line by means of a very porous macromolecular filter. The filtered plasma is reunited with the whole blood, warmed to physiological temperature, and returned to the patient. Cryogel removal is achieved with the bulk of the plasma returned to the patient accompanied by the passage of albumin and

Fig. 19 Comparison of sieving coefficients as a function of molecular diameter for dialysis (Cuprophane PT-150), hemofiltration (RP-69), and plasma separator membrane modules. The sieving coefficient is the ratio of the concentration of the solute in the filtrate (C_F) to that in whole plasma (C_P) and is represented as $SC = C_F/C_P$. (From Ref. [2].)

low-molecular-weight plasma. The composition of cryogel is shown in Fig. 16.

Cryogel exists even in a healthy individual, and the level of cryogel increases with the aging process (Fig. 17). So removal of this cryogel might contribute to the maintenance of physical youth. This is explainable on a physiological level by the increase of fibrinogen during the aging process (Fig. 18).

Cryofiltration has been used for the treatment of malignant rheumatoid arthritis. The initial intensive treatment was approximately 30 sessions in six months. After one year, treatment from once a month to once every three months kept the syndrome under control.

Thermofiltration

For the removal of lipids such as LDL cholesterol, the formation of cryogel is not desirable. Thus, for the removal of LDL cholesterol, thermofiltration was developed by Y. Nosé and P. S. Malchesky, with the second filter's environmental temperature kept at around 37–40°C.^[3] Cryogel is formed when the heparinized plasma is cooled down below 35°C, so cryogel formation is prevented by this method, and effective removal of LDL cholesterol was established for the treatment of arteriosclerosis. A once-a-month session of thermofiltration should be sufficient to maintain the LDL cholesterol level within a reasonable range.

Sorbent systems including leukocyte filters

The utilization of chemical sorbents such as charcoal and resins has been investigated since 1963 for use in the

artificial kidney and for drug overdose. For biomedical applications of sorbents in the extracorporeal circulation, the system must be free from particle release and must be biocompatible. Direct perfusion of blood over sorbents (hemoperfusion) in clinical use has been hampered due to damage to blood cellular components and embolization. The microencapsulation of sorbents, the direct perfusion of sorbents with plasma, and the application of sorbent membranes have made the chronic application of sorbent devices clinically safe.

Recently, many specific adsorption columns have been developed (Table 5). The mechanisms include

Fig. 20 Comparison of solute extraction for hemodialysis, hemofiltration, and membrane plasmapheresis, illustrating the effect of increasing molecular weight on solute removal. Only plasmapheresis provides the transfer of protein-bound toxins. For effective hepatic assist, it is necessary to remove molecules up to the size of albumin. (From Ref. [2].)

Fig. 21 Filtrate flux is represented as a function of the transmembrane pressure for dialysis, hemofiltration, and plasma separation. The shaded regions represent normal operating ranges. Filtration flux is equal to the number of milliliters per minute transferred per meter squared (ml/min/m²). (From Ref. [2].)

electrostatic, hydrophobic, immunosorption, and others. The FDA has approved some of them, but most are not allowed for use in the United States.

Similar to Polymixin B bound polystyrene fiber, removal of endotoxins by a specially designed adsorption column was developed for the treatment of septic patients and multi-organ failure patients. Various types of adsorbents are packed in the form of beads or granules inside the column. Also, adsorbents are adhered to the polymeric fibers and packed in the column.

The centrifugal separation method effectively separates not only plasma but also leukocytes and erythrocytes. Leukocyte removal is achieved, and thus leukocytapheresis results in not only plasma modulation but also cellular modulation.

Recent advances in apheresis technologies have introduced various types of cellular adsorption columns and cellular filters (Table 6). The effective removal of leukocytes is possible with such columns. The selective removal of granulocytes and lymphocytes is also becoming possible. Filter material used for leukocyte removal includes polymeric thin fibers, netted or woven fibers, and polymeric sponges.

Recent blood purification technologies are expanding from classical hemodialysis, hemofiltration, and plasma separation to selective removal of pathological plasma macromolecules and pathological cellular factors by specifically designed adsorption columns or adsorption filters. Theoretically, for some disease states to be treated, it is essential to provide not only macromolecular modulation but also cellular modulation. Recently, immunologically active molecules such as cytokines (molecular weight below

30,000 daltons) should be considered for removal in the treatment of some immunologically-induced diseases, even though this hypothesis still needs to be proven.

For the treatment of autoimmune diseases, it is necessary to produce an immunosuppressive state through the removal of immunologically active macromolecules and cells. Along with the treatment of immunologically deficient states, such as a malignant tumor or an infectious prone state, it is necessary to induce immunostimulation in the patient.

Immunostimulation can be established with bio-compatible columns or filters. Thus, plasma therapy could induce both immunosuppressive and immunostimulative states.

CONCLUSION

Dialysis is effective in treating renal failure because of its ability to remove solutes of low molecular weight (generally less than 5000 daltons), including water molecules. The dialysis procedure does, however, have limitations in the removal of solutes whose molecular weight is larger or that are protein bound. Such abnormal concentrations of solutes exist in many disease states. Hemofiltration, sorption, and plasma exchange have been applied as solute removal techniques in the removal of plasma solutes that cannot be removed by conventional dialysis (Figs. 19 and 20). Pore sizes in the membranes dictate molecular removal. Because pore sizes are different, transmembrane pressures required for molecular removal by hemodialysis, hemofiltration, and plasma separation are quite different (Fig. 21).

Blood Vessel Mechanics

Ruth J. Okamoto

Departments of Mechanical Engineering and Biomedical Engineering, Washington University, St. Louis, Missouri, U.S.A.

INTRODUCTION

The primary role of the cardiovascular system is to distribute oxygenated blood to organs and tissues. The vascular system (vasculature) is the distribution system and includes arteries, arterioles, capillaries, venules, and veins. Oxygen exchange occurs in the capillaries, while arteries and veins serve as conduits and to regulate blood flow. While blood vessels share common structural features, there is a wide variation in the structural details of vessels located in different parts of the vascular tree, because of differences in blood pressure and blood flow. Thus, while common governing principles can be delineated for blood vessels, the structure and mechanical properties of specific blood vessels must be investigated individually.

This article begins with a description of the structural features of blood vessels. Experimental methods for studying blood vessel mechanics are described and their strengths and limitations identified. Finite elasticity is presented as a theoretical framework for interpreting experimental observations. Differences between blood vessel mechanics are examined in light of differences in the mechanical environment during development and after maturity. The ability of blood vessels to respond to their mechanical environment is discussed, and examples of normal and pathologic responses to changes in mechanical loads are provided. The article concludes with comments on current and future directions in understanding blood vessel mechanics, in particular, developing a more detailed understanding of the relationships between the biochemical and mechanical environments. Because of the brevity of this article, it cannot provide a complete literature review, but instead highlights a few of the many papers written on this topic, and the reader is referred to lengthier review articles where appropriate.

BLOOD VESSEL SIZE, STRUCTURE, AND FUNCTION

This section briefly summarizes the relationship between blood vessel size, location, and structure; the

work of Rhodin^[1] provides an excellent in-depth description. Two principles govern blood vessel dimensions: (1) the inner (lumen) diameter of vessels decreases as their flow decreases and (2) the ratio of wall thickness to lumen diameter in large and medium vessels is proportional to the transmural (internal minus external) pressure. The drop from arterial to venous pressure is primarily due to the resistance in the small arteries and arterioles and many tiny capillaries.^[2] Venules and veins, which return de-oxygenated blood to the heart, are under lower pressure than arteries and have a much smaller wall thickness to diameter ratio, as shown in Fig. 1.

All blood vessels are lined with a layer of endothelial cells, have a medial (middle) layer of smooth muscle cells in an extracellular matrix of collagen and elastin, and have an adventitial (outer layer) of fibroblasts in a primarily collagenous extracellular matrix. The endothelial cells serve an important function as mechano-sensors and regulators of wall shear stress because of blood flow.^[3] In large arteries, the media is structured into alternating layers of elastic fibers and smooth muscle cells called lamellar units.^[4] The smooth muscle cells are elongated and appear to be oriented predominantly in circumferential direction, although the orientation may change through the wall thickness in larger mammals. In smaller muscular arteries, the media is predominantly composed of well-organized layers of smooth muscle cells with few elastic fibers interspersed between them, and the lamellar units are no longer evident.

Capillaries are composed of a single layer of endothelial cells that is integrated into the surrounding tissue. The media of venules and veins are also composed primarily of smooth muscle cells; however, the orientation of the smooth muscle cells can be either circumferential or axial. Fig. 1 graphically shows the relative proportions of endothelial cells, elastic fibers, and collagen and smooth muscle cells under each type of blood vessel. The consequences of these structural differences on blood vessel mechanics have been illustrated by a variety of experimental methods, described in the following section.

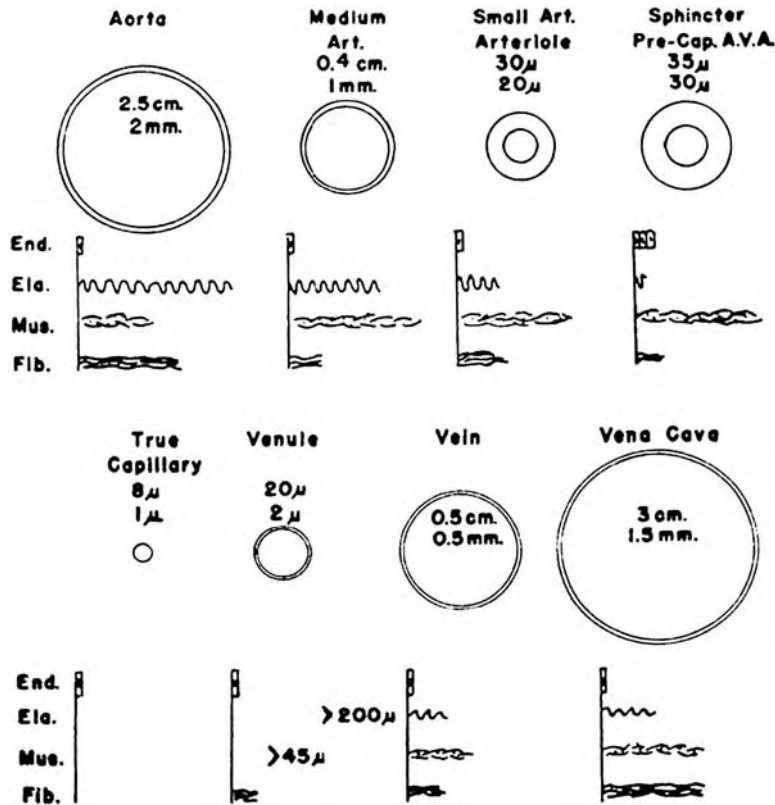

Fig. 1 The relative sizes of human blood vessels. The numbers above each vessel type show their lumen diameter and wall thickness. The bars below each vessel type show the relative proportion of endothelium (End.), elastic fibers (Ela.), smooth muscle cells (Mus.), and collagen (Fib.). The true capillary contains only endothelial cells and is not discussed in the text. Source: Reproduced with permission from The American Physiological Society (see Ref. [52]).

EXPERIMENTAL METHODS

In Vivo Studies

In vivo studies give insight into the mechanics of blood vessels undergoing physiologic loading and deformation and generally use non-invasive imaging modalities. McVeigh provides a useful review.^[5] Ultrasound is used for real-time measurement of vessel dimension changes during the cardiac cycle. Magnetic resonance imaging currently has more limited temporal resolution but is useful for reconstruction of dynamic vessel geometry. Computed tomography (CT) scans provide high-quality spatial resolution, but currently, they do not yet have the temporal resolution to measure deformation during the cardiac cycle.^[6] Pulse wave velocity (PWV) is used to infer vessel stiffness within a finite length of the vessel. The modified Moens-Korteweg equation^[7] relates the PWV to the elastic modulus in the circumferential direction (E_c):

$$PWV = \sqrt{\frac{E_c h}{2R_i \rho}} \quad (1)$$

where h is the vessel wall thickness, R_i is the vessel lumen radius, and ρ is the density of blood (1.05 g/cm³). This equation assumes that the vessel is thin walled (i.e., $h \ll R_i$), straight, and linearly elastic

within the range of physiologic pressures. Vessel lumen radius and wall thickness must be measured non-invasively or estimated from post-mortem measurements of excised tissue. The velocity is usually determined by calculating the time it takes for a flow or pressure wave to pass two locations. A finite distance separates these locations, so E_c calculated from this equation is an average modulus.

A second widely calculated index is vessel compliance (distensibility). Several equations are given in the literature, but all rely on the basic definition of compliance as a change in vessel volume during the cardiac cycle divided by the pulse pressure (the difference between the systolic and diastolic pressure). In most vessels, with the exception of the ascending aorta, vessel length does not change appreciably within a cardiac cycle, so compliance is defined with respect to either an area change or diameter change,^[8] e.g.:

$$C = \frac{d_{sys} - d_{dias}}{d_{dias}(P_{sys} - P_{dias})} \quad (2)$$

where d_{sys} , P_{sys} , d_{dias} , and P_{dias} are the measured luminal diameters and pressures at systole and diastole, respectively. Invasive pressure measurements (e.g., with a catheter) should be made in the same location as diameter measurements, but compliance in central arteries is often calculated from the more easily measured

brachial artery pressures. Compliance does not require the measurement of vessel wall thickness, but it should be emphasized that it includes both structural and material properties that cannot be decoupled. For instance, two rubber tubes of the same material and inner diameter, but different wall thicknesses, will have different values of compliance.

The circumferential wall tension, T_c , can also be estimated from *in vivo* measurements of transmural pressure, P , and the corresponding lumen radius R_i . If the wall thickness, h , is also known, the average circumferential wall stress, $\bar{\sigma}_c$, can also be estimated. For a thin-walled artery (i.e., $h \ll R_i$), the relationships are:

$$T_c = PR_i; \quad \bar{\sigma}_c = \frac{T_c}{h} = \frac{PR_i}{h} \quad (3)$$

These equations, both known as the Law of Laplace, are used to compare wall tension and average circumferential wall stress between different arteries or species. Unlike PWV or compliance, T_c and $\bar{\sigma}_c$ do not depend on vessel stiffness, but still require accurate measurements or estimates of P , R_i , and h at each pressure of interest.

In Vitro Studies

When a blood vessel is dissected free of its surrounding tissue, it usually retracts (shortens) in the axial direction. The ratio of the *in situ*, or *in vivo*, length to the retracted or *in vitro* length of a vessel segment is called the *in vivo* axial stretch ratio. Excised tissue used for *in vitro* tests may include tubular vessel segments, vessel rings, vessel strips, or rectangular segments.

During *in vitro* studies, the excised tissue is usually bathed in a physiologic salt solution (PSS). The exact composition of the PSS varies from laboratory to laboratory. Humphrey gives a concise summary.^[8] The composition of the PSS can be modified to activate the smooth muscle cells, or conversely, to render the vessel segment passive (i.e., no contractile force is generated by smooth muscle cells). To obtain active properties, the bathing solution is modified by increasing the calcium concentration and adding substances that activate smooth muscle, such as potassium chloride or norepinephrine. If active properties are being studied, it is important to keep the bathing solution near physiologic temperatures, as smooth muscle activation is temperature dependent. To obtain passive properties, the PSS is modified to omit calcium and add relaxing agents, such as papaverine or sodium nitroprusside. The difference between the response of the activated vessel segment and the passive response is considered the active contribution of the smooth muscle cells.

Uniaxial Tests

Rings and strips of isolated blood vessel tissue are used for uniaxial tests in which only one direction is subject to mechanical loads. Uniaxial tests are the simplest to set up, but provide limited information about possible differences in the mechanical response in the axial and circumferential directions and may overestimate or underestimate passive properties.^[9] Furthermore, because only one direction has an applied load, they do not measure any coupling between the responses in the axial and circumferential directions. Nonetheless, they have been useful in delineating the active response of vascular smooth muscle. The active response can be measured isometrically, that is, the specimen is incrementally stretched to specified lengths and the active force is measured after an equilibration period. Alternatively, specimens can be tested isotonicity, where the specimen is stretched to specified force levels and the length is adjusted to maintain that force. Rings and strips are also useful for studying viscoelastic properties^[10] where the simple setup facilitates studies over a wide range of frequencies.

Biaxial and Shear Tests

Mechanical tests on excised vessel segments using computer control provide a more complex loading environment.^[11] An excised blood vessel is placed in a bath of PSS, and the ends of the vessels are secured over hollow cannulae. The vessel is stretched in the axial direction to the *in vivo* axial stretch ratio. The vessel is then inflated over a range of pressures while measuring the increase in outer diameter and axial force. With appropriate measurements of vessel dimensions, this data can be used to calculate compliance or intrinsic mechanical properties of blood vessels. In addition, by changing the axial stretch ratio of the vessel before or during inflation, a wide range of loading conditions can be investigated. These vessel segment test systems are thus biaxial (control loading in both the circumferential and axial directions). In some systems, a twist can be applied to one cannula and the applied torque measured to obtain estimates of the response to axial shearing.^[12,13] While more expensive and complex than uniaxial test systems, these systems have been extremely useful in delineating the intrinsic mechanical properties of a number of blood vessels.^[14,15] Note that not all tests of excised tubular segments of blood vessels are biaxial. Often, the axial stretch ratio and axial force are not reported, and only a pressure–diameter curve is obtained.^[16,17]

Tests of planar biaxial specimens (rectangular or square) are less common than tests of vessel segments, primarily because of vessel geometry. In some vessels,

notably the ascending aorta and pulmonary artery, the vessel segments are quite short compared to the vessel diameter, and planar biaxial testing has been used to delineate mechanical properties^[18,19] of these vessels.

Testing of Vessel Components and Layers

Early experiments on vessel segments delineated the contributions of elastin and collagen to blood vessel elasticity by the addition of elastase or collagenase to selectively remove the elastin or collagen from the vessel wall. These studies^[20,21] established that elastase treatment resulted in an immediate and irreversible dilation of the vessel from its intact, unloaded state, but the vessel was still able to withstand large transmural pressures. Collagenase had little effect on the vessel's deformation at low transmural pressures, but resulted in vessel rupture at much lower transmural pressures than normal, suggesting collagen is important in maintaining the structural integrity of blood vessels.

Experimental methods have also been developed to test the medial and adventitial layers of blood vessels separately. Usually, the vessel is tested in its intact configuration, followed by removal of the adventitial layer by dissection. If the vessel is inverted, or if strips are used, it is also possible to remove the media and test the adventitial layer of some vessels.^[22,23]

Opening Angle Measurements

Intact, but unloaded, blood vessels are in a state of circumferential residual strain.^[24] Rings isolated from vessel segments often spring open when cut radially (Figs. 2A and B). This phenomenon is characterized by an opening angle α (Fig. 2B) and can be used to quantify the circumferential residual strain. It is possible, although technically difficult, to separate the layers of the blood vessel wall before measuring the opening angle in some vessels. The opening angle of each layer may be different, suggesting that even a single radial cut does not relieve residual strain throughout the vessel wall. The implications of circumferential residual strain are discussed in the framework of finite elasticity below.

Morphologic Measurements

After testing, many investigators preserve the test specimen for morphological measurements, either by freezing or formalin fixation. Preserved specimens can be sectioned and stained to identify histologic features, including the thickness of the intimal, medial, and adventitial layers. If preserved with formalin, blood

vessels may be fixed with a transmural pressure equal to the physiologic pressure or at zero pressure and at the *in vivo* length or the unloaded length. These conditions will affect the measured wall thickness and should be noted when using morphologic data. If vessels are fixed under physiologic pressure, incompressibility is used to determine the wall thickness in the unloaded configuration. When computerized measurements are made from stained tissue sections, the luminal area and wall cross-sectional area may be reported. Fixation and embedding can cause tissue shrinkage, which may underestimate tissue dimensions, particularly wall thickness, although the effect can be minimized by a careful choice of fixative and embedding agents.^[25]

In Situ Studies

In situ studies allow the investigator to manipulate mechanical loads over a wider range than *in vivo* studies, as well as alter the biochemical environment by changing the fluid both in and surrounding the blood vessel. In these tests,^[26,27] the vessel is isolated from the circulation. This allows the vessel to be inflated from zero pressure to supraphysiologic pressures under controlled loading conditions. The advantage of these tests is that external structures supporting the vessel remain intact, while the disadvantage is that the axial stretch ratio cannot be independently controlled.

THEORETICAL FRAMEWORK

In vivo, *in vitro*, and *in situ* measurements of blood vessel mechanics are interpreted within a theoretical framework. In many cases, that framework has been linear, isotropic elasticity, a branch of continuum mechanics. The continuum hypothesis assumes that the macroscopic response of a body can be described by locally averaged quantities. When applied to solid mechanics, the quantities of interest are the components of stress and strain.^[24] For a linearly elastic material, the relationship between stress and strain is linear and without time dependence. When the material has no preferred direction, it is isotropic, and the relationship between stress and strain components is described by a single elastic modulus. However, the definitions of stress and strain used in linear elasticity assume that the displacements of the body are small relative to its size, an assumption that is generally not true for blood vessels. An alternative formulation is incremental elasticity,^[28] in which non-linear behavior is linearized around an operating point, such as the mean arterial blood pressure and *in vivo* axial stretch ratio.^[29] The simplicity of incremental linear elasticity

Fig. 2 Opening angle and effect on transmural stress distribution (A) A closed ring of mouse descending thoracic aorta. A radial cut is made at the dotted line. (B) The open ring, showing measurement of the opening angle, α , as defined by Fung. (C) The effect of opening angle on the transmural distribution of circumferential stress in the rabbit carotid artery. Larger opening angles lead to more even distribution of circumferential stress at systolic pressure (120 mmHg). (D) Circumferential stress concentration, defined as the circumferential stress at the inner wall divided by the average circumferential stress as a function of opening angle. Panels (C) and (D) Source: Reproduced with permission from American Society of Mechanical Engineers (see Ref. [35]).

is appealing, but its application is limited to small changes in deformations and loads near the linearization point.

Non-linear continuum mechanics, in particular finite elasticity, provides a more general framework for interpreting mechanical test data for blood vessels, as described in texts by Fung^[24] and Humphrey.^[8] While this framework comes with the cost of added experimental and analytical complexity, the availability of computational methods for solving finite elasticity problems^[30,31] has made the framework more accessible.

Finite elasticity assumes that the blood vessel undergoes substantial deformations from a stress free to a loaded state, such that the dimensions of the blood vessel in the loaded state have changed substantially and thus introduce non-linear geometric relationships. The stresses in the elastic material are related by a non-linear function to the strains. This function is known as the constitutive relation.

Pseudo-Elasticity

Fung and co-workers observed that the response of blood vessels to mechanical load is viscoelastic, but has a weak dependence upon strain rate over several orders of magnitude, and introduced the concept of pseudo-elasticity to describe the viscoelastic behavior of blood vessels in a more tractable form.^[32] A pseudo-elastic

material is an elastic material in which the constants in the constitutive relation are different in loading and unloading. This concept has been widely employed in blood vessel mechanics within the framework of finite elasticity.

The constitutive relation contains parameters that are determined from experimental data. In the case of in vitro tests of vessel segments, the measured pressure, force, diameter, and applied axial stretch can be converted to stress and strain and the experimental data used to estimate parameters in constitutive relations. These parameters can then be used in computational models. Biaxial data has been used to fit parameters in several types of constitutive relationships, most commonly using a hyperelastic strain energy function, in which stresses are obtained from the derivatives of the strain energy with respect to strain or other measures of deformation. While pseudo-elasticity has been broadly adopted in the biomechanics community, some models also include viscoelastic effects.^[33] A recent review by Vito and Dixon^[34] describes many of the constitutive models proposed for blood vessels in the past decade.

Residual Strain and Layered Models

Including the circumferential residual strain in wall stress calculations provides a more uniform distribution

of wall stresses through the wall thickness (Fig. 2C). As the opening angle increases, the circumferential stress concentration (i.e., inner wall stress divided by mean wall stress) may disappear (Fig. 2D). Models that individually describe properties of each layer of the blood vessel wall also affect the distribution of wall stresses.^[8,35,36] These models require experimental measurements to determine the residual strains and constitutive relations for each layer, as well as morphologic measurements of their relative thickness.

Models of Blood Vessel Growth and Remodeling

In the past two decades, interest has focused on how blood vessels adapt to changes in mechanical loads during both development and adulthood. Two principles of adaptation (remodeling) have been identified: normalization of wall shear stress and normalization of circumferential and axial wall stress. Shear stress on the inner surface of the blood vessel wall, τ_w , can be expressed as^[3]:

$$\tau_w = \frac{32\mu Q}{\pi D_i^3} \quad (4)$$

where μ is the blood viscosity, Q is the volume flow rate, and D_i is the inner (lumen) diameter of the artery. Since flow in large arteries is pulsatile, the shear stress varies within each cardiac cycle. Typical (homeostatic) values of time-averaged τ_w are approximately 15 dyne/cm² and are similar between arteries within an animal and between different animal species.^[3] Average circumferential stress ($\bar{\sigma}_c$) is given by Eq. 3, while estimates of local values of circumferential and axial wall stress require a constitutive relationship, as described above. Homeostatic values of $\bar{\sigma}_c$ are approximately 200–300 kPa in elastic arteries.^[36]

Liu and Fung^[37] propose indicial response functions to describe remodeling, where the time course of tissue growth or degradation after a sudden (step) change in a quantity, such as pressure, is measured and then used to describe changes in that quantity after an arbitrary change in the input quantity. Taber and co-workers^[36] developed a theoretical framework to explain blood vessel growth as a response to altered local stresses. It was recognized that growth and remodeling involved cellular response to altered stress or strain, and that this could trigger local biochemical processes, such as protein synthesis or degradation. To explain the consequences of this mechano-transduction, Humphrey and co-workers^[38] developed constrained mixture models that describe remodeling of individual constituents (i.e., collagen, elastin, and smooth muscle cells), where the rates of

growth and degradation can vary between components. An important assumption is that the tissue stress is the sum of the component stresses multiplied by their mass fractions, but the zero-stress state of each constituent can be different, and this zero-stress configuration can change as the constituent grows or degrades.

ELASTIC ARTERIES

The large elastic arteries include the aorta, carotid, larger branches of the aorta, and pulmonary arteries. The distinction between elastic and muscular arteries is based on the histologic observation of well-organized medial lamellae,^[39] rather than on size, although the larger conduit arteries tend to be elastic and the smaller ones muscular. Of the large elastic arteries, the mechanics of aorta and carotid have been the most intensively studied. The ascending aorta, which carries oxygenated blood from the left ventricle, originates at the aortic valve. Its elasticity helps reduce the pulsatility of downstream flow. Approximately 25% of the aortic flow leaves through blood vessels, branching from the aortic arch, that provide blood flow to the head and upper limbs,^[40] and a further 50% of the blood flow leaves through side branches in the descending thoracic and abdominal aortas. The remaining 25% flows from the distal end of the aorta into the left and right femoral arteries. Thus, the diameter of the aorta decreases along its length, with concurrent changes in the number of lamellar units and organization of elastic fibers. From a mechanics point of view, the aorta is not a single structure, and thus each region has been studied separately.

Passive Properties

When a segment of an elastic artery is inflated while held at its *in vivo* length, the diameter change with pressure is non-linear and may appear as a reverse S-shape (Fig. 3). The slope of the pressure–diameter curve appears slightly steeper at low transmural pressures, becomes more compliant, and then becomes stiffer again at or above the physiologic blood pressure range. The non-linearity of the pressure–diameter relationship is often overlooked, and a single value compliance or stiffness is calculated for a vessel over the entire physiologic pressure range,^[41] or an incremental circumferential elastic modulus is calculated as shown in Eq. 3. When biaxial data are fit to anisotropic constitutive relationships, the parameter fits indicate that arteries are nonlinear and anisotropic, although the direction of anisotropy is not consistent for all arteries. Although the pulmonary arteries are

Fig. 3 Internal pressure and axial force for rat carotid artery as a function of the deformed outer radius for different axial stretch ratios ($\lambda_z = 1.14, 1.25, 1.37$). The artery was obtained from an 18-week old Wistar rat eight weeks after inducing hypertension with a renal clip. Source: Reproduced with permission from The American Physiological Society (see Ref. [14]).

considered elastic arteries, the pressure range in the pulmonary arterial circulation (10–20 mmHg) is much lower than in the systemic circulation (80–120 mmHg) in mammals. Hence, pulmonary arteries have a lower wall thickness to diameter ratio and are more compliant than the aorta, although their radii are similar.^[2] Biaxial tests of passive canine pulmonary arteries show their mechanical response is nearly linear under physiologic loads.^[18]

Active Properties

Elastic arteries held at a constant pressure contract in response to smooth muscle activation (Fig. 4). The amount of contraction is a function of the concentration of the activating agent, as well as the composition and arrangement of the smooth muscle cells in the artery studied. The active response of the carotid artery has been widely studied.^[17,42] When an activated segment contracts at a constant length, the active smooth muscle contribution increases with circumferential strain. When an activated artery is slowly inflated and deflated, a similar shift in the pressure–diameter curve is seen. The maximum active response appears to occur near the physiologic range of blood pressures. If the contractile response (CR) is defined as $CR = (D_a - D_p) / D_p$, where D_a and D_p are the measured outer diameters of the carotid under activated and passive conditions at a given transmural pressure, the maximum CR for the carotid artery in Fig. 4 is approximately 20% at 100 mmHg.

MUSCULAR ARTERIES AND ARTERIOLES

Segments of muscular arteries (e.g., brachial, renal, mesenteric, iliac, or coronary arteries) also exhibit a non-linear pressure diameter relation when inflated at their in vivo length under passive conditions (Fig. 4). Most muscular arteries contract circumferentially to a larger degree than elastic arteries when the smooth muscle cells are stimulated with potassium chloride^[17] or in response to other vasoactive substances, although the coronary artery may be an exception. While fewer studies have been conducted on the multiaxial properties of passive muscular arteries, there has been a recent interest in the passive properties of the individual layers of coronary arteries. In strips from aged human coronary arteries, the media appears less stiff than the adventitia, and the thickened intima contributed to the mechanical response.^[23] In contrast, inflation of tubular segments of porcine coronary arteries at their in vivo length indicated that the medial layer was stiffer than the adventitial layer, and the thin intima could not be separated from the media.^[22] These studies illustrate the diversity of mechanical responses in similar arteries, likely due to age and species differences.

Arterioles are small arteries having nerves and at least one layer of smooth muscle cells and ranging in diameter from 10 to 125 μm .^[7] As regulators of regional blood flow, their active properties are of primary interest to physiologists. Under basal (non-stimulated) conditions, isolated segments of arterioles exhibit non-linear pressure–diameter relations similar to larger arteries.^[24] When stimulated with potassium

Fig. 4 Pressure vs normalized diameter curves from elastic (carotid and internal thoracic) and muscular (iliac, renal, mesenteric, and coronary) arteries. Open symbols: vessels tested under passive conditions; Closed symbols: vessels tested after stimulation with 120 mM KCl. Source: Reproduced with permission from The American Physiological Society (see Ref. [17]).

chloride and norepinephrine, arterioles contract substantially.^[43]

VEINS

Venous pressure is much lower than arterial pressure, and the ratio of vessel diameter to wall thickness is larger in veins, as illustrated in Fig. 1. A consequence of this structural difference is that veins may collapse when the external pressure is lower than the internal pressure in a vein. The major component of the venous wall is the smooth muscle cells, which may be oriented either circumferentially or axially, depending upon the vein. Venous volume can be changed substantially by smooth muscle activation or relaxation.^[24] A second structural difference is the presence of one-way valves in many veins, which serve to prevent blood from pooling in the lower limbs when standing. Mechanical properties of veins have been studied far less frequently than arteries, and little biaxial test data is available. Canine jugular veins and human saphenous veins exhibit both non-linear diameter–pressure and force–pressure relations, but this non-linearity is evident at much lower pressures in the canine jugular vein.^[44]

BLOOD VESSEL DEVELOPMENT, ADAPTATION, AND AGING

In mammals, the arrangement of the major blood vessels occurs during fetal development. However, the fetal circulation differs greatly from the post-natal period.^[2] At birth, when the pulmonary system begins to function and umbilical circulation ceases, blood pressure rises rapidly in the systemic circulation (i.e., aorta) and drops in the pulmonary circulation. This is reflected in a rapid accumulation of extra cellular matrix proteins in the aorta after birth and a decrease in those proteins in the pulmonary artery. Mean arterial blood pressure continues to rise slowly until adulthood. As body mass increases, blood vessel size and wall thickness increase to accommodate increased flow and pressure. The production of elastin by vascular smooth muscle cells appears to end at maturity, except under wound healing conditions.^[8]

The lumen diameters of arteries during development and maturity have been shown to normalize shear stress. As blood flow leaves the aorta through side branches. For example, the diameter of the aorta decreases, keeping τ_w at the homeostatic value.

As Eq. 4 implies, an increase in blood flow through the vessel lumen, without an increase in lumen diameter,

also increases τ_w . Elastic arteries respond to a sudden increase in blood flow with endothelial cells producing nitric oxide to induce vasorelaxation and increasing lumen diameter. This is followed by a further slow increase in lumen diameter if the higher flow rate is maintained.^[45] The vasorelaxation and increase in lumen diameter return τ_w to or near the homeostatic value.

Conversely, an increase in systemic blood pressure induces wall thickening without an increase in lumen diameter,^[14,42] but with an increase in basal smooth muscle tone.^[42] In this case, the remodeling appears to return both τ_w and $\bar{\sigma}_c$ to homeostatic values. A sudden increase in pressure initially increases D_i , increasing $\bar{\sigma}_c$ and reducing τ_w . This causes the endothelial cells to increase smooth muscle activation, reducing D_i and returning τ_w to the homeostatic value. If the increased pressure is maintained, the wall thickness gradually increases, thus reducing $\bar{\sigma}_c$ to near homeostatic values.^[14]

Many studies of blood vessel mechanics and adaptation have focused on animals that are just reaching maturity; however, the mechanics of aging human blood vessels are substantially different. The changes include an increase in structural stiffness, as measured by higher PWV,^[41] thickening of the intimal layer,^[23] and increase in opening angle.^[46] The stiffening is thought to be caused by increased synthesis of collagen and increased crosslinking of collagen molecules.^[47] These studies suggest that studies of human blood vessels, as well as those using animal models, will be needed to characterize adaptation during aging.

VASCULAR DISEASE AND ALTERED BLOOD VESSEL MECHANICS

Vascular diseases such as hypertension also lead to altered blood vessel mechanics. Nichols et al. provide a useful overview.^[40] Atherosclerosis, or hardening of the arteries, is a common occurrence during aging. Atherosclerotic plaques are focal regions where accumulations of lipids and fibrous caps cause local changes in arterial mechanics. Plaques are most common in regions of low or oscillating wall shear stress, such as vessel bifurcations.^[3] Recent work has focused on the mechanics of atherosclerotic plaque rupture, where the fibrous cap detaches from the plaque. These studies require computational models that allow the local heterogeneity of the tissue to be modeled.^[48]

Vascular aneurysms are local enlargements of a blood vessel lumen, accompanied by changes in vessel wall morphology and microstructure, which may lead to potentially fatal rupture. Aneurysms most commonly occur in the ascending aorta, abdominal aorta, cerebral arteries, and lower limb veins. Ascending aortic aneurysms are associated with congenital

connective tissue disorders, such as Marfan Syndrome, and usually consist of enlargement (dilation) of the vessel around its entire circumference.^[40] Abdominal aortic aneurysms, which occur predominantly in older patients with other cardiovascular risk factors, are characterized by the disappearance of elastic fibers from the aortic wall and increased stiffness with an asymmetric bulge on the anterior side. In both of these conditions, a large aortic diameter is associated with an increase in the risk of aneurysm rupture.^[40] In vitro biaxial tests suggest that tissue in both ascending and abdominal aortic aneurysms is stiffer than non-aneurysmal tissue and is somewhat anisotropic.^[19,49] Intracranial aneurysms are characterized by a loss of elastic fibers and local thinning and are typically saccular, i.e., almost spherical with a small connecting neck to the main vessel. They have been modeled as thin-walled membranes subject to pulsatile loading, but a very limited amount of mechanical test data is available, perhaps due to difficulty locating and isolating the small segments.^[8]

Diabetes is generally associated with stiffening of the blood vessel walls through the formation of sugar-mediated collagen crosslinks.^[50] Most measurements are of regional properties, such as PWV, with little in vitro mechanical testing of human tissue to date; however, animal models, such as streptozocin-induced diabetes, also show an increase in aortic stiffness.^[51]

CONCLUSIONS

The vascular system is a complex network of blood vessels that serve multiple functions in the distribution of blood to organs and tissues. As summarized in this article, blood vessel mechanics have been studied at the system, regional, and tissue levels. Understanding the complex relationships between blood vessel mechanics and biological and biochemical processes is the future challenge for this field. Modeling the alterations in blood vessel mechanics in transgenic animal models for human disease is just one example. Engineering of vascular tissue grafts is another. Integrative models that explain mechanical responses at the vascular tissue and cellular levels are needed to allow biomechanics researchers, physiologists, and biologists to link the ever-growing bodies of knowledge in each of these areas.

Bone Cement

Julie Hasenwinkel

Department of Bioengineering and Neuroscience, Syracuse University, Syracuse, New York, U.S.A.

B

INTRODUCTION

Acrylic bone cement has been used extensively for the fixation of total joint replacements since its introduction by Sir John Charnley over forty years ago. To date, all commercial bone cements have been based on poly(methyl methacrylate) (PMMA), a polymer that was developed just prior to and during World War II. PMMA was first introduced for medical applications in 1937 when it was used as a denture-base material, and the self-curing resin was subsequently used for cranioplasties and for filling other skeletal defects. In recent years, the application of bone cement in orthopedic surgery has been expanded to vertebroplasty, a procedure in which cement is injected percutaneously into the vertebral body in order to stabilize fractures that occur primarily as a result of osteoporosis. Another variation of this procedure is kyphoplasty, during which a balloon is inserted percutaneously into the vertebral body, inflated to restore the height of the compressed vertebrae, and subsequently filled with injected bone cement to stabilize the fracture. These newer applications of bone cement have been successful in relieving pain and restoring vertebral strength and function to patients.

Although the variety of applications for PMMA in medicine and dentistry illustrate the importance and utility of this polymer as a biomaterial, the focus of this chapter is the application of bone cement for total joint fixation. Approximately 50% of all total joint replacements utilize bone cement to achieve implant fixation, and currently the survival probabilities of cemented total joint arthroplasties average at least 90% after 15 years, especially for hip and knee implants in patients over age 50. In this application, the primary functions of bone cement are to stabilize the prosthesis and transfer mechanical loads between the implant and the bone. PMMA does not chemically bond with either interface, but rather serves as a grouting or space-filling material. Commercial bone cements are supplied as two component systems, consisting of a powder and a liquid, which are mixed in the operating room during the surgical procedure and delivered to the implant site prior to introduction of the prosthesis. As the polymerization reaction proceeds in situ, the powder/liquid admixture experiences a transition from the liquid state

to the solid state, forming a rigid amorphous polymer. This polymerization reaction along with the important physical properties of bone cement, including rheological and setting characteristics, mechanical properties, porosity, and residual monomer, are critical to its success in orthopedic surgery. These properties, which have been extensively investigated, along with the chemistry, mixing, and delivery of bone cement will be discussed.

CHEMISTRY AND POLYMERIZATION REACTION

Chemical Components

Commercial bone cements are supplied prepackaged with the powdered portion contained in a polymeric pouch and the liquid portion contained in a glass ampule. The powder and liquid components contain a variety of chemical ingredients that play an important role in the polymerization process. The powdered portion of the cement contains approximately 90% (by weight) prepolymerized beads of PMMA or PMMA-based copolymers.^[1] The remainder of the powder is typically composed of benzoyl peroxide (BPO), an initiator for the polymerization reaction, and barium sulfate (BaSO_4) or zirconium dioxide (ZrO_2), both of which are radiopacifiers. The liquid portion of acrylic bone cement contains three basic components: methyl methacrylate (MMA) monomer, *N,N*-dimethyl-*p*-toluidine (DMPT), and hydroquinone (HQ).^[1] DMPT is a tertiary aromatic amine that acts as an activator in the polymerization reaction. Hydroquinone is added to the liquid to limit spontaneous polymerization of the monomer due to exposure to heat or light during storage.^[1] It acts as a free radical scavenger and is termed an inhibitor. The structures of these chemical components are shown in Fig. 1.

There is a wide variety of commercial bone cement formulations used worldwide. These different products vary in their exact chemical composition, specifically the relative proportions of initiator, activator, and monomer, along with the types of copolymers used in the powder portion of the cement. Variations in chemical composition affect many of the important mixing, handling, and rheological characteristics of the material during its application in the operating theater

Fig. 1 Chemical structures of the powder and liquid components of acrylic bone cements.

along with the physical properties of the polymerized cement. The specific chemical compositions of seven different commercial cements are shown in Table 1. All of these commercial cements are mixed in a 2:1 (wt/vol) powder-to-liquid ratio, as recommended by their manufacturers.

Polymerization Reaction

The polymerization process by which PMMA and other vinyl polymers are formed is known as free radical or addition polymerization. In bone cement, this polymerization reaction has three major kinetic processes: initiation, propagation or growth, and termination. The process of initiation in free radical polymerization encompasses the reaction or set of reactions that generate the primary radicals that give rise to the active center for polymer chain growth. Radicals can be formed by several different methods including the collision of two monomer molecules of sufficient energy or the decomposition of an initiator molecule by means of energy generated from heat, light, or chemical reaction. In the case of cold-cured PMMA, primary radicals are generated by the chemical reaction of BPO and DMPT. The scheme shown in Fig. 2 outlines a possible mechanism for the reaction of BPO and DMPT, proposed by Horner and Schwenk.^[2] As this figure illustrates, radical formation is not the primary result in amine-peroxide reactions. The toluidine and benzoyloxy free radicals arise from the breakdown of the unstable intermediate products of the initial polar reaction.^[3] Horner and Schwenk^[2] have concluded that the benzoyloxy radical is primarily responsible for initiating polymerization of methyl methacrylate.

Propagation is the process by which PMMA polymer chains grow by the addition of MMA monomer units to

the active center of a free radical. Polymer chain growth is influenced by thermodynamic, chemical, and kinetic conditions. In order for the process to be thermodynamically favorable, it must result in an overall decrease in the free energy of the reacting system. Monomer molecules must have sufficient chemical reactivity to participate in the propagation reaction. And from a kinetic standpoint, the rate of propagation must be on the order of one thousand times higher than the rate of termination in order to grow high polymer chains with sufficient molecular weight. The propagation phase of polymerization is a period of rapid chain growth in which a portion of the available monomer molecules in the system is consumed. A significant consequence of the propagation phase is an increase in the viscosity of the system. This change is due to increases in both the polymer concentration in the system and the molecular weight of the growing PMMA chains.

Termination is the final step in the polymerization process, whereby propagation ceases with the annihilation of radicals in the system. Termination and the formation of “dead” polymer chains occurs via two main mechanisms: combination or disproportionation. Combination is the term used to describe the simple connection of two macroradical chains through mutual reaction. In this case, two radical chains of length m and n combine to form a single polymer chain of length $m+n$. Disproportionation involves the transfer of a hydrogen atom from one radical chain to another and results in two polymer chains.

Physical Aspects of Mixing

When the powder and liquid components of bone cement are mixed together, there are several physical events that occur during the polymerization process. These events include: 1) solvation of polymeric materials in the powder, as well as the BPO into the liquid;

2) diffusion (swelling) of liquid into the organic matrix of the powder; 3) polymer–polymer diffusion from the liquid to the solid phase; and 4) monomer evaporation from the mixture.^[1] In this physical transition, the mixture goes through different states that are often referred to as sandy, stringy, doughy, and finally rigid or set.^[10] During this process, the BPO from the powder and the DMPT from the liquid participate in a redox reaction which produces free radicals that initiate polymerization of the MMA monomer. Physically speaking, the polymerization process of bone cement can be divided into four different phases: 1) the mixing phase; 2) the waiting phase; 3) the working phase; and 4) the hardening or setting phase.^[4]

The mixing phase is simply the initial combination of powder and liquid, typically in a commercial mixing system. The second phase, or waiting phase, occurs during the mixing process while the cement slurry is gradually transformed into a more homogeneous mixture. The waiting phase is characterized by a cement viscosity that is too low for the material to be handled and manipulated by the surgeon. Once the viscosity has increased to an appropriate level, due to the solvation and swelling of the polymer beads, the working phase commences and the cement is transferred from the mixing system into a delivery system or cement gun for insertion into the implant site. During this phase, the cement has a doughy consistency that allows it to flow through the cement gun into the interstices of the bone and around the metallic implant upon its insertion. It is critical that the surgeon delivers the cement, inserts the implant, and manipulates the prosthesis into its final position during the working phase. The final phase is the setting or hardening phase, which is characterized by a sharp increase in cement viscosity associated with the rapid polymerization of the methyl methacrylate monomer in the mixture. This entire process occurs over the course of six to twelve minutes, depending on the particular cement composition, the cement mass, and

Fig. 3 Time course of the mixing, waiting, working, and setting phases for three different commercial bone cements at 23°C. (Figure courtesy of Ref. [4].)

the ambient temperature. Figure 3 shows the time course of these four phases for Palacos R, Osteobond, and Simplex P.

The final cement mass is actually an inhomogeneous multiphase material with a matrix of PMMA, derived from the polymerization of the methyl methacrylate monomer, surrounding the prepolymerized polymer beads and radiopacifier particulate phase.^[5,6] This is illustrated in Fig. 4. In this sense, bone cement is actually a polymeric composite material. It is interesting to note that the molecular weight of the polymerized cement is commonly higher than the molecular weight of the prepolymerized polymer beads. For Simplex P, the average molecular weight of the powder is between 179,000 and 194,000 g/mol, whereas the molecular weight of the set cement is 242,000 g/mol.^[1,7] From these data, it is hypothesized that the PMMA matrix derived from the liquid monomer yields a higher molecular weight during the polymerization process than the preexisting polymer beads embedded in the matrix.^[7-9]

PHYSICAL PROPERTIES OF BONE CEMENT

Exotherm

During the polymerization reaction, the carbon double bond in the methyl methacrylate monomer is cleaved

and replaced by a single bond. This process results in the release of 130 cal/g of heat for each bond that is broken.^[1] Therefore, the reaction is highly exothermic which leads to a large rise in the temperature of the material during the setting process. The degree of this temperature rise is dependent on the mass and thickness of the cement, the ambient temperature, and the efficiency of heat dissipation to the surroundings. In a comparison of nine different bone cements, Hansen et al.^[10] found a temperature range of 66–82.5°C at the center of 6 mm samples. Meyer et al.^[11] demonstrated a peak exotherm of 60°C for Simplex P when measured in a 3 mm thick specimen and an exotherm of 107°C for a 10 mm thick specimen. Wang et al.^[12] reported temperatures between 67 and 124°C at the center of the cement mantle in vivo, depending on the cement composition.

Although the exothermic character of the polymerization reaction and its potential adverse effects, including thermal necrosis and implant loosening, have been a longstanding concern in the literature,^[13-15] in vitro studies have shown that the temperatures at the bone-cement interface average 40–43°C.^[16,17] This decrease in temperature at the bone-cement interface in the in vivo scenario is due to the relatively thin cement mantle, the wet environment, and the dissipation of heat by the metallic implant.^[18] Eriksson found that an exotherm in excess of 47°C is sufficient to cause thermal necrosis of bone; protein denaturation occurs at 56°C.^[19] Therefore, it is important to limit the temperature increase at the bone-cement interface.

Viscosity and Rheology

The viscosity and rheological properties of bone cement play an important role in the handling characteristics of the material. These properties are often the most apparent difference between the various commercial bone cements from the surgeon's perspective. The viscosity of the powder/liquid admixture increases over time as the polymerization process proceeds. The initial increase in viscosity is due to swelling and solvation of the polymer beads as the monomer ingresses during the wetting process. A more significant increase in viscosity with

Fig. 4 Scanning electron micrographs of Palacos-R bone cement. The sample on the left was etched with methyl isobutyrate to better reveal the PMMA bead microstructure within the polymerized matrix. The image on the right shows the two halves of a fracture surface after three-point bend testing. The bright white spots distributed throughout the matrix are zirconium dioxide radiopacifier.

Table 2 Mean false apparent dynamic viscosity (Pa · s) of selected bone cements^a

Shear rate (s ⁻¹)	Formulation		
	Simplex P	Zimmer regular	Zimmer LVC
1.00	800	500	100
10.00	500	200	30
97.00	220	80	6

^aMeasurements were made three minutes after commencement of mixing.

(From Ref. [20].)

time corresponds to the increase in weight fraction of polymer in the material as the monomer is polymerized. At a constant shear rate of 97sec^{-1} , the apparent viscosity of Simplex-P bone cement increases threefold, from $200\text{Pa}\cdot\text{s}$ to $600\text{Pa}\cdot\text{s}$, between 3 and 7 min after mixing.^[20]

In addition to the dynamic viscosity changes over the course of the polymerization reaction, the viscosity of PMMA-based cements is also dependent on the shear rate, as shown Table 2. Most polymer solutions and melts are pseudoplastic or shear-thinning, meaning their viscosity decreases with increasing shear rates. This phenomenon is attributed to an alignment of polymer chains along the direction of the applied force, decreasing the resistance to flow. Therefore, the viscosity of bone cement is dependent on the shear force applied in mixing the powder and liquid components. The rheological properties of bone cement, which vary across commercial brands, influence both the ability of the surgeon to handle the material and the ability of the cement to penetrate into the porous bone interface and obtain an adequate mechanical interlock.

Residual Monomer

During the polymerization of bone cement, the conversion of methyl methacrylate is always less than 100%. This is largely due to the rather uncontrolled in situ free radical polymerization process, which lacks the application of additional heat or significant pressures typically used in commercial polymerization processes. One result of this incomplete conversion is the presence of residual monomer (MMA) within the bulk of the cement mantle in vivo. Residual monomer has been implicated in chemical necrosis of the bone,^[21] and it can also affect the material properties of the cement. During the early clinical use of acrylic bone cements for total joint fixation, there was a great deal of concern about the potential toxic effects of unreacted methyl methacrylate on patients.^[13–15,22,23] Hypotension, local tissue irritation, and alveolar lesions have all been

attributed to the release of monomer from polymerizing bone cement.^[24] Although these are valid issues of concern, the clinical success of acrylic bone cements has overshadowed the issue of monomer toxicity. According to Wixson and Lautenschlager,^[18] the larger issues with regard to monomer are the extent of polymerization and its effect on the material properties.

There are several factors that effect the monomer phase of bone cement both during and after the polymerization process. First, methyl methacrylate is highly volatile, leading to significant evaporation upon exposure to air. Monomer loss through evaporation can approach 5%,^[24] and this is dependent on the rate of mixing and the amount of material exposed to air.^[25,26] Residual monomer due to incomplete polymerization has been measured at 3.3% in samples of Simplex P stored in air 30 to 60 minutes after mixing.^[8] This amount declined over time when samples were stored in both air (2.4% after 215 days) and water at 37°C (1.4% after 4.5 months).^[8] The change in residual monomer content over time is due to a combination of continued polymerization and leaching of the monomer into water. Unreacted MMA can influence the mechanical properties of the cement by affecting the degree of polymerization and molecular weight of the polymer, and by acting as a plasticizer within the set polymer. As residual monomer content increases, the strength of the polymer is expected to drop due to a decrease in the length of polymer chains in the bulk material.

Porosity and Volumetric Shrinkage

Porosity and volumetric shrinkage, due to the conversion of monomer into polymer, are two factors that adversely affect the performance of commercial cements. According to Wixson et al.,^[27] there are at least five potential sources of porosity in the bone cement system: 1) air which initially surrounds the powdered constituents; 2) air trapped during the wetting of the powder by the liquid monomer; 3) air stirred into the admixture during spatulation; 4) air trapped during the transfer of the cement mixture to the delivery system; and 5) monomer volatilization during the curing process. There are two different types of pores in polymerized bone cement: macropores ($d > 1\text{mm}$) and micropores ($d \approx 0.1\text{--}1\text{mm}$).^[28] In general, pores act as stress risers and initiating sites for crack formation. Topoleski et al.^[9] found that pores in bone cement act as nucleation sites for microcracks. The stress concentration of the pores is particularly important in fatigue loading, because the relatively low stress intensity allows for the development of a microcracking damage zone over time.^[9] This analysis predicts that a reduction in porosity may enhance the fatigue life of the material.^[9] Although Topoleski et al. also suggested that

Table 3 Mechanical properties of human bone, PMMA, and prosthesis material

	Ultimate stress (MPa)			Modulus (GPa)
	Tensile	Compressive	Shear	
Commercial PMMA	68.9	103		2.1
Simplex P (hand mixed)	25	77	41	2.0
Wet cortical bone	123	166	84	17.2
Wet lumbar vertebrae	3.9	6.3	2.2	0.34
316L stainless steel	480			200

(From Ref. [30] and Ref. [31].)

porosity-enhanced microcrack nucleation may form a larger damage zone and effectively blunt cracks,^[9] the general consensus is that all efforts should be made to reduce both micro- and macropores in bone cement.

Many monomers undergo shrinkage during polymerization due to the difference in density between the monomer and its polymer. The density of methyl methacrylate is 0.937 g/cm³ whereas the density of PMMA is 1.18 g/cm³. There is approximately a 21% decrease in volume with the polymerization of pure monomer to polymer. In the case of commercial bone cements with a 2:1 powder-to-liquid ratio, one-third of the original volume is composed of monomer; therefore, the theoretical shrinkage is reduced to about 7%. This is a maximum shrinkage value, and smaller values are usually observed experimentally due to monomer evaporation, incomplete polymerization, and residual porosity.^[8] Gilbert et al. found volumetric shrinkage values of 6.67±0.40 and 6.50±0.24% for vacuum-mixed Simplex-P and vacuum-mixed Endurance bone cements, respectively.^[29] Shrinkage of the setting cement can have several different detrimental effects on the material. Volumetric contraction can induce residual stresses in the bulk of the cement mantle. The shrinkage process is also capable of inducing porosity along the stem of the implant and retracting the cement from the porous bony interface.^[29] In a constrained material, volumetric contraction can result in the growth of pores that are already present due to entrapped air. High residual stresses and large pores will increase the likelihood of cement fracture and failure.

Mechanical Properties

The mechanical properties of bone cement are very relevant to the clinical performance of the material. The cement mantle must be able to transfer loads from the implant to the surrounding bone, and in serving this function, it experiences a combination of tensile, compressive, and shear forces. The three components of a joint prosthesis construct, bone, cement, and metal, have very different mechanical properties, as shown in

Table 3.^[30,31] The cement is viewed as the weak link in the construct,^[32] due to its low tensile strength and modulus of elasticity with respect to cortical bone and metallic implant materials.

Table 4 shows the range of values, obtained from the literature, for eleven different mechanical properties of commercial cements. The mechanical properties of bone cement are dependent on a number of different variables, including cement formulation, mixing method, curing and aging conditions, and test conditions.^[21] Lewis^[21] has discerned several different trends in an extensive review of cement mechanical properties. First, for a given formulation, the mixing method has a significant influence on the tensile properties of the material. For example, vacuum mixing yields a mean increase of 44% in ultimate tensile strength versus hand mixing (attributed to reduced porosity).^[27] Lewis found that the cement formulation and mixing method have a strong effect on the ultimate compressive strength and compressive modulus. He proposes that the chemical composition, powder size and distribution, polymer morphology, rheological properties, and porosity are

Table 4 Summary of relevant mechanical properties for acrylic bone cements

Property	Value
Ultimate tensile stress (MPa)	23.6–49.2
Compressive strength (MPa)	72.6–117
Three-point flexural strength (MPa)	49.9–84.5
Four-point flexural strength (MPa)	52.7–90.0
Tensile modulus (GPa)	1.58–3.08
Compressive modulus (GPa)	1.94–3.10
Three-point flexural modulus (GPa)	1.29–2.91
Four-point flexural modulus (GPa)	1.95–3.12
Tensile strain to failure (%)	0.86–2.05
Fracture toughness (K _{Ic} , Mpa*m ^{1/2})	1.03–2.02
Fatigue endurance limit (MPa)	6.9–17.0

(From Ref. [21].)

the primary factors that influence the compressive strength of bone cement.

Although static mechanical tests give useful information for comparisons among different types of cements, fatigue tests are a more accurate predictor of the clinical performance of bone cement. Stresses *in vivo* are believed to be much less than the quasistatic strength of the cement; however, hip and knee implants are subjected to cyclical loading in their service environment which can lead to fracture and failure of the cement through fatigue mechanisms. Fatigue failure and fatigue crack propagation have been implicated as the “primary cement failure mechanisms that contribute to aseptic loosening of the prosthesis.”^[21] In a retrieval analysis of cemented femoral components from postmortem asymptomatic patients, Jasty et al.^[33] found evidence of debonding at the cement-prosthesis interface and fatigue crack initiation at this interface and at voids in the cement. The clinical success of cemented implants is highly dependent on maintaining a bone-cement-prosthesis construct free of aseptic loosening. The loosening phenomenon involves interfacial failure between the cement and the bone and/or the implant, bond failure, bone remodeling, and cement failure.^[21] The large modulus mismatch between the cement and surrounding bone and the propensity for debonding at the cement-implant interface contribute to these mechanisms. Cracks that typically develop due to flaws in the bulk of the cement or stress overloads at the cement-implant interface^[34] contribute to cement fracture and failure. Also, cement particles produced by fracture or loosening can evoke an osteolytic response, increasing loosening and hastening failure of the implant.

MIXING AND DELIVERY TECHNIQUES

Vacuum Mixing

Many improvements have been made to bone cement since its introduction by Charnley. The most dramatic area of improvement has likely come in the form of better mixing and delivery methods, such as vacuum mixing,^[27] which have significantly reduced the amount of porosity and improved the mechanical properties of commercial cements. Prior to the advent of vacuum mixing technology, manual or hand mixing was the primary mixing method for combining the powder and liquid components of bone cement. In this process, generally the powder component is added to the liquid in a polymeric bowl and the mixture is stirred with a spatula at a frequency of 1 to 2 Hz for 45 to 120 seconds. This type of spatulation process can introduce a significant amount of air into the mixture during the blending phase and result in a relatively high degree of trapped porosity in the set cement, as high as 10% or

greater. Demarest et al.^[35] first introduced the concept of mixing the powder and liquid components of bone cement under partial vacuum as a means of reducing this porosity. Wixson et al.^[27] subsequently demonstrated that an effective vacuum mixing unit can reduce the porosity in bone cement to 0.1%.

The reduction in porosity of acrylic bone cements associated with vacuum mixing has translated into improved mechanical properties, thus elevating vacuum mixing to the primary mixing method for clinical use. Vacuum mixing results in significantly higher compressive, diametral tensile, and uniaxial tensile strengths as compared to hand mixing.^[27] Perhaps more clinically relevant is the significant improvement in fatigue resistance that accompanies vacuum mixing.^[27] There are currently a wide variety of commercially available vacuum mixing systems, including the Advanced Cement Mixing System (Stryker Instruments, Kalamazoo, MI), the MixOR System and Vortex™ Vacuum Mixer (Smith & Nephew, Memphis, TN), the Optivac® (Biomet Merck, Sjobo, Sweden), and the HiVac™ Bowl and Syringe systems (Summit Medical, Gloucestershire, UK). Although each system has its own unique features, the general operation of each includes mixing the powder and liquid components of the bone cement under a partial vacuum until the desired viscosity is achieved, followed by delivery of the cement through a nozzle-fitted syringe.

Other Mixing Methods

Other bone cement mixing methods that have received considerable attention include the use of centrifugation to decrease porosity and prechilling of the liquid component of the cement prior to mixing in order to improve the workability and decrease the porosity of the cement. Centrifugation typically involves hand mixing the cement and then placing it in a centrifuge for 30 to 180 seconds at maximum speeds ranging from 2300 to 4000 rpm.^[21] This process is designed to induce the flow of bubbles from the bulk of the mixture out to the surface of the mixture, thus significantly reducing trapped porosity prior to the complete polymerization of the cement. Burke et al.^[36] demonstrated that centrifugation not only significantly reduces the porosity of bone cement, but also increases the fatigue life by 136%, compared to hand mixing. The effectiveness of centrifugation in reducing porosity and improving mechanical properties is dependent on the relative viscosity of the cement formulation. The cement viscosity has to be low enough to allow bubbles to flow through it and to the surface. Davies et al.^[37] demonstrated that centrifugation was most effective with Simplex P bone cement, reducing the porosity from 9.4 to 2.9% and increasing the mean fatigue life from 15,000 to 70,000 cycles.

Prechilling of the liquid component of bone cement has also been investigated as a means of improving mixing and reducing porosity. In 1990, Hansen and Jensen^[10] studied nine different bone cements, focusing on their handling characteristics, doughing time, setting time, and exothermic temperature. They compared the effects of manual and vacuum mixing, along with the effects of mixing the components at room temperature versus 5°C. At room temperature, they were unable to adequately vacuum mix high-viscosity cement formulations due to the reduction in setting and working time associated with vacuum mixing. Prechilling the cement components sufficiently prolonged the setting time and preserved a lower viscosity during the handling period, which enabled successful vacuum mixing and the expected reduction in porosity.

FUTURE DIRECTIONS IN BONE CEMENT RESEARCH

Much of the recent and current bone cement research is focused on improving cement properties and interactions with the biological environment through changes in cement chemistry and formulations. One example of this is the development of bioactive bone cements, which are designed to improve interfacial bonding with bone for enhanced mechanical fixation and biological performance. There are two different types of bioactive cements, ones in which bioactive agents are added to existing PMMA-based bone cements, and others that rely on the design of alternative matrices for these bioactive agents.^[38] Other chemical compositions are also being investigated as alternatives to the current acrylic cement formulations. Vazquez, Deb, Liso, and others^[39–43] have studied a number of different tertiary aromatic amines as alternatives to DMPT in the redox initiation system, with the goals of decreasing the polymerization exotherm, increasing the setting time, and reducing the degree of leaching of toxic residual chemicals after polymerization. They have demonstrated in vitro biocompatibility, reduced exotherms and increased setting times, and comparable mechanical properties and residual monomer content as compared to current commercial cements; however, it remains to be seen whether these alternate cement chemistries will have an impact on clinically used formulations.

Finally, another approach to improving the properties of powder–liquid bone cements has been the development of two-solution bone cement with the same chemical constituents as current commercial formulations.^[44,45] In this design, PMMA powder is predissolved in methyl methacrylate monomer to form two separate high viscosity, porosity-free solutions with BPO added to one and DMPT added to the other. Because of their high initial viscosity, similar to the

viscosity of powder–liquid cements in the dough stage, these solutions can be simultaneously mixed and delivered to the surgical site from a single closed system. This approach eliminates the issues of technique sensitivity due to cement mixing, transfer, and delivery. Hasenwinkel et al.^[44,45] have also shown that relevant material properties such as the polymerization exotherm, setting time, mechanical properties, and residual monomer content of two-solution cements can be controlled by the concentration and ratio of initiator chemicals along with other factors. These cements compare favorably in these properties to current powder–liquid cements and hold promise for the future.

CONCLUSIONS

Acrylic bone cements have had a significant impact on medicine and specifically orthopedic surgery since their introduction by Charnley in the 1960s. While significant research efforts have led to improvements in material properties and clinical outcomes over the past forty years, it is clear that there is still potential for alternate materials and formulations for these applications. However, until further progress is made, powder–liquid based acrylic bone cements remain the gold standard for fixation of total joint prostheses.

B

INTRODUCTION

The recent advances in orthopedic trauma research have brought up a new era in understanding and treating skeletal injuries. Since the beginning of the last century, metallurgic advances and mechanical principles have been introduced in orthopedic science with particular reference to trauma surgery. The further understanding of bone healing biology and bone biomechanics has led orthopedic surgery to the evolution of bone fracture fixation. An overview of the main fracture fixation techniques in modern orthopedic surgery, with emphasis on the biological and biomechanical principles of each, is presented in this article. Indications, complications, surgical techniques, and controversies surrounding each method of treatment are noted, but not discussed in depth. Internal and external fixation devices are described, namely wires, screws, plates, intramedullary nails, and several types of external fixators.

BONE BIOLOGY

Bone Structure

Bone is a living tissue organized so as to support the human body and serve as an attachment for muscles, allowing locomotion as well as protecting vital structures. The basic unit of bone is the osteon, consisting of concentric lamellae around a central canal of 20 microns, occupied by blood vessels. These lamellae are formed by cells (osteocytes) and matrix composed of organic (40%) and inorganic components (60%). Organic components include collagen, proteoglycans, and growth factors. Inorganic components include calcium hydroxy-apatite and osteocalcium phosphate. Bone is either cortical or cancellous. Cortical, or compact, bone (80% of the skeleton) is formed of tightly assembled osteons and has a relatively high Young's modulus. It is mainly found in the outer aspect of long bones. Cancellous bone is formed by less

densely assembled osteons and has a smaller Young's modulus. It is mainly found toward the ends (epiphysis) of long bones.

Bone is three times lighter than iron but ten times more flexible, although bone and iron have the same tensile strength. Bone is, nevertheless, anisotropic and has a modulus of around 18 giganewtons/m². Fractures can be caused by direct or indirect trauma. The latter type can be traction, angulation, rotational, or compression fractures, or fractures caused by a combination of these forces.^[1]

Biology of Bone Healing

The immediate reaction to fracture is an inflammatory phase that lasts up to 72 hours. The ends of the fractured bone do not actively participate in this process, but are in fact dead. They play only a passive role in the bridging process between the more distant living bone edges. Injured tissues and platelets release vasoactive mediators (which induce vasodilatation) and cytokines. Cytokines influence migration and proliferation of mesenchymal stem cells and their differentiation to osteoprogenitor cells, as well as matrix synthesis (i.e., members of the Tissue Growth Factor- β superfamily, such as Bone Morphogenetic Proteins 2 and 7, Platelet-Derived Growth Factor, Fibroblast Growth Factor, Insulin Growth Factor, and Interleukins 1 and 7). During this process macrophages remove the dead tissue.

Following the inflammatory phase, the reparative response begins and can last from two days to two weeks. Development of the repair tissue includes organization of the fracture hematoma, the appearance of fibroblasts and chondroblasts between the bone ends, and the formation of cartilage (type-II collagen). The clot is then replaced by provisional bone called callus. Three types of calluses are recognized: the external (or bridging) callus, which ossifies by endochondral ossification to form woven bone; the internal (or medullary) callus, which forms at a

slower rate, and the periosteal callus, which ossifies by intramembranous ossification. When enough callus is formed to bridge the ends, a remodeling phase will take place. This phase may last up to seven years and consists of remodeling of the woven bone to form mature cortical and cancellous bone, affected by mechanical function according to Wolff's law.

The initial bridging process can be achieved either by callus formation (secondary bone healing) or no callus formation (primary bone healing). The amount of callus formed depends on the amount of movement of the fractured bone ends. Rigid internal fixation can abolish this micromotion and lead to primary bone healing with little or no callus formation. In this situation the bone ends do not undergo resorption but are recanalized by Haversian systems (osteons) directly.^[1]

Bone Healing and Fracture Fixation

Development of external callus is the most rapid of all processes. It predominates in fractures treated with external fixation devices. Primary bone union, by contrast, is the slowest method of healing, and artificial stability must be maintained for many months. The advantage of rigid fracture fixation is that it allows early patient or limb mobilization. An example of this type of bone healing is a fracture rigidly and anatomically fixed with a compression plate. Intra-articular fractures require accurate or anatomical reduction and stable fixation in order to minimize the late onset of posttraumatic arthritis. Fractures at a distance from the joint can be allowed to heal without necessarily achieving full apposition of the fracture ends, provided that there is no axial or rotational deformity. A new concept known as biological fixation is aimed at reducing surgical trauma produced while exposing the fracture ends. It also involves less-rigid internal fixation. A more flexible fixation is thought to induce formation of callus and is achieved by bridging the fracture area with an implant, without fixing all intermediate fragments. New implants have been designed in order to achieve this type of fixation.

FRACTURE MECHANISM

Five different mechanisms of injury—tension, compression, shear, bending, and torsion—can be described in association with the most common skeletal injuries. Comminution is the expression of the amount of energy transmitted to the bone during the injury.

MATERIALS

The most commonly used materials for fracture fixation devices are cold-worked stainless steel (ISO 5832-1), unalloyed titanium (ISO 5832-2), and titanium alloy (Ti-6Al-7Nb, ISO 5832-11). Titanium has the advantage of producing fewer artifacts during magnetic resonance imaging (MRI) and is therefore very useful in spinal surgery, where imaging of the neural structures might be required after surgery. For certain fractures, biodegradable materials composed mainly of polyglycolic or polylactic acid have been developed, and they are currently under evaluation. Theoretically, they offer the advantage of gradual transfer of load to the bone and elimination of the need for removal. However, their tensile strength and rate of degradation are not ideal, and reported high incidence of inflammatory reactions has made them unpopular.

INTERNAL FIXATION

Wire Fixation

The simplest method to hold two fragments together has been simple wire fixation. This is still commonly used in wrist fractures. The wires can be introduced percutaneously and either buried under the skin or left protruding through the skin. In the latter case, it is necessary to remove them when satisfactory bony healing has been achieved, in order to minimize risk of infection. Other anatomical areas where wires can be used include the medial malleolus, the foot, and the hand. Wires are also being used in a circular manner, usually in order to supplement fixation of a long-bone fracture or in fractures around a previously implanted hip prosthesis. This is known as the cerclage wiring technique.

A particular method of wire fixation is known as tension band wiring. It consists of using straight, smooth wires and a figure-of-eight wire. This technique is applied in anatomical areas, where forces displacing the fracture fragments are of tensile nature. Typically, this situation is encountered in fractures of the olecranon at the elbow, where the triceps tendon tends to displace the bony fragments (Fig. 1). Another application of tension band wiring is in fractures of the patella where the extensor mechanism of the knee displaces the fracture fragments.

Screw Fixation

Screws can be used in isolation or in combination with other fixation devices, such as plates and intramedullary nails. Screw fixation alone is rarely used in

Fig. 1 Tension band wiring of an olecranon injury.

long-bone fractures, because it can fail. In such cases they are used as an adjunct in order to compress the fracture fragments. Screws are also used in the proximity of joints and in intra-articular fractures, and different diameters and types of screws are available.

In the 1950s, a group of surgeons from Switzerland founded the Association for the Study of Internal Fixation (AO) and popularized the use of standardized screw designs. Most manufacturers now use the same types and diameters as well as the same screw heads, so it is quite possible to continue treatment of a patient originally treated in another country.

Biomechanical Characteristics

A screw is a complex device with a four-part construction: head, shaft, thread, and tip. The main use of the screw in orthopedics is to fix two fragments together by compressing them against each other. The head serves as an attachment for the screwdriver, which can be hexagonal, cruciate, or slotted in design. It also serves as a counterforce against compression generated by the screw during insertion into the bone.

The shaft is the smooth portion of the screw between the head and the threaded portion. There are three different screw diameters to consider: the core diameter, the thread diameter (threaded part), and the shaft diameter (smooth part).

The thread has four characteristics: shape, depth, pitch and lead. The shape is asymmetrical—flat on the upper surface and rounded underneath. The depth of the thread is half the difference between the thread diameter and the core diameter. The thread is deeper in cancellous screws and shallower in cortical screws. Pitch is the distance between adjacent threads, and lead is the distance that the screw advances into the bone with a turn of 360°. The tip of the screw is either blunt-rounded (requires pretapping), or fluted or trocar (self-tapping).

Screw Types

Screws are mainly two types: cancellous and cortical. Either type can be fully or partially threaded.

Cancellous screws are designed to provide a better hold in the softer cancellous bone, so they have a deeper thread and coarse pitch. Bone screws usually require predrilling and tapping, but some screws are self-tapping. Screws are produced in diameters of 6.5 mm (large cancellous screws), 4.5 mm (large cortical screws), 3.5 mm (small-fragment cancellous and cortical screws), or smaller screws usually employed to fix hand fractures (2.7 mm, 2 mm and 1.5 mm). Partially threaded cancellous screws come in two thread lengths: 16 mm or 32 mm.

The Lag Screw Principle

Compression of two fragments can be achieved with the lag screw technique, in two ways. The screw can be designed as a lag screw, which means being partially threaded with the thread near to the tip. On the other hand a plain, fully threaded screw can be inserted in such a way as to act as a lag screw. The latter can be achieved by drilling a large-diameter proximal hole (sliding hole) in which the screw has no perches and a smaller (diameter equal to the screw core diameter) distal hole (tread hole) in which the screw has got strong perches. By inserting the screw, compression of the distal fragment to the proximal one can be achieved. The lag screw is best positioned at a right angle to the fracture plane.

There are four principal applications of screws:

1. In the cancellous epiphyseal or metaphyseal bone, as lag screws
2. In cortical bone with plates
3. With intramedullary nails to increase construct rigidity
4. To permit displacement in an axial direction (dynamic hip or dynamic condylar screw)

Plate Fixation

The AO group has also influenced plate design, and several manufacturers offer similar sizes. Large plates accommodate 4.5 mm screws and tend to be used in lower-limb fractures. Smaller plates accommodating 3.5 mm screws are available for fractures around joints or for forearm fractures (Fig. 2). Mini-plates for hand and foot fractures can accommodate 2.7 mm and 1.5 mm screws. Plates are available in different shapes to accommodate the anatomy of the bone that needs internal fixation (e.g., condylar plates for fractures of the distal femur and tibial head buttress plates for fractures of the proximal tibia). With dynamic compression plates, an additional improvement in design of the screw holes has allowed axial compression to be applied as the screws are fully tightened. More

Fig. 2 Plating of a forearm fracture.

recently, plates have been designed to hardly touch the bone surface, the screws being locked to the plate holes. These plates act as internal splints and are named LC-DCP (low-contact dynamic compression plate). One of the most commonly used plate designs is the so-called dynamic hip screw (DHS) used in the fixation of extracapsular fractures of the femoral neck. This design consists of a plate with a fixed-angle barrel, inside which slides a large partially threaded screw. This results in axial loading being translated to compression force at the fracture side, enhancing callus formation and healing.^[2]

Biomaterial and Biocompatibility

The most commonly used material for plate manufacturing is stainless steel, but titanium is more biocompatible and offers desirable plasticity. Plates and screws must be of the same material to prevent galvanic corrosion.

Principle of dynamic compression

The dynamic compression plate has specially designed screw holes, which have an inclined plane at one end so the two ends are at different levels. When the screw is inserted at the higher-level end and tightened down, it slides along this plane, pulling the plate and causing compression of the bone fragments. If, on the other hand, the screw is placed at the center of such a hole, the screw does not move and is said to be a neutral position.

Positioning and type of structural support

Plates can be used as:

1. Buttress devices, usually around joints.
2. Dynamic compression devices, usually in bones with uneven loading (i.e., femur) where there is a

tension and a compression side. The plate should always be placed on the tension side to achieve fracture healing.

3. Static compression devices: The forearm bones are the best example.
4. Neutralization devices, used to protect single screw fixation (lateral malleolar fractures).
5. Bridging devices, used for length restoration without fracture fixation. These can be augmented occasionally with bone graft.

Plates and screws in different bones

Every bone requires a certain number of screws when a single plate is applied. The humerus requires three to four screws on each side of the fracture, whereas the femur requires at least four, the radius and ulna six, and the tibia six to four.

INTRAMEDULLARY NAILING

History and Development of the Technique

The first reported intramedullary device is found in Simson's *Textbook of Surgery* (1883), where the author describes the use of ivory pegs introduced into the medullary canal of a bone. Hey-Grooves (1921) inserted the first metallic femoral intramedullary device during the First World War, and Smith-Petersen treated hip fractures with percutaneous medullary devices. Professor Gerhard Kuntscher (1939) focused his research and clinical work on intramedullary devices for fracture fixation and since, he has been considered the pioneer of the modern era of intramedullary nail fixation.^[3] See Figs. 3 and 4.

Fig. 3 Tibial nailing (anteroposterior view).

Fig. 4 Tibial nailing (lateral view).

Basic Biomechanical Definitions

Inertia (Newton's first law)	If a zero net external force acts on a body, the body will remain at rest or move uniformly.
Force	A push or pull causing external (acceleration) and internal (strain) effect
Moment (M)	Rotational effect of a force on a body about a point
Deformation	Change of shape of the material to which the force is applied. Deformation may be linear (i.e., compression or tension) or bending and torsion.
Rigidity or stiffness	Measure of amount of load required to produce unit deformation under given load configuration
Resistance to deformation	In bending, defined as bending rigidity; in torsion, defined as torsional rigidity.

Biomechanical Characteristics of Intramedullary Fixation

The most important mechanical factors in a biologically compatible intramedullary fixation system are strength, rigidity, and gripping strength.^[1] The amount of load that a structure can withstand before failure occurs is its strength. In characterizing an intramedullary nail, two modes of rigidity need to be considered: torsional rigidity and bending rigidity.

Torsional rigidity is the amount of torque needed to produce (or resistance to) a unit amount of torsional (rotational) deformation. It depends on both material properties (shear modulus, G) and structural properties (polar moment of inertia, J). Bending rigidity is the amount of force required to produce (or resistance to) a unit amount of deflection. It depends on both

material properties (elastic modulus) and structural properties (area moment of inertia, I). In both cases the resistance to deformation is very strongly influenced by the distribution of material about the axis (neutral axis) of bending or torsion. Along the neutral axis, no stress is present. Maximum stress occurs along the outermost fibers of the material in both bending and torsion. How the material is distributed away from the neutral axis is represented by the moment of inertia. In cases of bending, this is called the area moment of inertia, I , whereas polar moment of inertia, J , is used for cases of torsion. In other words, the more material can be distributed away from the neutral axis, the higher the moment of inertia and the greater the capability of the implant to bear load.

For example, two cylindrical nails containing the same amount of metal in the cross section (one being hollow with a greater diameter, and the other being solid with a smaller diameter) will have different values for I and J . Although both nails have the same cross-sectional area of metal, the larger nail is stiffer in bending and torsion because both I and J are larger, due to the fact that the material is distributed farther away from the bending or the torsional axis.^[4] Reaming increases the implant–bone interface contact area, allows larger nails to be inserted, and increases torsional and bending rigidity, respectively.

Gripping strength is the resistance to slipping at the implant–bone interface and is essential for the transmission of torque between fracture fragments. Gripping strength can be augmented by cortical reaming to increase the length of cortical contact. Gripping is optimized by the interlocking screw placement.

Nails are made of stainless steel 316L (L designates low interstitial carbon content, which is less susceptible to corrosion in vivo), 22:13:5 steel, titanium, titanium–aluminum–vanadium (Ti–6Al–4V), and titanium–aluminum–niobium (Ti–6Al–7Nb). The smaller-diameter nails should be made of alloys having superior fatigue strength.

Technical Characteristics

The working length—not true nail length—is the important biomechanical factor. Working length is defined as the length of a nail between the most proximal point of fixation in the distal fragment and the most distal point of fixation in the proximal fragment, and is directly related to the implant stiffness. Bending stiffness is inversely proportional to the square of the working length. Torsional stiffness is inversely proportional to the working length. In other

words, a short working length increases nail rigidity in both bending and torsion. In any case, a fracture should be bypassed by at least 5 cm by the intramedullary nail, because the peak stress around the distal screw holes may exceed the endurance limit of the metal.

The diameter of the nail is the principal factor that alters bending stiffness, and is related to the fourth power (of the radius) in a cylindrical nail.

A wide range of nail widths is available, to match different bone configurations. Nails may have a small diameter (i.e., Rush rods and Ender pins) relative to the medullary canal or a large diameter (Kuntscher, Kempf and Crosse, Russell and Taylor, AO/ASIF) to fit the canal following reaming.

The curvature of the nail can simulate bone anatomy (i.e., a femoral nail is usually curved in a sagittal plane) or facilitate nail insertion (i.e., humeral or tibial nail proximal to sagittal curvature to accommodate insertion portals offset from the center of the medullary canal).

Cross-Sectional Geometry

Nails can be hollow (can be inserted over a guide rod following reaming) or solid (can be inserted reamed or unreamed) (i.e., AO/ASIF). Slotted nails may be open-sectioned or close-sectioned. Open-sectioned nails may be slotted anteriorly (i.e., AO/ASIF) or posteriorly (i.e., Kempf and Cross). The presence of a slot increases the torsional flexibility of the implant and reduces hoop stresses during insertion. Nails may be cylindrical, cloverleaf, rectangular, or square in shape. The cross-sectional shape affects bending and torsional stiffness.

Locking Capacity

Most intramedullary nails are designed to allow interlocking fixation with screws at both ends of the bone. The great variety in the number, location, and angle of screw holes offers advantages over specific indications. Two screws proximally and two screws distally are usually applied, allowing control in rotation and bending and allowing fixation of comminuted fractures. Oblique screws (usually applied proximally for femoral or humeral nails) reduce the rotational deformation around the screw and alleviate the need for a second screw. Proximal locking capacity in the upper femur has been extensively modified to treat fractures proximally (e.g., initially the Y Kuntscher nail was used; more recently the Russell and Taylor reconstruction nail has been used) and from the subtrochanteric region.

Dynamic interlocking fixation

This technique involves the use of proximal interlocking screws only. In this type of fixation there is control in bending and rotation of the bone around the fracture, but the bone transfers the main axial load. Dynamic fixation is used in axially stable fractures and in some nonunions, and potentially increases the fatigue life of the nail.

Static interlocking fixation

This technique involves the use of proximal and distal interlocking screws. It controls rotation, bending, and axial loading, and may reduce the fatigue life of the implant as the nail becomes the load-bearing device. Static fixation is used in comminuted and metaphyseal fractures.

Dynamization of static interlocking fixation

This technique involves conversion of static to a dynamic fixation by removing the interlocking screws from the longest fragment. This is necessary in nearly 2% of femoral fractures. Dynamization is indicated in nonunions because it potentially increases the axial compression forces at the fracture site and augments fracture healing. Dynamization increases the fatigue life of the implant as its load-bearing capacity is decreased.

Systemic Effects of Intramedullary Nailing

Effect of reaming and nail insertion on blood flow, fracture union, and bone porosity

Normal bone blood flow is centrifugal from the endosteum to periosteum. Cortical reaming and nail insertion damages the medullary endosteal blood flow, resulting in avascularity of significant portions of the diaphyseal cortex. On the other hand, reaming increases the periosteal blood flow, which is not dependent on the nutrient artery.

There is a marked increase in blood flow during the first two weeks following reaming. After six weeks, flow in cortical bone recovers to normal when periosteal blood flow remains high, because the normal centrifugal pattern of flow is reversed.^[5] The disturbance in vascular supply is the basis of osteoporosis of cortical bone seen after intramedullary nailing rather than the stress shielding.^[6] Reaming also weakens the bone and the recommended bone removal (being no more than 4 cm and no more than half the original cortical thickness).

Fracture healing proceeds mainly by the formation of periosteal callus, which is largely independent of endosteal blood supply. Reaming products (fibroblasts, bone, and mesenchymal stem cells) induce bone on subperiosteal surface and augment the periosteal callus.^[7]

Effects of reaming and nail insertion in intramedullary pressures; fat intravasation and pulmonary complications

In experimental animal models, pressure can increase as much as 300 mmHg (and in some cases has increased up to 1000 mmHg). In patients with femoral fractures, elevations of intramedullary pressure between 140–830 mmHg have been observed. Fat embolization is a well-known complication of intramedullary nailing of the lower limbs. There is some controversy in the literature with regard to the extent of fat embolization that results from the reamed vs. unreamed technique. It seems logical, however, to consider that reaming may cause the accumulated effect of fat emboli, compared with the single-nail passage of the unreamed technique. Bone marrow fat embolization in the lung may cause mechanical obstruction of pulmonary vessels. Several pathogenetic pathways have been suggested (e.g., that the high thromboplastin content of bone marrow may cause increased coagulation or activation of the alternative pathway of disrupted fat cells' coagulation by-products. These mechanisms however, do not seem strong enough to explain all of the observed changes. Some authors therefore have recently postulated the adverse effect of fat in the lung endothelium. Direct or cytokine-mediated toxicity has been postulated, but at present there is insufficient evidence to support one hypothesis or the other. It is known, however, that the use of the unreamed nailing technique evokes a reduced systemic inflammatory response and fewer embolization effects.^[8]

EXTERNAL SKELETAL FIXATION

History and Development of the Technique

Two and a half thousand years ago, Hippocrates first described a method of external skeletal fixation for a tibial fracture (Fig. 5). Proximal and distal frame-type wooden rings were interconnected with long double bars on each side of the leg. This configuration permitted wound inspection and allowed fracture healing. Malgaigne in 1853 described a claw device for patellar fractures. Clayton Parkhill, innovator of the modern version of an external fixator, in 1897 presented to the

Fig. 5 Hybrid external fixation of a distal tibial fracture.

American College of Surgeons a device designed with two pins above a fracture line and two below, joined externally by a clamp. Lambotte in 1909 and Humphry in 1917 were the first advocates of the use of threaded pins. During the Second World War, external fixation devices became popular among army surgeons, although they fell into disrepute in North America because of their lack of rigid fixation and due to pin track infection. Charnley in 1948 popularized an external compression device for joint arthrodesis, that has remained attractive to this day. Hoffmann from Switzerland in 1954 presented his successful external fixation device with multiplanar frames that increase stability; Hoffman's external fixation technique has become a standard in modern orthopedic surgery. In 1970, Dr. Giovanni De Bastiani from Verona, Italy, introduced the dynamic axial fixator. To facilitate union, the telescopic portion of De Bastiani's unilateral fixator can be unlocked to provide dynamic compression. In 1980 Professor Ilizarov from Kurgan, Siberia, treated Italian explorer Carlo Mauri for the infected nonunion of his tibia. Since then, the Ilizarov method of external fixation and the distraction osteogenesis technique first popularized by Professor Ilizarov became significant parts of the orthopedic armamentarium. See Fig. 5.^[9]

Biology of Fracture Healing Following External Fixation

Fracture healing and construct rigidity

Knowledge of the basic biology of fracture healing and of the biomechanical principles of the external fixation device are necessary to obtain the full benefit of the technique. Fracture healing is divided into two patterns: primary and secondary healing. Primary

healing is achieved by callusless union, following rigid stabilization of the fracture to prevent interfragmentary motion. In contrast, secondary healing is achieved by periosteal and endosteal callus formation as a result of interfragmentary strain or motion following less rigid fixation. Remodelling of the bone cortex, however, takes time, and rigid fixation devices (i.e., plates) may need to remain in situ for up to 18 months before removal. Thus, rigid fixation not only precludes the development of callus, but also results in the protracted biomechanical dependency of fracture healing on the fixation system. Early external fixators employed rigid frames in multiplanar configurations to achieve primary healing. Although they did occasionally achieve anatomical restoration, it is now known that these techniques may have delayed or even prevented union. Current external fixation systems, while maintaining alignment and length, allow micromotion at the fracture site and promote callus formation (secondary healing).^[9]

Dynamization of an external fixator

Dynamization is the conversion of an external fixator from a statically locked device to a more load-sharing construct to promote micromotion at the fracture site. In current practice, dynamization is usually recommended after the initial stages of fracture healing. Progressive closure-type dynamization is achieved by sliding a telescopic component of the fixator body and approximating the bone ends. This controlled load-sharing eliminates fracture gaps; enhances callus formation; and accelerates maturation, union, and remodelling.

Elements and Design of External Fixators

External fixators are composed of a bone anchorage system in the form of wires or pins, articulations, and longitudinal supports.^[10] The two types of external fixator are pin and ring. Pin fixators are further subdivided into simple fixators, which provide independent application of single pins, and clamp fixators, which permit spatially constrained pin clusters.

Pin fixators can be used in four basic configurations: 1) a unilateral frame with a support device and half-pins on one plane constitutes a unilateral one-plane configuration; 2) the addition of a second plane of half-pins forms a unilateral two-plane configuration; 3) trans-fixation pins connected to support devices at either side are used to build the bilateral one-plane configuration; and the addition of a second plane of half-pins (or possibly transfixion pins) forms a bilateral two-plane configuration.

Ring fixators consist of complete or partial rings connected by rods or articulated devices. Rings are attached to bone with wires or half pins. Pinless fixators have been developed, designed to be attached to the bone by clamps rather than pins or wires. These devices have proven strong enough for temporary fixation in cases of emergency stabilization. They are relatively easy to apply and prevent pin loosening, pin track infection, and neurovascular injury.

Hybrid fixators combine wire and half-pin fixation. These devices are used for intraarticular fractures (wires) with diaphyseal extension (pins). Ilizarov external fixators employ complete modular rings with tensioned plain or olive-tipped wires. Although they are only 25% as stiff axially as unilateral fixators, Ilizarov external fixators have similar stiffness in bending and shear. This satisfies the main biomechanical principle of secondary fracture healing by enhancing micromotion and callus formation. Wire diameter and tension are the most important factors affecting frame stability.

Ilizarov external fixators are particularly useful in high-energy injuries because they create minimal surgical trauma, in malunions and nonunions as well as in osteomyelitis. Limb deformities and discrepancies in length can be corrected by the technique of distraction osteogenesis as well as by salvage arthrodesis of the knee, ankle, and hind foot.

Biomechanical Principles of External Fixation

Half-threaded pins

The most significant parameter affecting the stability of an external fixator is the radius of the pin.^[9] The bending stiffness of the pin is proportional to the fourth power of the radius of the implant. However, the diameter of any pin should not exceed 30% of the diameter of bone diaphysis because this increases the risk of fracture. Pins vary in diameter from 2.5 to 6 mm. Optimal pin design strives for greater core diameter, to increase rigidity. Bicortical fixation with the threaded part is preferred, and radial preload techniques can improve screw fixation and prevent loosening. Radial preload can be achieved by first drilling a pilot hole slightly smaller than the root diameter of the pin or by using tapered-root diameter screw design. This results in lower bending stresses at the entry-site cortex and reduced rate of osteolysis and loosening.

Wires

Kirschner wires under tension are used for Ilizarov frames. These wires are 1.5–1.8 mm in diameter.

Increasing wire tension and diameter, and decreasing the diameter of the ring enhance fixation stability. The yield point for a Kirschner wire has been measured at 120 kg/mm², which equals 210 kg for a 1.5 mm wire and 305 kg for a 1.8 mm wire. The optimal wire tension should not be greater than 50 % of the yield strength (or 105 kg for 1.5 mm wire and 150 kg for 1.8 mm wire). The average tension for most trauma applications recommended for Ilizarov frames is 80–90 kg.

Optimal frame configuration

1. Ilizarov frames with tensioned wires positioned at 90° angles to each other increase overall stability, compared with wires applied at smaller angles.
2. Minimizing the ring diameter as much as clinically possible (no less than 2 cm around the entire ring) increases stability.
3. Increasing the number of fixation devices (screws or wires) to the bone, spreading them evenly over the bone, and using large-framed fixators increase stability.
4. When multiplanar frames are used, then delta or triangular configuration offers greater stability.
5. The closer the frame is to the bone, the more stable the construct will be.
6. Fracture reduction reduces stresses at the pin–bone interface, off-loads the implant, and decreases the rates of pin loosening.

Advantages of an External Fixator

1. Provides a method of fixation in Gustilo type II and III open fractures in which other methods of treatment (i.e., internal fixation) would devitalize and contaminate larger areas of soft tissue, increasing the risk of infection and limb loss.^[2]
2. Compression, neutralization, and distraction of fracture fragments are possible.
3. Direct surveillance of the wound is possible, including neurovascular status, skin viability, and muscle compartmental pressure.
4. Additional treatment is possible by means of dressings, skin grafting, debridement, and bone grafting without distracting the bone fixation.
5. Immediate motion of the proximal and distal joint is allowed.
6. Extremity elevation is allowed by suspension from ropes from overhead frames, aiding edema resolution and relief of the posterior soft tissue.
7. Early patient mobilization is allowed.
8. Application can be performed under local anesthesia if necessary.
9. Can be applied in infected or noninfected nonunions.

10. Can be used for joint arthrodesis.
11. Could correct malunions following appropriate osteotomy.
12. Can be used for limb lengthening procedure or for deformity correction.

Disadvantages of an External Fixator

1. Pin track infection may complicate fixation; requires meticulous care.
2. Requires training on how to mechanically assemble the frame.
3. The frame can be cumbersome, and the patient may reject it for aesthetic reasons.
4. Fracture through pin track may occur.
5. Unless the limb is adequately protected, refracture after frame removal may occur until the underlying bone remodels the disrupted cortex and redevelops original strength.
6. May be expensive.
7. If the fixator needs to bridge a joint, joint stiffness may occur.

Absolute Indications for External Fixation

1. Gustilo type II and III.
2. Fracture associated with burns.
3. Fractures requiring additional plastic or vascular surgical procedures.
4. Fractures requiring destruction (i.e., associated with significant bone loss).
5. Limb lengthening.
6. Arthrodesis.
7. Osteomyelitis and nonunions.

Relative Indications for External Fixation

1. Certain pelvic fractures and dislocations.
2. Open, infected pelvic nonunions.
3. Reconstructive pelvic osteotomy.
4. Following tumor excision with autograft or allograft replacement.
5. Femoral osteotomies in children.
6. Limb reimplantation.
7. Polytraumatized patients.
8. Correction of congenital joint contractures.
9. Supplement to inadequate internal fixation.
10. Ligamentotaxis. Reduction of comminuted intra-articular fractures by traction of the ligaments and capsule around the joint.
11. Fixation of fractures in patients with head injuries having frequent seizures or spasms.
12. Fixation of floating knee fractures (ipsilateral fracture of distal femur and proximal tibia).

CONCLUSION

Fracture fixation remains currently the treatment of choice for bony injuries. Internal or external fixation can be alternatively or in combination employed to stabilize skeletal trauma. However, orthopedic surgery has evolved over the last 25 years. Modern technologies like tissue engineering have come to the front line of research and clinical practice, and more biological methods of treating fracture disease are emerging.

Bone–Implant Interface

D. A. Puleo

Center for Biomedical Engineering, University of Kentucky, Lexington, Kentucky, U.S.A.

B

INTRODUCTION

Placement of endosseous implants has improved the quality of life for millions of people. It is estimated that over 500,000 total joint replacements, primarily hips and knees, and between 100,000 and 300,000 dental implants are used each year in the United States alone. Total joint arthroplasty relieves pain and restores mobility to people such as those afflicted with osteoarthritis, and dental implants provide psychological and aesthetic benefits in addition to improving masticatory function for edentulous patients.

Past achievements in the use of endosseous implants have led to the use of these devices in expanded patient populations. Whereas implants once were placed exclusively in elderly patients who are relatively sedentary as they approach the end of their lifespan, prostheses now are being placed in younger, more active patients. This trend has led to a steady increase in the number of devices implanted. Consider, for example, hip and knee replacements. Knee procedures are growing at an average rate of 14% per year, and hip replacements at 3% per year. In addition, with the “graying” of the U.S. population (meaning that the proportion of the population 55 years or older is steadily increasing), more and more people will be candidates for orthopedic and dental implants.

The success of endosseous implants depends on acquiring and retaining stable fixation of the device in the bony site. In turn, stable fixation largely depends on obtaining intimate apposition of bone to the implant. Several factors—including the particular implant, the surgical procedure (and site of implantation), and the patient—can compromise periprosthetic bone formation. Subsequent to the immediate postoperative phase, in which infection can be a cause of failure, the primary mode of failure is loosening, or loss of fixation between bone and implant. In this case, a soft, fibrous membrane is present at the interface and thereby decreases stability as the implant is mechanically loaded. Therefore, much effort is being devoted to enhancing stable initial fixation at the bone–implant interface.

DEVELOPMENT OF THE BONE–IMPLANT INTERFACE

Following implantation of a biomaterial in bone, events analogous to those that occur during fracture healing will occur. The nature of the bone–implant interface will depend on factors that affect the body’s normal response to injury, which involves inflammation, repair/modeling, and remodeling/maturation. Fig. 1 schematically depicts events at the bone–implant interface.

Insertion of an implant into a surgically prepared site will result in the adsorption of proteins from blood and other tissue fluids. Although still incompletely understood, these adsorbed biomolecules play a significant role in the unfolding of subsequent events at the interface, such as the adhesion and function of cells. Initially, a hematoma will be present between the implant and bone. Fibrin within the coagulated blood serves as a scaffold for the infiltration of inflammatory cells. Cytokines and growth factors secreted by macrophages can stimulate invasion by mesenchymal cells, including osteoprogenitor cells. With adequate chemical, biochemical, and mechanical factors, the osteoprogenitor cells will differentiate into osteoblasts that begin synthesizing woven bone. With time, the woven bone will be remodeled into mature, lamellar bone, which further stabilizes the implant.

As shown in Fig. 1, bone formation in the periprosthetic region can occur in two directions. Not only does the healing bone approach the biomaterial, but bone formation can also begin on the implant surface and extend outward. The terms distance osteogenesis and contact osteogenesis have been used to describe these phenomena.^[1] Distance osteogenesis is similar to normal appositional bone growth, in which the surrounding bone is a source of osteogenic cells and provides a substrate for these cells to produce new bone matrix. The distance between implant and bone decreases as distance osteogenesis proceeds and the newly formed bone approaches the implant. In this case, cells and their matrix will be present between implant and bone.

In contact osteogenesis, bone formation occurs directly on the implant surface and moves outward toward the surrounding bone. For this to happen,

Fig. 1 Schematic representation of the events at the bone–implant interface. **a:** Protein adsorption from blood and tissue fluids. **b:** Inflammatory and connective tissue cells approach the implant. **c:** Formation of an afibrillar mineralized layer and adhesion of osteogenic cells. **d:** Bone deposition on both the bone and the implant surfaces. **e:** Remodeling of newly formed bone.

osteogenic cells must be recruited to the implant surface and subsequently must be induced to differentiate into osteoblasts that will secrete bone matrix. As indicated previously, fibrin provides a pathway for migration of osteogenic cells toward the implant. Once at the surface, these cells initially deposit a collagen-free organic matrix that contains important non-collagenous bone proteins. The matrix provides sites for the nucleation of calcium phosphate crystals and subsequent crystal growth. Finally, a collagenous matrix that mineralizes is secreted adjacent to the collagen-free layer. This process results in the mineralized, collagen-free layer separating periprosthetic bone from the implant, with the interfacial layer being similar to the cement lines found at bone interfaces, such as between osteons.

Extrapolating from the study of dental implants placed in cortical bone of rabbits, Roberts has described the expected time course for development of the bone–implant interface in humans.^[2] The process is divided into four stages: 1) woven callus, 2) lamellar compaction, 3) interface remodeling, and 4) compacta maturation. In stage 1, over a period of about six weeks, woven bone forms to bridge gaps between implant and bone. In stage 2, lamellar bone forms within the woven bone scaffold to provide additional support for the implant by 18 weeks. In stage 3, remodeling of the interface also occurs by 18 weeks to repair damage to periprosthetic bone resulting from the implantation procedure. In stage 4, further maturation and long-term maintenance of the supporting bone bed occur through 54 weeks after implantation.

Osseointegration

The term osseointegration is used frequently when discussing the bone–implant interface. Unfortunately, various investigators use different definitions of the term, which can be confusing when interpreting

and comparing different studies. The concept of osseointegration was developed by Brånemark's group after noticing what appeared to be direct contact between bone and titanium (Ti) bone chambers.^[3] This observation led to nonalloyed (commercially pure) Ti being used to construct root form dental implants. Even Brånemark's use of the term osseointegration has undergone an evolution. In 1977, the term was used to describe intimate apposition of bone to Ti implants without intervening tissue.^[4] Several years later, osseointegration was defined as a "direct structural and functional connection between ordered, living bone and the surface of a load-carrying implant."^[5] Although bone cells and mineralized tissue approach the surface of the implant, regions without direct contact also are observed at higher magnification (Fig. 2). Osseointegrated implants have regions in which they are separated from the surrounding bone by at least a 20–40 nm layer of amorphous, collagen-free material. Considering the many factors affecting bone–implant interactions, osseointegration occurs only under precisely controlled conditions.

FACTORS INFLUENCING THE BONE-IMPLANT INTERFACE

As indicated in the preceding section, the host response to implants placed in bone involves a series of cell and matrix events that ideally culminate in intimate apposition of bone to biomaterial. For this intimate contact to occur, bone damaged during surgical preparation of the implant site must be repaired, and gaps between bone and implant must be filled. Additionally, unfavorable conditions that disrupt the newly forming tissue and lead to formation of a fibrous capsule must be minimized.

Implant Materials

In an attempt to enhance the stability of endosseous implants, a large number of implant materials and designs have been used. Although a treatment of the various designs intended to alter interfacial mechanics is beyond the scope of this chapter, it is nonetheless important to note that changes in implant design impact biomechanical attributes and thus affect the bone-implant interface.

Bioinert materials

Historically, so-called bioinert materials have been used principally for endosseous implants. These materials include oxide ceramics, such as alumina (Al_2O_3), and metals that form stable surface oxides, such as Co-Cr alloys, commercially pure Ti, and Ti-6Al-4V. Because these surface oxides are chemically stable, it was thought that the implant materials would only minimally affect host tissues and that host responses would minimally affect the material properties.

Although oxide ceramics were important for early research on porous implants (discussed further in the section on cementless implants), their brittleness makes them generally unsuitable for use in highly loaded sites. Consequently, metallic biomaterials are predominantly used for load-bearing prostheses such as hip, knee, and dental implants.

Bioinert materials are not exactly inert, however. Metallic ions and particles are released into surrounding tissues even from Ti and its alloys, which form a stable TiO_2 surface film. For example, metal levels in tissues encapsulating implants have been measured at up to 21 ppm Ti, 10.5 ppm Al, and 1 ppm V around Ti-6Al-4V, and up to 2 ppm Co, 12.5 ppm Cr, and 1.5 ppm Mo around Co-Cr-Mo.^[6] Depending on the amount of metal released, grey to black tissue discoloration may be observed, a phenomenon called metallosis. Because of the blood vessel network adjacent to the implant, metallic species can be

distributed systemically. Even in patients with well-functioning implants, the level of Ti in the serum of recipients of Ti alloy devices may be elevated threefold over levels in control groups. The level of Cr in recipients of Co-Cr alloy implants may be five- and eightfold higher in serum and urine, respectively.^[7] In light of the potential for metallic species to affect the differentiation and activity of bone cells,^[8] they consequently may affect the integration of implants in bone.

Another consequence of the lack of reactivity of bioinert materials is that even though bone will approach, and may even directly contact, the implant surface, bone will not bond to the material. In the case of an osseointegrated implant, as shown in Fig. 2, regions with apparently direct apposition of bone to implant will exist, but they are unlikely to provide significant resistance to shear and tensile loading. Furthermore, there will also be regions where an even weaker electron-lucent zone separates the implant from bone. High resolution immunocytochemical studies have demonstrated that this interfacial layer is rich in noncollagenous proteins such as osteopontin (OPN) and bone sialoprotein (BSP), as well as certain plasma proteins such as $\alpha_2\text{HS-glycoprotein}$.^[9] The absence or relative paucity of serum proteins, such as albumin, in this layer indicates selective accumulation/deposition of molecules at the bone-implant interface.^[9] Because they contain Arg-Gly-Asp and polyacidic sequences, OPN and BSP are believed to play roles in cell adhesion and binding of mineral. With materials other than commercially pure Ti, the interfacial zone becomes thicker. In more extreme cases, a fibrous capsule with a thickness in the microns scale will separate bone from implant. The search for a stronger bone-implant interface has led to the development of bioactive materials.

Bioactive materials

Hench et al. conducted pioneering research in the development of bioactive materials.^[10] Rather than have a material sit passively in tissues, these researchers hypothesized that materials should be designed to have controlled surface reactivity under aqueous conditions. The original Bioglass[®] formulation (45S5) contained 45 wt% SiO_2 , 24.5 wt% CaO , 24.5 wt% Na_2O , and 6 wt% P_2O_5 . By inducing ion exchange reactions, release of calcium and phosphate, alteration of interfacial pH, and nucleation and crystal growth, chemical bonding between bone and biomaterial can be achieved (Fig. 3a). During formation of a bonelike carbonated apatite on the surface of bioactive glasses, bone bonding is enhanced by the interdigitation of collagen fibrils (produced by adjacent osteoblasts) with

Fig. 3 Transmission electron micrographs showing the interface between bone (B) and bioactive materials. (a) Bioglass[®] (BG). (b) Hydroxyapatite (HA). I = intervening apatite layer. The arrows in frame (a) indicate the banding pattern of collagen fibers in bone. (From Ref. [11]. Reprinted by permission of John Wiley & Sons, Inc.)

the mineralizing layer. By changing the formulation, such as by altering the silica content, the reactivity of the material can be controlled. Furthermore, it is speculated that chemical changes in the interfacial microenvironment stimulate bone cell activity and thus enhance bone bonding.^[12]

The chemical similarity of calcium phosphate (Ca-P) ceramics to the inorganic matrix of bone has made them a subject of intense investigation. The two most commonly studied Ca-P materials are hydroxyapatite [HA; $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] and tricalcium phosphate [TCP; $\text{Ca}_3(\text{PO}_4)_2$]. Because these materials are composed primarily of calcium and phosphate ions, which are normally present in the bone microenvironment, they participate in solid-solution equilibria at the interface. Partial dissolution of calcium and phosphate from the implant causes supersaturation of the tissue–implant interface microenvironment with respect to apatite, and thereby results in reprecipitation of bone-like carbonated apatite.^[13] Matrix proteins and glycosaminoglycans secreted by adjacent cells adsorb on, and become incorporated into, the mineralizing surface layer, resulting in bonding with bone (Fig. 3b). A collagen-free bonding zone of up to a micron in thickness

separates the implant from surrounding bone. Because alterations in the microstructure, such as phase composition and crystallinity, affect dissolution and reprecipitation of Ca-P materials, such changes also modify the bioactivity of these materials.

A frequent observation reflecting the ability of bioactive materials to form strong chemical bonds with bone is that attempting to remove them results in fracture of either implant or bone. The fracture lines run across, rather than along, the interface. At weaker interfaces, such as between bioinert materials and bone, failure generally results in separation of the implant from the surrounding tissue.

Modes of Fixation

The lifetime of endosseous implants is dependent on stability of the bone–implant interface. Furthermore, this lifespan can be divided into two parts: the initial period following implantation, during which stable fixation must be obtained; and the remaining time, during which stable fixation must be retained. Several studies have shown that early subsidence of hip implants correlates with, and can be used to predict, eventual failure.^[14] Overall, stable initial fixation is a necessary, although not sufficient, requirement for long-term implant stability. To this end, two approaches have been used to achieve fixation of endosseous implants.

Cemented implants

Cemented implantation involves the use of polymethyl methacrylate (PMMA) as a bone cement to anchor the implant in place. Partially polymerized PMMA has a doughy consistency. It is inserted into the prepared implantation site during surgery, and the implant is subsequently pressed into the still-soft PMMA. As the PMMA continues to cure, a solid layer of polymer is interposed between the implant and surrounding bone. The cement interdigitates with the walls of the surgically prepared bone cavity. As the implant is loaded, forces are transmitted from the implant through the cement and to the surrounding bone. Because cemented implants have two interfaces (one between metal and polymer, and one between polymer and bone), the long-term stability of an implant depends on retaining the integrity of both interfaces.

With respect to the cement–implant interface, approaches to both minimize and maximize bonding have been investigated. The chemical nature of the polymer and metallic implant precludes chemical bonding, but mechanical interlocking can be obtained. To minimize interaction, polished surfaces have long been used successfully. In light of reports of debonding

at the interface between PMMA and smooth implants,^[15] prostheses with matte finish surfaces were investigated to allow for mechanical interdigitation. Implants precoated with PMMA to facilitate adhesion between implant and cement also have been tested and used. Rougher implants have shown excellent results, but when debonding does occur, micromotion between the rough surface and polymer can cause abrasion and result in the generation of particulate matter, leading to bone resorption and loosening of the implant.

Analysis of the cement-bone interface of some implants retrieved from humans has shown a thin shell of trabecular bone around the polymer, whereas other samples have a layer of fibrous tissue or fibrocartilage interposed between bone and cement (Fig. 4). In addition to interfacial biomechanics, which will be discussed further in a later section (Additional Factors Affecting Bone Ongrowth or Ingrowth), the cement-bone interface is affected by the mechanical, thermal, and chemical trauma generated during the

(a)

(b)

Fig. 4 Contact radiographs of sections of retrieved cemented femoral stems. (a) Significant contact of bone with the cement. (b) Less bone-cement contact. I = implant; C = cement; B = bone. (From Ref. [16]. Adapted by permission of The British Editorial Society of Bone and Joint Surgery.)

implantation procedure. The surface of the surrounding bone bed is inevitably damaged during the broaching and/or reaming procedures used to prepare the cavity for the implant. Also, the polymerization reaction for PMMA is exothermic, which may expose periprosthetic bone to elevated temperatures. Exposure of bone to a temperature of between 44 and 47°C for 1 min. significantly decreases the bone formation rate and often is considered to be a threshold for thermal necrosis.^[17] Intraoperative measurements have shown a median maximum temperature of 48°C (range 41–67°C) at the interface between PMMA and acetabular bone.^[18] Additionally, the methyl methacrylate monomer and dimethyl-*p*-toluidine initiator can have toxic effects on the surrounding bone cells.

Furthermore, integrity of the cement mantle surrounding the implant is essential for stable support of the prosthesis. Fragmentation of bone cement, resulting from repeated loading during the implant service life, stimulates an inflammatory reaction involving macrophages and cytokines, eventually leading to bone resorption. This phenomenon has been termed osteolysis. The destruction of periprosthetic bone, which is reflected in radiolucent spaces surrounding the implants, allows formation of a soft tissue membrane interposed between the cement and bone. Believing that this type of reaction was unique to bone cement, early reports classified this phenomenon as “cement disease.” Subsequent studies have shown that many types of particulate matter, particularly the ultrahigh-molecular-weight polyethylene commonly used as a bearing surface in joint replacements, can induce osteolysis. For bone cement, mantle thickness is an important factor; thicker layers produce better clinical results.

Cementless implants

Although cemented implants have benefited millions of patients, the loosening that often occurs 10 to 20 years after implantation requires complicated and less successful revision surgery. To expand the use of implants in younger patient populations, noncemented implants were developed. Because the afibrillar mineralized layer at the bone-implant interface would not be expected to have substantial tensile or shear strength, mechanical interdigitation is needed to stabilize the implant. With cementless devices, the original concept was that fixation could be obtained by direct mechanical interlocking between bone and implant; the implant is press-fitted directly into an undersized bony cavity. Undersizing of the cavity is intended to decrease gaps and force initial mechanical interdigitation between the implant and surrounding bone.

Several designs of cementless implants have been explored. The goal of each, however, has been to

encourage mechanical interlocking by promoting bone ongrowth or ingrowth. Macrointerlock surfaces range from those having a matte or textured finish to those that are grit-blasted. Grit-blasted surfaces have fared well in both hip and dental implants. For example, the sandblasted and acid-etched titanium SLA surface used for root form dental implants exhibits good interfacial bone contact, even under loaded conditions.^[19] An alternative approach is the use of microinterlock implants, which have porous surfaces to allow ingrowth of bone. Porous coatings have been produced by sintering or diffusion-bonding metallic beads or fibers to select regions of the implant surface. Plasma-spraying techniques also have been used to deposit rough and porous coatings.

For a cementless implant to become stably fixed, the surface must not simply allow tissue to infiltrate the coating; it must also allow formation of bone within the pore volume (Fig. 5). The optimal pore size for bone ingrowth is still a subject of debate. Early work by Hulbert et al. using oxide ceramics showed that a minimum interconnected pore diameter of approximately 100 μm was needed for adequate bone ingrowth.^[21] Smaller pore sizes allowed incomplete mineralization or even prevented mineralization of the infiltrating fibrous tissue. Later work by Bobyn et al. using metallic implants showed good bone ingrowth with pore sizes between 50 and 400 μm .^[22] More recent discussions have presented the possibility that much smaller pores may allow bone ingrowth when bioactive, rather than bioinert, substrates are used.

A newer cementless approach that may be an adjunct to textured or porous surfaces is to use osteoconductive or osteoinductive coatings, which enhance apposition of bone from existing bone surfaces or which stimulate de novo bone formation, respectively. The most studied of these methods is the use of bioactive calcium phosphate coatings. The ability of Ca-P coatings to enhance bone formation at the tissue-implant interface depends on

Fig. 5 Backscattered electron micrograph showing good ingrowth of bone into a porous coating. (Ref. [20]. Reprinted by permission of The Journal of Bone and Joint Surgery.)

several factors, including the type of calcium phosphate and its crystallinity, thickness, and adhesion to the implant. The first two factors play a large role in determining the degradability of these Ca-P coatings. Although some dissolution is needed for reprecipitation of carbonated apatite, too-rapid degradation could lead to disintegration of the Ca-P coating. To date, most clinical research has focused on high-density, highly crystalline HA. Examination of implants retrieved from animals and humans reveals apposition of bone within two or three weeks post surgery.^[23] Even though short-term clinical results have been encouraging,^[24,25] the dissolution of coatings as well as cracking and separation from metallic substrates remain concerns.^[26,27] Although still in a research stage, the use of osteoinductive biomolecules, such as the bone morphogenetic proteins, to induce periprosthetic osteogenesis is intriguing.

ADDITIONAL FACTORS AFFECTING BONE ONGROWTH OR INGROWTH

During periprosthetic osteogenesis, anything that affects or interferes with the recruitment, migration, or function of osteogenic cells will affect implant integration. This section will discuss patient-related factors and the surgical procedure, which also play significant roles in determining the nature of the bone-implant interface.

Preparation of the implantation site by reaming, broaching, or drilling, for example, can cause bone damage via mechanical and/or thermal means. Healthy bone cells and their supporting vasculature are needed not only for repair of the damaged bone itself but also for bone formation to proceed toward the implant. Although dental implants are placed in sites that are prepared by drilling but subsequently heal well (become osseointegrated), meticulous surgical care is needed. As mentioned in the section on cemented implants, a temperature of between 44 and 47°C is considered the threshold for thermal damage.^[17] Thus, copious irrigation and controlled drill speed are needed to prevent overheating of the bone bed during preparation of the implantation site.

Gaps between bone and the implant reduce the likelihood of good bone apposition. Dental implants fit well into precisely prepared sites, but joint replacements do not fit nearly as well in the medullary cavity. For example, even though a range of sizes of hip implants is available, geometric differences between the implant and femoral canal permit only sporadic bone-implant contact to be achieved initially.^[28] Furthermore, because bone has limited ability to bridge gaps, excessive space makes good fixation difficult to obtain. For example, although 1.5–2-mm gaps can be spanned

in animal models, the process may take up to three months, even under unloaded conditions.^[29] Loading of the implant (further discussed later in this section) will likely delay bridging, or may even prevent it. Because of the closer proximity of bone to the implant, better ingrowth is observed on the anterior and medial aspects of femoral components. Osteoconductive and osteoinductive coatings are being explored to enhance bridging.

A related factor that affects the fate of implants is the type of bone—compact or cancellous—adjacent to the implant. Implantation into compact bone will provide better primary support of the prosthesis than will placement in cancellous (spongy) bone. However, woven bone, which is rapidly synthesized (up to 50 μm per day), can form between the trabeculae of the cancellous bone to bridge the gap.^[2] Subsequent formation of stronger, but slower growing, lamellar bone within the woven bone framework (lamellar compaction) can provide good secondary fixation.

In the dental implant literature, the quantity and quality of bone are major considerations in surgical planning. Because the clinical success of an implant will depend, in part, on how much of its surface is in intimate contact with bone, quantitative factors, such as the thickness and height of bone present at the site of implantation, are important. Bone quality is less easily determined, but it relates to the degree of bone density present. Type 1 bone provides good anchorage in compact bone, but type 4 bone provides a soft texture that will poorly support an implant. The significance of these differences becomes apparent when the success of implants placed in the mandible, which has higher bone density, is compared to the poorer results of implants placed in the less dense maxilla.^[30]

Excessive motion at the bone–implant interface has been long recognized as a factor that interferes with periprosthetic osteogenesis and thereby results in fibrous encapsulation. Some investigators speculate that relative motion between bone and implant damages the fibrin network and the new vasculature that are part of the early bone healing process, consequently rerouting the healing response into repair by scar tissue. Considering the complexity of the tissue–implant interface and reports of mechanical loading altering cell responses *in vitro* and *in vivo*,^[31] this explanation may be too simplistic. Regardless of the precise mechanisms of failure, a two-stage procedure for placing dental implants has been commonly used, and limited weight-bearing following joint arthroplasty is prescribed. Two-stage dental implantation involves inserting the root form implant and then allowing three to six months for bone healing before the abutment and crown are attached. Similarly, protected weight-bearing of joint implants for up to six weeks after surgery is intended to allow initial bone repair. The

Fig. 6 Photomicrograph of a loaded implant showing fibrous tissue (FT) between titanium (Ti) and bone. (Ref. [33]. Reprinted by permission of John Wiley & Sons, Inc.)

critical amount of relative motion between implant and bone has not been definitely established, but minimization of loading during the early postoperative period is generally accepted as necessary to obtain good initial fixation. Results from animal studies suggest that the threshold for excessive micromotion is between 50 and 150 μm .^[32] Below this level, movement at the interface is tolerated, and bone ingrowth/ongrowth can occur. Motion above this threshold interferes with bone repair and results in fibrous encapsulation of the implant (Fig. 6).

Patient factors may further affect development of the bone–implant interface. Age, health condition, diseases, and medications or treatments that severely compromise healing can be contraindications for receiving an implant. These conditions may include metabolic bone diseases, such as osteoporosis or Paget's disease, and radiation therapy following tumor resection. Uncontrolled diabetes, chronic smoking, and systemic administration of glucocorticoids also can interfere with periprosthetic bone repair.

CONCLUSION

Long-term success of endosseous implants depends on obtaining and maintaining a stable bone–biomaterial interface. Significant advances have been made in understanding events at the interface between bone and implants. Advances in biomaterials and their processing, implant design, and surgical technique have improved the success of endosseous implants. Under certain circumstances, these implants can become intimately apposed by bone. However, numerous factors can shunt the bone repair process to a situation in which the implant becomes encapsulated by fibrous tissue. Further improvements in the performance of endosseous implants will require modifications in implant materials and designs, further manipulating biological responses to stimulate early periprosthetic

bone formation and to subsequently retain the supporting bone tissue.

Christian Lindqvist

Department of Oral and Maxillofacial Surgery, Helsinki University and University Hospital, Helsinki, Finland

INTRODUCTION

The possibility of using biodegradable devices in bone surgery has been studied intensively for more than 40 years. The first clinical trials of use of such materials in fracture surgery took place more than 30 years ago, with disappointing results. The stability of the devices was not adequate, and osteosynthesis did not result in rigid, function-stable fixation. Research since the early 1970s has resulted in major improvements, however. Advances in polymer chemistry and material processing procedures has improved the quality of biodegradable materials to the extent that clinical use has become safe: Stability has been achieved and maintained for a sufficiently long time to allow normal bone healing to occur.

In the human skeleton, the facial bones seem to be optimally suited for the use of biodegradable devices. An osteotomy or sagittal mandibular fracture can be repaired using biodegradable screws that allow free postoperative mandibular movement. Some other fractures can be treated and certain reconstructions undertaken with resorbable plates and screws, requiring no maxillo-mandibular fixation (MMF). Considering their value in achieving the goal of avoiding MMF in surgery of the facial bones, the question remains, why biomaterials are not used more extensively in maxillofacial surgery today.

One explanation relates to the fact that the devices available are fairly large, and some are inconvenient to use. Another explanation for the limited use of biomaterials in surgery of the facial bones is that many surgeons consider that there remains significant need for improved development of absorbable fixation devices, although some say that bioresorbable screws and plates are excellent solutions for a problem that does not exist. By this is meant that the metallic devices commercially available today are so reliable, stable, and easy to use that there is no need for absorbable materials. For example, it is believed that small titanium plates and screws can be safely left in the body,

even after the implant has ceased to serve any function (i.e., after fracture or osteotomy consolidation). Another factor limiting the use of biodegradable devices may be the adverse reactions noted after use of poly-L-lactic acid (PLLA) or polyglycolic acid (PGA) plates and screws. Sterile skin fistulas and swellings have been described in the vicinity of absorbable plates and screws. The clinical resorption time seems to be unknown, and whether the products of degradation are harmful to patients is also uncertain.

OVERVIEW

Modern titanium plates and screws are very different from devices used at the beginning of the era of rigid fixation. In the beginning, stainless steel plates meant for forearm fractures were used in treating mandibular fractures.^[1] Significant progress has since been made, improving both the quality of materials (i.e., enhancing their biocompatibility), and the design and surfaces of implants. The titanium microplates used in midfacial fracture and osteotomy surgery are excellent examples. Plates and screws as small as these are almost always left in place, with no known need for their removal. It is not known whether it is justifiable to leave plates and screws in place, nor what are the safe limits of plate and screw sizes. Although many manufacturers claim that their implants are made of pure titanium, other metals (e.g., aluminium and nickel) have been found in soft and hard tissues around titanium implants.^[2] Titanium, thought to be biologically inert, has been found in fairly large quantities in lymph nodes and distant organs after the placement of dental implants.^[3] There have also been reports of tumors in the vicinity of metallic prostheses.^[4-7] Postoperative radiation may cause problems in cancer surgery. Metallic devices used in the fixation of access osteotomies have disturbed radiologic examinations. Bioresorbable material can be considered tissue equivalent and does not cause scattering in neighboring structures. Furthermore, the

material does not disturb postoperative imaging, which is extremely important in oncologic patients, for whom early detection of possible recurrence or metastasis is of utmost importance.

In the growing skeleton, restriction of growth caused by metallic fixation devices may lead to consistent asymmetry.^[8] There are also several reports of passive intracranial translocation of metallic hardware, causing great concern and discussion.^[9] Plates, screws, and wires have been found embedded in the dura.^[10]

The foregoing discussion suggests reasons that nonfunctional implants should be removed, at least in growing individuals. Hazards related to removal operations, inconvenience to patients, and costs to patients and society must be considered in determining whether biomaterials can be considered safe to use.

Biomaterials used today all degrade to CO₂ and water, but absorption times differ significantly and depend on various factors. If degradation is rapid, tissues may not be able to tolerate some products of degradation. Swelling, sterile skin, or mucosal fistulas may develop. Traces of biomaterials have been found in tissues several years after implantation, a period of time that is excessive in relation to fracture healing. Currently used copolymers seem to disappear totally within a period of two years, although some investigators claim that the materials never totally degrade. Despite this surgeons universally regularly use bioresorbable suture materials, which they leave in place without hesitation.

It should be a goal that bioabsorbable screws and plates disappear soon after fracture consolidation. Degradation should occur in a way that makes it possible for tissues to tolerate end products. Various factors, including the material's means of sterilization, affect degradation rate. Research proceeding in laboratories and clinics worldwide will overcome these problems associated with use of biodegradable devices. One such problem relates to the size of the devices. Recent advances in materials research have made it possible for screws, rods, pins, and tacks to be significantly smaller than before. Bioabsorbable screws for mandibular osteotomy fixation are nearly as small as metallic screws in clinical use. Miniplates and miniscrews are likely to be of size and strength similar to those made of titanium.

Various chemicals can be incorporated into implants, increasing indications for implant's use. It would be useful, especially when working in contaminated areas, if antibiotics could be incorporated into screws and membranes. Growth factors and enzymes could also be incorporated into implants, to accelerate healing and bone growth.

This article describes the basic research and recent progress in the use of bioresorbable materials in the craniofacial region.

MATERIALS USED

Materials in use in the beginning of the era bioabsorbable materials were mainly homopolymers of poly-L-lactide (PLLA). Unfortunately, the first promising reports on the use of poly-L-lactide devices were soon followed by reports of long-term adverse reactions during resorption.^[11] These reports created doubt in the international craniomaxillofacial surgery community, which led to further research on both biomaterials engineering and the behavior of these materials in vivo.

The self-reinforcing (SR) method developed by Törmälä and Rokkanen represents a cornerstone in circumventing some of the problems associated with use of the early polymers.^[12] See Fig. 1. This internationally patented SR technique entails sintering the polymer material to yield a composite in which matrix and reinforcing elements are of the same polymer. With this technique, it is possible to avoid using large implants, while producing strong implants that provide adequate mechanical stability to the healing bone. This technique also solves the problem of the increased relative crystallinity of polymers during their in-vivo degradation, which some have speculated as causing the complications seen in highly crystalline polymers such as pure poly-L-lactides (PLLA). The advent of the SR technique has also made it possible to obtain strong, malleable devices from the amorphous poly (L/DL) lactide (PLDLA). Without the SR technique, plates must be heated before bending to correspond to the underlying bony structure. Plates manufactured in the self-reinforcing technique can be bent with pliers at room temperature, making them easy to use. The use of these plates and screws has gradually become accepted worldwide, even though several surgeons have

B

Fig. 1 Self-reinforcing structure is seen in an electron microscopy image. The long fibers are protruding out of the fractured surface of an SR-PLLA rod.

questioned the mechanical strength of the bioabsorbable devices, especially in the load-bearing bone of the craniofacial skeleton, the mandible. In 2002, Maurer et al.^[13] published a finite element study on the strength of several different bioabsorbable screws in the fixation of sagittal osteotomies. They concluded that, as concerns chewing forces, all materials studied were sufficiently stable at the osteotomy gap.

Different materials are available today, both self-reinforced and non-self-reinforced. However, most are copolymers of D- and L-lactic acid (PLDLA) or PLA and PGA (PLGA). Currently, most devices are manufactured by combining two polymers (mainly poly-L-lactide with D-lactide or polyglycolide). This combining of two polymers reduces the crystallinity of the material (considered to be a cause of the clinically reported adverse reactions), and avoids the long degradation time of PLLA homopolymers.

EXPERIMENTAL STUDIES

The use of bioabsorbable plates and screws was first reported in the 1970s.^[14] The plates and screws were used in the fixation of mandibular osteotomies in sheep^[15,16] and in the fixation of frontal bone craniotomies in lambs.^[17]

Suuronen and coworkers undertook a series of studies on the use of SR-PLLA plates and screws for fixation of mandibular osteotomies in 92 sheep.^[15,16] The SR-PLLA plates and screws were compared with similar metallic devices for fixation. SR-PLLA screws, SR-PLLA plates and screws, and SR-PLLA plates and metallic screws were used in both the condylar neck and mandibular body areas. (See Fig. 2.) The SR-PLLA plates were composed of four plate layers. SR-PLLA screws or SR-PLLA plates and metallic screws provided sufficient fixation of mandibular bone osteotomies. The body osteotomies healed with heavy callus formation in both groups. The plate and screw

Fig. 2 X ray showing osteotomy on the mandible of a sheep, fixed with SR-PLLA plate and screws. Only the screw holes can be seen in the X ray.

prototypes used in these studies were too large for clinical applications.

Peltoniemi et al. used SR-PGA miniscrews and PLDLA plates or titanium miniplates and screws to fix frontal bone craniotomies in lambs.^[17] During the follow-up period (4 to 104 weeks), no clinically manifested foreign body reactions or differences in consolidation were observed. Fixation with SR-PGA miniscrews resulted in thicker bone and wider connective tissue-filled bone defects than fixation with titanium devices on the contralateral (control) side. The SR-PGA screws were hydrolyzed and fragmented at 4 to 6 weeks, and were resorbed by 12 weeks. Histologically, PGA degradation was accompanied by a nonspecific foreign-body reaction and initial transient osteolysis with decreased osteoid formation around PGA screw channels, but intense compensatory osteoid formation followed after PGA resorption.

CLINICAL STUDIES

The first clinical reports on the use of resorbable plates and screws were published by Bos et al.^[18] Although the biocompatibility of bioabsorbable sutures is well-documented in the literature, implants used for osteofixation have been associated with certain complications.^[11] However, as a result of research that continued in spite of difficulties, it was possible to resolve some of the complications and regain interest and confidence in these biodegradable devices.

Orthognathic Surgery

Orthognathic surgery of the cranio-maxillofacial (CMF) skeleton is needed to rehabilitate patients with congenital or acquired abnormalities of the facial skeleton. The most common orthognathic procedures are mandibular bilateral sagittal split osteotomy (BSSO) and maxillary Le Fort I osteotomy. Fuente del Campo et al. performed maxillary osteotomies with thin SR-PLLA plates and titanium microscrews with successful outcomes.^[19] The longest follow-up time was 17 months. Apart from two cases, the fixation was stable. No complications were reported except for the exposure of one plate in one patient through the mucosa of the mouth one month postoperatively, which was treated by plate removal.

Suuronen and coworkers reported successful fixation of sagittal mandibular osteotomies with SR-PLLA screws without maxillomandibular fixation (with follow-up exceeding 10 years).^[20] Widening of screw holes during healing has been detected in nearly 25% of screw holes. This phenomenon, however, has not caused any subjective or objective signs or

symptoms. The long-term stability of these orthognathic procedures has been similar to the stability of traditional metallic devices.

Similar results were reported by Turvey and coworkers,^[21] who used SR-PLDLA plates and screws in 70 patients. The patients underwent 194 osteotomies of the maxilla and/or mandible with stabilization of each osteotomy achieved by use of self-reinforced polylactide bone plates and/or screws of size and configuration similar to those of titanium systems. They concluded that patients' acceptance of the material was good (70/74) and that stabilization was accomplished as planned in all patients. Three patients experienced problems that resulted in immediate loosening of bone screws. The remaining 67 experienced no short-term problems (6 to 24 months), and healing progressed uneventfully. In each case, acceptable occlusion and favorable aesthetic changes were noted.

Laine and coworkers recently analyzed all complications in orthognathic procedures carried out in the Department of Oral and Maxillofacial Surgery at Helsinki University Central Hospital during the past 10 years (between November 1991 and November 2001).^[22] During this period we operated on 163 patients who underwent 329 orthognathic osteotomies fixed with bioresorbable (both SR-PLLA and SR-PLDLA) devices. (See Fig. 3.) No postoperative intermaxillary fixation was used. Patients' acceptance was generally excellent and very few complications occurred during the 10-year follow-up. The complications were minor and did not affect the end results of the operations. Minor complications occurred in 14 patients (8.6%). Only one patient (0.6%) experienced a postoperative infection. The other minor complications consisted mainly of dehiscence of the wound and plate exposure, together with granulation tissue in the operation field. The remainder of the complications occurred early in the study, when large screw heads on top of bone irritated the patient and had to be removed. The newly developed devices used in the beginning of the trial led to insufficient fixation and resulted in open bite in three patients (1.8%). (The early devices are no longer used.) Based on the study by Laine et al., it can be concluded that bioresorbable devices are safe to use in orthognathic procedures, although there is a learning curve, as in the introduction of all new methods.

Trauma Surgery

In CMF trauma surgery, selection of patients for bioabsorbable devices is very important. If the patient's cooperation is not adequate (e.g., if he or she is an alcoholic or drug addict), these devices should not be used. The key is that bioabsorbable systems not be

Fig. 3 Orthognathic procedures. (A) Intraoperative view of sagittal osteotomy of the mandible fixed with SR-PLDLA miniplates and screws. The mandible has been advanced 5 mm. (B) Panoramic tomogram showing split on both sides. Because the plate and screws are not radiolucent, only the screw holes can be seen.

used in load-bearing situations; they should be limited to use in load-sharing situations, only.

Self-reinforcing PLLA lag screws have been used in the fixation of anterior mandibular fractures in 11 patients.^[23] Healing in all cases has been uneventful without postoperative maxillomandibular fixation (follow-up exceeds 4 years). Today, SR-PLDLA miniplates are mainly used for mandibular trauma surgery at Helsinki University Central Hospital. (See Fig. 4.) Yerit et al. (2002) followed 22 patients with a variety of patterns of fracture of the mandible, who underwent management with a biodegradable fixation system.^[24] After surgery, maxillomandibular fixation was applied in three cases. The follow-up period averaged 49.1 weeks. The complication rate was low in this study. Mucosal dehiscence on top of the resorbable device was present in two patients. In one of these cases, the material had to be replaced with titanium plates. Mucosal healing and consolidation of the fracture was normal in all other patients. Yerit et al. were able to conclude that self-reinforced biodegradable osteosynthesis materials provide a reliable alternative to conventional titanium plate systems.

Fig. 4 Trauma surgery. (A) Intraoperative view of anterior mandibular fracture fixed with SR-PLDLA miniplates and screws. (B) Close-up of panoramic tomogram shows good reduction of fragments (visibility not impaired by plates and screws).

Cancer Surgery

To make it possible to remove a malignant tumor from the base of the mouth or tongue, access osteotomies frequently need to be made in the mandible. For such patients, the use of bioabsorbable devices offers many benefits over conventional metallic plates and screws. Bioabsorbable devices are radiolucent and tissue equivalent; hence they do not disturb postoperative imaging or radiotherapy and do not cause scattering of radiation. Dental implants are often needed as post-surgical rehabilitation. Bioabsorbable screws can be used to fix the access osteotomy and, simultaneously, to place the dental implant. (See Fig. 5.)

Suuronen and coworkers reported on 16 access osteotomies fixed with SR-PLDLA miniplates and screws.^[25] With the exception of one access osteotomy carried out at Le Fort I level, all were mandibular swing osteotomies and all patients received postoperative radiotherapy. Follow-up for the 16 patients now exceeds one year. No problems were encountered during the operation, although postoperatively three patients developed problems with fixation and two patients experienced non-union after six weeks, one requiring splinting and one healing spontaneously. Only one patient required another operation due to the failure of fixation.

Fig. 5 Oncologic surgery. (A) Intraoperative view of anterior mandibular access osteotomy fixed with SR-PLDLA miniplates and screws. Titanium dental implants were placed simultaneously to facilitate proper rehabilitation of the masticatory system. (B) Bioresorbable plates and screws do not inhibit imaging, enabling early detection of metastasis or recurrence in the region. Only screw holes can be seen in outer cortex.

Fixation of Bone Grafts

Bone grafts are often needed in the mandible and maxilla, either to enable placement of dental implants for dental rehabilitation, or to replace lost bone. Bioabsorbable bone grafts are ideal for bone grafting. (Grafts always resorb to some extent, and metallic screws must be removed because they sit on top of the graft and disturb the patient.) Suuronen et al.^[20] used SR-PLDLA and SR-PLLA lag screws to fix conchondral (rib) grafts to replace a lost mandibular condyle in 10 patients. All recoveries were uneventful without graft displacement.

Pediatric Surgery

The second SR device to be commercially available is SR-PLGA (80/20). Ninkovic et al.^[26] reported on early experience with SR-PLGA miniplates and screws in four patients for osteofixation in cranial remodelling

operations. None of the plates broke, and sufficient fixation stability was achieved without additional support. In a recent review, Suuronen et al.^[20] concluded that the use of SR-PLGA (80/20) should be limited to pediatric use because of its PGA component and because children seem to tolerate rapid resorption better than adults. (In the growing skeleton, rapid resorption is essential to avoid growth impairment.)

CONCLUSION

The use of bioabsorbable self-reinforced plates and screws in CMF surgery is an appealing alternative to titanium devices. They do not disturb growth in the growing CMF skeleton, and hence do not require a second (removal) operation. They do not interrupt postoperative imaging, which is extremely important for early detection of possible metastasis or recurrence. The fact that SR plates and screws gradually lose their strength may even enhance ossification of the osteotomy; however, the use of these devices should be restricted to those operations wherein miniplate fixation is stable enough.

According to reports in the international literature, the plate should not be placed immediately under the incision (especially in the mandible), but should be placed low, under the nonattached gingival tissue in the mandible to enable good soft tissue coverage and blood supply for removal of resorbed polymer. This reduces the risk of dehiscence and makes the plate less palpable and less disturbing to the patient. If the plate is exposed immediately after the operation, revision and closure are necessary. The plate and screws should be carefully examined and any loose material removed to prevent future problems. Good closure of the wound is essential because the plate will not degrade properly if it is not covered by soft tissue.

A new bioresorbable fixating method has recently been introduced that uses tacks and a tackshooter instead of screws.^[27] This new device was used in 15 children who underwent various cranioplasty procedures to demonstrate its reliable application in cranial bone osteofixation. Stable, secure fixation was obtained intraoperatively, with operating time reduced 10–15% compared with earlier use of plates and screws. The use of tacks and a tackshooter reduces operating time and risk of infection and blood loss. This consequently reduces costs, and makes the tackshooter very useful in selected craniofacial cases.

Based on reports in the international literature, it can be concluded that the use of the newest biomaterials presents a learning curve, as occurs with any innovation in methods and materials. Similar to the case when titanium devices were first used, problems with biomaterials are rare and complications can be

regarded as minor. The only difference is the rare occurrence of granulation tissue, which does not require surgical treatment.

B

INTRODUCTION

Bone remodelling is the biological process whereby living bone tissue renews itself in the course of life. This article explains the details of this process, including the separate activities of osteoclasts (the bone-resorbing cells) and osteoblasts (the bone-forming cells); and discusses recent findings that explain how remodeling leads to mechanically adapted bone tissue, and the role of the mature bone cells or osteocytes in this process. A hypothesis is presented that relates osteocyte apoptosis resulting from disuse, to the loading-aligned tunnelling activity of osteoclasts. Last, the article discusses how adaptive remodelling leads to unwanted bone loss, e.g., around arthroplastic implants and after tooth extraction.

BONE TISSUE

Bone is a living connective tissue that consists of bone cells surrounded by their extracellular matrix (ECM). In all connective tissues, the ECM contains collagen, but in bone, the collagen is mineralized and is therefore hard. The combination of long collagen fibers that are pliable but resistant to stretch, and calcium-phosphate crystals that are brittle but hard, provides the unique material properties of bone ECM: stiff as well as tough, and therefore very strong. A second factor contributes to the strength of bone: the strain-adapted inner structure of bone tissue. In both trabecular bone that has a spongelike structure and in compact bone that is more or less solid, the tissue elements have a tendency to run in one of the major directions of habitual loading. This phenomenon was described by the end of the nineteenth century by Wolff,^[1] and is sometimes called Wolff's Law, or the Law of Bone Remodeling. It makes a skeletal element (a bone) much stronger for its normal tasks than when the tissue material had been evenly distributed, and is therefore an important contribution to skeletal strength. A third factor contributing to skeletal performance is the continuous renewal of tissue during life. Because bone is a living tissue, it is

able to renew itself by cellular activity by removing old, fatigued tissue and replacing it with new material. This process continues throughout the life of the individual, and is called bone remodeling.

BONE REMODELING BY BASIC MULTICELLULAR UNITS (BMUs)

Since the pioneering work of Frost,^[2] it has become generally accepted that bone tissue renews itself by means of basic multicellular units (BMUs). These are groups of bone-resorbing cells (or osteoclasts), and bone-forming cells (or osteoblasts), that act in coordinated fashion to first resorb a small area of existing bone tissue and subsequently refill the gap with new bone. This process is called bone remodeling.^[3] In trabecular bone, consisting of struts and plates, remodeling is a surface phenomenon. The osteoclasts dig a trench along the surface of the strut or plate, which is subsequently filled in by osteoblasts that produce new bone matrix. During the process of filling, some osteoblasts are entombed in the new ECM and become osteocytes. (See the article titled *Histogenesis* in this encyclopedia.) In compact bone, the osteoclasts literally eat themselves deep into the old bone. They dig a tunnel whose tip is called the cutting cone (Fig. 1). The gap made by the osteoclasts is subsequently filled in by osteoblasts, but a small channel is left open in the center of the tunnel where one or more blood vessels grow during the process of refilling (see Fig. 1). These blood vessels ensure that the osteocytes of the new bone that fills the tunnel are close enough to the circulating blood to receive nutrients and discard their waste products. The length of tunnel that is in the process of being filled by osteoblasts is called the closing cone (Fig. 1). The filled-in tunnel is called an osteon or Haversian system, and the central canal is the Haversian channel. In trabecular bone, the filled-in trench is called a (hemi-)osteon, because it resembles an osteon cut in half along its length (Fig. 2). The large pores of the spongelike trabecular bone are filled with

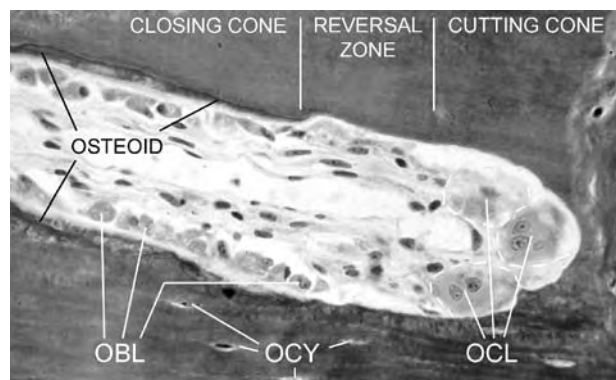

Fig. 1 Longitudinal section of cortical bone illustrating the typical histology of remodeling by a BMU. Osteoclasts (multinucleated giant cells; OCL) erode bone tissue and are followed by osteoblasts (small mononucleated cells; OBL) that refill the gap with new bone tissue. Osteocytes (OCY) are former osteoblasts embedded within the bone matrix. The spherical end of the tunnel, where osteoclasts are active, is called the cutting cone, and the zone where osteoblasts refill the tunnel is called the closing cone. In the reversal zone the bone surface is bare. In the closing cone a narrow channel—the Haversian channel—will be left open to allow space for one or two blood vessels. The filled-in resorption tunnel is the new osteon. (Figure reproduced with permission from Ref. [8].)

loose connective tissue containing many blood vessels; the osteocytes of the new bone are therefore always close to circulating blood. However, it is quite likely that new vessels will also sprout along the remodeling (hemi-)osteon, although the abundance of existing vessels makes their formation less evident than is the case in compact bone.

Because osteons and (hemi-)osteons are replacing preexisting bone tissue, they are called secondary (to distinguish them from the first bone tissue in the developing skeleton). Secondary osteons are thick-walled tubes packed together to make a thick layer of compact bone tissue, whereas (hemi-)osteons are half-tubes packed to form a trabecula, while the other half of the tube consists of loose connective tissue with blood vessels.

THE ADAPTED NATURE OF SECONDARY BONE

As already mentioned, remodeled bone is adapted to the prevailing loads of daily usage. Adaptation means two things: First, the density of the bone tissue relates to the magnitude of habitual loads; second, the osteons and (hemi-)osteons run in the direction of habitual loading. Compact or osteonal bone is found in areas where loads are concentrated; for instance, in the diaphyses of tubular bones. Because mechanical loads are transmitted mostly along the length of the diaphysial

tube, the osteons also run in parallel along the length of the tube.^[4] Trabecular bone is found in areas where the orientation of applied mechanical loads resulting from normal usage is diverse (e.g., in the spine or near the joints of long bones). Because movements involving joints are often complex, it follows that the morphology of trabecular bone around joints is also complex, and that its load-oriented structure is less obvious than in diaphysial compact bone. Recent computer simulations, however, have confirmed that the tissue elements (the (hemi-)osteons of the trabeculae) in trabecular bone are aligned in the dominant loading directions, the same as the osteons in compact bone.^[5] Bone tissue is thus able to renew itself in accordance with the magnitude and orientation of the daily mechanical loads placed upon it, as originally postulated by Wolff.^[1] The question remains how the bone cells perform this task.

STRAIN-RELATED REMODELING

BMUs literally move through preexisting bone tissue during remodeling. In order for the new (hemi-)osteon to align in the direction of strain, the resorption tunnel or trench must be dug along the direction of strain. Through their resorbing activity, therefore, osteoclasts determine not only the width of the future (hemi-)osteon, but also its orientation. The activity of the osteoblasts

Fig. 2 Histological picture of a remodeled trabecula, showing the longitudinal orientation of secondary (hemi-)osteons. Bone ECM stains pink (or gray in black-and-white reproduction). The dashed line indicates the border of a secondary (hemi-)osteon on the upper side of the trabecula. Its lamellae (indicated by arrows) are oriented along the length of the trabecula, demonstrating that resorption occurred along the longitudinal surface. The resorption trench was subsequently refilled with lamellar bone by osteoblasts. Note the osteocyte lacunae, which show up as flattened white ovals dispersed through the ECM. (Figure reproduced with permission from Ref. [6].)

that follow the group of osteoclasts at the bone resorption site determines the extent to which the defect is refilled. This osteoblastic activity is important because, in the long run, it determines the amount of bone mass. Inadequate refilling during remodelling is the cause of osteoporosis, an important threat to skeletal health in old age. Orientation, however, is determined by the osteoclastic activity, more precisely by the direction in which the team of resorbing osteoclasts moves. So how do osteoclasts know their way; how are they steered by the loading process? A recently developed theory links the very local tissue strains around a progressing BMU to the activation of osteoclasts and osteoblasts, respectively.^[6-9] This theory is based on the concept that the cells involved in mechanosensation are neither osteoclasts nor osteoblasts, but osteocytes.

OSTEOCYTES AND MECHANOSENSING
