Handbook of Food Products Manufacturing. Edited by Y. H. Hui

66.1 INTRODUCTION

Flavoring milk is changing the image of milk. Flavored milks offer choices to those consumers who are not interested in plain milk. Flavored milks are milks to which a flavor along with a sweetener are added. Flavoring milk is a way of adding value to milk.

The concept of incorporating fruit flavors in milk on a commercial basis originated in 1921 when such a beverage was prepared and sold at a Wisconsin state fair. In the mid-1930s flavored milks acquired a nutritional significance of added vitamin C when oranges and lemons were blended with milk for immediate consumption (Henderson 1971). Popularity and consumption of flavored milks has increased ever since.

Incorporation of flavors makes milk more appealing to both kids and adults. Milk is flavored using various flavors such as fruits (strawberry, orange, banana, raspberry, grape), cocoa/chocolate, vanilla, coffee, caramel, cappuccino, peanut butter, root beer, and vegetable. There has been an increase in milk and nutrient intake by offering flavored milks as part of the National School Lunch Program and School Breakfast Program (Guthrie 1977, Johnson et al., 2002, Burrington 2002).

66.2 PROCESSING OF FLAVORED MILKS

66.2.1 Aspects to be Taken in Consideration for Formulating Flavored Milk

Fluid milk is about 88% water (Henderson 1971). Most flavors are water soluble so the flavors mostly stay in solution. Fruit flavors can sometimes be a bit difficult because citric acid used in these flavors can denature milk proteins. Also, at the pH of milk the citrus flavors such as lemon and orange do not taste the same.

Chocolate milks need a stabilizer system to suspend the cocoa particles so they do not settle out over time. To stabilize/suspend the cocoa particles typically kappa II carrageenan is used at a level of 0.02–0.03%. Carrageenan reacts with milk proteins to form a shear reversible gel. Gums such as cellulose, guar gum and xanthan gum are also used, especially in milk shake products where both body and foaming are desired. When the body of full fat milk has to be mimicked in the low fat/nonfat counterparts stabilizers play an important role. Reducing sugars and carbohydrates results in lowering total solids, hence a slightly higher level of stabilizers helps to improve mouthfeel of these products (Henderson 1971).

66.2.2 Different Flavored Milks

66.2.2.1 Chocolate Milk. The chocolate flavor of chocolate milk comes from the various sources of flavorings supplied by manufacturers in the form of cocoa, natural or Dutch chocolate, chocolate liquor, or chocolate syrup.

Chocolate milk is manufactured by addition of the various dry ingredients namely stabilizer, sweetener, to the cold milk and agitation continued for about 30 min until all the powder is dissolved. This is followed by batch or high-temperature short-time (HTST) pasteurization. Temperature is higher (generally 81.1°C or 178°F) than that used for fluid milk (generally 71.7°C or 161°F) because of added sugars. After pasteurization product must be cooled to 4.4°C (40°F) or lower as soon as possible. If sodium alginate is used as a stabilizer then it should be added to warm milk. If carrageenan is used as

the stabilizer then homogenization after addition of the powder is not recommended because of the possibility of settling. Carrageenan complexes with milk proteins keeping the cocoa particles in suspension. Typically kappa carrageenan is used in chocolate milks. For a thicker or a more shake like mouth feel gums such as guar or locust bean are also added to increase viscosity. Once a processing procedure is established it should be consistently followed to create an uniform product. Cocoa source and amount should be the same for uniformity in product color and flavor (Henderson 1971).

There are certain concerns of adding chocolate to milk. The calcium in the milk is bound to the oxalic acid in the chocolate resulting in an insoluble calcium oxalate complex, making calcium unavailable for absorption. Some children are allergic to chocolate or have skin problems aggravated by it (NDC 1995).

66.2.2.2 Natural Orange Juice Flavored Milk. A typical formulation is milk 56.8%, orange juice 38%, sugar 5%, and stabilizer 0.2% w/w. Milk (4°C) is stirred while the stabilizer and sugar dry mixture are added rapidly to reduce foaming. Stabilizers such as sodium carboxymethyl cellulose or propylene glycol alginate can be used. This milk stabilized mixture is then aged at 4°C for 15 min. Cold (4°C) orange juice is added just below the surface of the milk to minimize foaming. The natural orange juice flavored milk is then preheated, homogenized, pasteurized, cooled to 4°C, and packaged.

66.2.2.3 Banana Milk. Ripe bananas are peeled and pulp is pureed in a blender. The puree is quickly added to raw milk in a ratio of 1 : 5. The mixture is immediately warmed to 38°C, homogenized at 2000 psi, heated to 80°C for 15 s, and collected in sterile containers.

Banana puree develops a slightly brown discoloration while being prepared, but pasteurization of banana milk prevents further darkening. The brown discoloration in the banana puree has been reported to be inhibited by blanching banana puree, addition of antioxidants such as citric acid, ascorbic acid and potassium metabisulfite. In the final product food grade colors have also been reported to have been used (Rehman and others 1992, Ayub and Zeb 2002).

66.2.2.4 Mango Flavored Milk. Preparation of mango pulp preserve: Ripe mangoes are washed and peeled. Pulp is extracted using a pulper having a sieve size of about 40 mesh. Obtained pulp is heated to 85°C for 3–4 min.

Three parts of milk is mixed with one part of pulp (w/w). Sweetener is also incorporated. Stabilizer such as carrageen is optional. The mixture is blended to form a homogeneous mass. The homogenous mix is thermally processed at 90°C for 30 min (Ibrahim and others 1996).

66.2.2.5 Date Milk. Preparation of date syrup: Dates with half their weights in water are cooked in a pressure cooker for half an hour. Syrup strained and squeezed through cheese cloth. This is followed by concentration of date syrup by vacuum evaporation.

Milk is sweetened with sweetener (corn syrup or non caloric sweetener) and 3–5% date syrup is incorporated. Mixture is bottled or canned and retorted/sterilized at 120°C for 30 min (Yousif and others 1996).

66.3 FLAVORED MILK WITH ADDITIVES

Flavored milks are fortified with 10 essential vitamins and minerals as in case of MoonPie®. Caffeine as much as in cola is added to flavored milks and these flavored milks are

positioned as energy drinks by Hyper Cow™ for consumers of ages 15–25, typically upper-high school to graduate school students (Anon 2004).

66.4 FLAVORED MILK BASED BEVERAGES

Swerve, a milk beverage introduced by Coca-Cola is made with nonfat milk and provides 30% of the recommended dietary intake of vitamin A, vitamin C, vitamin D, and calcium. It is available in three flavors namely Vanana (combination of vanilla and banana), blooo (mix of blueberry and strawberry), and chocolate.

Swerve contains more than 50% milk and therefore carries the real seal, use of which is administered by the American Dairy Association. This product is available in 12 oz. cans and product is retort processed. Swerve is sweetened with sucralose and high fructose corn syrup which keeps calories low, to about 150 per can.

Raging cow, a milk beverage introduced by Dr Pepper/Seven Up Inc. (DPSU). It is available in five flavors namely, Chocolate Intensity, Pina Colada Chaos, Caramel Craze, Berry Mixed Up, and Jamocha Frenzy. Each of these flavored milk beverages contain four vitamins and minerals (Dahm 2004).

66.5 FLAVORED CARBONATED MILK BEVERAGES

The purpose of carbonation is to impart a unique sparkle or effervescence, enhance the flavor, mouthfeel and provide a refreshing aftertaste (Vinderola et al., 2000). Carbonation of milk also extends its shelf-life up to 8 weeks. Blueberry, strawberry, raspberry, peach, rootbeer, chocolate, and bubblegum flavored milks have been reported to be carbonated.

Typically the sweetener and stabilizer are added to the raw milk and pasteurized. The mix is then cooled to about 22°C and flavored. This complete mix is further cooled to 2°C for carbonation. Carbonation is conducted using a carbonator. Product is carbonated in the CO_2 pressure range of 0.35–1.5 kg/cm^2 (5–22 psi). Carbonated flavored milks are packaged in the CO_2 pressure range of 0.35–1.05 kg/cm^2 (5–15 psi) and refrigerated.

Carbonated blends of fruit juice and milk are produced in two flavors namely strange strawberry and odd orange, contain no added sugars and are fortified with calcium and marketed under the name of Freekee Soda by Britvic Soft Drinks. Other examples of carbonated beverages are e-Moo and Refreshing Power Milk (RPM). RPM comes in flavors such as vanilla cappuccino, Brazilian chocolate, and chocolate raspberry (Anon 2003a,b,c: 2004).

66.6 FLAVORED MILK POWDERS

The advantage of having flavored milk in powdered form is increased shelf and easy in bulk transportation of the product. Flavored milk powders are prepared using either spray drying or freeze drying.

66.6.1 Manufacture of Powdered Flavored Milks

66.6.1.1 Mango Milk Powder. A way to manufacture mango milk powder is as follows. Ingredients are taken in the following proportions. Fifty-two percent concentrated milk (30% solids), 14% cream (40% fat), 36% fruit pulp, 10% sugar, 0.4% stabilizer. The concentrated milk, cream and sugar are well mixed and preheated to 50°C followed by the addition of

sodium alginate and glycerol monostearate in a 1 : 1 ratio at rate of 1% total solids in mix. The heated mix is filtered, homogenized, pasteurized, and cooled. To this mix mango pulp is added and mixed. This mango milk mix is filtered and dried to obtain mango milk powder (Sharma and others 1974; Berry 2003; Dwyer 2003).

66.6.1.2 Banana Milk Shake Powder. One manner in which banana milk shake powder is manufactured is as follows. Ripe bananas are peeled, cut, blended with 1–1.5% distilled water. The puree is heated to 90°C for 10 min and cooled to 40°C. Pasteurized milk is condensed using a vacuum evaporator to 36% total solids and cooled to 40°C. A stabilizer (carboxy methyl cellulose) is dissolved in hot water at 60°C and added to this condensed cooled milk at the rate of 0.015% (w/w total solids). The stabilized condensed milk is then homogenized and mixed with the banana puree, homogenized again and spray dried. Ground sugar may be added to the spray dried banana milk shake powder (Laxminarayanana and others 1997; Paoletti and others 1992).

66.7 LOW CARBOHYDRATE FLAVORED MILKS

The recent advent of the Atkins low carbohydrate diet has sparked an interest among beverage manufacturers to lower their drinks in the carbohydrate contents. Reduced fat chocolate milk with 90% fewer carbohydrates than regular chocolate milk has been introduced by HP Hood under the "Carb Countdown" brand name. The Hood Carb Countdown dairy beverages are approved as a part of the Atkins Nutritional Approach™ eating plan, which is a low carbohydrate diet. An example of a lactose free milk is Refreshing Power Milk of Mac Farms.

Ultrafiltration is a membrane filtration technique which is characterized as having a molecular weight cut-off from 3000 to 100,000, the most common being 10,000 MW. Ultrafiltration rejects all the large milk components namely proteins, fats allowing the lactose, minerals, and water to pass through the membrane. It is here that with the addition of water or diafiltration even more lactose from the milk can be washed off. Use of ultrafiltration increases the percentage of protein in fluid milk as a method of fortifying proteins in fluid milk (Twiford 2004). This allows the flavor and mouth feel enhancing properties of milk proteins to be achieved naturally as opposed to adding nonfat dry milk which often leaves a cooked flavor in the fluid milk as well as increased sweetness from the excess lactose in NFDM. For the preparation of "low carb" or "carb free" dairy beverages ultrafiltration or a combination of ultrafiltration and diafiltration is used (Yau and others 1989; Lederer and others 1991).

66.8 FLAVORED MILKS AND NUTRITION

Each brand of flavored milk has its own formulation. The nutrient contribution of flavored milks are almost similar to their unflavored milk counterparts. Flavored milks are typically higher in carbohydrate content and hence provide more energy.

66.9 MYTHS ABOUT FLAVORED MILKS

There are several myths about flavored milks namely; nutritionally flavored milks are not similar to unflavored milks, flavored milks have a high sugar content, too much caffeine is

present in chocolate milk, flavored milks are not good for teeth. Putting the myths of flavored milks into perspective, both flavored and unflavored milks have about the same type and amount of nutrients such as protein, calcium, magnesium, phosphorous, riboflavin, vitamin A, vitamin B_{12}, as well as several other essential nutrients. Chocolate is the most popular flavored milk, has lesser sugar per 8 oz. serving than cola sodas. The amount of caffeine in chocolate milks is about the same as in decaffeinated drinks. High sugar foods not good for the teeth are particularly those that stick to the teeth. Being fluid, flavored milk are in contact with teeth for a short time, moreover calcium and phosphorous in flavored milks protect the teeth from decay (NDC 1995).

66.10 PACKAGING FLAVORED MILKS

Packaging involves materials, style, shape, special features, and graphics. Packaging influences purchase decisions, especially first-time trials.

What sets Raging Cow apart from other flavored milks and dairy drinks is the fact that it is the first milk beverage to be bottled on the recently FDA accepted commercial low acid aseptic plastic bottles. Raging Cow is unique with its closure, too. The flip top can be opened and closed with one hand, does not require the removal of the closure to remove the introduction seal and opens a full 220° to prevent the closure from touching the face of the consumer (Anon 2003a,b,c; 2004).

Milk Chugs™ are plastic, pints, quarts, 8 oz. multipack bottles. The highlight of this package is that it is resealable, has a flared cap that is easy to grip, and is a round, tapered, easy to hold bottle, which resembles the shape and size of old fashioned milk bottles. It is designed for portability, to suit the on-the-go consumer. It fits in the car cup holders, bags, coolers, and lunch sacks. Oberweis Dairy, North Aurora, IL, launched milk and coffee blends in single serve 12 oz. polyethylene terephthalate (PET) bottles (Anon 2003a,b,c; 2004).

Tetra Pak's LFA-20 filler for high density polyethylene (HDPE) bottles uses hydrogen peroxide gas to achieve package sterilization, unlike fillers for paperboard composite packages. LFA-20 filler is used to package Raging Cow milk drink and Slammers, line of flavored milk drinks (Anon 2003a,b,c; 2004; Higgins 2004).

Chocolate milk in aluminum cans competes in soft drink vending machines. The National Milk brand of chocolate milk are packaged in aluminum cans. The body of the can is first filled with chocolate-flavored milk. Twelve ounce cans are filled with only 11 oz. of flavored milk because retorting processing requires extra headspace. Containers are pressurized with liquid nitrogen gas and an aluminum end is seamed onto the open end of the can, sealing the can. This milk is then sterilized by the retorting process, which is essentially heating the contents of the can to a specified temperature for a predetermined time. The retorting temperature is typically 126.7°C (260°F). The goal of retort processing is to obtain commercial sterilization through the application of heat. This renders the product shelf-stable for an extended shelf-life. In this case, the chocolate milk has an ambient shelf-life of 12 months, which is about 11 months longer than traditionally pasteurized chocolate milk. Unlike traditional soft drink cans, which use color printing directly on the cans, the National Milk cans are unprinted. After retorting, roll-feed labels are cut and wrapped around the can. Cans convey through a heat tunnel, where labels shrink to fit the cans' counters. The image of a milkman holding an old fashioned bottle of fresh milk, is intended to communicate the product's nutritional value.

Byrne Dairy wanted to target the younger market. On their paperboard container they introduced a company mascot – a likeable, friendly-faced cow named "Byrnsie™" which was an instant hit with kids. NutraBrand Innovations Devon, PA introduced MegaMilk™ which is fat free milk that comes in three flavors namely, chocolate, strawberry, and vanilla – and is sold in pint-sized cartons with superheroes such as Batman and Superman on the package. Slammers flavored milks has various cartoon characters such as Tweety, Bugs Bunny, and superheroes such as Spiderman and Wolverine in action on their label. The label Swerve brand of flavored milks have a figure of a grinning cow wearing glasses, which also appeals to kids (Anon 2003a,b,c; 2004).

Extended shelf-life packaging is achieved primarily through filling in sanitary environments with packaging that has been sterilized. Hydrogen peroxide is the most commonly used sterilizing agent and packaging material is generally rinsed or blown dry with hepafiltrated air after sterilization. In some cases, plastic packaging can be blow molded with a sealed top using hepafiltrated air. The top is then trimmed in the filler just before filling. Both paperboard and plastic packaging materials can be manufactured with barrier layers that block light penetration and oxygen migration. This can be particularly beneficial for milk as milk tends to take on off-flavors when it suffers prolonged exposure to light or oxygen (Higgins 2004).

Multipack packaging is particularly suited to warehouse and club stores which are characterized by less frequent visits and larger consumer purchases. For fluid flavored milks this means everything from cases that hold two or more gallons, to cartons containing six, 12, or 24 single serve bottles (Anon 2004).

66.11 FUTURE OF FLAVORED MILKS

It would not be surprising in the future to see dairy-based beverages containing phytosterols and more of such health beneficial components incorporated.

67.1 INTRODUCTION/BACKGROUND

While communities in the Middle East and Asia adopted fermented milks into their diets almost as soon as man began to domesticate animals, the inhabitants of Europe

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

developed a tradition of cheesemaking. Indeed, around 1000 AD, a number of varieties of cheese had been cited by early writers, and this domination of cheese over other dairy fermentations largely persisted until the early part of the 20th century (Robinson and Wilbey 1998). Some fermented milks did, of course, find favor with local populations, and buttermilk was one product that became popular in Scandinavia and, through immigration, in North America as well. However, it was not until 1910 when Metchnikoff published his work about the health promoting properties of yogurt that small sections of the general public began to take a serious interest in fermented milks (Räsić and Kurmann 1983; Tamime 2002b). In North America, acidophilus milk was marketed as beneficial health food; while in Russia, the traditional drinks of kefir and koumiss received more serious attention from the medical authorities (Alm 1991; Koroleva 1991).

However, it was not until the mid-1950s that various forms of sweetened and fruit-flavored yogurt went first on sale in urban areas in Switzerland. As figures of production rose (see Section 67.3), so manufacturers retained interest in yogurt by introducing an ever-wider range of fruit flavors. Around the 1990s, signs of the market saturation were beginning to appear, even though the per capita consumption in many Western countries remained comparatively low. The solution was provided by a resurgence of interest in "health-promoting" properties of cultures like *Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus rhamnosus*, *Lactobacillus reuteri*, *Lactobacillus johnsonii*, and *Lactobacillus gasseri* along with various species of *Bifidobacterium*. In addition, it was noted that these probiotic cultures are much less acid tolerant, and even in the presence of *Streptococcus thermophilus*, the acidity of "probiotic or bio-yogurts" rarely exceeds 1 g/100 mL. The resultant products are, therefore, more mild in flavor and, as a consequence, a whole new group of consumers emerged who, irrespective of their views about the value of probiotic cultures, enjoyed the sensory properties of this new range of fermented milks.

Nevertheless, the retail value of the yogurt market in the United Kingdom was around £814 million (Anon 2003a), in the United States was US $2396 million (Jelen and others 2003), and such figures are common place around the world.

67.2 CLASSIFICATION AND DIVERSITY OF PRODUCTS

The "traditional" lactic acid bacteria used in fermented milks belong to the genera of *Lactococcus*, *Leuconostoc*, *Streptococcus*, and *Lactobacillus*; the former two genera are mesophilic, whilst the latter types are thermophilic (Campbell-Platt 1987; Kurmann and others 1992). Examples of probiotic microorganisms are *Lactobacillus* spp., *Pediococcus acidilactici*, *Bifidobacterium* spp., *Enterococcus* spp., and *Saccharomyces boulardii*. Many yeasts species have been identified in kefir grains from different countries, and for more details refer to the review by Tamime and Marshall (1997); however, only one mold (i.e., *Geotrichum candidum*) is used in viili production.

Nevertheless, taking into account the flora that dominate in these products, Robinson and Tamime (1990) classified fermented milks based on the main metabolites of the starter cultures (e.g., type of organic acid and carbonyl compounds produced, presence of carbon dioxide in the gel and/or production of ethanol), and Table 67.1 illustrates how some products fall within such a scheme of classification.

TABLE 67.1 A Scheme of Classification of Fermented Milk Products.

Type of Fermentation	Example of Products	Microorganisms
Lactic		
Mesophilic-type	Buttermilk	*Lactococcus* spp. and *Leuconostoc* spp.
	Tätmjölk	*Lactococcus* spp. including ropy strains
	Dickmilch	Similar to buttermilk + yeast
Thermophilic-type	Yogurt, zabadi	*Lactobacillus delbreuckii* subsp. *bulgaricus* + *Streptococcus thermophilus*
	Bulgarian buttermilk	*Lb. delbreuckii* subsp. *bulgaricus* (on some occasions *S. thermophilus* or cream culture may be present)
Probiotic-type	ABT, Philus	*Lactobacillus acidophilus* + *Bifidobacterium lactis, animalis* or *bifidum* + *S. thermophilus*
	ACT4	Similar to ABT + *Lactobacillus casei*
	Actimel	Yogurt + *Lb. casei* (strain Imunitass)
	Gaio	*S. thermophilus* + *Enterococcus faecium*
	BRA	*Bifidobacterium infantis* + *Lactobacillus reuteri* + *Lb. acidophilus*
	Yakult	*Lactobacillus casei* (strain Shirota)
	Aktifit	Similar to ABT + *Lactobacillus rhamnosus* GG
Yeast-lactic	Kefir	Many LAB[a] + lactose-fermenting yeasts + *Acetobacter aceti*
	Koumiss	*Lb. delbreuckii* subsp. *bulgaricus* + *Lactococcus* spp. + yeasts + *A. aceti*
Mold-lactic	Viili	Similar to buttermilk + *Geotrichum candidum*

[a]LAB = lactic acid bacteria.

67.3 PATTERNS OF PRODUCTION

There are no data available worldwide in the dairy industry to indicate the true global production of every type of fermented milk produced each year in any one country. Tables 67.2 and 67.3 show annual production figures of these products in some selected countries, and the overall pattern of production over the past few decades is steadily increasing. As mentioned earlier, the popularity of fermented milks in many countries may be due, in part, to tradition; especially in countries of the Balkans, East European countries, and the Middle East, the incorporation of fruit in yogurt and/or the health promoting properties associated with "nontraditional" microorganisms. Nevertheless, the principles underlying the various aspects of manufacture have altered little with time, and an understanding of these basic tenets is essential for efficient control at plant level.

67.4 MANUFACTURE OF FERMENTED MILKS

As mentioned elsewhere, there are now numerous types of fermented milk manufactured in different parts of the world that could be classified as gel/liquid, concentrated/strained, frozen, or dried. Recent publications dealing with the major types of yogurt and related products include those by Tamime and Marshall (1997), Tamime and Robinson (1999), Tamime and others (2001), Robinson and others (2002), Jaros and Rohm (2003) and Anon. (2003b).

The quality of all fermented products is governed by the compositional and microbiological qualities of the raw milk, added ingredients, processing of the milk base and handling the coagulum after the fermentation stage. The main difference of set- and stirred-type products is the nature of the gel structure; however, in the former type, the processed milk is fermented in the retail container, whilst the stirred-type is fermented in bulk in large tanks. Nevertheless, the manufacturing stages of all fermented milk products are broadly similar, and the process parameters of these operations have been detailed by Tamime and others (2001) and Anon. (2003b), and in the present context, details of the manufacturing stages of some industrialized fermented milk products are discussed below.

67.4.1 Fermented Milks with Lactic Starter Cultures

These fermented milks are the most popular types in the dairy industry worldwide (see Table 67.1), and some examples are as follows.

67.4.1.1 The Use of Mesophilic Strains. Blends of the microflora of the genera *Lactococcus*, *Leuconostoc*, and *Pediococcus* are commonly used during the manufacture of products denoted as "mesophilic" lactic acid fermentations, and this term is used for strains whose growth optima is between 20°C and 30°C.

Buttermilk. At present, traditional or natural buttermilk is not commonly manufactured in large factories, as it is the by-product of butter making after churning ripened or cultured cream. However, the industrialized product is currently known as "cultured" buttermilk. This fermented milk is made from skimmed milk that has not been fortified and heated to ~90°C for up to 20 s, cooled to 60°C, and homogenized at 18–20 MPa, cooled and fermented at 20°C with a mixture of mesophilic lactic acid bacteria known as DL culture (see Table 67.1). After reaching the desired acidity, the gel is thoroughly stirred, homogenized at 5–10 MPa pressure and 20°C, cooled to 4°C, and packaged. The primary objective of postfermentation homogenization of the gel is to smooth the product without any lumps (Tamime and others 2001). Furthermore, deaeration of the milk before the heat treatment stage is highly recommended during the manufacture of cultured buttermilk and closely related products because defects such as lumpiness and granules in the gel will be minimized.

In some countries, for example the United States, the total solids (TS) content of buttermilk may be fortified up to 11.4 g/100 g and the fat content may range between 0.25 and 1.9 g/100 g. In Poland, fortification of the milk base of buttermilk is practiced, while in Scotland buttermilk may have 13.33 g/100 g TS and 0.2 g/100 g fat (Muir and others 1999; Tamime and others 2001).

Some advances in the technology of cultured buttermilk may include progress in different scientific fields, and the following papers are recommended for further reading (Klaver and others 1992; de Vos 1993; Butler and McNulty 1995; Heiler and Schieberle 1996, 1997a,b; Roushdy and others 1997; Tamime and Marshall 1997; Butler and O'Donnell 1999; Ervol'der and others 1999; Tuitemwong and others 2001; Rodas and others 2002).

Scandinavian Sour Milk Products. In Norway, Sweden and neighboring countries, traditional buttermilks that are slimy or ropy are widely produced and herbs or grasses are added to the milk (i.e., by rubbing the interior of the milk pails) to produce thick fermented

milks. The products are known as tätmjölk, täetmjölk, filmjölk, tåttfil, långjölk, and filbunk, and the fermentation relies on the indigenous undefined mesophilic microflora present in the milk. At present, mixed cultures of *Lactococcus* spp., including the ropy variants, is used to manufacture these products in large factories in a manner similar to cultured buttermilk. However, filbunk is made from whole milk and consumed immediately. In some old scientific publications, the starter culture used was known as *Bacterium laticus longi* and, at present, some scientists have suggested the name *Lactococcus lactis* biovar *longi* as a variant strain of *Lactococcus* spp. capable of producing exopolysaccharides (EPS) (Tamime and Marshall 1997).

In the commercial production of filmjölk, whole milk is standardized (i.e., fat content ranging from 0.5 to 3 g/100 g), preheated to 70°C, homogenized at 17.5–20 MPa, deaerated, heated to 90–95°C for 3–6 min in an external holding tube section of the plate heat exchanger, and cooled to 20°C. The starter culture is composed of a mixture of *Lc. lactis* subsp. *lactis*, *Lc. lactis* subsp. *cremoris* (i.e., the acid producer), *Lc. lactis* biovar *diacetylactis*, and *Leu. mesenteroides* subsp. *cremoris* (i.e., flavor and aroma producer). The milk is fermented for ~20 h at 20°C (titratable acidity ~0.9 g/100 mL), agitated, cooled and finally packaged (Anon. 1987).

Ymer. This is a Danish concentrated fermented milk and may contain (g/100 g) solids-not-fat (SNF) 11 including the protein 5–6 and fat 3.5. The starter culture used is similar to buttermilk, and a similar product, lactofil, is made in Sweden.

Currently in Denmark, the ultrafiltration (UF) process is used to produce all the ymer commercially. Skimmed milk or possibly standardized milk is heated, UF at 50°C (i.e., SNF 11 g/ 100 g), homogenized at 23 MPa and 65°C, heated to 90°C for 5 min and fermented with a buttermilk starter culture until pH 4.5. After heavy stirring, blending with cream (36 g fat/100 g), cooling in a plate heat exchanger to 12°C, the product is packaged and transferred to a cold store (Bøejgaard, personal communication). Alternatively, ymer could be made using nozzle separators similar to quarg, concentrated yogurt or skyr (Tamime and Marshall 1997; Tamime and Robinson 1999; Tamime and others 2001; Figs 67.1 and 67.3).

Cultured Cream. This fermented milk product has a pleasant acidic taste, "buttery" aroma and nutty meat-like flavor (Tamime and Marshall 1997). The manufacturing stages can involve standardization of cream to fat content (low-fat cream to 10–12 g/100 g or high-fat cream to 20–30/100 g), preheating to 70°C, homogenizing at 15–20 MPa (low-fat cream) or 10–12 MPa (high-fat cream), heating to 90°C for 5 min, cooling to 20°C, inoculation with mixed starter cultures similar to those used for filmjölk making, and fermentation for 18–20 h to an acidity of 0.8 g/100 mL (Tamime and Marshall 1997; Folkenberg and Skriver 2001; Anon. 2003b). After fermentation, the cultured cream is cooled quickly and packaged. However, a slight reduction in viscosity will occur due to mechanical handling of the product (i.e., cooling, pumping, and packaging), and for this reason some manufacturers produce a set-type product or employing the addition of stabilizers (optional) (Lee and White 1993).

Optional processes in cultured cream technology may include: (1) the addition of citric acid to the cream before processing to enhance the metabolic activity of the starter culture, (2) postfermentation heat treatment and followed by homogenization and hot packaging; a process similar to the manufacture of cream cheese, (3) the use of a probiotic microflora with the starter culture (Tamime and Marshall 1997), and (4) a reduction in syneresis of

cultured cream was achieved using EPS microfloras and *S. thermophilus* with the mesophilic starter culture (Adapa and Schmidt 1998).

67.4.1.2 The Use of Thermophilic Strains. The majority of fermented milks consumed in Europe and North America are manufactured with species of bacteria with growth optima of 35–45°C, and this characteristic derives from the fact that the species in question are either of intestinal origin, e.g., *Lb. acidophilus* or *Bif. bifidum*, or evolved in the Middle East where the ambient temperature in the summer is often well in excess of 35°C, for example, *Lactobacillus delbreuckii* subsp. *bulgaricus* and *S. thermophilus*. However, beyond sharing certain morphological similarities and a tolerance of temperatures much higher than those associated with mesophilic strains, the two groups differ quite markedly, especially with respect their behavior in milk. Consequently, the role of the two groups in the manufacture of retail products is best considered separately.

Yogurt. The continued use of *Lb. delbreuckii* subsp. *bulgaricus* and *S. thermophilus* for the manufacture of yogurt was, at least initially, historical in origin, but there are good reasons for continuing with the tradition, for when growing in milk, the two organisms interact synergistically. This interaction depends upon two main facts. First, *S. thermophilus* grows more rapidly than *Lb. delbreuckii* subsp. *bulgaricus* in milk, and ferments lactose homofermentatively to give L(+) lactic acid as the principal product. Carbon dioxide is also liberated by the breakdown of urea in the milk by urease and, usually, formic acid (up to 40 μg/mL). All three metabolites stimulate the growth of *Lb. delbreuckii* subsp. *bulgaricus*. Second, Although some free amino acids occur naturally in milk or are released during the heat treatment, the level of glutamic acid, histidine, cysteine, methionine, valine, or leucine, for example, are not present at levels sufficient to support extensive growth of *S. thermophilus*. However, *Lb. delbreuckii* subsp. *bulgaricus* can hydrolyze casein – especially β-casein – by means of a wall-bound proteinase to release polypeptides and, as *S. thermophilus* can readily hydrolyze these peptides, the free amino acids that are essential for further development of both species become available.

The practical result of this synergy is that both species grow rapidly and actively metabolize sufficient lactose to lactic acid to complete the fermentation of milk to yogurt within 3–4 h using an active bulk starter culture – one species alone might take 12–16 h to produce the same level of acidity. In addition, metabolites liberated by the two species give yogurt a flavor that is distinctly different from any other fermented milk. Acetaldehyde levels up to 40 mg/kg are the major component of the flavor profile (Marshall and Tamime 1997). Some strains of the two species can also produce EPS material, such as glucans, or polymers involving glucose, galactose, and rhamnose as the constituent sugars (Sikkema and Oba 1998; Laws and Marshall 2001; Laws and others 2001). The presence of these metabolites enhances considerably the viscosity/consumer appeal of the retail yogurt.

Bovine milk is usually the base material for making yogurt in the Western world, although ovine, caprine, or buffalo milks can also be employed. The fat content of bovine milk tends, depending on the breed of cow, diet, and stage of lactation, to be in the range of 3.0–4.5 g/100 g, and this value has to be adjusted according to consumer taste and/or market demand; the fat content of retail yogurt can range from 0.1 to 4.5 g/100 g. However, the critical feature of any milk is the level of SNF which, in bovine milk varies from 8.5 to 9.0 g/100 g according to the season of the year, with

around 4.5 g/100 g being lactose and 3.3 g/100 g being protein (2.6 g/100 g casein and 0.7 g/100 g whey proteins); these proteins, together with minerals like calcium and phosphorous, give rise to the basic gel structure of the product.

Today, various levels of SNF (g/100 g) are sought by manufacturers but, in general, the recognised categories are: drinking yogurt 11, cheap/cooking yogurt 12, standard base for stirred yogurt 13–14 or top-of-the range, natural set yogurt 17–18.

On an industrial scale, this elevation of the SNF can be achieved by using single-stage evaporator (EV) or UF at 70°C and 50°C, respectively. Both processes remove water and, hence, raise the levels of both residual fat – assuming that prior separation took place – and SNF in the milk base, but UF does allow some losses of lactose and minerals (Grandison and Glover 1994). In terms of product quality, either process is acceptable and, while the final choice may depend on the cost and/or availability of process plant, some data suggest that EV gives rise to a smoother coagulum, whilst the UF produces a firmer yogurt (Lankes and others 1998). The alternative route is to add skimmed milk powder to the liquid milk at ~40°C, and systems of hoppers and high speed blenders (e.g., some units operate completely under vacuum and deaeration of the reconstituted milk is not required) can be employed to ensure full and rapid incorporation of the milk powder.

Once the desired level of SNF has been achieved the milk will be usually be homogenized at 70°C. Heat treatment follows, and at temperatures well above normal pasteurization of market milk. One of two alternative systems is usually employed, and while one involves passing the milk base through a plate heat exchanger with a holding-tube of sufficient capacity to raise the temperature to 90–110°C for up to 5 min, the other system necessitates heating the milk in a process vessel to 80–85°C with a holding time of 30 min. The former system is the treatment of choice for large-scale operations. This heating over an extended period of time alters the physicochemical properties of the caseins and denatures the whey proteins and, as a result, β-lactoglobulin becomes attached to the κ-casein, so improving the texture (set yogurt) or viscosity (stirred yogurt) of the final product. Other essential actions of the heating stage are: (1) a partial breakdown of the whey proteins to amino acids that stimulate the activity of the starter culture; (2) an expulsion of oxygen from the milk that is beneficial for the growth of the micro-aerophilic starter bacteria; and (3) a reduction in the indigenous microflora in the milk that might otherwise compete against the added lactic acid bacteria.

After the heat-treatment stage, the milk will be cooled to 42–43°C ready for the addition of the starter culture consisting of a 50 : 50 mixture of *Lb. delbrueckii* subsp. *bulgaricus* and *S. thermophilus*. In general, the milk will be cooled in a plate heat exchanger and transferred at the desired temperature to an insulated fermentation vessel of 5–10,000 L capacity, but smaller dairies may carryout the fermentation in same vessel previously employed to heat-treat the milk (i.e., batch process). How the culture is added to the milk will depend upon its physical form, that is, a liquid culture prepared in the diary (anticipated addition rate of 20 mL/L of process milk), or a concentrated freeze-dried or frozen purchased for direct inoculation into the processed milk (Tamime 2002a; Anon. 2003b).

Once the milk has been inoculated, it will follow one of the two routes illustrated in Figure 67.1 involving incubation chambers or fermentation tanks. In the case of set yogurt, the retail cartons are "palletized" and transferred to a special tunnel. The tunnel is divided into two sections and, while warm air at 42°C is blown through the first part, the second section acts as a "cooler.") The pallets of yogurt cartons move through the

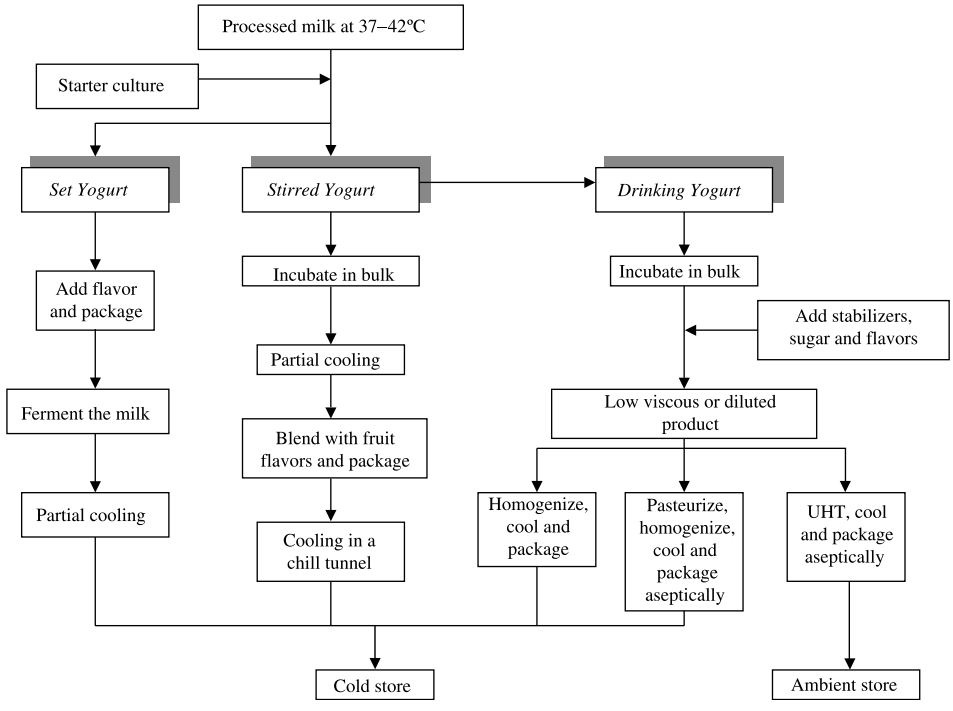

Figure 67.1 *Flow chart showing the processing stages of set, stirred and drinking yogurts. Adapted from Tamime and Robinson (1999) and Anon. (2003b).*

tunnel on a conveyor belt and, although the warm coagulum is in motion during the fermentation period, minimum structural damage is achieved by fitting smooth rollers.

During the manufacture of stirred yogurt, the milk is fermented in bulk in special incubation tanks (Tamime and Greig 1979; Tamime and Robinson 1999). There are two main types of tank in commercial use, namely insulated fermentation tanks which are used only as "incubators," and multipurpose tanks, that is, jacketed tanks that are used for all stages of yogurt production.

As the fermentation begins, the population of *S. thermophilus* develops rapidly (Robinson 2000). Over the next 2 h, however, the synergistic influence of the streptococci encourages more rapid growth and metabolism in *Lb. delbrueckii* subsp. *bulgaricus* and, after 4 h, the populations of each starter organism may well exceed 2.0×10^7 cfu/mL. The other result of this microbial activity is that the acidity of the milk will have risen to around 1.0–1.2 g/100 mL lactic acid (around pH 4.2–4.3).

At this acidity – which is probably the maximum level acceptable to consumers of stirred fruit yogurt in the West, the milk proteins will have coagulated to form a firm gel (Lucey and others 2000). Further acidification may cause the protein gel to shrink and expel whey to the extent that it can become a definite fault in set yogurts.

Final processing, for example, for set yogurt fermented in retail cartons, cooling is usually achieved by blowing cold air through the incubation room, but it is important that the rate of cooling can affect the structure of the coagulum. Excessive chilling rates can lead to whey separation due to contraction of the protein filaments, which, in

turn, affects their hydrophilic properties (Rasic and Kurmann 1978). However, a typical cooling rate of set yogurt using a continuous cooling tunnel is as follows: (1) temperature drop to 35°C should be reached within 30 min, (2) a further drop in temperature to 18–20°C in another 30–40 min, and (3) final cooling to <5°C takes place in the refrigerated cold store (Anon. 2003b).

Cooling of the base for stirred yogurt requires the circulation of chilled water (2°C) through the jacket (i.e., in-tank cooling system) of the vessel, or pumping the warm yogurt (42°C) through a plate or tubular cooler to cool the yogurt base to 20–25°C before mixing it with fruit/flavors and packaging. For details of the different packaging systems available, for example, cup fillers, form-fill-seal units and carton fillers refer to the publications by Robinson and Tamime (1993) and Tamime and Robinson (1999). Final cooling to 5°C takes place in a chill tunnel (i.e., quick cooling) and/or refrigerated cold store. However, when using a chill tunnel, the temperature drop of the packaged and palletised yogurt cups is from 20°C to <4°C in few minutes (Tamime and others 2001).

Bulgarian Buttermilk. This product is mainly produced in Bulgaria, and the manufacturing stages are similar to yogurt. Unlike the more popular cultured buttermilks fermented with mesophilic cultures, Bulgarian buttermilk is produced by *Lb. delbrueckii* subsp. *bulgaricus* acting alone (Tamime and Marshall 1997). Pasteurized whole milk provides the substrate for the fermentation, and incubation at 40–42°C for 12–16 h is employed to achieve the desired level of acidity. It is reported (Tamime and Marshall 1997) that the product has a flavor reminiscent of yogurt, that is, a flavor dominated by acetaldehyde. However, on some occasions *S. thermophilus* or a cream culture could be added to *Lb. delbrueckii* subsp. *bulgaricus* (Robinson and others 2002).

Drinking Yogurt. This product is really a stirred yogurt with low viscosity (i.e., ~11 g/100 g) and it is flavored with fruit juices, synthetic flavors, coloring compounds, and in some instances stabilizers are added to increase the viscosity of low solids fermentate. Traditionally, in some countries a whole- or low-fat fermented milk is diluted with either water, cheese whey, or whey from the manufacture of concentrated yogurt (see subsequent section), and the mixture is homogenized to improve the stability of the milk solids content in the aqueous phase followed by heat treatment to extend the shelf-life of the product.

Three different types of commercially produced drinking yogurt may be marketed, and these are illustrated in Figure 67.1 (Robinson and others 2002; Anon. 2003b). In brief, the fermented milk is processed as follows: (1) short shelf-life product, for example, 2–3 weeks at refrigerated temperature – the fermentate is homogenized, cooled, and packaged; (2) medium/extended shelf-life product, 1–2 months at refrigerated temperature – the fermentate is heated, homogenized, cooled, and aseptically packaged; and (3) long shelf-life product, for example, several months at room temperature – similar to the process described in (2), but the fermentate is ultraheat treated (UHT).

Concentrated Yogurt. This type of concentrated product (e.g., labneh, laban zeer, and mastou in the Arab countries, tzatziki in Greece, or Greek-style in the United Kingdom is manufactured from plain/natural, stirred-type yogurt, and the synonyms for closely related products that are produced in many countries have been reviewed recently by Tamime and Robinson (1999) and Robinson and others (2002). For example, ymer and chakka/shrikhand (in Denmark and India, respectively) are derived from milk fermented with a mesophilic starter culture, while the microflora of skyr (in Iceland) consists of a

yogurt starter culture, *Lactobacillus helveticus* and a lactose-fermenting yeast (for further details refer to section 67.4.2.2, and Puhan and others 1994).

Traditionally, most of these concentrated products were manufactured using the cloth bag method, which will not be reviewed, as it is not widely used in Europe and North America. At present, the traditional process has been mechanized using one of the following techniques, that is, nozzle separator, membrane filtration, or product formulation. The latter method will not be reviewed as the milk (i.e., 24–26 g/100 g total solids containing ~10 g fat/100 g) is handled and processed in a similar way to that used for the production of set-type yogurt.

Two systems, that is, mechanical separators (also known as quarg or nozzle separators) and UF, are available to manufacture concentrated or strained yogurt; these processes are similar to those used for the production of quarg. Figure 67.2 illustrates the manufacturing stages of concentrated yogurt where two options are available for production. In either process the fermented skimmed milk is stirred vigorously, thermized at 57°C for 1–2 min (Tamime and others 2001) or at 65°C for 30–300 s (Bøejgaard, personal communication), passed through a duplex filter to remove any large clots, cooled to 40–45°C, concentrated to 15–18 g solids/100 g, partially cooled, standardized with cream or blended with fruit (optional) and, finally packaged. However, in the second option (i.e., extended

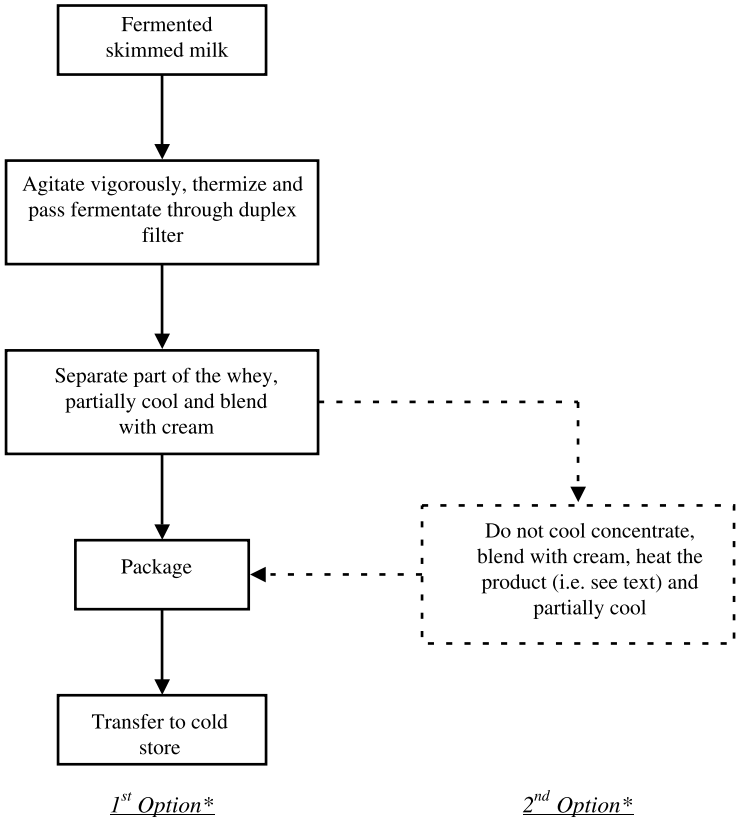

Figure 67.2 *Flow chart for the manufacture of strained/concentrated yogurt. Refer to text for more details.*

shelf-life concentrated yogurt), the fat standardized product is blended and vigorously mixed with a suitable stabilizer (optional) in the buffer tank, heated to 70°C, partially cooled, packaged, and finally transferred to the cold store.

The process control of the nozzle separator is governed by: (1) model type and size of the separator, (2) number and diameter of the nozzles, (3) temperature of separation, (4) concentration factor, and (5) the solids content in the whey; these aspects have been detailed by Tamime and others (2001). However, recent developments in the design of the nozzle separators have made it feasible to use fermented whole milk for the production of concentrated yogurt, but no published data are available (Tamime 2003).

The UF system has been also used for the production of concentrated yogurt, and the process line is similar to those shown in Figure 67.1, but UF modules replace the nozzle separator. Review of the processing conditions using the UF technology during the manufacture of concentrated yogurt have been reported by Tamime and Robinson (1999), Tamime and others (2001), and Tamime (2003).

67.4.1.3 The Use of Probiotic Strains. The word "probiotic" was defined by Fuller (1989) as "a live microbial feed supplement, which beneficially affects the host animal by improving its intestinal microbial balance." This definition stressed the requirement of viability of the probiotic cultures and introduced the aspect of a beneficial effect on the host and, today, this definition of probiotic is the most generally used (Charteris and others 1998; Fooks and others 1999); however, other definitions of probiotic have been reviewed by Gardiner and others (2002).

In practice, fermented milks are excellent vehicles for the transfer of selected strains to humans (Tamime 2002a,b), and a wide selection of lactic acid bacteria have been used in probiotic products around the world (see Table 67.4).

While milk drinks are popular some societies, "spoonable" yogurt-like products have acquired the major share of the probiotic dairy products market in the West (Robinson 2000). Consequently, manufacturers of therapeutic products have concentrated on the production of so-called "bio-yogurts" – Codes of Practice or Legislation curtail the use of the term "yogurt" as *Lb. delbrueckii* subsp. *bulgaricus* is not the dominant culture involved.

TABLE 67.4 The Main Species of Microorganisms that have been Used as Human Probiotics.

Lactobacillus spp.	*Bifidobacterium* spp.	*Enterococcus* spp.	*Saccharomyces* spp.
Lb. acidophilus	*Bif. adolescentis*	*Ent. faecalis*	*S. boulardii*
Lb. amylovorous	*Bif. animalis*[a]	*Ent. faecium*	
Lb. casei	*Bif. breve*		
Lb. crispatus	*Bif. bifidum*		
Lb. fermentum	*Bif. infantis*		
Lb. gallinarum	*Bif. lactis*[a]		
Lb. gasseri	*Bif. longum*		
Lb. johnsonii			
Lb. plantarum			
Lb. salivarius			
Lb. reuteri			
Lb. rhamnosus			

[a]Some *Bif. lactis* strains are synonymous for *Bif. animalis* and vice versa.
Source: Tamime (2002b) Itsaranuwat and others (2003).

As mentioned earlier, probiotic products must, to provide any benefit for the consumer, contain high counts of both *Lb. acidophilus* (or other recognized species – see Table 67.4) and *Bifidobacterium* spp., with "high" meaning above the "therapeutic minimum" of 1.0×105 cfu/mL for each organism (Robinson and Samona 1992). Thus, *Bifidobacterium* spp., as with the *Lactobacillus* spp., have a distinct role to play in the ecology of the human intestine, and members of the both genera have been positively identified as benefiting specific groups of patients (MacFarlane and Cummings 2002; Ouwehand and others 2002).

67.4.2 Fermented Milks with Yeasts and Lactic Starter Cultures

These are alcoholic milk beverages, and some typical examples, such as kefir, koumiss, acidophilus-yeast milk, and acidophiline, are mainly produced in northeast Caucasian mountains, in the Steppes, Mongolia, and former USSR. Only kefir has been commercially developed, and a limited volume is produced in Western Europe and the rest of the world. The following papers are recommended for further reading regarding aspects of microbiological quality, processing conditions, and nutritional and "functional" or neutraceutical properties of these products (Tamime and Marshall 1997; Kilic and others 1999; Michelli and others 1999; Muir and others 1999; Assadi and others 2000; Guzel-Seydim and others 2000a,b, 2003; Özer and Özer 2000; Jankowska and others 2001; Lourens-Hattingh and Viljoen 2001; Mainville and others 2001; Beshkova and others 2002; Frengova and others 2002; Robinson and others 2002; Simova and others 2002; Verachtert 2002; Anon. 2003b; Cheirslip and others 2003; Paraskevopoulou and others 2003; Farnworth and Mainville 2003).

67.4.2.1 Kefir and Koumiss. Kefir is made using milk of different species of mammals (e.g., cow, sheep, or goat), whilst koumiss is traditional made from mare's milk; however, the latter product will not be reviewed since the production system is not commercialized. Kefir has a lactic/sour taste, a foaming and effervescent characteristic as a result of CO_2 production and ethanol content as high as 2% depending on the yeast species present in the starter culture (i.e., in the form of grains). The microflora of the starter cultures for these products is not well defined, and may contain lactic acid bacteria (*Lactococcus*, *Lactobacillus*, *Leuconostoc* species, and *S. thermophilus*), *Acetobacter* spp., yeasts (*Saccharomyces*, *Kluyveromyces*, *Candida*, and *Torulaspora* species) and possibly *Geotrichum* spp. (Witthuhn and others 2004).

The commercial preparation of the kefir milk base is similar to yogurt making (i.e., preheating to 65–70°C, homogenization at 17–20 MPa and heating to 90–95°C for 5 min) and followed by cooling the milk to 22–25°C, which is the incubation temperature; however, the subsequent stages of manufacture are as follows.

First, the traditional process relies on seeding the processed milk base at ~22°C with kefir grains (2–10 g/100 mL) and fermenting for 12–24 h; on the following day, the grains are separated, washed in cold water and reused subsequently to produce more kefir (Schoevers and Britz 2003). The fermentate is cooled to ~10°C, blended with fruit (optional), packaged and stored at 5°C. Traditionally, glass bottles are used to package kefir as they can withstand the CO_2 pressure generated by the yeast; alternatively, semirigid containers may be used when lower volumes of CO_2 is produced in the kefir, but the container may lose its shape (i.e., bulge) due to the pressure that still exists inside the package.

Second, for commercial-scale operation, Koroleva (1991) developed a process in which kefir grains were used to ferment the milk and, after separating the grains, the fermentate (i.e., referred to as a bulk starter culture) was added to the processed milk base at 23°C at a rate of 3.5 mL/100 mL, incubated at 23°C for 20 h, cooled ~15°C, and "ripened" for 12 h allowing the yeast to grow and ensuring maximum stability of the coagulum. The subsequent stages of manufacture are similar to those described during the production of traditional kefir. Currently, starter cultures companies, such as Rhodia Foods and Danisco, have developed defined kefir starter cultures (e.g., freeze-dried) that can be used either for direct-to-vat inoculation (DVI) for the production of kefir or as a bulk starter culture. The latter type of starter culture is used to inoculate the processed milk at ~22°C; however, by using either DVI or kefir bulk starter, the "ripening" stage is not required and no kefir grains are produced in the final product. The properties of such types of kefir using different milks and starter cultures (i.e., grains, DVI, and bulk starter culture) were recently reported by Wszolek and others (2001).

67.4.2.2 Skyr. This is an Icelandic, concentrated, fermented skimmed milk product that is produced commercially using the cloth bag method (i.e., traditional process) or a nozzle separator similar to the production of quarg in Germany. The total solids content ranges between 17.5 and 20.8 g/100 g for the mechanized and the traditional skyr, respectively (Tamime and Marshall 1997).

This fermented milk product is only produced in Iceland and, in the late 1980s, one of us (AYT) was involved in the technology transfer of skyr to Scotland. A frozen skyr starter culture was brought from Iceland that consisted of *S. thermophilus*, *Lb. delbreuckii* subsp. *bulgaricus*, *Lb. helveticus*, and a lactose-fermenting yeast; however, some authors have reported that the microorganisms in the skyr starter culture consist of *Lactococcus* spp., *Lb. casei*, and yeast (Fondén and others 2003). The commercial method of production of natural skyr using the nozzle separator is shown in Figure 67.3 and can be summarized as follows. Skimmed milk is fortified with diluted skyr from the previous day's batch at a rate of 15 g/L of milk (optional), heated, cooled to 40°C, inoculated with an active liquid starter culture and rennet (6 mL/100 L) and fermented for ~5 h (pH 4.7). The fermentate is agitated vigorously, cooled to 18°C, fermented for 20 h (pH 4.2), heated to 68–70°C, cooled to 40°C, separated from the whey, partially cooled, packaged, and stored, A second fermentation stage is necessary for the yeast to grow and produce the required flavors in the product including alcohol (0.3–0.5%) and CO_2, and the heat treatment of the fermentate before the separation stage helps to inactivate the yeast (i.e., extend the shelf-life of the product) without drastically reducing the count of the lactic acid microflora.

Traditionally the whey is utilized in Iceland in food preparations, pickling of food, as an animal feed, and/or consumed as a beverage. However, UF of the whey from the nozzle separator to produce retentate of the same level of total solids as skyr could be utilized to increase the yield (see Fig. 67.3); to enhance the consumption of skyr, the product could be mixed with fruit flavors, sugar, and cream.

67.4.3 Fermented Milks with Mould and Lactic Starter Cultures

This Finish fermented milk product is similar to some Nordic fermented milks and is called viili, but the mesophilic lactic starter culture (e.g., a blend of *Lactococcus* and *Leuconostoc* ropy strains) is enriched with a mould, *G. candidum*. The fat in cows' milk is standardized to 2.5 g/100 g (the SNF is not fortified or homogenized), and the

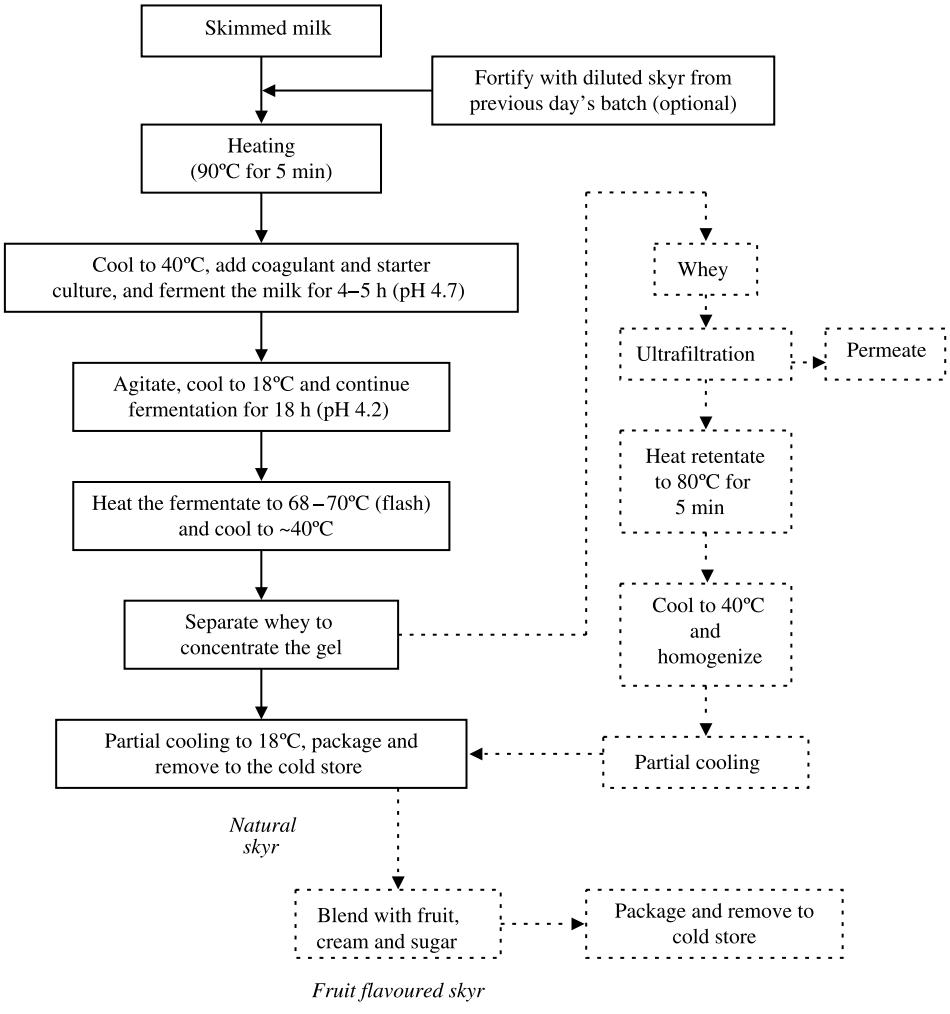

Figure 67.3 *Generalised flow chart for the production of skyr.*

milk is heated to 92–96°C for 4–5 min, cooled to 18–20°C, fermented to pH 4.4, blended with fruit (optional), packaged, and transferred to the cold store (Tamime and Marshall 1997; IDF 1988).

The product is mildly sour, aromatic in taste, and the texture is smooth, thick, and stretchy; the flavor is similar other buttermilk products, but it has a slight musty aroma that is attributed to *G. candidum*.

67.5 CONCLUSION AND FUTURE TRENDS

It is clear from the range of fermented milks on the market and their uptake by consumers that such products provide a major source of income for the dairy industry. For this success to continue, a degree of innovation will be needed. Evidence of "new products" can be found in relation to modified blends of fruit flavorings in standard

stirred yogurts, the higher solids and fat contents in, for example, Greek-style yogurts and the use of "new" cultures that enhance the organoleptic or alleged therapeutic properties of the products.

Indeed, the future for fermented milks looks extremely bright provided, of course, that manufacturers avoid two obvious dangers. One would be to allow onto the market alleged "health-promoting" products with low bacterial counts, or alternatively, high counts of an inappropriate organism(s) (Robinson and others 2002), while the other would involve a link being established between certain fermented milks and a food-borne infection like salmonellosis (Al-Haddad and Robinson 2003). As both these risks should be easy to control, there is no reason why the Western markets for fermented milks should not continue to expand.

68.1 INTRODUCTION

Fermented milk has many variants, for example, yogurt, ymer, kefir, cultured buttermilk, filmjolk (Scandinavian sour milk), culture cream, and koumiss. It is prepared by the inoculation of milk products with a starter culture. Lactic acid bacteria is usually used for fermentation (e.g., yogurt) or a combination of this and yeast fermentation (e.g., kefir). A starter culture converts part of lactose in milk product to lactic acid, produces carbon-dioxide, acetic acid, diacetyl, acetadehyde, and several other substances. The microorganism used in kefir and koumiss production also produces ethyl alcohol to provide taste and aroma. The low pH of fermented milk inhibits the growth of putrefactive bacteria. That is why fermented milk can sustain the quality of product over its shelf-life better than most other milks.

68.2 BACKGROUND

Fermented milk including kefir and yogurt originated from the Middle-East in and around Turkey at slope of Mt. Elbrus in the Caucasus, and subsequently became popular in Eastern and Central Europe. By accident, microorganisms of various kinds were fermented in a pitcher of milk at the right temperature and became activated with symbiosis. In the 11th century the name of "Yogurt" becoming well-known and it metamorphosed to "Yogurt" from the 11th century onward. Yogurt culture is mostly thermophilic bacteria. It prefers high temperature at 40–45°C while kefir culture, a mesophile, prefers moderate temperature at 25–28°C. The name kefir is derived from "kef," a Turkish name which means pleasurable. Kefir is fermented from different types of lactic acid bacteria, and yeast which are capable of forming alcohol at approximately 0.8%.

68.3 CLASSIFICATION OF FERMENTED MILK IN ASIA

68.3.1 Yogurt

In Asia, "yogurt" is the most popular fermented milk, consumed by over approximately 1.8 billion kg (LE 2003). The consumption is highest in countries around the Mediteranian, Japan, Korea, and South-East Asia. Consumers in each area prefer different types of aroma, flavor, and texture. For instance in Thailand, Vietnam, Indonesia, and Malaysia, consumers prefer less viscous liquid product while in the mediteranian area they prefer higher viscous liquids. In Japan people prefer cultured drinking yogurt with probiotics dominating usage. Yogurt is classified according to the way of preparation as follows:

- Set yogurt is the yogurt which is incubated and cooled in final packages.
- Stirred yogurt is the yogurt which is fermented in large vats, structured, and then filled into the final packaging.
- Drinking yogurt is the yogurt in liquid form where it is produced similar to stirred yogurt, but difference in formula and texturizing process, yielding a much thinner product by adding fruit syrup before being packed.

Figure 68.1 *Product variants of stirred yogurt, set yogurt, and pasteurized drinking yogurt.*

- Frozen yogurt is the yogurt which is incubated in a tank and frozen like ice-cream.
- Concentrated yogurt is the yogurt which is incubated in tanks, concentrated and cooled before being packed. This type is sometimes also called "strain yogurt" or "labneh". This is extremely popular in the Middle-East, particularly Saudi Arabia. A more liquid variant is called "laban" or "salty yogurt."

68.4 TRENDS OF FERMENTED MILKS IN ASIA

In Asia, drinking milk is becoming less popular in more and more countries (Fig. 68.2), while fermented milk is becoming more popular. Drinking yogurt and stirred cup yogurt have been growing dramatically in Asia with the growth rate of between 4.8% to 5.5% from year 2001 to year 2002 (Fig. 68.1). Currently in the Thai and Vietnamese markets, the growth is double digit (11%), the fastest in South-East Asia. Preference on taste profile is very much regionally influenced. The consumers in each area prefer their own

Figure 68.2 *Product variants of UHT drinking yogurt in South East Asia.*

taste, flavor, and texture. The method of preparation, the types of culture, and the choice of ingredients play a major impact on the characteristics. Looking at new trend in Asia, we can see the following:

- More variations: switch from basic yogurts toward special value-added and luxury yogurts.
- Yogurt targeted at new consumption moments, meal replacers.
- Yogurt packaging becoming more and more aimed at convenience; fun and attractive.
- Health awareness leading to more "balanced diet". Product with nonfat and high calcium, low sugar and added vitamins and minerals and fiber and use of prebiotic and probiotic cultures. Product with neutraceutical benefits such as adding omega 3, omega 6, or DHA.
- Food scares fueling increased interest in GMO free, gelatin free, natural, and organic products.

68.4.1 Yogurt Types on the Basis of Texture Characteristics

Besides the classification of yogurt by the way of preparation or production, the texture characteristic and functionality can be a key area to categorize into additional groups.

- Yogurt mousse – aerated yogurt;
- Probiotic yogurt – these products distinguish themselves on the health benefits of the cultures they contain;
- Petit Suisse/Fromages frais – the product is fermented with cheese cultures; after whey separation the fresh curd is processed into a yogurt-like texture.

68.4.2 Requirement for Fermentated Milk Production

As yogurt is a regional product, the method of preparation, types of cultures, and choice of ingredients have a major impact on the final product. Each of these choices make the differentiations. Factors that play a crucial role in the production of good quality yogurt are as follow:

1. Milk quality
2. Quality and functionality of other ingredients (stabilizer, texturizer)
3. Pasteurization of milk
4. Homogenization of milk
5. Type of culture, format (ready set or direct vat set)
6. Fermentation process for mother culture and starter culture.

68.4.2.1 Milk Quality. The milk for yogurt preparation must have a low bacteria count, not contain any enzymes, bacteriophages, antibiotics, or any substance such as residue from CIP solution which may slow down the development of the yogurt culture.

- The milk ingredient may be made from fresh milk, ranging from skimmed milk to whole or recombined milk.
- In case of using recombined milk, it is important to ensure proper hydration. Correct hydration is also critical for protein stabilization.
- Nowadays, the application for other types of milk ingredient has become more popular such as whey protein and caseinate. These variants many times contribute to product stability, taste, and cost.

TABLE 68.1 Strength and Weakness of Milk Components Used in Yogurt Production.

Milk Ingredients	Strength	Weakness
Skimmed milk powder	Composition	Viscosity Protein content
Caseinate	Viscosity Protein content	Smoothness Dissolution
Total milk protein	Composition Protein content	Viscosity
Whey protein concentrate	Water binding Smoothness	Viscosity

- The purposes of milk ingredients are to supply substrate for culture growth, provide nutrients which include macronutrients (protein, fat, calories), and micronutrients (vitamins, minerals, nutraceuticals which are probiotic and prebiotic).
- Types of milk ingredient also produce desirable flavor compounds, provide desirable body and texture (Table 68.1).
- Casein can help developing of coagulum, whereas whey protein helps to form water binding, viscosity, and gelling. In terms of color, fat globules and casein can play an important role as well as riboflavin, which can provide yellow and greenish colors.
- Whey powder can improve flavor, texture, enrich nutritional value, reduce syneresis, and benefit neutraceutically. The overall functionality of milk ingredients can influence fermentation rate and quality of yogurt production.

68.4.2.2 Quality and Functionality of Other Ingredients (Stabilizer, Texturizer). Hydrocolloides (also known as stabilizer, texturizer) are used commonly for commercial purposes. They can bind water, increase viscosity, and help to prevent separation in yogurt. The types of stabilizers and dosages which should be added depending on desired product characteristic, is determined by the manufacturer. The primary aims of using texturizers are:

- Body firmness
- Smooth appearance
- Synersis prevention
- Gel formation
- Full taste, good mouth-feel
- Limit damage during structuring.

Common type of stabilizer in current use are:

- Pectin
- Gelatin
- Modified food starch
- Xanthan
- Guar
- Locust bean gum
- Polysaccharides produced by yogurt culture.

In natural yogurt no stabilizer is required because the firm and fine gel with high viscosity will come automatically. Stabilizers can be used in fruit yogurt and pasteurized yogurt to ensure stability.

Pectin is the commonly used stabilizer in the world. It is proved to be the most effective stabilizer. Pectin is made from the peel of various types of citrus fruits (apple, orange, and pomelo). Chemically pectin consists of partially esterified galacturonic bonds existing of macromolecules acid, which via its 1,4-glucosides (carboxyl groups are esterified with methoxyl group). Pectin is divided into two groups, high-ester pectin (HE) having a degree of esterification above 50% and low-ester pectin (LE) having a degree of esterification below 50%. High ester pectin is suitable for fermented milk.

How Does Pectin Work to Stabilize Protein? In natural milks with pH 6.6–6.7, caseins are found in stable micelles with a negative net charge. The micellar structure is broken down during fermentation at pH 5.2, the net charge of the casein is sufficiently low for curd formation to begin. Further fermentation causes a three-dimensional network of aggregated casein to build up, entrapping the surrounding serum phase. Maximum aggregation is obtained at pH 4.6, corresponding to the isoelectric point of caseins. By decreasing the pH further (e.g., pH 4), the net charge of casein becomes positive. High ester pectin can be bound to the protein surface as the blocks are negatively charged at pH 3.6–4.5, a typical level of acidified beverage. Bound to proteins, the long pectin molecule (molecular weight of up to 150,000) protect them from reaggregation through stearic stabilization.

The Method to Add Pectin. It depends on the process equipment and recipe.

There are three possibilities to add pectin:

- Prepare pectin solution: 0.05–5% pectin should be preblended with a minimum of five parts sugar. Strong agitation is necessary. A maximum 4–5% pectin solution.
- Pectin dispersion: 10% pectin and 90% sugar solution (65% SS saturated). The dispersion should be made at room temperature without subsequent heating to avoid partial pectin dissolution and increase in viscosity.
- Direct addition 10–20% pectin with 90% sugar for predrying. Strong agitation is necessary. Homogenization should take place in warm conditions to secure proper dissolution (upstream 60°C).

68.4.2.3 Pasteurization of Milk. The milk is pasteurized before being inoculated with the starter. This pasteurization results in improving the bacterial quality of milk by reducing level of psychotrophs and mesophiles. The objectives of pasteurizing milk are:

- Improving the properties of milk as the substrate for the bacteria culture.
- Ensuring that the coagulum of the finished yogurt will be formed.
- Reducing the risk of whey separation in the end product.

The optimum heat treatment is at temperature of 90–95°C for 5 min. This condition can denature 70–89% of the whey protein. In particular the beta-lactoglobulin, which is the principle whey protein, interacts with keppa casein, thereby helping to give the yogurt a stable "body."

68.4.2.4 Homogenization of Milk. Homogenization reduces the size of fat globules. It helps to improve the stability and consistency of fermented milk as it prevents "cream-off or fat separation" during the incubation period. Homogenization covers the fat globules with casein, a thin protein layer forming part of protein network. In case of extra proteins are being added to milk, homogenization also improves their distribution. It can be applied subsequently after pasteurization. The temperature for homogenization influences the viscosity. The higher the homogenization temperature, the more is the viscosity. Generally, it is recommended at 20–25 Mpa at 65–70°C. Homogenization is frequently utilized even for production of low fat cultured milk.

68.4.2.5 Types of Culture. Starter cultures for fermented milk products can be classified according to their preferred growth temperatures and their functionality as follows:

- A mesophillic bacterium is a bacterium which has optimum growth at 20–30°C.
- Thermophillic bacterium is a bacterium which has optimum growth at 40–45°C.
- Probiotic bacteria are a bacterium that colonies in the intestines and promote health growth (Tables 68.2 and 68.3).

The culture for fermented milk may be of single strain or multiple strain. Some *Strep. diacetylactis* bacteria are powerful acidifiers that can be used alone as acidifying cultures, but they are used primarily together with *Str. cremosis/lactis*. It is not possible to use a pure *Leuc. citrovorum* in milk which is conditional upon the availability of nutrients produced by *Str. lactis* or *Str. cremoris*. *Leuc. citrovorum* grows very slowly in milk in the absence of acid-producing bacteria, and cannot produce aroma substances in such conditions.

Forms of Starter Culture

- Liquid for propagation for mother culture which is nowadays very rare.
- Deep-frozen which is concentrated culture for preparation of bulk starter.
- Freeze-dried which is the concentrated cultures in powder form.
- Deep-frozen which is the superconcentrated cultures in readily soluble form, for direct inoculation of product.

Preservatives of Starters. The lower the temperature, the better the culture keeps. Modern forms of starter cultures can be stored in condition as recommended below in Table 68.4.

Stage of Propagation. Recently, cultures have generally been used as bulk starters as well as for direct use in production. Cultures in various stages propagation are known by the following names.

- Commercial culture, master culture – the original culture from the laboratory.
- Mother culture – the culture prepared from master culture.
- Intermediate culture – an intermediate step in the manufacture of large volume of bulk starter.
- Bulk starter – the starter used in production.

TABLE 68.2 Types of Culture Bacteria Used for Each Product.

Type of Bacteria		Product
	Mesophillic bacteria	
Old name	*Streprococcus cremoris*	Cheddar cheese
New name	*Lactococcus lactis ssp. Cremoris*	
Old name	*Streptococcus lactis*	Feta cheese
New name	*Lactococcus lactis ssp. lactis*	Continental cheese Mold-ripened cheese Cottage cheese Quarg
Old name	*Leuconostoc citrovorum*	Lactic butter
New name	*Leuconostoc mesenteroides ssp. cremoris*	
Old name	*Streptococcus diacetylacis*	Culture buttermilk
New name	Cit^{+}Lactococci	
	Thermophillic bacteria	
Old name	*Streptococcus thermophillus*	Yogurt
New name	*Streptococcus salivarius ssp.*	Emmental cheese
Old name	*Lactobacillus bugaricus*	Mozzarella
New name	*Lactobacillus delbrueckii ssp. bugaricus*	Yogurt
Old name	*Lactobacillus helveticus*	Grana cheese
New name	*Lactobacillus helveticus*	
	Probiotic bacteria	
Lactobacillus acidophilus		Culture DKY
Bifidobaterium bifidum		Culture DKY
Lactobacillus reuteri		Culture DKY

Preparation of Culture. The handling of the starter for production of fermented milk demands strict standards of hygiene. Very careful attention must be paid to the manufacturing technology and choice of process equipment. The risk of airborne infection by yeasts, molds, fungi, and bacteriophages must be absolutely minimized.

TABLE 68.3 Essential Data for Some Important Bacteria.

Bacteria	Optimum Growth Temp (°C)	Max. Salt Tolerance for Growth (%)	Acid Formation, Ferment (%)	Citric Acid Ferment
		Steptococci		
Str. Lactis	~30	4–6.5	0.8–1.0	−
Str. cremoris	25–30	4	0.8–1.0	−
Str. diacetylactis	~30	4–6.5	0.8–1.0	+
Str. thermophillus	40–45	2	0.8–1.0	−
Leuc. citrovorum	20–25	–	Small	+
		Lactobacillus		
Lb. helveticus	40–45	2	2.5–3.0	−
Lb. lactis	40–45	2	1.5–2.0	−
Lb. bulgaricus	40–50	2	1.5–2.0	−
Lb. acidophilus	35–40	–	1.5–2.0	−

TABLE 68.4 Storage Conditions and Shelf-Life of Cultures.

Type of Culture	Storage	Shelf-Life (months)
1. Freeze-dried super-concentrate (for direct incubation product)	Freezer below −18°C	Minimum 12
2. Deep-frozen	Freezer below −45°C	Minimum 12
3. Freeze-dried concentrated culture (for preparation of bulk starter)	Freezer below −18°C	Minimum 12
4. Deep-frozen concentrate culture (for preparation of bulk starter)	Freezer below −18°C	Minimum 12
5. Freeze-dried culture in powder for preparation of mother culture	Freezer below +5°C	Minimum 12

The preparation of culture comprises of the following stages:

- Heat treatment of medium
- Cooling to inoculation temperature
- Inoculation
- Incubation
- Cooling the finished culture
- Storage the culture.

HEAT TREATMENT OF MEDIUM. Skimmed milk is the medium most frequently used for starter production. Fresh milk from selected source which is proved to be free from antibiotic may be used as well. The medium can be modified by addition of growth factor such as Mn^{2+} (Manganese) to promote growth of *Leuc. citrovorum*. Phage-inhibiting media (PIM) offer an alternative for production of single-strain or multistrain starters. These media contain phosphates, citrates, or other chelating agents which make Ca^{2+} (calcium) insoluble. To remove Ca^{2+} from media protect lactic acid bacteria from being infected by phage as phages require Ca^{2+} for proliferation.

The media is heated to 90–95°C for 30–45 min. The heat treatment improves the properties of the medium through destruction of bacteriophages, elimination of inhibitor substances, some decomposition of protein, expulsion of dissolved oxygen, and destruction of original living microorganisms.

COOLING TO INOCULATION TEMPERATURE. The cooling temperature in order to inoculate the culture depends on type of culture (mesophillic bacteria or thermophillic bacteria) which may be recommended by supplier. Typical incubation temperature of mesophillic bacteria is 20–30°C and of thermophillic is 42–45°C.

INOCULATION. The amount of starter used, the propagation temperature and the fermenting time should be kept constant. The amount of starter used can affect the relative proportions of different bacteria which produce lactic acid and aroma substances. The optimum dosage which generally recommended is 2–3%.

INCUBATION. The incubation time can vary from 3 to 20 h depends on dosage of inoculum. During incubation period the bacteria multiply rapidly and ferment lactose to lactic acid, some of bacteria provide aroma substance such as diacetyl, acetic acid and propionic

acids, ketone, and aldehyes of various kinds, alcohols, esters, and fatty acids as well as carbon-dioxide.

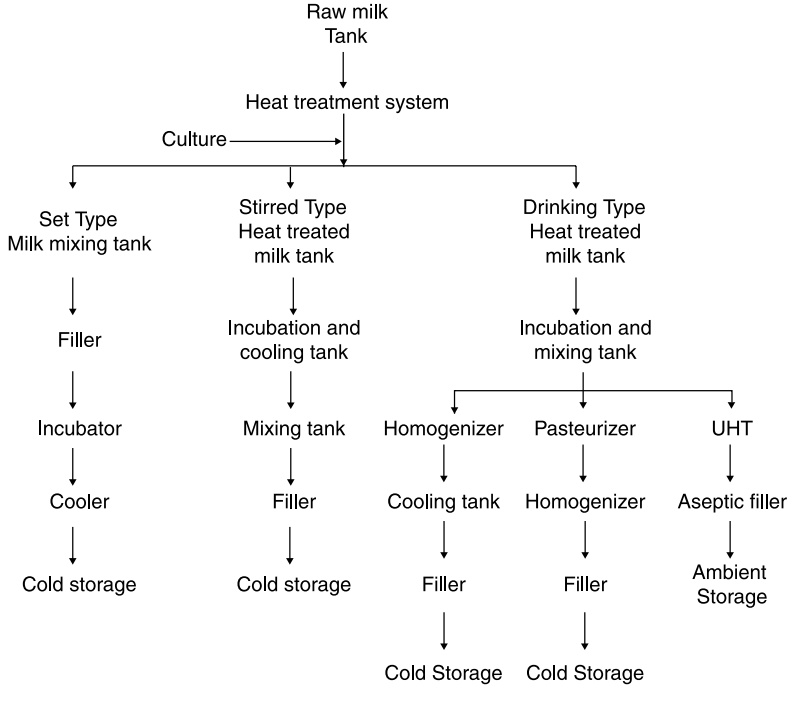
The culture which are commonly used for fermented milk in Asia are mixed culture of *Str. thermophillus* and *Lb. buegaricus*, which coexists in symbiosis and together produces the desired characteristics of the yogurt, such as pH, flavor, and aroma. Acetaldehyde is recognized as major flavor component in yogurt. Formation of acetaldehyde does not become evident until a certain level of acidification at pH 5.0. It reaches the maximum at pH 4.2 and stabilizes at pH 4.0. Most yogurts have a ratio between cocci to bacilli of between 1 : 1 to 2 : 1. The factor affecting the ratio of cocci to bacilli is the incubation temperature. At 40°C the ratio is about 4 : 1 while 45°C is 1 : 2. The optimum temperature for inoculation is thus 43°C to achieve cocci to bacilli ratio of 1 : 1, with the rate of inoculum of 2.5–3% and an incubation time of 3–4 h.

In addition, some strain of bacteria produce exopolysacharides (EPS) which have a notable influence on the structure of yogurt. The type of EPS and the fermentation period when the culture starts producing EPS both have impact on the final product. In this case, the low fermentation temperature (30–35°C) usually gives smooth and viscous yogurt. When fermenting with the same culture, it gives at temperature 40–45°C. One of the reasons is that at lower temperatures generally more EPS is produced.

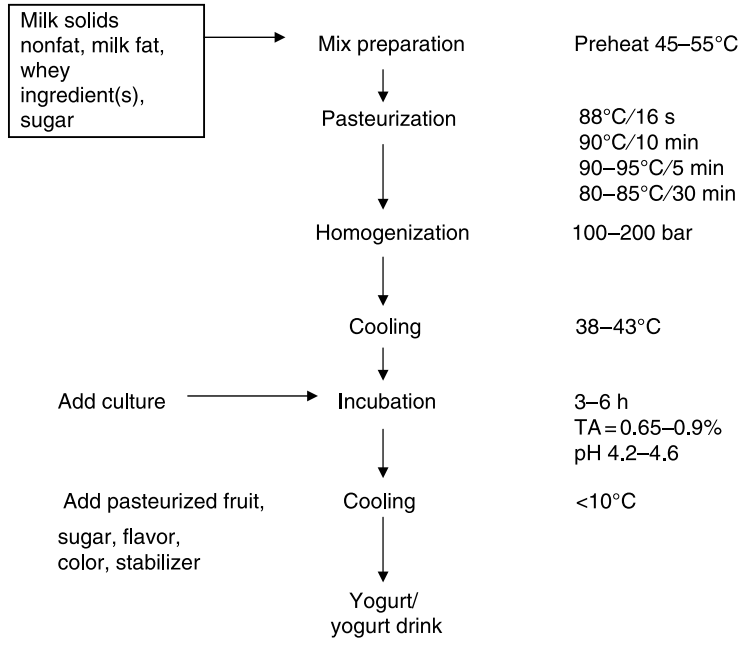
COOLING THE CULTURE. Cooling temperature at 10–12°C is common practice when culture is intended to be used within 6 h.

68.4.2.6 The Fermentation Process for Bulk Production

General Process Flow



Flowchart 1 *Process flowchart to compare different types of fermented milk in Asia.*



Flowchart 2 *Processing flowchart to basic production.*

68.4.2.7 Shelf-Life of Product. The Shelf-life of a pasteurized DKY product is approximately 1 month storage and distribution when the temperature does not exceed 7°C. In UHT drinking yogurt, shelf-life can be 6–10 months depending on the UHT process. Most spoilage problems are due to yeasts and molds which can become contaminated from starter, sugar syrup, fruit preparation, packaging machinery, and so on. Cleaning and sanitation minimize problems of spoilage and can extend shelf-life further.

68.4.3 Process Detail of Product Type

68.4.3.1 Set Yogurt/Stirred Yogurt. In order to reduce installation costs, it is possible to use the same plant for production of both stirred and set yogurt. The pretreatment of the milk intended for either product is identical up to cooling down of incubation temperature. The starter is metered into the stream of milk as it is pumped from an intermediate storage tank to the filling machine.

Flavoring/Packaging. Flavoring can be continuously metered into the milk stream prior to the filling machine. If fruit or additives with particles should be added, these have to be dosed into the packages or cups first before they are filled with fermented milk.

An Alternative Production System. In production of set yogurt, the milk is pretreated in the same way as for stirred yogurt, then cooled to a temperature of less than 10°C, preferably to 5°C, and pumped into one, two or more tanks. Following inoculation and thorough stirring, the milk is ready to be heated in-line to incubation temperature before being packed in containers. Bulk starter culture can also be added in-line prior to heating to incubation temperature.

Incubation and Cooling. Following packaging, the packages after crating and palletizing, are being trucked to the final cold store (an incubation room able to accommodate a large number of filled pallets). After adequate incubation the pallets are trucked to a conveyor passing through the cooling sections enclosed in a tunnel.

INCUBATION. The filled packages/containers are placed in crates of open design and at a certain distance from each other so that the circulating warm/cold air in the incubation and cooling room or chamber can reach every individual container. The crates are normally stacked on pallets, which are then trucked into the incubation room. This ensures uniform quality, provided that the temperature is accurately controlled.

COOLING. When the empirically determined optimum pH (typically 4.5) is reached, it is time to start cooling. The normal target temperature is 18–20°C; it is important to stop further growth quickly, which means that a temperature of about 35°C should be reached within 30 min, and 18–20°C after another 30–40 min. Final cooling, normally down to 5°C, takes place in the chill store, where the products are held to await distribution. The pallets (crates) are stationary during incubation. They are placed in the incubation room/chamber in such a way as to facilitate first in/first out handling. In a typical incubation period of 3–3.5 h, it is very important that the product is not exposed to any mechanical disturbance during the last 2–2.5 h, when it is most sensitive to the risk of whey separation.

The cooling capacity should be adequate to achieve the abovementioned temperature program. As a guide, it may be mentioned that the total cooling time is about 65–70 min for small packages (0.175–0.2 kg sizes) and about 80–90 min for large packages (0.5 kg size). Eventually, regardless of the type of incubation/cooling chamber, the set yogurt is cooled to about 5°C in the chill store.

68.4.3.2 Drinking Yogurt. A low-viscosity drinkable yogurt, normally with a low fat content, is popular in many countries such as Thailand, Vietnam, Malaysia, Japan, China, and so on. The yogurt intended for production of drinking yogurt is produced in the ordinary way as described above. Following stirring up and cooling to about 18–20°C, the yogurt is transferred to the buffer tank prior to the process alternatives. Stabilizers and flavors are mixed with the yogurt in the tank. The yogurt mix can then be treated in different ways, depending on the required shelf-life of the product.

Long-life Drinking Yogurt. Because of the tendency towards larger and more centralized production units, the markets in Asia are becoming geographically larger and transport distances are longer. Therefore, it is necessary to extend the shelf-life of the product beyond normal. In some countries it is difficult to maintain the integrity of the cooling chain. Therefore, there is demand for a sterilized yogurt that can be stored at room temperature.

The shelf-life of cultured milk products can be extended in two ways:

- Production and packing under aseptic conditions such as in bottles;
- UHT heat treatment of the finished product, either immediately before packing or in the UHT package.

68.4.3.3 Frozen Yogurt. Frozen yogurt can be manufactured in two ways. Either yogurt is mixed with an ice cream mix or a yogurt mix is fermented, before further processing. Frozen yogurt can be divided into soft-served and hard-frozen types. The mix intended for soft-served yogurt differs somewhat from that of the hard frozen type. Typical recipes are as follows.

Hard-Frozen Yogurt. As in the case of conventional ice cream, the yogurt is prefrozen and whipped in a continuous ice-cream freezer. Whipping takes place in a nitrogenous atmosphere to avoid oxidation problems during subsequent storage. The frozen yogurt leaves the freezer at $-8^{\circ}C$, which is somewhat lower than the temperature of conventional ice cream. This gives it an optimum viscosity that suits most filling machines.

Liquid fruit flavoring or sugar can be added in the freezer. Frozen yogurt with different flavors can be produced in parallel freezers from a common yogurt mix. After freezing, the frozen yogurt is packed into cones or cups or family size packs in the same way as conventional ice cream. The packs then go into a hardening tunnel, where the temperature is reduced to $-25^{\circ}C$.

Frozen yogurt bars can be frozen continuously in a regular ice cream bar freezer. Since the yogurt is frozen directly to $-25^{\circ}C$, it can be transported to the cold store immediately after packaging.

Shelf-Life and Distribution. *Hard-frozen* yogurt which is whipped with nitrogen can be kept in cold storage for 2–3 months without any adverse effects on its flavor or texture. Distribution requires an unbroken cold chain right up to the instant of consumption. In the case of the mix for *soft-served yogurt* (not subjected to UHT treatment), a maximum storage temperature of $+6^{\circ}C$ is recommended. This mix has a storage life of a couple of weeks. Soft-served yogurt is consumed immediately after freezing.

68.4.3.4 Concentrated Yogurt. In concentrated yogurt the dry matter (DM) of the product is increased after fermentation. Whey is drained off from the coagulum. The manufacturing principles are identical with the manufacturing of quarg. The only difference is the type of cultures used. Concentrated yogurt is known under names such as "strained" type yogurt and Labneh.

68.4.3.5 Kefir. Kefir is one of the oldest cultured milk products. It originates from the Russian Caucasus region (bordering Turkey). The raw material is milk from goats, sheep, or cows. Kefir is produced in many countries, although the largest quantity – an annual total of about 5 L per capita – is consumed in Russia. Kefir is viscous and homogenous, and has a shiny surface. The taste is fresh and acid, with a slight flavor of yeast. The pH of the product is usually 4.3–4.4. A special culture, known as kefir grain (Fig. 68.3), is used for the production of kefir. The grains consist of proteins, polysaccharides, and a mixture of several types of microorganisms, such as yeasts and aroma, and lactic-acid forming bacteria. The yeasts represent about 5–10% of the total microflora (Fig. 68.5).

The kefir grains are yellowish in color and about the size of a cauliflower floret, that is, about 15–20 mm in diameter. The shape of the grains is irregular. They are insoluble in water and in most solvents. When steeped in milk, the grains swell and become white. During the fermentation process, the lactic-acid bacteria produce lactic acid, whereas the lactose-fermenting yeast cells produce alcohol and carbon-dioxide. Some breakdown of protein also takes place in the yeast metabolism, from which kefir derives its special

yeast aroma. The contents of lactic acid, alcohol, and carbon-dioxide are controlled by the incubation temperature during production.

68.4.3.6 Cultured Cream. Cultured cream has been used for years in some countries. It forms the basis of many dishes in the same manner as yogurt. Cultured cream can have a fat content of 10–12% or 20–30%. The starter culture contains are *Str. lactis* and *Str. cremoris*, whereas *Str. diacetylactis* (D and DL cultures) and *Leuc. citrovorum* (DL and L cultures) bacteria are used for the aroma (Fig. 68.4).

Cultured cream is bright, has a uniform structure, and is relatively viscous. The taste is mild and slightly acid. Cultured cream has a limited shelf life. Strict hygiene is important to product quality.

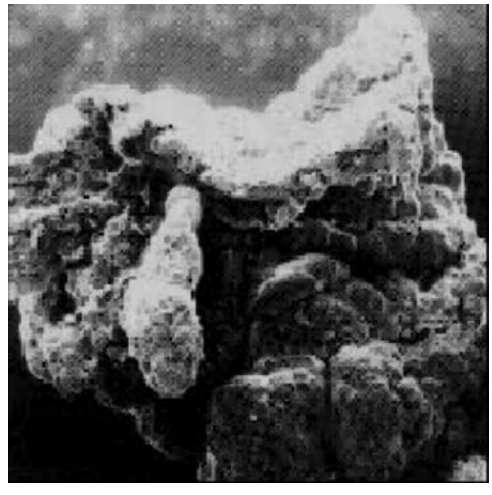


Figure 68.3 *Kefir grain.*

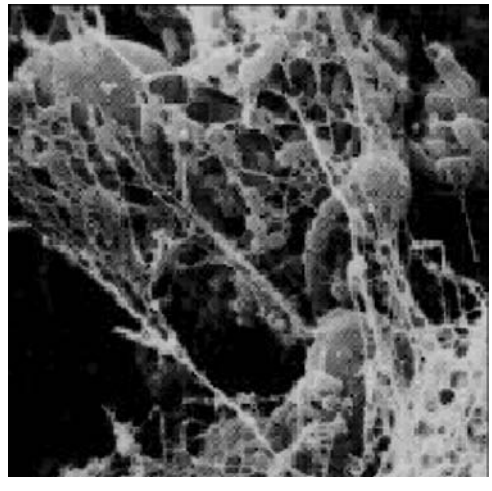

Figure 68.4 *The microorganisms in cultured products often live in symbiosis with each other.*

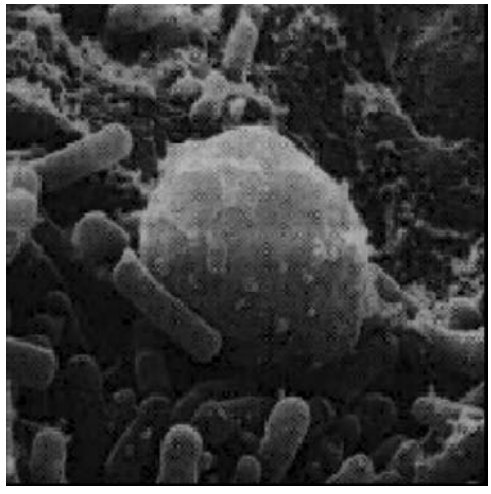

Figure 68.5 *Yeast and lactic acid at the surface of a kefir grain, seen through an electron photomicroscope.*

Yeast and molds can develop in packages which are not airtight. These microorganisms occur mainly on the surface of the cultured cream. In the event of extended storage the lactic-acid bacteria enzymes, which break down β-lactoglobulin, become active and the cultured cream goes bitter.

The cultured cream also loses its flavor because carbon-dioxide and other aromatic substances diffuse through the packages.

Production. The process line for production of cultured cream includes equipment for standardization of the fat content, homogenization, and heat treatment of the cream, and also inoculation and packing.

Homogenization. The cream is homogenized. For cream with 10–12% fat the homogenization pressure is normally 15–20 MPa (150–200 bar) at 60–70°C. Up to a certain point, an increase in homogenization temperature improves the consistency.

For cream with 20–30% fat the homogenization pressure should be lower, 10–12 MPa (100–120 bar), as there is not enough protein (casein) to form membranes on the enlarged total fat surface.

Heat Treatment. The homogenized cream is normally heat treated for 5 min at 90°C. Other time/temperature combinations can be used if the homogenization technique is carefully matched to the heat treatment.

Inoculation and Packing. The pretreated cream is cooled to an inoculation temperature of 18–21°C. One to two percent of bulk starter culture is then added. Inoculation can take place in a tank or in the packages. The fermentation time is 18–20 h. When fermentation is completed, the cultured cream is cooled quickly to prevent any further pH reduction. The viscosity of the fermented cream may be very high, and it may therefore be difficult to pack.

In spite of precautions, the mechanical treatment to which the cultured cream is subjected during stirring, pumping, and packing also causes a slight deterioration in the consistency of the product – it will become thinner.

Cultured cream is bright, has a uniform structure and is relatively viscous. The taste should be mild and slightly acid. The cream is sometimes inoculated, packaged, and fermented in the packages to avoid mechanical treatment. After inoculation of the cream and subsequent packing, the product is stored at 20°C until the acidity of the fat-free phase is about 85°C, which takes about 16–18 h. The packages are then carefully transferred to the chilled store, where they are kept for at least 24 h at a temperature of about 6°C before distribution. Cultured cream is often used in cooking.

68.4.3.7 Buttermilk. Buttermilk is a by-product of butter production from sweet or fermented cream. The fat content is about 0.5%, and it contains a lot of membrane material including lecithin. The shelf life is short, as the taste of the buttermilk changes fairly quickly because of oxidation of the membrane material content. Whey separation is common in buttermilk from fermented cream, and product defects are therefore difficult to prevent. Buttermilk is growing in popularity. Consumers have a preference for a silky taste and more yellow color.

68.4.3.8 Fermented Buttermilk. Fermented buttermilk is manufactured on many markets in order to overcome problems such as off-flavors and short shelf-life. The raw material can be sweet buttermilk from the manufacture of butter based on sweet cream, skim milk, or low-fat milk.

In all cases the raw material is heat treated at 90–95°C for about 5 min before being cooled to inoculation temperature. Ordinary lactic-acid bacteria are most commonly used. In some cases, when the raw material is skim milk or low fat milk, grains of butter are also added to the product to make it look more like buttermilk.

68.4.3.9 Probiotic Cultured Milk Products. Probiotic culture milk is a "functional food or neutaceutical product." The name is applied to foods with near-medicinal properties that promote health. "Food for special health use" is another term for the same thing. Japan is at present the leading country for "functional food" and has a great preventive program of schemes to lower the costs of medical treatment. Lactic acid bacteria have been used since time immemorial to ferment foods. The special strains of bacteria normally used in production of yogurt, as well as other types such as *Lactobacillus* (*L.*) *acidophilus*, *L. reuteri* (a relative newcomer), Bifido-bacteria and certain species of *Lactococcus lactis*, are among those that have been found of interest for production of functional foods.

How a Lactic Acid Bacterium Function in the Intestine. The four characteristics that are of primary importance are:

- Ability to colonize and survive
- Adhesive capacity
- Ability to aggregate
- Antagonistic effects.

L. acidophilus and Bifido-bacteria are important members of the human intestinal flora. The former normally predominates in the small intestine and the latter in the large intestine. Production of these important bacteria is reduced in some people as a result of medication, stress, or old age. In many people, reduced production of intestinal bacteria can cause symptoms such as swelling, indigestion, and pronounced illness.

Consumption of live *L. acidophilus* and Bifido-bacteria in milk products is an ideal way to restore the balance of the intestinal flora. Apart from the possible prevention and relief of diarrhea, literature indicates that *L. acidophilus* and Bifido-bacteria may help to:

- Reduce the cholesterol level in the blood
- Relieve lactose mal absorption (lactose intolerance)
- Strengthen the immune system
- Reduce the risk of stomach cancer.

The production of probiotic bacteria is similar to drinking-yogurt. However, the preferred temperature for growth is around 32–38°C and it needs longer fermentation time (60–72 h).

68.5 CONCLUSION AND SOME REMARKS ON MARKET'S TRENDS

The fermented milk landscape is very broad and colorful. The functionalities are growing. What started centuries ago purely as a basic form of nutrition is today moving towards fulfilling needs beyond basics. Enhanced nutritional needs as well as emotional needs are the routes being pursued by manufacturers who are looking for new categories, niches, and points of differentiation. What we can safely say about the future is that the further development of this categories will continue. The reasons are not only commercial but also social and cultural. Companies across Asia today are investing significant amounts of resources to bring new innovations to the market place. Branding, positioning, differentiation on functional and emotional benefits, quality, taste, packaging, robustness, survivality in the supply chain are the key issues for the future.

69.1 INTRODUCTION

Although dairy cows produce the greatest amount of world milk supply mostly from developed countries, more people drink the milk of goats than milk of any other single species on a worldwide basis (Haenlein and Caccese 1984; Park 1990, 1994b). The FAO yearbook shows that dairy goat and dairy sheep farming is very important for the national economy of many countries, especially in the Mediterranean region. Dairy goat farming is a vital sector of agricultural businesses in developed countries of the Mediterranean region such as France, Italy, Spain, and Greece. This fact may prove that goat and sheep dairying is not necessarily synonymous with underdevelopment and poverty (Haenlein 2002).

However, production of goat milk is very important in countries of the underdeveloped world, where it provides basic nutrition and subsistence to the rural people, which are the majority of their populations. Production of goat milk and its products of cheeses and yogurt is also a valued part of the total dairy industry in developed countries, where it provides diversity to sophisticated consumer tastes, and supports people with medical afflictions, such as allergies and gastrointestinal disorders, who need alternative dairy products (Haenlein 1986, 1996, 1997; Park 1992b, 1994b). Thus, goat milk serves in a general way

TABLE 69.1 Average Daily Supply of Calcium and Protein Per Person (FAO 1995) in Relation to Recommended Dietary Allowances (RDA, 800 mg for Calcium and 60 g for Animal Protein; NRC 1964).

		From Animal Sources	
	Total Supply (mg)	(mg)	(% of RDA)
Calcium			
Africa	384	132	16
Asia	329	125	16
Europe	896	684	86

three types of markets around the world, such as (1) home consumption, (2) specialty gourmet interests, and (3) medical needs.

Home consumption of goat milk is important in the prevention of undernutrition and malnutrition, since milk is the superior source of calcium and protein, and to millions of rural poor people cow milk is not available or not affordable. A daily minimum supply of 800 mg calcium per person is widely recommended, as is also a minimum of 60 g protein from animal sources (NRC 1964). Table 69.1 shows how far below these recommendations the average supply of calcium and protein is estimated to be especially in Africa and Asia.

69.2 PRODUCTION OF GOAT MILK

69.2.1 Goat Milk Production in the World Compared to Other Dairy Species

The changes in trends of world human population and milk production during the last 20 years are shown in Table 69.2. While the world population of people increased by 39% from 4.4 to 6.1 billion during the last 20 years, the milk supply tonnage from cows increased by 20%, from buffaloes by 168%, from sheep it did not change, but from goats it is estimated to have risen from 7 to 12 million MT or 71% (FAO 1986, 2003). At the same time, dairy cow numbers increased by 6%, buffaloes by 37%, but goat numbers jumped by 63% from 457 to 743 million head during these last 20 years. Thus, the worldwide dynamics of goat numbers and goat milk production tonnage are impressive. Likewise, the upward trends in goat population numbers and in goat milk production tonnage, especially in Africa and Asia, reflect the recognition of people for the significant contribution, that goat milk and its products make to people's nutrition and their social well-being.

69.2.2 Breeds and Milk Production

Several hundred different breeds of goats are officially recognized worldwide, some specifically for Mohair or Cashmere fiber production, the majority for dual purpose production of meat and milk, and a few selected single purpose breeds for meat or milk production. They have been described and illustrated in detail in recent publications (Muňoz and Tejon 1980; Haenlein 1981; Mason 1981; Acharya 1982; Rubino 1990; Gall 1996; Devendra and Haenlein 2003). Goat breeds have also been categorized morphologically as well as by level of milk production into high, medium, and low milk-producing breeds, but feeding, climate, and management systems are often the major factors determining the level of milk production by different goats and by breeds (Flamant and Morand-Fehr 1982). On the other hand, superior genetic selection for high milk yield per day and for long lactations (up to 10 months) has established several breeds as so-called "improver" breeds for developing countries. These are especially the Swiss breeds: Saanen, Alpine, Toggenburg, Oberhasli; and also the American La Mancha and Anglo-Nubian, the Mediterranean Maltese, Canaria, Malagueňa, Murciana-Granadina, Damascus, and the Indian Jamunapari. Table 69.3 shows the levels of top milk production records achieved through superior genetic selection within breed and through excellent management of the individual does of some of the dairy goat breeds. These records also demonstrate, that improvement in milk production tonnage is possible without increasing population numbers, which is environmentally important, where increased herd numbers can lead to overgrazing pressure on the natural pasture regrowth, that has caused much concern in the past in some regions with dangerous desertification problems and public antagonism to goats (Haenlein 2001). The average

TABLE 69.3 Leading 10-Months Milk, Fat, and Protein Production Records of Officially Tested Individual Does of U.S. Dairy Goat Breeds (ADGA 2003), and Official U.S. Breed Average Production Records (Thomas and Haenlein 2004).

All	(10,362)	821	30	3.7	25	3.0	(385)

production records for each breed shown in Table 69.3 are also much above those reported for other single purpose and even more for dual purpose goat breeds.

Different from the production of mohair from the U.S. Angora industry, statistics of the U.S. dairy goat industry concerning population numbers and milk marketing are not readily available, because no central organization is keeping track of this other than the voluntary registration of pedigreed goats by a minority of U.S. goat keepers (Haenlein 2001). Estimates of the total U.S. dairy goat population have been reported to be about 1 million head with an estimated 50,000 MT commercial goat milk/year (Haenlein 1986; Thomas and Haenlein 2004). The state of Wisconsin processed currently around 7000 MT/year. About 12,000 MT of goat milk are manufactured into powder in California annually, and an ever growing number of presently at least 100 farmstead cheese makers produce an increasing number of artisanal goat cheeses, soft and aged, for the rising U.S. cheese market. Consumption of cheeses in the United States, especially specialty cheeses from goat and sheep milk, has increased from 8 to 14 kg/head/year during the last 20 years.

Approximately 300 U.S. goat breeders have a license for marketing goat milk. It has been estimated, that a potential but unfulfilled goat milk market of 12,000 MT/year exists in the United States just for "biomedical" reasons of people afflicted with allergies and gastrointestinal disorders, calculated from a conservative average need of 1 L goat milk/1000 persons/week (Haenlein 1986). However, 22 U.S. states have presently no licensed goat dairy farm/processor, and three-quarters of the larger U.S. cities have no fluid goat milk available in stores. Urban U.S. consumers are thus confronted with the choice of mail ordering frozen goat milk from another state or buying goat milk powder from a Health Food store or keeping their own goat in the backyard of their home. Compare this situation with the dairy goat industry in Taiwan, where UHT goat milk is delivered daily to the doorsteps of consumers by a well organized cooperative (Morgan 1996). French goat milk is also exported widely into other countries, where potential markets with a deficit supply exist. It has been reported, that, for example, in Brazil 4.5 million liters of goat milk are marketed annually generating $12 million, but that a potential market of 12 million liters exists despite the higher retail price compared to cow milk (Vidal and others 2004).

69.2.3 Economics of Improved Goat Milk Production

As seen in Table 69.3, the improvement of goat milk production is not only possible genetically, that is, through selection within breed or crossbreeding between breeds, but is also achievable through superior management, that is, disease control and supplementary feeding. Searching the world research literature, it becomes clear that much more is known about the benefits of superior management, than is practiced today, and that is lacking in extension education of the many people in the "hinterland," who keep and depend on goats for their livelihood. It has been proven repeatedly (Table 69.4), that goats' low productivity in many regions is mostly due to underfeeding in energy and protein sources, which can be corrected by supplementary feeding in addition to the pasturing, and which is not costly but profitable contrary to widespread popular opinions (Sands and McDowell 1978; Yazman 1984; Devendra 1987; Morand-Fehr 1990; Sagar and Ahuja 1993; Hatziminaoglou and others 1995; Haenlein and Abdellatif 2004). The reason is the milk price : feed price ratio. As long as the supplement feed price/kg to the farm is less than half of the price of milk/kg from the farm, it is profitable to buy

TABLE 69.4 Economics of Improved Goat Milk Production.

Influence of feeding level (Sands and McDowell 1978)								
Feeding multiples of maintenance requirements					Expected milk yield/lactation, kg			
1.15–1.50–1.80–2.45					50–198–305–535			
Influence of plane of nutrition in India (Devendra 1987)								
Low plane of nutrition before and after kidding:					49 kg Lactation milk yield			
Medium plane before kidding and high plane during lactation:					109 kg Lactation milk yield			
High plane before and after kidding:					152 kg Lactation milk yield			
Economics of goat herds in eight districts of Rajasthan, India (Sagar and Ahuja 1993)								
Milk production, kg/doe/year:	113	135	178	254	375	434	576	595
Expenditures, Rupees/doe/year:	29	23	102	48	164	80	160	174
Net income, Rupees/doe/year:	84	112	76	206	211	354	416	420
Economics of goat husbandry in Greece (Hatziminaoglou and others 1995)								
Gross income/doe/year	$ 66 – Extensive Feeding				$ 135 – Intensive Feeding			
Expenses/doe/year	$ 58 – Extensive Feeding				$ 111 – Intensive Feeding			
Net income/doe/year	$ 8 – Extensive Feeding				$ 24 – Intensive Feeding			
Average net income in four quartiles of 120 U.S. goat herds, official records (Haenlein and Abdellatif 2004)								
Milk yield, kg/doe/lactation:				514	701	820	1050	
Cost of concentrate feed/doe/year, $:				83	91	98	109	
Income over feed cost/doe/year, $:				183	262	302	395	

concentrate feeds or grains to supplement the basic forage ration of the goats. This ratio of $<0.5:1$ also rules an improved feeding system, where 1 kg supplement should be fed for each 2–3 kg milk/doe/day, depending on fluctuations of price, composition in protein and energy, and body condition of the doe.

Obviously, the economics of goat milk production is not only very much influenced by the price of feeds, which generally comprise 50% of the cost of milk production, but also by the price of goat milk payable to the producer or by the market price paid by consumers (Haenlein 1997, 1998). If the goat milk producer can manage direct sales of his/her milk, cheese and/or yogurt to consumers, as seen along highways, for example, in Venezuela, Holland, France, Germany, or through mail orders, for example, in the United States, then a best possible price/kg goat milk is obtainable. Many goat milk producers are not in that fortunate position, but live in remote areas, and what they want to sell has to go through a wholesale dealer and distributor, who often takes as much a share or more of the final retail price as the producer is paid. Thus, the producer has to calculate what his/her production costs per kg goat milk are, in order to survive economically (Ace 1978; Yazman 1984; Olorunnipa and others 1990; Gebremedhin and Gebrelul 1991).

Economic theory states, that the cost of production per unit of product is decreased by increasing the numbers of products per production unit. This applies also to goat milk production. As seen in Table 69.4, net income increases with higher level of milk production. Furthermore, the cost/kg goat milk decreases with higher levels of production/goat and the economic "break-even" price of goat milk decreases (Yazman 1984). Compared to pricing cow milk, it has been determined that the farm gate price for goat milk for a sustainable farm operation must be at least 1.5–2.5 times higher because of higher labor costs. Herd sizes of at least 120 dairy goats with lactation yields of 700 kg/doe maybe needed for an enterprise with an economic future. Labor is a major restraint in dairy management of cows and more so of goats, because of their smaller size and lower volume of milk produced per animal. Total labor requirement in the production of 100 kg goat milk ranges between 57–145 min compared to cows requiring only 7–31 min/100 kg milk production (Kapture 1991). At \$6.00/h labor, 100 kg cow milk requires at most \$3.10 labor cost compared to \$14.50 for the production of goat milk, which is a difference of 4.7 times, explaining the need for the price difference for milk between the two species. Using current U.S. prices for feeds including hay, buck service, veterinary costs, and milking supplies, minus the gain from sale of kids and the fertilizer value of goat manure, but not including fixed overhead, the total production cost of goat milk has been estimated to be about \$70.00/100 kg compared to a current farm gate price for cow milk at \$29.00/100 kg (USDA-ARS 1968; Haenlein 1997). At a yield ratio of 10 kg milk : 1 kg cheese, the milk cost for goat cheese making appears to be at \$7.00/kg cheese. These figures compare with actual prices received on U.S. dairy goat farms for Grade A–3.5% fat goat milk ranging from \$26.00 to \$97.00/100 kg (the later for direct sales at the farm) (Editor 1991), and average commercial prices for goat milk in France at the equivalent of \$51.00/100 kg, in Italy \$47.00, in Spain \$44.00, and in Greece \$36.00 (IDF 2000). Although these countries, and the Mediterranean region in general, are the world's premier countries of successful commercial organization of goat milk, goat cheese, and yogurt production, the average milk production levels per doe are much below those of American dairy goats (Table 69.3), partly because much pasturing is part of their management system. Average annual milk production per doe in France has been at 364 kg, in Spain at 109 kg, in Italy at 104 kg, and in Greece at 73 kg (IDF 2000).

In regions, where most goat meat is supplied by dual purpose dairy or bush goats rather than by single purpose meat goats, a decision must be made by the goat farmer on whether it is more economical to sell most of the available milk and nurse the kids with commercial milk replacer feed, or whether it is more profitable to feed the milk to as many goat kids as possible for sale of kid meat (Haenlein 1997). The decision of alternatively marketing goat milk instead of feeding it for goat meat production can be made on the basis of a formula for R-values (Gall 1990):

$$R = \frac{\text{Kid weight gain (kg)} \times \text{Kid weight price (\$)}}{\text{Milk amount fed (kg)} \times \text{Milk price (\$)}}$$

If R is less than 1.00, then goat milk is more economically sold in the market than fed to kids. If kid weight price is at least more than six times the milk price, then milk feeding for goat meat production is profitable. The formula can also be used to calculate a necessary goat meat price at a given goat milk price, for example, at \$70.00/100 kg milk a break-even price for meat sale would have to be \$4.20/kg for a 25 kg goat kid, that had required 150 kg goat milk to grow to that bodyweight (i.e., 6 kg milk for 1 kg goat meat).

An additional aspect of goat milk pricing is the need for incentive payments to the producer in order to meet and improve health standard requirements for fluid milk, and optimum milk composition for the interests of cheese and yogurt yields. Score cards are used in Europe for the payment of bonus or penalty monies for certain desirable levels of some goat milk contents such as coliform bacteria, listeria, lipolysis, bacteria counts, somatic cell counts (SCC), pH, fat, solids, protein, casein, water, and the absence of antibiotics and sediment. European limits for goat milk to be pasteurized are $<$1.5 million/mL bacteria count, but for raw milk processing $<$0.5 million/mL (IDF 2000). Present SCC limits in goat milk are 1.35 million/mL in France, 1.6 in Spain, 1.743 in Italy, compared to European cow milk SCC limits at 0.4 million/mL. This reflects the research and enforcement dilemma for commercial goat milk production. Officially it has not yet been recognized, that goat milk production is seasonal, which means that average goat milk composition increases in fat, protein and SCC normally without any pathological reasons toward the end of the lactation, which coincides with the autumn season, during which most dairy goats are at the end of their lactation (Haenlein 2002; Borges and others 2004). Any enforcement of the present European cow milk SCC limits to goat milk production is not only not possible, but would be unfair and discriminatory. A separate SCC standard, which takes normal seasonal changes in goat milk composition into account, must be developed. Differential payments for contents of solids are applied by the goat milk powder manufacturer in California, and by commercial processors for goat cheese in several countries as an incentive for higher cheese yields per volume of delivered milk.

The situation of allowing raw goat milk sales for fluid milk consumption and cheese production is quite variable between countries and between states of the United States (Editor 2004), for example, in Arkansas, raw milk sales are illegal, meaning that all milk has to be pasteurized, but on-farm sales directly to the consumer are allowed, as are "incidental sales." The definition for incidental sales is that the monthly number of gallons (3.8 L) of goat milk sold should not be exceeding 100 gallons. A survey of U.S. states found that 29 states allow raw milk sales for human consumption, two states permit raw milk sales with a medical prescription, four states prohibit the sale of raw milk for human consumption, but allow it for animal consumption, and 15

states prohibit the sale of raw milk totally (Editor 2004). Most European countries allow direct farm sales of raw milk, and the organized marketing of certified raw milk according to national regulations, which monitor the presence of pathogenic microorganisms. Such milk is especially popular in France, United Kingdom, and Austria. Thus one can find in the grocery stores of their cities the paper cartons of goat milk with the appropriate labels of certification and nutrient contents for fat, lactose, protein, and energy contents nicely displayed right next to the paper cartons of cow milk, organic milk, and acidophilus milk.

69.2.4 Uniqueness of Goat Milk

The higher price economically necessary for a good goat milk enterprise is also justified by unique quality characteristics of goat milk and its products, which are related to physiological, metabolic, nutritional, and anatomical differences between goats, cows, and sheep. Goats, when pastured, spend more time browsing and less time grazing than cows or sheep, they may walk longer distances, and get along with less frequent water intake. Great differences are also found for goats in the metabolism of minerals, especially molybdenum, copper, iodine, selenium, magnesium, and iron (Haenlein 2001). Unique differences in several important constituents and physical parameters of goat milk, such as proteins, lipids, minerals, vitamins, carnitine, glycerol ethers, orotic acid, enzymes, fat globule size, casein polymorphisms, between goats, cows, and sheep are therefore not surprising, and are significant for goat milk in human nutrition, justifying its higher price.

69.3 CHEMICAL COMPOSITION OF GOAT MILK

69.3.1 General Compositional Characteristics of Goat Milk

Proximate composition of goat milk generally resembles that of cow milk, although the former contains more fat, protein and minerals, and less lactose and casein than the latter (Table 69.5). Several reports (Parkash and Jenness 1968; Jenness 1980; Haenlein and Caccese 1984; Juarez and Ramos 1986; Park 1991) have shown general and detailed chemical composition of goat milk. As known in cow milk, composition of goat milk is

TABLE 69.5 Comparison of Average Composition of Basic Nutrients Among Goat, Cow, and Human Milk.

Composition	Goat	Cow	Human
Fat, %	3.8	3.6	4.0
Solid-not-fat, %	8.9	9.0	8.9
Lactose, %	4.1	4.7	6.9
Protein, %	3.4	3.2	1.2
Casein, %	2.4	2.6	0.4
Albumin, globulin, %	0.6	0.6	0.7
Non-protein N, %	0.4	0.2	0.1
Ash, %	0.8	0.7	0.3
Calories/100 mL	70	69	68

also expected to be varied with diet, breed, animals within breed, parity, environmental conditions, feeding and management conditions, season, locality, and stage of lactation (Schmidt 1971; Underwood 1977). Some of the variations in composition may be related to the lack of standardized dairy production practices in the dairy goat industry and difficulty in procuring milk samples representing pooled bulk milk from various herds and farms (Chandan and others 1992).

On average, cow milk contains about 12.2% total solids (3.2% protein, 3.6% fat, 4.7% lactose, and 0.7% ash), while goat milk contains about 12.1% total solids (3.4% protein, 3.8% fat, 4.1% lactose, and 0.8% ash) (Table 69.5; Posati and Orr 1976; Haenlein and Caccese 1984). These compositional figures are only average values which do not represent individual animals, and considerable differences exist between breeds and among individual goats.

The lower casein in goat milk compared to cow milk is closely related to coagulation property and yield of curds during cheese manufacture. Goat and cow milks contain substantially higher levels of protein, casein, calcium, phosphate and ash than human milk (Table 69.5). This difference in compositional characteristics of milk is believed to be strongly correlated with the growth rates of the young between different species, where the newborn of goats and cows grow a lot faster than human infants.

69.3.2 Factors Affecting Composition and Physicochemical Properties of Goat Milk

69.3.2.1 Diet. The effect of diet on milk composition appears to be similar in both goat and cow milk, although some variations of results have been observed (Juàrez and Ramos 1986). An increase in the energy content of the diet in high-yield goat breeds during lactation tended to augment milk production and reduced the fat content (0.2–0.4%) while raising the nitrogen content (0.1–0.15%) (Fehr and Le Jaouen 1976; Juàrez and Ramos 1986). Merlin and others (1988) reported that type of feed affected the total protein content of milk, whereas fat content was not changed. Water deprivation for 48 h resulted in reduction of milk yield, and higher lactose and protein contents (Dahlborn 1987).

The restricted roughage and high concentrate diets are accompanied by a decrease in the level of dietary fiber. The entire diet of the cow has to contain at least 17% crude fiber to prevent a depression in milk fat (Schmidt 1971). The role of dietary crude fiber levels on milk fat depression was also observed in goat milk by Calderon and others (1984). In a review on the effects of nutritional manipulation on composition and yield of goat milk, Morand-Fehr and Sauvant (1980) reported that goats fed a high concentrate diet (about 15% of their total requirements from concentrates) underwent nearly a 20% increase in milk yield, with slight decrease in fat content and increases in lactose and protein contents. Depression of fat content was similar to that for dairy cows, and there were no differences in either milk protein or total solids composition with the high-concentrate diet. Low-fat diets resulted in a drop in the milk fat content (Le Jaouen 1972), while adding protected lipids led to an appreciable increase in milk fat content (Morand-Fehr and Flamant 1983). However, high protein diets did not change the nitrogen content of the goat or cow milks (Vignon 1976). Increasing the protein content of the diet above the normal recommended standards had no effect on yield but caused only a slight increase in the nonprotein nitrogen content of cow milk (Juàrez and Ramos 1986).

69.3.2.2 Breed. The Saanen is best known as the Holstein of the goat world, producing a high quantity of milk with somewhat low fat levels (Haenlein and Caccese 1984). The other extreme case is the Nubian breed, which is equivalent to the Jersey breed of cows. Nubians produce less milk with higher solids, including fat and solids-not-fat (SNF). The Toggenburg, LaMancha, Oberhasli, and Alpine breeds produce milk yield and composition in between the Saanen and Nubian (Haenlein and Caccese 1984).

Variation in the fat content among the different breeds is greater than variation in protein content (Ramos and Juàrez 1981). The fat and total solids contents of the milk of imported Alpine, Saanen, and Anglo-Nubian breeds in tropical environments were lower than those of the same breeds raised under temperate climate conditions, which might be attributed to both improper diet and the higher temperatures (Juàrez and Ramos 1986). Indigenous breeds (e.g., West African Dwarf and Red Sokoto) have much richer composition but lower yields compared to those of the Swiss breeds.

69.3.2.3 Stage of Lactation. The milk production of the dairy goat at kidding starts out at a relatively high level and continues to increase to a peak approximately 3–4 weeks after freshening (Fig. 69.1; Le Jaouen 1987), where a similar trend with a peak at 3–6 weeks would occur in dairy cows (Schmidt 1971). The high production may be held for a few weeks, then the milk yield gradually declines toward the end of lactation (Fig. 69.1).

The fat, solids-not-fat, and protein contents of cow milk are high in early lactation, fall rapidly and reach a minimum during the second to third months of lactation, and then increase towards the end of lactation (Schmidt 1971). This results in an inverse relationship between the yield of milk and percentage composition of these components (Fig. 69.1). In goat milk, fat and protein contents decrease from onset of lactation to the fourth or fifth month and then remain low for a variable length of time, increasing at the end of lactation. Lactose content in both goat and cow milk shows some fluctuations during lactation, which is different from fat and protein contents, being first low, rising in mid lactation and decreasing again at the end of lactation (Renner 1982; Larson 1985).

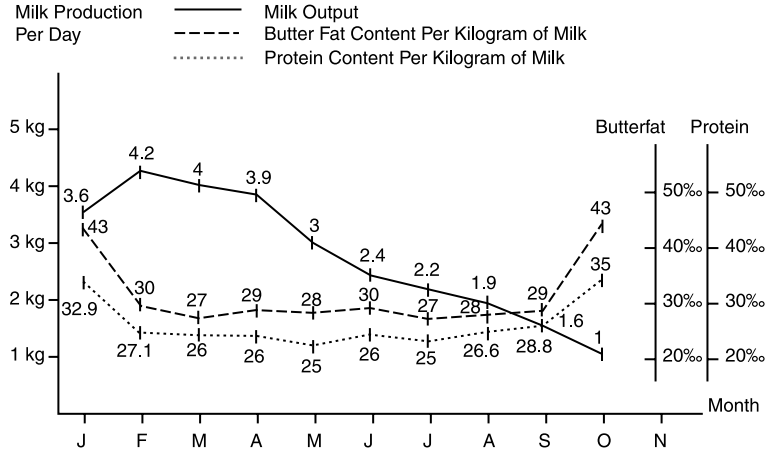

Figure 69.1 *Changes in milk yield, fat and protein contents during different stages of lactation in goat milk (Le Jaouen 1987).*

69.3.2.4 Season. Fat and SNF levels in goat milk vary with season (Fig. 69.1). In the temperate climate, late summer milk contains lowest fat and SNF contents (Parkash and Jenness 1968; Chandan and others 1992). Fat content of milk may vary as much as 2% and SNF as much as 1%, depending on the season. A Canadian study demonstrated that cheese yield varied directly with seasonal deviations in levels of fat and protein in milk (Irvine 1974).

Natural breeding usually results in goats freshening at the beginning of spring, although artificial breeding methods are practiced for year-round milking. The seasonal variations in milk composition are concommitantly involved with lactation stages in overall observed fluctuations of milk constituents (Chandan and others 1992).

69.4 CHEMICAL CHARACTERISTICS OF GOAT MILK COMPARED TO OTHER SPECIES MILK

69.4.1 Lipids

69.4.1.1 General Composition of Goat Milk Lipids. Goat milk is considered a naturally homogenized milk, where its fat globule size is smaller than in cow milk. Average diameters of fat globules for goat, cow, buffalo and sheep milks were reported to be 3.49, 4.55, 5.92, and 3.30 μm, respectively (Fahmi and others 1956). Smaller fat globules of goat milk make a better dispersion and a greater surface area of the fat for better digestion by lipases. The percent fat of goat milk is comparable to cow milk, but the physical and chemical structures are significantly different between the two species.

For gross characterization of milk fat, goat milk contains 97–99% of free lipids and 1–3% bound lipids of total milk fat (Table 69.6). The ratio of bound to free lipids is comparable to that for cow milk (Cerbulis 1982). Goat milk has similar fractional compositions of free lipids compared to cow milk. Free lipids of goat milk contained 96.8% triglycerides, 2.2% diglycerides, and 0.9% monoglycerides, whereas bound lipids contained 46.8% neutral lipids and 53.2% polar lipids (8.5% glycolipids and 44.7% phospholipids). Quantitative analysis of the phospholipid fraction of bound lipids of goat milk revealed that it had 35.4% phosphatidyl ethanolamine, 3.2% phosphatidyl serine, 4.0% phosphatidyl inositol, 28.2% phosphatidyl choline, and 29.2% sphingomyelin (Cerbulis and others 1982).

Most cholesterol in goat milk, as in cow milk, is in a free state (52 mg/100 g fat) with a small portion in ester forms, which constitutes less than 4% of the total cholesterol (Jenness

TABLE 69.6 Quantitative Distribution of Lipids in Bound and Free Fractions of Goat Milk.

Lipid Components	% Total Lipid
Free lipids	97–99%

1980; Chandan and others 1992). Fatty acid composition of cholesterol esters reveals that goat cholesterol esters have greater palmitic and oleic acid fractions than the cow counterparts (Table 69.7) (Jenness 1980; Juàrez and Ramos 1986). Average 66% free and 42% of esterified cholesterol was associated with goat milk fat globules (Keenan and Patton 1970). The level of unsaponifiable matter in goat milk is 24 mg/100 mL or 46 mg/100 g fat, which is comparable to that in cow milk (Arora and others 1976).

69.4.1.2 Fatty Acid Composition of Caprine Milk. Caprine milk has significantly higher levels of short and medium chain length fatty acids (MCT) (C4 : 0–C14 : 0) than cow and human milks (Table 69.7; Jenness and Patton 1976; Jenness 1980; Juàrez and Ramos 1986; Jensen and others 1990; Haenlein 1992). Comparative study on fatty acids composition of total lipids showed that goat milk contains almost twice as much capric, caproic, caprylic, and lauric acids than cow milk, which is correlated to "goaty" flavor in goat milk (Jenness 1980; Haenlein and Caccese 1984; Juàrez and Ramos 1986). (Table 69.7). Goat milk has a unique characteristic in the lauric : capric fatty acid (C12 : C10) ratio, where caprine milk is significantly lower in this ratio than cow milk (0.46 vs. 1.16) (Iverson and Sheppard 1989).

In light of long chain fatty acids, both goat and cow milk fats contain remarkably high concentrations of C16 : 0 and C18 : 1 (oleic), which are common to most mammals (Table 69.7). Levels of long-chain fatty acids (C16 : 0, C18 : 0, and C18 : 2) in goat milk were significantly different between milking herds (Alonso and others 1999). Five branched-chain fatty acids (BCFA) (*iso*- and *anteiso*-C15 : 0, *iso*- and *anteiso*-C17 : 0, and *iso*-C16 : 0) with $>0.1\%$ of the total fatty acid methyl esters and another 31 (the most monomethylated) with $<0.1\%$, including 4-ethyloctanoate were identified in caprine milk. Numerous BCFA (all having more than 11 carbons) were identified and quantified (Massart-Leen and others 1981), and over 20 volatile BCFA were identified in caprine cheese (Ha and Lindsay 1991). Caprine milk fat has a range of other monomethyl-branched components, mostly with methyl-substitution on carbons 4 and 6, which are virtually absent from cow milk with only a trace amount of 6-methyl-hexadecanoate detected (Alonso and others 1999).

The positional isomers of cis- and trans-octanoate in goat milk fat were 86% of the cis-C18 : 1 in oleate ($\triangle 9$) form, as opposed to 96% in cow milk (Jensen 1973; Jenness 1980). Both goat and cow milk fat contain adequate amounts of essential fatty acids for human infants.

Conjugated linoleic acid (CLA) has gained a great attention in recent years because of its several beneficial effects on health. The CLA content of goat milk can be increased by dietary manipulation and supplementation with certain ingredients such as addition of seed oil. Feeding canola oil at 2% and 4% of grain intake to Alpine does, compared to the non-treated control group, increased CLA in milk by 88% and 210%, respectively (Mir and others 1999).

69.4.1.3 Free Fatty Acids in Caprine Milk. Free fatty acid (FFA) is measured by acid degree value (ADV), which is a measure of lipolysis or degree of formation of FFA in milk and dairy products. Goat milk has higher sensitivity to spontaneous lipolysis than cow milk due to the difference in lipase distribution. Free fatty acid content of goat milk is 3.11 μeq/mL compared with cow milk (3.0 μeq/mL) and buffalo milk (3.4 μeq/mL) (Agnihotri and Prasad 1993).

Goat, sheep, and cow cheeses had similar FFA profiles, with the exception of 4-ethyloctanoic acid which was present in goat and sheep cheese, but was absent in

cow cheese (Ha and Lindsay 1991). The 4-methyloctanoic acid content in goat Cheddar cheese increased significantly from day 1 to week 12 of the aging period (Attaie and Richter 1996). The threshold concentration of 4-ethyloctanoic acid for goaty aroma was 1.8 ppb (Boelens and others 1983) and 6.0 ppb (Brennand and others 1989) in diluted citric acid solution at pH 2.0.

FFA fraction of goat milk has been shown to be related to "goaty" flavor intensity in the milk. A positive correlation was found between goaty flavor and free fatty acids (5.6 and 2.7 meq/L in samples stored for strong and weak flavor) (Bakke and others 1977). Concentration of FFA increased during storage at 4°C, where the FFAs initially consisted of short chain acids, then long chain FFA such as C16 : 0 and C18 : 0 increased after 10 days of storage (Bas and others 1978).

69.4.2 Proteins

69.4.2.1 Major Proteins and Caseins in Goat Milk. Goat milk has six principle proteins: β-lactoglobulin (β-Lg), α-lactalbumin (α-La), κ-casein (κ-CN), β-casein (β-CN), α_{s1}-casein (α_{s1}-CN), and α_{s2}-casein (α_{s2}-CN) (Jenness 1980; Haenlein and Caccese 1984; Carles 1986; Mikkelsen and others 1987; Park 2006). These goat milk proteins were named after their corresponding cow milk proteins because of their homologous nature of both species milks in composition and properties (Whitney and others 1976). The casein composition in goat milk is influenced by genetic polymorphism on the casein loci as described in the following section (Tziboula-Clarke 2003).

β-casein is shown to be the major component of the casein fraction in goat milk, whereas α_{s1}-casein is the major casein in cow milk. Total casein content of goat milk is slightly lower than that of cow milk (Table 69.8). Goat milk has markedly different levels of α_{s1}- and α_{s2}-CN from those levels of cow milk, where goat milk has much lower α_{s1} and higher α_{s2}-CN than cow milk (Chandan and others 1968; Remeuf and

TABLE 69.8 Comparison of Concentrations of Protein Moieties Among Goat, Cow, and Human Milks.

Proteins	Goat	Cow	Human
Protein (%)	3.5	3.3	1.2
Total casein (g/100 mL)	2.11	2.70	0.40
α_{s1} (% of total casein)	5.6	38.0	–
α_{s2} (% of total casein)	19.2	12.0	–
β (% of total casein)	54.8	36.0	60–70.0
κ (% of total casein)	20.4	14.0	7.0
Whey protein (%) (albumin and globulin)	0.6	0.6	0.7
Nonprotein N (%)	0.4	0.2	0.5
Immunoglobulin			
IgA (milk: μg/mL)	30–80	140	1000
IgA (colostrum: mg/mL)	0.9–2.4	3.9	17.35
IgM (milk: μg/mL)	10–40	50	100
IgM (colostrum: mg/mL)	1.6–5.2	4.2	1.59
IgG (milk: μg/mL)	100–400	590	40
IgG (colostrum: mg/mL)	50–60	47.6	0.43

Source: Jenness (1980), Remeuf and Lenoir (1986), Renner and others (1989), Chandan and others (1992), and Park and Haenlein (2004).

Lenoir 1986). However, goat milk shows considerable variations in its α_{s1}-CN content ranging from 2.7 g/L to only 0.12 g/L (Mora-Gutierrez and others 1991), which is genetically regulated in different breeds.

69.4.2.2 Whey Proteins. While caseins are the major proteins in milk, whey or serum protein fractions consist of mainly three components, which are bovine serum albumin, β-Lg, and α-La. Whey proteins also include some immunoglobulins and proteose-peptone fractions (Whitney and others 1976; Jenness 1980). β-Lg and α-La are the two whey proteins generally contained in significant quantities.

It was reported that β-Lg contents are similar in the two species milks, but goat milk contains nearly twice as much α-La as cow milk (Jenness 1980). However, Storry and others (1983) indicate that the α-La content in the two species is approximately equal but the β-Lg content in goat milk is practically double the α-La content.

β-Lg in goat milk has been separated and sequenced (Juàrez and Ramos 1986). Goat β-Lg has three less-negatively charged and one more positively charged residues than bovine β-Lg at pH values of 5–9 (Jenness 1982). This difference in ionizable groups may expound the difference in titration curves previously noted for the two proteins and the slower electrophoretic mobility of goat β-Lg at alkaline pH levels (Juàrez and Ramos 1986).

Goat α-La has been confirmed to be similar to that of the bovine homolog by various optical analyses, where the two species proteins have equal exposure of Tyr, Trp, and Lys groups in their conformation (Jenness 1980). α-La is present in all milks which contain lactose, since it is required for biosynthesis of lactose at meaningful rates (Ebner and Schanbacher 1974). α-La is considered best as a modifier protein, since it changes the apparent K_m of the substrate, glucose, and does not appear to participate directly in the catalytic reaction (Ebner and Schanbacher 1974). Four disulfide bonds are found in α-La as the major component, and the isolation of an α-La with three disulfide bonds from an α-La B preparation accounts for approximately 5% of the total α-La (Brown and others 1969).

69.4.2.3 Amino Acid Composition. The characteristics of the amino acid compositions in goat milk proteins show that differences between casein fractions are much greater than differences between species (goat vs. cow) within a casein fraction (Park 2006). The α-CN contains more aspartate, lysine, and tyrosine than β-CN, while the latter has more leucine, proline, and valine contents than the former. The β-Lg contains significantly less aspartate than α-La, whereas the opposite trend is noted for alanine and glutamate concentrations (Davis and others 1994).

Total amino acid contents in goat and other nonprimate milks were substantially greater than those in human and primate milks (Davis and others 1994). Other commonalities in all species milks were essential amino acids (EAA) 40%, branch-chain amino acids (BCAA) 20%, and sulfur amino acids 4% of the total amino acids. The EAA contents of goat and cow milk were greater than those of human milk, whereas the opposite trend was observed for the BCAA contents (Davis and others 1994). Goat, cow, and human milks have a satisfactory balance of EAA equalling or exceeding the FAO-WHO requirements for each amino acid for human infants (Jenness 1980).

69.4.2.4 Nonprotein Nitrogen and Other Nitrogen Moieties of Goat Milk. Nonprotein nitrogen (NPN) contents in goat and human milk are much higher than in cow milk (Park 1991; Table 69.9). In comparison with cow milk, goat milk has

a higher NPN, 8.7% as opposed to 5.2%, and a lower proportion of coagulable proteins and caseins, 70.9% and 75.6% compared to 73.0% and 77.8%, respectively (Grappin and others 1981). Similar values of casein content (% of total nitrogen) were reported by Jenness (1980). True protein is calculated as crude protein minus NPN, where the ratios of casein to true protein for goat and cow milks are 82.7% and 82%, respectively.

The composition of NPN indicates, that it contains several nitrogenous compounds, and its components (mg N/100 mL) in cow milk include: 0.17 ammonia N, 6.54 urea N, 0.19 creatinine, 3.55 creatin, 1.55 uric acid, 2.20 α-amino N, and 5.63 unaccountable N, respectively (Rowland 1937; Jenness and Patton 1976). NPN contents in goat and cow milk also are different between different breeds, indicating that Nubian has higher NPN levels than Alpine goats, like the Jersey cow has higher NPN than the Holstein cow milk (Table 69.9; Park 1991, 1992a).

69.4.3 Minor Proteins, Enzymes, and Other Constituents

Goat milk has comparable levels of lactoferrin, transferrin, and prolactin to those of cow milk (Table 69.10). Human milk contains more than 2 mg lactoferrin/mL, which amounts to being 10–100-fold higher than in goat milk. Goat and cow milk contain transferrin levels of 20–200 μg/mL, while human milk contains <50 μg/mL. Goat milk has higher levels of folate-binding protein than cow milk, causing actual folate content being lower in the former than the latter (Table 69.10; Ford and others 1972; Renner and others 1989; Chandan and others 1992). The protease activity in fresh goat milk is greater than in cow milk (Anjaneyulu and others 1985).

Goat milk has different distributions of enzymes compared to cow milk (Table 69.10; Chilliard and others 1984; Chandan and others 1992). Lysozyme concentrations of goat and cow milks are comparable (Table 69.10), where goat milk contains in average 25 μg of lysozyme, 425 μg of ribonuclease, and 36 μM of lipase/100 mL (Chandan and others 1968). Ribonuclease level in cow milk is much greater than in

TABLE 69.10 Minor Proteins, Enzymes, and Other Constituents in Goat Milk.

Constituents	Concentration Ranges
Lactoferrin	20–200 μg/mL
Transferrin	20–200 μg/mL
Prolactin	44 ng/mL
Folate-binding protein	12 μg/mL
Lysozyme	25 μg/100 mL
Ribonuclease	425 μg/100 mL
Lipase	36 μM/100 mL
Lactate dehydrogenase	47 μM/s/mL
Malic dehydrogenase	50 μM/s/mL
Xanthine oxidase	19–113 μL O_2/h/mL
Alkaline phosphatase	11–13 mg/L
Orotic acid	13 mg/L
Carnitine	16.4 mg/L
ATP	19 mg/L
Free amino acid	48 mg/L
Sialic acid protease	13.89 mg/L

goat milk, where this enzyme is identical to bovine pancreatic ribonuclease (Juàrez and Ramos 1986).

Alkaline phosphotase level of goat milk ranged from 11 to 13 mg/L. Some researchers reported that this enzyme can be inactivated at around 45°C. These reports indicate that the effectiveness of the alkaline phosphatase test for pasteurization of goat milk may not be as good as generally assumed from cow milk (Juàrez and Ramos 1986).

Xanthine oxidase activity of goat milk is less than 10% of that of cow milk (Chandan and others 1992). Xanthine oxidase has been implicated in the spontaneous development of undesirable oxidized flavors in market milk and other dairy products, and interest in this enzyme has increased, because of its possible involvement in development of atherosclerosis in humans (Juàrez and Ramos 1986). Caprine xanthine oxidase contains higher amounts of aspartic acid, glutamic acid, proline, and glycine and lower amounts of serine than bovine xanthine oxidase (Zikakis and others 1983).

Lipase activity in goat milk is significantly correlated with spontaneous lipolysis, which may be attributed to its specific lipolytic system. Significantly lower lipoprotein lipase activity was observed in fresh goat milk cooled to 4°C, compared to the enzyme activity in cow counterparts. Lipases play a major role in flavor development in milk and dairy products during milk processing and storage.

Goat milk has in average 47 μ moles/s/mL of lactic dehydrogenase and 50 μ moles/s/mL of malic dehydrogenase (Jenness 1980).

69.4.4 Carbohydrates

The major carbohydrate of goat milk is lactose. Average lactose content of goat milk is 4.45%, which is about 0.2–0.5% less than that of cow milk which is 4.66% (Posati and Orr 1976; Chandan and others 1992). Cow milk contains insignificant levels of monosaccharides and oligosaccharides, while their presence in goat milk is not known (Chandan and others 1992).

69.4.5 Minerals

Goat milk contains higher calcium, phosphorus, potassium, magnesium, and chlorine, and lower sodium and sulfur contents than cow milk (Table 69.11; Chandan and others 1968; Haenlein and Caccese 1984; Park and Chukwu 1988, 1989). Human milk contains only one-quarter to one-sixth of calcium and phosphorus. Although the fluctuation of macromineral contents may not be considerable in goat milk, their levels can vary, depending on the breed, diet, animal and stages of lactation (Park and Chukwu 1988; Park 2006).

A close inverse relationship was observed between lactose content and the molar sum of sodium and potassium contents of goat or other species milks (Konar and others 1971; Park and Chukwu 1988). Chloride is positively correlated with potassium and negatively with lactose, but sodium is not significantly correlated with K, Cl, and lactose (Park 2006).

Unlike most of macrominerals, levels of trace minerals are affected by diet, breed, animals, and stages of lactation (Park and Chukwu 1989). Mean concentrations of Mn, Cu, and Fe in French-Alpine goat milk were 0.33, 5.0, and 1.7 mg/L, while Anglo-Nubian goat milk contained significantly higher levels of Cu (1.36 vs. 1.69 mg/L) and Zn (7.9 vs. 11.9 mg/L) (Park and Chukwu 1989). In Norwegian bulk goat milk, a positive correlation was observed between levels of Co and P, K, Na, Ca, Al, and Mg (Brendehaug and

Abrahamsen 1987). Zinc content is the highest among trace minerals, and Zn contents in goat and cow milks are greater than in human milk (Park and Chukwu 1989). Iron contents of goat and cow milks are significantly lower than in human milk (Table 69.11).

The respective average Mo contents of goat and cow milks are 12.4 and 25.9 μg/L (Table 69.11) (Hart and others 1967). The supplementation of 1.1 mg Mo/day in goat's diet produced 12 μg/L of Mo in milk, while 13.0 mg Mo/day elevated Mo in milk to approximately 70 μg/L (Jenness 1980). Selenium is an essential trace mineral. It is a component of glutathione peroxidase, which detoxifies peroxide. Selenium deficiency is correlated with liver necrosis, abnormal cardiac function, and even cancer (Debski and others 1987; Park 2006). Goat and human milk contain higher concentrations of selenium than cow milk (Table 69.11). Less than 3% of the total selenium is associated with the lipid fraction of milk. Glutathione peroxidase was higher in goat milk than in human and cow milk. (Debski and others 1987).

69.4.6 Vitamins

Goat milk supplies adequate amounts of vitamin A and niacin, and excesses of thiamin, riboflavin, and pantothenate for a human infant (Table 69.11; Parkash and Jenness 1968; Ford and others 1972). Goat milk has higher amounts of vitamin A than cow milk. Since goats convert all β-carotene into vitamin A in the milk, caprine milk is

whiter than most bovine milk. Vitamin B in goat and cow milks is synthesized in the rumen, whereby the B levels may be independent of diet (Mann 1988).

Compared to cow milk, goat milk is deficient in folic acid and vitamin B_{12} (Collins 1962; Davidson and Townley 1977; Jenness 1980; Haenlein and Caccese 1984; Park and others 1986). Cow milk has five times more folate and vitamin B_{12} than goat milk, where folate is necessary for the synthesis of hemoglobin (Collins 1962; Davidson and Townley 1977). However, both goat and cow milks are deficient in pyridoxine (B_6), vitamin C and vitamin D, where these vitamins must be supplemented from other food sources (McClenathan and Walker 1982).

Lavigne and others (1989) showed that high temperature and short-time (HTST) pasteurization method was the best processing method for goat milk to preserve various vitamins as well as extend the shelf-life. The HTST, flash, and UHT process were better than LTLT and autoclave treatment methods in preservation of thiamine, riboflavin, and vitamin C in goat milk (Lavigne and others 1989).

69.5 PROTEIN POLYMORPHISM AND RENNETABILITY OF GOAT MILK

69.5.1 Protein Polymorphism in Goat Milk

It has been shown that a direct relationship exists between protein allelic variants and differences in casein (CN) content, and in physicochemical properties of milk (Jordana and others 1996). Milk protein polymorphisms are caused either by the substitution of amino acids or by the deletion of several of them, and they can be detected through electrophoresis of milk and/or analysis of DNA (Moioli and others 1998).

An association has been established between the existence in the Saanen and Alpine dairy breeds of at least seven alleles and various amounts of α_{s1}-CN in the milk (Tables 69.8 and 69.12) (Grosclaude and others 1987; Mahe and Grosclaude 1989). Polymorphism of α_{s1}-casein controls the level of α_{s1}-casein excretion in milk, and more than 18 allelic genotypes have been identified in goat milk (Tziboula-Clarke 2003). Each one of the alleles α_{s1}-CN^A, α_{s1}-CN^B, and α_{s1}-CN^C contribute approximately 3.6 g CN/L milk, whereas α_{s1}-CN^E contributes only 1.6 g, α_{s1}-CN^F, and α_{s1}-CN^G 0.5 g, and α_{s1}-CN^0 appears to be a null allele (Jordana and others 1996). The allele E (medium) is related to an intermediate content, and those F and G (weak) are associated with low contents of α_{s1}-casein (0.5 g/L per allele) (Tziboula-Clarke 2003).

Grosclaude and others (1987) reported that the relationship between total casein content (TC) and α_{s1}-CN content can be calculated as $TC = 19.59 + 0.64\ \alpha_{s1}$. Quantitative variations of α_{s1}-CNs were also reported in Italian goat breeds in relation to the coagulation properties of the goat milk (Ciafarone and Addeo 1984; Ambrosoli and others 1988). In characterization of the six caprine α_{s1}-CN variants, Brignon and others (1990) found that variants A and B had the closest homology with the ovine and bovine sequences. The higher amount of α_{s1}-CN is likely to be associated with alleles α_{s1}-CN^A, α_{s1}-CN^B, and α_{s1}-CN^C in goats. These alleles are normally high in caprine species, while the other alleles are defective mutants. The decreased rate of α_{s1}-CN synthesis associated with allele α_{s1}-CN^F is due to altered RNA splicing, as a consequence of an exonic point deletion (Leroux and others 1992).

Considering the economic contribution of dairy goat production in France, Spain, Italy, Greece, and other countries, it would be important to evaluate the gene frequency of

TABLE 69.12 Protein Variants in Goats.

α_{s1}-CN alleles in different dairy goat breeds, as well as to determine the effect of the α_{s1}-CN genotype as criterion in selection programs.

69.5.2 Variants and Alleles at the Milk Protein Loci

There are six major proteins found in goat and sheep milk, and caseins are nearly 80% of the total protein amount. Four types of caseins α_{s1}, α_{s2}, β, and κ are mainly affecting cheese yield and quality (Moioli and others 1998). The genes coding for the four caseins are closely linked, where the heritable transmitted unit is the haplotype (Grosclaude 1988). The major whey proteins in goat and cow milk are α-lactalbumin and β-lactoglobulin.

In most European dairy goat breeds such as Alpine, Saanen, Poitevine, Garganica, Maltese, Murciana-Granadina, Malaguena, a polymorphism with ten alleles (A, B_1, B_2, B_3, C, D, E, F, G, O) was found (Table 69.12) (Martin 1993; Jordana and others 1996; Moioli and others 1998; Tziboula-Clarke 2003). The α_{s1}-CNs A, B, C, and E differ only due to a few amino acid substitutions, while α_{s1}-CNs D and F show considerable structural differences, consisting in internal deletions of 11 and 37 residues respectively, which include the multiple phosphorylation sites (Martin 1993).

69.5.3 Genetic Typing

Milk protein content ranges between 2.5% and 4.4% in most dairy goats. The four caseins (CN) such as α_{s1}-CN, α_{s2}-CN, β-CN, and κ-CN, are the main components accounting in ruminants for 76–86% of the total protein (Ciafarone and Addeo 1984; Swaisgood 1992).

At DNA level, polymorphisms are due either to point mutations or to DNA rearrangement phenomena (Moioli and others 1998). For point mutations, such as single nucleotide substitution, differences between two individuals are detected using restriction enzymes which cut DNA only at a specific DNA sequence: different alleles will be displayed by the electrophoresis gel with bands of different lengths (Moioli and others 1998). When the point mutation is not recognized by any endonucleases, allele-specific primers can be built for the two different variants and used independently in a polymerase chain reaction (PCR) with a second common primer to amplify the region where the mutation has occurred (David and Deutch 1992).

For genetic typing, rearrangement phenomena consist of insertions, deletions and inversions of DNA fragments (Moioli and others 1998). The most common are microsatellites, which consist of repeated sequences of two, three, or four nucleotides (Moioli and others 1998). Specific microsatellites contained within a stretch of sequenced unique DNA can be individually amplified by means of the PCR (polymerase chain reaction) using a pair of flanking unique oligonucleotides (Soller 1990). Amplified sequences produced from different individuals exhibit highly polymorphic length variation and are used to construct linkage maps by estimating recombination frequencies from individuals belonging to families.

69.5.4 Effect of Milk Protein Polymorphism on Renneting Properties

Goat milk has a poorer coagulating ability, which is due essentially to its lower casein content and to specific properties of casein micelles as composition, size, and hydration. On average, the firmness of the gel of goat milk is clearly lower, and the gel from goat milk with an equal casein content is not as firm as from cow milk (Storry and others 1983). Proportions of the four caseins (α_{s1}, α_{s2}, β, and κ) are not the same in the two milks and there are great variations of α_{s1}-casein content in individual goat milks due to the occurrence of genetic polymorphism of this casein, which may have great repercussions on their cheesemaking properties (Remeuf 1992).

Intensive studies have been conducted on the effect of milk protein polymorphism on milk composition, which influences the renneting process. In goat milk, the ten CN alleles are associated with different amounts of α_{s1}-CN. Remeuf (1993) reported that the alleles are correlated with total N, casein and fat content. He also noted that micellar size (AA $<$ EE and FF) and micellar mineralization (FF and EE $>$ AA) were affected by α_{s1}-CN genetic variants. The same author postulated that considerable differences in the renneting speed, curd firmness and cheese yield may be attributable to the three groups of alleles. Best parameters were obtained by homozygous α_{s1}-CN AA goats. In relation to taste with alleles, allele A gives goat cheese the sweetest flavor, while allele F provides the sharpest taste (Vassal and Delacroix-Buchet 1994).

69.6 PHYSICOCHEMICAL PROPERTIES AND PROCESSING CHARACTERISTICS OF GOAT MILK

69.6.1 Physicochemical Properties and Processing Variables

Goat and cow milk fats have a similar level of the unsaponifiable matter (Table 69.13). However, goat milk fat contains more unsaturated fatty acids than the cow counterpart, because the former has higher iodine values than the latter. Saponification value is higher and refractive index is slightly higher in cow milk than in goat milk, whereby both indices reflect the number of carbons and saturation in the fatty acids in the milks. Most short chain acids (C4–C8) in goat milk triglycerides are esterified at position *sn*-3 of the glycerol, while the longer chains (C10 or greater) are at position *sn*-2 (Park 2006). Triglycerides are synthesized from a pool of long-chain 1,2-diglycerides (Tziboula-Clarke 2003). Goat milk fat contains more soluble volatile fatty acids and less insoluble volatile fatty acids than cow milk fat.

TABLE 69.13 Comparison of Physicochemical, Renneting Variables, and Micelle Structure of Goat Milk with Those of Cow Milk.

Characteristics	Goat Milk	Cow Milk
Physicochemical values[a]		
Unsaponifiable matter of milk fat (%)	0.41 ± 0.02	0.41 ± 0.02
Iodine value	30.44 ± 2.57	27.09 ± 1.26
Saponification value	228.6 ± 5.24	232.3 ± 7.61
Refractive index	1.450 ± 0.39	1.451 ± 0.35
Renneting variables[b]		
Renneting time (min)	19.6	35
Firmness of gel (mV)	43.9	75
Setting speed of gel (mV per min)	3.6	2
Volume of water retained in centrifuged curd	5.0	8.6
Micelle Structure[b]		
Noncentrifugal casein (% of total casein)	8.7	5.7
Average diameter (nm)	260	180
Hydration of micelle (g/g MS)	1.77	1.9
Mineralization of micelle (g/ca/100 casein)	3.6	2.9

Source: [a]Anjaneyulu and others (1985); [b]Remeuf and Lenoir (1986).

Goat milk has shorter renneting time than cow milk, whereas the firmness of goat milk gel is substantially less than that of cow milk (Table 69.13). The rennet setting speed of the gel for goat and cow milk are 3.6 and 2 mV/min, but the weak structure of goat gel causes some difficulties in manufacturing hard goat cheeses.

Goat milk has a different micelle structure compared to cow milk (Table 69.13). Caseinate micelles of goat milk contain more calcium and inorganic phosphorus, are less solvated, less heat stable, and lose β-CN more readily than bovine micelles (Jenness 1980). The average mineralization level in goat milk is higher than in cow milk (Table 69.13). However, the degree of hydration in goat milk is lower, resulting in an inverse relationship between the mineralization of the micelle and its hydration in goat milk (Soods and others 1979; Remeuf and Lenoir 1986).

Soluble casein content of goat milk is higher than in cow milk. Goat and cow milk have 10 and 1% soluble casein at 20°C, while 25 and 10% soluble casein at 5°C, respectively (Juàrez and Ramos 1986). Low storage temperatures have a marked influence on micellar system. Cooling leads to a partial solubilization of colloidal calcium phosphate and of β-CN (O'Connor and Fox 1973).

69.6.2 Heat Stability of Goat Milk

Heat stability of goat milk is considerably less than for bovine milk. High ionic calcium content and low micellular solvation in caprine milk may contribute to heat instability (Remeuf 1992). Goat milk has a great sensitivity toward heat treatment (Chandan and others 1968; Lavigne and others 1989), whereby it is usually unable to withstand UHT treatment (Patton and others 1980). However, recently goat milk is routinely processed by the UHT method in commercial goat dairies such as in the Wisconsin dairy goat cooperative. A great variability in heat stability exists between individual milk samples. Heat coagulation times at 140°C were between 0.5 and 23.4 min (Chandan and others 1968),

while heat coagulation temperatures of individual goat milk samples ranged from 118°C to more than 140°C (O'Connor and Fox 1973).

Several methods including pH adjustment, addition of a calcium sequestrant, and preheating of milk, were proposed to improve heat stability of goat milk and to sustain UHT treatments for goat milk (O'Connor and Fox 1973; Patton and others 1980). However, the problem of stability in high temperature treated goat milk has not been resolved due to rapid destabilization and flavor alteration of UHT processed fluid goat milk.

The heat coagulation time versus pH profile for caprine milk samples heated at 140°C typically displayed a pronounced heat stability maximum at about pH 6.9, with low heat stability at both low and high pH (Fox and Hynes 1976; Tziboula 1997). The difference in the pH threshold between goat and cow milks may cause the variability in heat instability of goat milk, where the pH threshold of goat milk is around 6.9 while that of cow milk is 6.5–6.6 (Patton and others 1980). Goat milk shows a lower heat stability at its original pH of 6.7 when compared to cow milk. The differences between micellar characteristics or salt equilibria of the two milks also might be attributable to the lower heat stability of goat milk. Tziboula (1997) demonstrated that the heat stability of goat milk is dependent on the casein genotype, with milks high in α_{s1}-CN having a lower heat stability than those with a low α_{s1}-CN content.

69.7 GOAT MILK PRODUCTS AND THEIR MANUFACTURING TECHNOLOGY

Many types of dairy products can be manufactured from goat milk, including fluid products (low fat, fortified, or flavored), fermented products such as cheese, buttermilk or yogurt, frozen products such as ice cream or frozen yogurt, or butter, condensed and dried products (Malven 1977; Kehagias and others 1986). However, cheese is traditionally the main goat commercial milk product produced and consumed in large quantities around the world. Significant volumes of fluid, evaporated and powdered goat milk products have been marketed in the United States and New Zealand for the past several decades. Although literatures have been available on goat milk cheeses, research data on other manufactured dairy goat products have been scarce (Malven 1977; Kehagias and others 1986). The basic compositions of dairy goat products are shown in Table 69.14.

69.7.1 Beverage Milk

Using conventional processing equipment, fluid goat milk may be processed by standardizing to 2% fat and 10.5% SNF and fortified with vitamins A and D, and pasteurizing for retail sale (Loewenstein and others 1980). The general processing procedure for fluid cow milk may be applied for goat fluid milk processing, which is shown in Figure 69.2. Condensed goat milk may be used for standardization, even though nonfat dry milk should be used if available.

There are at least four important requirements for Grade A quality goat milk. Those are: (1) safe to drink, (2) good flavor, (3) low spoilage bacteria and somatic cells, and (4) minimum composition (Loewenstein and others 1984). For safe milk, it must be free of pathogenic bacteria, antibiotic, insecticide, and herbicide compounds (Loewenstein and others 1984; Park 2006).

69.7.2 Goat Milk Cheeses

Many different varieties of goat milk cheeses are produced worldwide, depending on diversity of locality, milk composition, and manufacturing techniques. Goat cheese composition would vary significantly between varieties due to the high variation in the seasonal composition of milk, modifications of manufacturing procedures, and multitude of aging time and conditions (Loewenstein and others 1980; Godina 1985; Park 1990). The varietal difference among cheeses is accounted for by the nature of physical and chemical changes during ripening (Fredriksen and Steinsholt 1978; Loewenstein and others 1984), which are affected by the cultures, chemicals, or flavor ingredients added to the curd during manufacturing processes (Lame and Hekmati 1975; Kosikowski 1977; Loewenstein and others 1980; Park 1990).

France has offered the best in goat milk cheeses, many of which are surface-ripened. France produces many exotic types of goat cheeses, including Crottin du Chavignol, Les Pyramides, Sainte Maure, Chabis and Chabicou (Kosikowski 1977). Other successful goat milk cheese producing countries are Norway, Spain, Greece, Portugal, Italy, and United States (Park and Guo 2006).

The Agricultural Handbook No. 54 of the USDA (Sanders 1969) describes over 400 varieties of goat cheeses and lists over 800 names of cheeses, made from goat milk or combinations of goat with other species milk such as cow, ewe, or buffalo (Park 1990).

Because the majority of goat cheeses are soft body types, the manufacture of goat cheese is referred to as a "cottage industry." A study on nutrient composition of U.S. goat cheeses showed that 20 out of 30 varieties investigated were very high or high moisture cheeses, suggesting that slow coagulation is the major mode of fabrication (Park 1990).

The traditional farmstead goat milk cheesemaking consists of the following nine basic steps (Le Jaouen 1987): (1) filtering of the milk, (2) pasteurizing, (3) renneting, sometimes preceded by acidification, (4) coagulation of the milk, (5) placing of the curds into cheese molds, sometimes preceded by predraining, (6) draining, sometimes interrupted by turning the cheeses over, (7) unmolding, (8) salting, (9) drying, and (10) ripening. These procedures are traditionally used for French soft body type farmstead goat cheese manufacture (Park and Guo 2006).

69.7.3 Goat Milk Yogurt

Goat milk yogurt is one of the traditional products from countries where fermented dairy foods originated (Park and Guo 2006). Goat milk yogurt can be made in a similar manner to the cow counterpart. The general manufacturing procedure for yogurt making is shown in Figure 69.3. One of the main problems in manufacture of goat milk yogurt is weak or lack of consistency in curd tension or viscosity upon agitation compared with cow yogurt. This is due in part to the difference in protein composition between the two milks, especially in casein contents.

The typical manufacturing steps for yogurt are shown in Figure 69.3 (Kosikowski 1977; Loewenstein and others 1980). The basic processing procedures of goat milk yogurt include: (1) preparation of milk, (2) standardization (standardized to 1.0–1.7% fat), (3) pasteurization (72°C for 20 s compared to cow yogurt 90.6°C for 40–60 s (HTST) or 85°C for 30 min (vat), (4) cool the pasteurized mix to 46.7°C (116°F) and hold in vat for up to 15 min, (5) inoculation (45°C) (Carefully introduce into warm milk or milk mixes 1.25% by weight of active *Lactobacillus bulgaricus* culture and 1.25% *Streptococcus thermophilus* culture), (6) packaging (set yogurt), (7) incubation (permit filled containers to remain in room at 45°C (114°F) for 3–5 h or until a firm, smooth gel has formed to

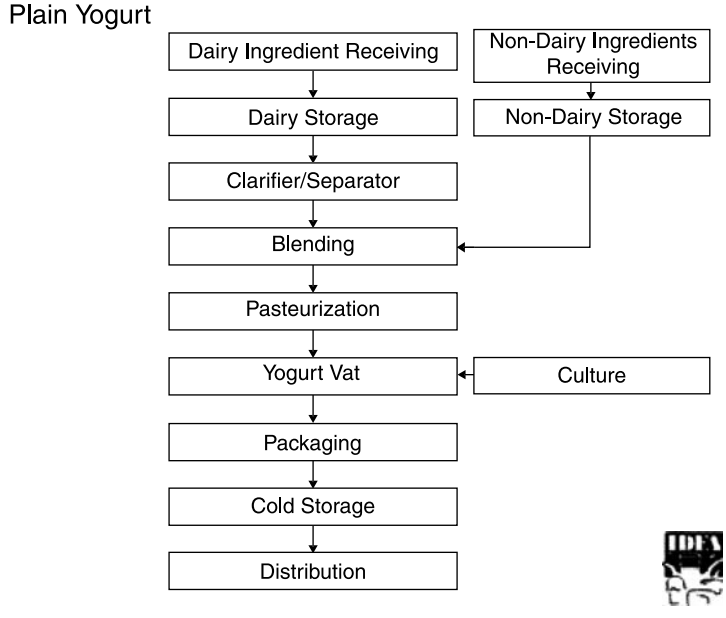

Figure 69.3 *Flowchart for manufacture of yogurt. (Adapted from FDA Workshop, St. Louis, MO, 2000.)*

pH 4.5), (8) chilling (yogurt is chilled to 7.2°C (45°F) in less than 1 h), and (9) storage and distribution (store the containers of yogurt at 4.4°C (40°F) or lower; the shelf life at this temperature is 30–60 days) (Kosikowski 1977; Park and Guo 2006).

69.7.4 Other Goat Milk Products

69.7.4.1 Other Fermented Goat Milk Products. Many other fermented goat milk products are produced and consumed in many parts of the world, such as buttermilk, acidophilus, sour dip, and kefir. Different culture microorganisms are used for these different types of fermented milk products, and incubation is stopped at different desired acidity (Park and Guo 2006).

Buttermilk is usually made from skim milk using the by-product from churning butter from sour cream. Goat buttermilk is made from skim milk (less than 0.5% fat); yogurt made from whole milk (3.25% fat), low fat milk (0.5–2.5% fat), or skim milk; sour cream must contain 18% fat in most states (Loewenstein and others 1980).

Acidophilus milk is pasteurized milk or low-fat milk inoculated with a probiotic *Lactobacillus acidophilus*, which destroys other competing bacteria antagonistic to man in the lower intestine. These organisms have the ability to implant themselves in the large intestines, survive the stomach acids and enzymes, low surface tension, and change nutrients (Kosikowski 1977). In the past the popularity of this product was limited by the flavor developed during fermentation. It is manufactured with skim milk or partially defatted milk, which is sterilized in an autoclave at 120°C for 20 min (15 psi), then tempered to 38°C. Next, a 5% inoculation of active *L. acidophilus* starter is introduced. The mixture is incubated at 38°C for 18 to 24 h until a curd forms with about 1.0% titratable acidity (Park and Guo 2006).

Kefir is an acidic, slightly foamy product, made from pasteurized and fat-standardized or decreamed goat milk, which has passed through a combined acidic and alcoholic fermentation of symbiotic lactic acid bacteria and yeast "kefir grains" (Kosikowski 1977). The finished product, kefir contains 0.6–0.8% lactic acid, 0.5–1.0% alcohol and carbon dioxide (Park and Guo 2006).

Ghee is an Indian (and Middle-East) clarified butterfat product which is manufactured by fermenting whole milk into curd and churning out butter, followed by heat clarification at 105–145°C (Kosikowski 1977; Chandan and others 1992). In the Middle East, casein is produced from skimmed milk. In Iran it is called *Kashk* or dried butter.

Sweet products made of goat milk are popular in Mexico, Norway, and India (Park and Guo 2006). In Mexico, the *Caheta* is a thick liquid of caramelized milk with sugar added, which is popular and sold as such or dried as small tarts. In Norway, *gjetost*, brown whey cheese, is produced by heat condensation and is similar in taste to *Cajeta*. *Gjetost* is a sweet caramel-color product with a firm texture in which lactose crystals may be noted. In India, a goat milk-based sweet is made by kneading chhana and cooking in sugar syrup over medium heat. *Khoa* is a heat-desiccated indigenous milk product used in the preparation of a variety of sweets (Park and Guo 2006).

Cosmetic goat milk products such as goat milk soap, hand lotion, and so on, have been produced and are increasingly popular in the United States and other countries like Switzerland. An internet search on goat milk soap shows a list of more than 5000 references. The number of home-based goat milk soap businesses has tremendously increased in recent years, and now generate substantially high annual revenues in the United States (Park and Guo 2006).

69.7.4.2 Evaporated and Powdered Goat Milk Products. Little research has been reported on evaporated and powdered goat milk products, while they are manufactured in the United States and New Zealand, marketed around the world (Park 2000; Park and Guo 2006). Evaporation is usually done under reduced pressure, primarily to allow boiling at a lower temperature and thus prevent flavor damage due to heating. The principal components of an evaporation plant are: (1) evaporation chambers operating as heat exchangers, (2) equipment for the production and maintenance of a vacuum, (3) separators for the separation of vapor and concentrate, and (4) a condenser for the vapor (Cross and Overby 1988; Park and Guo 2006). General composition of evaporated cow milk is 7.5–9.0% fat, 17.5–22% milk solids nonfat, and 25–31% total solids, while that of goat milk counterpart is shown in Table 69.14.

In manufacturing powdered milk, two different processing methods are used for dried milk products; roller drying, and spray drying process. In the roller drying process, milk or milk concentrate is applied in a thin film on the surface of a rotating, steam-heated metal drum (Park and Guo 2006). During the rotation the milk film dries and is continuously scraped off by a stationary knife located opposite the point of application of the concentrate. The spray drying process involves the transformation of fluid state into a dried particulate by spraying the milk into a hot drying medium. Four process stages of conventional spray drying include: (1) atomization of milk into a spray, (2) spray drying air contact (mixing and flow), (3) drying of spray (water evaporation), (4) separation of dried product from the air (Cross and Overby 1988).

69.7.4.3 Frozen Goat Milk Products. Goat milk ice cream can be manufactured, but little research has been documented (Loewenstein and others 1980). Three formulations made for three flavors of goat ice cream may be: (1) French vanilla mix with 14% fat, 10% MSNF, 18% sweetener (12% sucrose, 6% 36-dextrose equivalent corn syrup solids), 1.4% egg yolk solids, and 0.25% stabilizer-emulsifier; (2) chocolate mix: 14.6% fat (0.6% cocoa fat), 9% MSNF, 20% sweetener (14% sucrose, 6% 36-DE corn syrup solids), 3% medium fat cocoa, and 0.22% stabilizer-emulsifier; (3) premium white mix: 15% fat, 10% MSNF, 18% sweetener and 0.25% stabilizer-emulsifier (Park and Guo 2006).

69.8 ADVANTAGES OF GOAT MILK IN HUMAN NUTRITION AND HEALTH

Goat milk has been recommended as a substitute for cow milk for patients who suffer from allergies against cow milk or other food sources (Rosenblum and Rosenblum 1952; Walker 1965; Taitz and Armitage 1984; Van der Horst 1976; Park 1994b). Most patients who are allergic to cow milk proteins can tolerate goat milk well. Some caprine milk proteins have shown immunological cross-reaction with cow milk proteins, but infants suffering from gastrointestinal allergy and chronic enteropathy against cow milk were reportedly cured by goat milk therapy (Rosenblum and Rosenblum 1952; Walker 1965; Firer and others 1981; Park 1994b).

When compared to cow or human milk, many reports have shown that goat milk possesses unique characteristics, such as high digestibility, distinct alkalinity, high buffering capacity as well as certain therapeutic values in medicine and human nutrition (Gamble and others 1939; Walker 1965; Devendra and Burns 1970; Haenlein and Caccese 1984; Park and Chukwu 1988; Park 1991, 1994b).

Since goat milk contains high amounts of short chain and medium chain fatty acids (MCT) in its milk fat, goat milk may make at least three significant contributions to human nutrition (Haenlein 1981; Park and Haenlein 2006): (1) goat milk fat may be more rapidly digested than cow milk fat because lipase attacks ester linkages of short or medium chain fatty acids more easily than those of longer chains (Jenness 1980; Chandan and others 1992; Park 1994b), (2) these fatty acids have the unique metabolic ability to provide energy in growing children, and also exhibit beneficial effects on cholesterol metabolism such as hypocholesterolemic action on tissues and blood via inhibition of cholesterol deposition and dissolution of cholesterol in gallstones (Greenberger and Skillman 1969; Kalser 1971; Tantibhedhyangkul and Hashim 1975; Haenlein 1992), and (3) they also have been therapeutically used for treatment of various cases of malabsorption patients suffering from steatorrhea, chyluria, hyperlipoproteinemia, intestinal resection, coronary bypass, childhood epilepsy, premature infant feeding, cystic fibrosis, and gallstones (Greenberger and Skillman 1969; Tantibhedhyangkul and Hashim 1975; Haenlein 1992; Park 1994b).

Average diameters of the fat globule for goat, cow, buffalo and sheep milk were reported as 3.49, 4.55, 5.92, and 3.30 μm, respectively (Fahmi and others 1956; Juàrez and Ramos 1986). This smaller fat globule size of goat milk has an advantage of better digestibility compared to cow milk counterparts (Haenlein and Caccese 1984; Stark 1988; Chandan and others 1992; Park 1994b). Fat globule size of goat and other species milks may vary with breeds within species.

When fat in human milk is compared with that in cow milk, the former is absorbed more readily by infants than the latter (Grzesiak 1997). This is probably due to the difference in arrangement of fatty acids in the triglycerides (Jenness 1980; Heyman and others 1988). Due to the similarity of distribution of fatty acids over the positions in the triglycerides in goat and cow milks, the efficiencies of absorption of both milk fats are expected to be similar if fat globule size is not considered (Park 2006). Palmitic acid (C16 : 0) is shown to be primarily esterified in the two-position of the triglycerides in human milk fat, whereas the C16 : 0 acid is distributed nearly equally among the three positions in cow milk fat (Heyman and others 1988; Grzesiak 1997). If palmitic acid is located in the two-position, the digestive and absorptive processes are reportedly greatly enhanced (Park 2006).

The characteristics of goat milk proteins have also been shown to be advantageous, where they are digested more readily by stomach proteases. Their amino acids are absorbed more efficiently than those of cow milk, because goat milk caseins form a softer, more friable curd when acidified. These characteristics are related to differences in goat milk protein polymorphisms, especially lower contents of α_{s1}-casein, relative to cow milk (Jenness 1980; Haenlein and Caccese 1984; Juàrez and Ramos 1986; Chandan and others 1992).

Compared to cow milk, goat milk has been shown to have a better buffering capacity, which is good for the treatment of ulcers (Watson 1931; Park 1991, 1992a). The buffering capacity (BC) is influenced by proteins, primarily casein and phosphate systems in milk (Watson 1931). Nubian goat milk had highest levels of total N, protein, NPN and phosphate (P_2O_5) among the four milks of goat and cow breeds (Table 69.9). Because of the compositional differences, milk of the Nubian goat breed showed a higher BC compared with the milk of the Alpine goat breed, Holstein and Jersey cows (Park 1991). Major buffering entities of milks were influenced by species and breeds within species (Table 69.9). Regardless of breed, goat milk contained significantly higher NPN than cow milk. The higher levels of nitrogen moieties and phosphate in goat milk were positively correlated

with higher BC (Park 1991). Soy-based infant formulae contained less total N and NPN compared with natural goat and cow milks, and BC of the formulae were also lower than those of natural milks. This suggests that the higher BC in Nubian goat milk compared to cow milk can be of importance in human nutrition (Park and Haenlein 2004).

In a comparative growth trial (Mack 1953), children fed goat milk showed significantly greater nutrient bioavailability and growth parameters than those fed cow milk. In an iron bioavailability study of goat and cow milks using anemic rats, rats fed on goat milk had grown significantly better, had higher liver weights, hemoglobin iron gain, and higher iron absorption rates than those on cow milk (Park and others 1986). The anemic rats receiving the whole goat milk diet showed significantly greater hemoglobin regeneration efficiencies than those on the cow milk diet. On the other hand, goat milk has been blamed for the development of "goat milk anemia" due to the deficiency of folic acid in the milk (Fries 1959; Sandine and Daly 1979; Firer and others 1981; Perdue and others 1990; Haenlein 2004). Nevertheless, goat milk has been recommended as a nutritionally healthy and therapeutically functional food source for patients suffering from various allergies, as well as those who seek better nutrient absorption, greater nutrient bioavailability, and higher buffering capacity, and so on (Rosenblum and Rosenblum 1952; Walker 1965; Taitz and Armitage 1984; Park 1994b).

70.1 INTRODUCTION

Fundamental studies have opened new fields of research dealing with bioactive or biogenic substances, including peptides, which are derived from foods. First, bioactive peptides (BPs) were mentioned by Mellander in 1950, who described the effect of casein (CN)-derived phosphorylated peptides in the vitamin D-independent bone calcification of rachitic infants. Thereafter, several definitions have been given for BPs. One of the

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

Bioactive Agent: Milk	Bioactive Agent: Gut		Action
A. GI development, activity, and function			
Casein	casomorphins	↓	Gut motility, passage rate of digesta
		↓	Gastric emptying rate
		↑	Uptake of amino acids, electrolytes by intestinal epithelial cells
Casein	Casokinins (ACE-I)	↑	Blood flow to intestinal epithelium
Growth factors	IGF-1, TGF-α, EGF	↑	Growth in intestinal tract
Lactoferrin	Lactoferrin	↑	Proliferation of intestinal epithelial cells
B. Infant development			
Milk peptide	Milk peptide	↑	Lactotrope development in pituitary of suckling
Prolactin	Prolactin	↑	Lymphocyte trafficking, immune development
Growth factors	IGF-1, TGF-α, EGF, TGF-β	↑	Liver, organ development and function
PTHrP	PTHrP	↑	Ca^{2+} metabolism, uptake?
Prosaposin	Prosaposin?	↑	Neurological development?
C. Immunological development and function			
Immunoglobulins	IgG, IgA	↑	Passive immunity
Cytokines	Interleukins-1,-2,-6,-10; Tumor necrosis factor-α; Interferon-γ, Transforming growth factors-α,-β; Prostaglandins E_2, F_{II}; leukotriene B_4	↑	Lymphocyte trafficking, immune development
Prolactin	Prolactin	↑	Thymocyte trafficking, immunological development
Lactoferrin	Lactoferrin	↑	Humoral immune response to sheep RBC
		↑	T-helper cell ($CD4^+$) development
		↑	Natural killer cell activity
		↑	Lymphokine-activated killer cell activity
		↓	TFN-α
		↑	IL-6
Lactoferrin	Lf N-terminal peptides + Lactoferricin	↑	Humoral immune response
		↓	Inflammatory response to bacterial endotoxin
Caseins	Casomorphins Casokinins	↑	Immune response, phagocytic activity
D. Microbial activity			
a. Antibiotic activity – *Antibacterial, antiviral activity, non-immune disease defense:*			
Immunoglobulins	IgG, IgA	↑	Passive immunity to bacterial and virus disease
α_{S1}- Casein	Isracidin	↑	Bactericidal killing of several microorganisms
κ- /α_{S1}- Casein	Casecidins	↑	Bactericidal killing of several pathogenic strains of *Staphylococcus aureus* and lactobacilli
α_{S2}- Casein	Casocidins-I	↑	Bactericidal killing of *Staphylococcus carnosus,Escherichia coli*
κ- Casein	Kappacin	↑	Bactericidal killing of *Streptococcus mutans, Porphyromonas gingivalis, Escherichia coli*
Lactoferrin	Lactoferrin	↑	Bacteriostatic inhibition of iron-dependent bacteria
		↓	Viral attachment to and infections of cells
		↑	Lymphokine-activated killer cell activity
Lactoferrin	Lf+, Lactoferricin	↑	Bactericidal killing of Gram +/– enteropathogens
Glycolipids, Oligosaccharides	Glycolipids, Oligosaccharides	↓	Bacterial and viral attachment to intestinal epithelial cells (decoy receptors)
		↓	Bacterial colonization and viral infection
b. Probiotic activity – *Growth of Bifidobacteria and Lactobacilli in GI tract*			
Lactoferrin	Lactoferrin	↑	Growth of Bifidobacteria in GI tract
κ-Casein	κ-Casein	↑	Growth of Bifidobacteria in GI tract
Oligosaccharides	Oligosaccharides	↑	Growth of Bifidobacteria in GI tract

An arrow pointing down (↓) means a decrease of the biological action, whereas an arrow pointing up (↑) means an increase.

Figure 70.1 *Major categories of bioactivities in milk (A and others E), and their general effects and major effectors. Adapted from Schanbacher 1998.*

most appropriate is the following: components (genuine or generated) of consumption ready foods which may exert a regulatory activity in the human organism, irrespective of their nutritive functions (Meisel 2001). Bioactive substances of food origin could be delivered to the consumer in conventional foods, dietary supplements, functional foods, or medical foods whereby each category requires specific claims. In 1991 Japan has defined the concept of Food for Specified Health Use (FOSHU) and in 1993 the United States introduced health claims for foods having the properties of reducing diseases.

Recently, some guidelines for the manufacture of functional foods have been introduced in Europe also (Martin 2000).

Milk proteins are currently the main source of a range of biologically active peptides (Pihlanto-Leppälä 2001). Milk is known to contain an array of bioactivities which extends the range of influence of mother over young beyond nutrition alone. Several of these bioactivities are attributable to proteins and peptides secreted into milk by the mammary gland. (Fig. 70.1). The major categories of bioactivities in milk, and their general effects and major effectors are summarized in Figure 70.1. Four major bioactivity categories may be distinguished: (1) gastrointestinal development, activity, and function; (2) infant development; (3) immunological development and function; and (4) microbial activity, including antibiotic and probiotic actions.

Nevertheless, most of the bioactivities of milk proteins are latent, being absent or incomplete in the native protein and only fully manifested upon proteolytic digestion to release and activate an encrypted BP from within (Gobbetti and others 2002). Proteolysis may release BPs during gastrointestinal transit or during food processing. Digestive enzymes, naturally occurring enzymes in milk, coagulants and microbial enzymes, especially those from adventitious or starter lactic acid bacteria, generate BPs during milk fermentation and cheese maturation, thereby enriching the dairy products (Gobbetti and others 2002). Interestingly, several milk-derived peptides reveal multifunctional properties, that is, specific peptide sequences having two or more different physiological activities. Some regions in the primary structure of CN contain overlapping peptide sequences that exert different activities. These regions have been considered as strategic zones that are partially protected from further proteolytic breakdown (Fiat and others 1993).

The major peptide bioactivities in dairy products, their synthesis through food processing and their putative or *in vivo* physiological role are described in the following sections.

70.2 OPIOID PEPTIDES

Opioids are defined as peptides (e.g., enkephalins) which have an affinity for an opiate receptor and opiate-like effects, inhibited by naloxone. Milk protein-derived BPs may function as regulatory substances, defined exorphins, with pharmacological properties similar to enkephalins (Meisel and others 1989; Meisel and Schlimme 1990; Schanbacher and others 1998) (Table 70.1). The α_{S1}-casein-exorphin (α_{s1}-CN f90–96), β-casomorphins-7 and -5 (β-CN f60–66 and f60–64, respectively), and lactorphins (α-lactalbumin f50–53 and β-lactoglobulin f102–105) act as opioid agonists, while casoxins (e.g., κ-CN f35–42, f58–61, and f25–34) act as opioid antagonists (Meisel and FitzGerald 2000). An anticonvulsant and anxiolytic molecule, α-casozepine, not structurally related to benziodiazepines, was produced by trypsin hydrolysis of bovine α_{s1}-CN. It corresponded to α_{s1}-CN f91–100. As shown in conditioned defensive burying rat models, this peptide might play a role, as external ligand, in the regulation of the nervous system of the mammalian newborn (Miclo and others 2001).

The common structural feature among endogenous and exogenous opioid peptides is the presence of a Tyr residue at the amino terminal end (except for α_{S1}-casein-exorphin, casoxin 6, and lactoferroxin B and C) and of another aromatic residue, Phe or Tyr, in third or fourth position. The negative potential, localized in the vicinity of the phenolic hydroxyl group of Tyr, seems to be essential for opioid activity. Removal of the Tyr residue results in a total absence of activity (Chang and others 1981). The Pro residue

TABLE 70.1 Examples of Opioid Peptides Derived from Milk Proteins.

Bioactive Peptide	Sequence[1]	Precursor Protein (Fragment)[2]	IC_{50}^{3} (μmol/L)	Theoretical Yield of Bioactive Peptide Obtainable from 1 g Precursor Protein	References
Opioid agonists					
β-Casomorphin-7	YPFPGPI	β-CN f(60–66)	14.0	33.0	Brantl and others 1981

[1]The one-letter amino acids codes were used; Phosphoserine = S*.

[2]Unless otherwise indicated, the precursor protein is from bovine milk.

[3]In relation to opioid peptides, peptide concentration required to inhibit 3H-ligand binding by 50%.

in the second position is also crucial to maintain the proper orientation of the Tyr and Phe side chains (Mierke and others 1990).

Modulation of social behavior and analgesic effects were found following intracerebral administration of opioid peptides with agonistic activity, for example, β-casomorphins, to experimental animals. Orally administered milk protein-derived opioid peptides have been demonstrated to influence postprandial metabolism by stimulating secretion of insulin and somatostatin, to modulate intestinal transport of amino acids, to prolong gastrointestinal transit time and to exert antidiarrhoeal action (Meisel and Schlimme 1990).

Evidence for the *in vivo* liberation of β-casomorphins from β-CN was found in the small intestine of adult humans following cow's milk intake (Svedberg and others 1985), in the duodenal chime of Göttingen minipgs after feeding with bovine CN (Meisel 1986), in serum of newborn calves after milk intakes (Umbach and others 1985), and in plasma of pregnant or breastfeeding women (Koch and others 1988). β-Casomorphins were found in the analogous position of the native protein in cow, sheep, water buffalo, and human β-CN (Meisel and Schlimme 1996). A number of caseolytic bacterial species used in the manufacture of cheeses and other milk products may synthesize casomorphins (Hamel and others 1985). Several opioid peptides derived from α_{s1}- and β-CN, and α-lactalbumin were released by pepsin/trypsin hydrolysis of *Lactobacillus* GG fermented UHT milk (Rokka and others 1997). Proteolysis of α-lactalbumin with pepsin produced directly α-lactorphin, while digestion of β-lactoglobulin with pepsin and then trypsin yielded β-lactorphin. Contrarily to β-casomorphins, there is no current evidence for the liberation of lactorphins during gastrointestinal digestion (Pihlanto-Leppälä 2001).

70.3 CASEINOPHOSPHOPEPTIDES

Caseinophosphopeptides (CPPs) or mineral binding phosphopeptides may form soluble organophosphate salts and function as carriers for different minerals, especially Ca^{2+} (Meisel and Olieman 1998). It is thought that CPPs synthesized during CN digestion enhance the biodisponibility of Ca^{2+} in the diet by increasing the solubility of Ca^{2+} in the alkaline environment of the small intestine, where the maximal passive absorption of dietary Ca^{2+} takes place (FitzGerald 1998).

CPPs may derive from different phosphorylated regions of α_{s1}-, α_{s2}-, β-, and κ-CN (Fig. 70.2). Most CPPs contain a common motif, for example, a sequence of three phosphoseryl followed by two glutamic acid residues. The negatively charged side chains, in particular the phosphate groups, of these amino acids represent the binding sites for minerals. Dephosphorylated peptides do not bind minerals (Berrocal and others 1989) or chemical phosphorylation of α_{s1}- and β-CN increased the binding capacity and the stability of these proteins in the presence of Ca^{2+} (Yoshikawa and others 1981). While the anionic hydrophilic domain is important in mineral binding, the amino acid residues upstream and downstream from this region play a role in binding also. Approximately one mole of CPP could bind 40 moles of Ca^{2+}. The Ca^{2+} binding constants of CPPs are in the order of 10^2–10^3 M^{-1} (Sato and others 1983; Schlimme and Meisel 1995). Whey proteins such as α-lactalbumin, β-lactoglobulin, and lactoferrin may also give rise to peptides with mineral binding abilities (Vegarud and others 2000). Since these peptides are not phosphorylated, the binding sites for minerals may be dependent on the particular conformation.

CPPs are generated from CN by enzymatic digestion with pancreatic endoproteinases, especially trypsin. Other enzyme combinations, including chymotryipsin, pancreatin, papain, pepsin, thermolysin, and pronase, have been used for *in vitro* CPPs production (FitzGerald 1998). Proteolytic enzymes from a range of bacterial and fungal sources have been used also (McDonagh and FitzGerald 1998). CPPs were synthesized upon hydrolysis of six different types of sodium-caseinate by a partially purified proteinase of *Lactobacillus helveticus* (Corsetti and others 2003). CPPs are formed *in vivo* following digestion of CN by gastrointestinal proteinases (Naito and others 1972; Sato and others 1983; Meisel and Frister 1988). CPPs are relatively resistant to further proteolytic degradation (Hirayama and others 1992; Kasai and others 1995) and can accumulate in the distal ileum (Naito and others 1972; Meisel and Frister 1988). A number of *in vivo* feeding trials involving Ca^{2+} balance studies after administration of CPPs have failed to show a significant effect on the absorption of Ca^{2+} in rats, piglets, minipgs and vitamin D-deficient rats (FitzGerald 1998). Nevertheless, a 23% improvement in intestinal soluble Ca^{2+} was reported from *in vivo* rat studies when comparing conventional CPPs to β-CN derived CPPs (Han and others 1996). Very little information is available from human studies. CPPs increase Ca^{2+} and Zn^{2+} absorption from a rice-based infant gruel in human

adults by approximately 30%. No effect was seen when CPPs were ingested in either high or low phytate wholegrain cereal meals (Hansen 1995).

Although the main current applications of CPPs center on their ability to solubilize minerals, an anticariogenic mechanism has been attributed also. It is related to the ability of localising high level of amorphous Ca^{2+} phosphate at the tooth surface and, as a consequence, to depress demineralization and enhance remineralization of tooth enamel (Reynolds 1994). CPPs may also act as buffering agents against plaque acid. Based on these properties, the opportunity for the incorporation of CPPs into dental hygiene care products has been created (FitzGerald 1998).

70.4 IMMUNOMODULATORY PEPTIDES

Although the mechanisms are not currently elucidated, milk-derived peptides have shown immunomodulatory activity. α_{s1}-CN f194–199 (α_{s1}-immunocasokinin) and β-CN f193–202, f63–68, and f191–193 (immunopeptides), synthesized by hydrolysis with pepsin-chymosin, stimulated phagocytosis of sheep red blood cells by murine peritoneal macrophages and exerted a protective effect against *Klebsiella pneumoniae* infection in mice after intravenous administration (Gill and others 2000). β-Casomorphin-7 inhibited the proliferation of human colonic lamina propria lymphocytes where the antiproliferative effect of micromolar concentrations was reversed by the opiate receptor antagonist naloxone (Elitsur and Luk 1991). β-Casomorphin-7 and β-CN immunopeptides suppressed the proliferation of human peripheral blood lymphocytes at low concentrations ($<10^{-7}$ mol/L) but stimulated it at higher concentration (Kayser and Meisel 1996). Immunoenhancing properties have been attributed to CPPs also (Hata and others 1999). Several β-CN derived peptides enhanced the immunoglobulin IgG production in mouse spleen cell cultures.

The results obtained with human lymphocytes suggested that opioid peptides may affect the immunoreactivity of lymphocytes via the opiate receptor. There is indeed a remarkable relationship between the immune system and opioid peptides, because opioid μ receptors for endorphins are present in lymphocytes (Elitsur and Luk 1991). It is worth noting that glutamine-containing peptides may substitute for the free amino acid glutamine which is required for lymphocyte proliferation and utilized at a high rate by immunocompetent cells (Calder 1994). It is conceivable that such peptides exert a non-specific immunostimulation as a result of their trophic properties.

70.5 CYTOMODULATORY PEPTIDES

Based on various cytochemical studies, there is an increasing evidence of the possible involvement of milk-derived peptides as specific signals that may trigger viability of cancer cells. Bacterial hydrolysis of CN using commercial yogurt starter cultures yielded bioactive peptides that influence colon cell Caco-2 kinetics *in vitro* (MacDonald and others 1994). Bovine skimmed milk digested with cell-free extract of the yeast *Saccharomyces cerevisiae* was found to have antiproliferative activity towards leukaemia cells (Roy and others 1999). Purified peptides, corresponding to bioactive sequences of CN, revealed modulation of cell viability, for example, proliferation and apoptosis, in different human cell culture models (Hartmann and others 2000). Accordingly, apoptosis

of human leukaemia cells (HL-60) was induced by the opioide peptide β-casomorphin-7. Peptides from a lyophilized extract of Gouda cheese inhibited proliferation of leukaemia cells, even at low concentrations of 1 pmol/L (Meisel and Günther 1998). The antiproliferative effect of Gouda extract was shown to be the result of peptide-induced apoptosis. Cancer cell lines were more reactive to peptide-induced apoptotic stimulation than non-malignant cells.

70.6 ANTITHROMBOTIC PEPTIDES

The mechanism involved in milk clotting through interaction of κ-CN with chymosin and blood clotting processes, defined by the interaction of fibrinogen with thrombin, are comparable. In this regard, the C-terminal dodecapeptide of human fibrinogen γ-chain (residues 400–411) and the undecapeptide (residues 106–116) from bovine κ-CN are structurally and functionally quite similar (Clare and Swaisgood 2000). This CN-derived peptide, termed casoplatelin, affected platelet function and inhibited both the aggregation of ADP-activated platelets and the binding of human fibrinogen γ-chain to its receptor region on the platelets surface (Jollès and others 1986). A smaller κ-CN fragment (residues 106–110), casopiastrin, was synthesized by trypsin hydrolysis and exhibited antithrombotic activity by inhibiting fibrinogen binding (Jollès and Henschen 1982; Jollès and others 1986; Mazoyer and others 1992). A second segment of the κ-CN fragment, residues 103–111, inhibited platelet aggregation but did not affect fibrinogen binding to the platelet receptor (Fiat and Jollès 1989; Fiat and others 1993; Jollès and others 1986). Antithrombotic peptides have also been derived from κ-caseinoglycopeptides that were isolated from several animal species. Bovine κ-caseinoglycopeptide, the C-terminal end of κ-CN (residues 106–169), inhibited von Willebrand factor-dependent platelet aggregation (Chabance and others 1998). Two antithrombotic peptides, derived from human and bovine κ-caseinoglycopeptides, were identified in the plasma of 5-day-old newborns after breast-feeding and ingestions of cow's milk based formula, respectively (Chabance and others 1998). The κ-caseinoglycopeptide (106–171) of sheep CN decreased thrombin- and collagen-induced platelet aggregation in a dose dependent manner (Qian and others 1995).

70.7 HYPOCHOLESTEROLEMIC PEPTIDES

A tryptic hydrolysate of β-lactoglobulin showed hypocolesterolemic activity in rats (Nagaoka and others 2001). The serum cholesterol-lowering activity depends on the degree of fecal steroid excretion (Nagata and others 1982) which was high in rats fed with the hydrolysate. Studies on the hypocholesterolemic effects of proteins supported the hypothesis that a peptide with high bile acid-binding capacity could inhibit the reabsorption of bile acid in the ileum and decrease the blood cholesterol level (Iwami and othres 1986). The β-lactoglobulin tryptic hydrolysate also directly inhibited the *in vitro* absorption of micellar cholesterol in Caco-2 cells. Cholesterol is rendered soluble in bile salt-mixed micelles and then absorbed (Wilson and Rudel 1994). The micellar solubility of cholesterol in the presence of β-lactoglobulin tryptic hydrolysate was markedly low. Four bioactive peptides were identified in the hydrolysate which corresponded to β-lactoglobulin f9–14, f41–60, f71–75, and f142–146. Fragment 71–75, which had no peptic or tryptic digestive site, was chosen for animal studies, and it showed a

greater hypocholesterolemic activity than the drug β-sitosterol (Nagaoka and others 2001).

70.8 ACE-INHIBITORY (ANTIHYPERTENSIVE) PEPTIDES

Angiotensin-I converting enzyme (ACE, peptidyl-peptide hydrolase; EC 3.4.15.1) is a multifunctional ectoenzyme that is located in different tissues (e.g., plasma, lung, kidney, heart, skeletal muscle, pancreas, arteries, brain) and plays a key physiological role in the renin-angiotensin, kallikrein-kinin, and immune systems. This enzyme is responsible for the increase in blood pressure by converting angiotensin-I to the potent vasoconstrictor, angiotensin-II, and by degrading bradykinin, a vasodilatatory peptide, and enkephalins (Petrillo and Ondetti 1982). Therefore, ACE inhibition mainly results in a hypotensive effect but may also influence different regulatory systems involved in immuno-defense and nervous system activity (Meisel 1993). Recently, it has been demonstrated that treatment with brain-penetrating ACE inhibitors could slow the rate of cognitive decline in mild to moderate Alzheimer disease patients in comparison with other antihypertensive drugs (Ohrui and others 2004). The mechanism might be due either to the direct effects of brain-penetrating ACE inhibitors on renin-angiotensin system in the brain or to an increased level of brain substance P by ACE inhibitors. Increased substance P may augment the activity of neprilysin, a major amyloid-β peptide degrading enzyme in the brain, and thus may favourably influence the course of Alzheimer disease.

Antihypertensive are the most studied BPs. Exogenous ACE inhibitors having an antihypertensive effect *in vivo* were first discovered in snake venom (Ondetti and others 1977). Several ACE-inhibitory peptides were identified by *in vitro* enzymatic digestion of milk proteins or chemical synthesis of peptide analogs (Table 70.2) (Gobbetti and others 2002, 2004). ACE-inhibitors derived from milk proteins represent different fragments of CN, named casokinins (Meisel and Schlimme 1994), or whey proteins, named lactokinins (FitzGerald and Meisel 2000).

Structure-activity correlation among different peptide inhibitors of ACE indicate that binding to ACE is strongly influenced by the C-terminal tripeptide sequence of the substrate. ACE appears to prefer substrates or competitive inhibitors which mainly have hydrophobic (aromatic or branched side chains) amino acid residues at the three C-terminal positions. ACE inhibition studies with Trp, Tyr, Phe, or Pro residues were most effective in enhancing substrate binding (Cheung and others 1980). Nevertheless, the structure-activity relationship of ACE-inhibitory peptides has not yet been clearly established and very different hypotensive sequences have been derived from a large number of food proteins (Meisel 1997). It is postulated that the mechanism of ACE inhibition involves inhibitor interaction with an anionic binding site that is distinct from the catalytic site of the enzyme. Given the above, it is expected that peptide conformation, for example, the structure adopted in a specific environment, should contribute to ACE inhibitor potency (FitzGerald and Meisel 2000).

A number of *in vivo* and *in vitro* studies have demonstrated the antihypertensive effect of CN-derived peptides contained in dairy products (FitzGerald and Meisel 2000; Gobbetti and others 2004). Nakamura and others (1995) purified ACE-inhibitors from Calpis, a Japanese soft drink made from skim milk fermented by *Lactobacillus helveticus* and *S. cerevisiae*. The hypotensive peptides, Val-Pro-Pro and Ile-Pro-Pro, which originated from both α_{s1}- and β-CN, have been found in milk inoculated with *Lb. helveticus* (Yamamoto and

[1]The one-letter amino acids codes were used; Phosphoserine = S*.
[2]Unless otherwise indicated, the precursor protein is from bovine milk.

others 1994a) and in casein hydrolysates produced by *Lb. helveticus* CP790 extracellular proteinase (Yamamoto and others 1994b). In a placebo-controlled study, the blood pressure of hypertensive patients decreased significantly after 4 and 8 weeks of daily ingestion of 95 mL of sour milk that contained the two tripeptides; the ingested dose of ACE-inhibitory peptides ranged from 1.2 to 1.6 mg/day (Hata and others 1996). The effect of two fermented milks started by two *Lb. helveticus* strains also showed an *in vivo* ACE inhibition on normotensive rats (Fuglsang and others 2003). The pressor effect of angiotensin I (0.3 μg/kg) upon intravenous injection was significantly lower when rats were pre-fed with fermented milks. An increased response to bradykinin (10 μg/kg, intravenously injected) was observed using one of the two fermented milks. Also from this study, it was concluded that *Lb. helveticus* produces substances, which *in vivo*, can give rise to an inhibition of ACE. Sodium caseinates prepared from cow, sheep, goat, pig, buffalo, or human milk were hydrolyzed by a partially purified proteinase of *Lb. helveticus* PR4 (Minervini and others 2003). Various ACE-inhibitory peptides were found in the hydrolysates: the bovine α_{s1}-CN f24–47, α_{s1}-CN f169–193, and β-CN f58–76; ovine α_{s1}-CN f1–6, α_{s2}-CN f182–185, and α_{s2}-CN f186–188; caprine β-CN f58–65 and α_{s2}-CN f182–187; buffalo β-CN f58–66; and a mixture of three tripeptides originating from human β-CN. The highest ACE-inhibitory activity of some peptides corresponded to the concentration of the ACE inhibitor (S)-*N*-(1-[ethoxycarbonyl]-3-phenylprolyl)-ala-pro maleate (enalapril) of 49.253 μg/mL (100 μmol/L). UHT milk fermented with the probiotic *Lactobacillus* GG strain and subsequently digested by pepsin and trypsin enzymes has been found to contain ACE-inhibitory activities (Rokka and others 1997). Selected *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Lactococcus lactis* subsp. *cremoris* were used to produce two fermented milks that contained ACE-inhibitory peptides (Gobbetti and others 2000). The ACE-inhibitory activity of the fermented milk started by *Lb. delbrueckii* subsp. *bulgaricus* SS1 involved peptides such as β-CN f6–14, β-CN f7–14, β-CN f73–82, β-CN f74–82, and β-CN f75–82, The activity in the fermented milk produced by *Lc. lactis* subsp. *cremoris* FT4 had β-CN f7–14 in common but differed with fragments such as β-CN f47–52, β-CN f169–175, κ-CN f152–160, and κ-CN f155–160. All the above CN fragments had a higher proportion of hydrophobic residues (>60%). In particular, β-CN f73–82 and related intermediates contained the internal sequences (Val-Pro-Pro or Ile-Pro-Pro), previously isolated from the Calpis sour milk.

Meisel and others (1997) reported the presence of ACE-inhibitory peptides of low molecular mass in several ripened cheeses. In this study it was suggested that the ACE-inhibitory activity increases as proteolysis develops, but the ACE-inhibition index decreases when the proteolysis during cheese maturation exceeds a certain level (e.g., the ACE-inhibitory activity detected in medium-aged Gouda was about double that of the long-ripened Gouda cheese). Cheeses with low to medium time of ripening contained ACE-inhibitors and the peptides identified in Crescenza cheese corresponded to α_{s1}-CN f23–34 and α_{s1}-CN f23–27 (Maruyama and Suzuki 1993; Maruyama and others 1985, 1987a). The above findings agreed with a previous study (Smacchi and Gobbetti 1998) which demonstrated the presence of ACE-inhibitory peptides in Crescenza, Italico, and Gorgonzola cheeses. β-CN f58–72, which includes the sequence of β-casomorphin-7, was detected by immunoblotting and inhibitory ELISA in Cheddar, Jarlsberg, Norvegia, and Blue cheeses (Stepaniak and others 2001). ACE inhibitory peptides were also found in enzyme-modified cheese (EMC) obtained by hydrolysis of pasteurized cheese homogenized with Neutrase and enzyme preparation from *Lactobacillus casei* (Haileselassie and others 1999). A new type of ripened, low-fat cheese with bioactive properties

was manufactured by using *Lactobacillus acidophilus* and bifidobacteria as starter cultures (Ryhänen and others 2001). The ripened cheese was found to contain peptides with potential antihypertensive effects. Different types of Manchego cheese, manufactured by using different bacterial starters, showed *in vitro* ACE-inhibitory activity (Gòmez-Ruiz and others 2002). The highest ACE inhibition was found for the cheeses manufactured from raw milk and from pasteurized milk inoculated with *Lc. lactis* subsp. *lactis* and *Leuconostoc mesenteroides* subsp. *dextranicum*. Several peptides were identified as fragments of α_{s1}-, α_{s2}-, and β-CN which showed a large number of hydrophobic residues at the C-terminal positions. The peptide corresponding to β-CN f199–204 was chemically synthesized. It showed an *in vitro* ACE-inhibitory activity with IC_{50} of 397.4 μg/mL. The ACE-inhibitory and antihypertensive activities of water-soluble peptides from six representative bacterial (Gouda, Emmental, Edam, and Havarti) and moldy (Blue and Camembert) ripened cheeses were evaluated by *in vitro* and *in vivo* experiments (Saito and others 2000). Although a statistically significant decrease in the systolic blood pressure of spontaneously hypertensive rats was reported for Edam also, Havarti and Blue cheeses had the strongest depressive effect on the systolic blood pressure. Contrarily to what was reported by Meisel and others (1997), the highest ACE inhibitory activity was found for long ripened (8 months) Gouda cheese. Several peptides were identified from cheeses and chemically synthesized. Two peptides, α_{s1}-CN f1–9 and β-CN f60–68, showed a potent ACE inhibitory activity with IC_{50} of 13.4 and 14.8 μmol/L, respectively.

Ovine and caprine β-lactoglobulin were hydrolyzed with trypsin, chymotrypsin, proteinase K, and thermolysin. Four novel ACE-inhibitory peptides were purified and identified from caprine β-lactoglobulin digested with thermolysin: f46–53, f58–61, f103–105, and f122–125. The IC_{50} ranged from 34.7 to 2470 μmol/L (Hernàndez-Ledesma and others 2002). A tryptic digest of bovine α_{s2}-CN contained several casokinins. Peptides corresponding to α_{s2}-CN f174–181 and f174–179 had IC_{50} values of 4 μmol/L. Surprisingly, deletion of the C-terminal dipeptide of the above casokinins did not significantly alter their inhibitory activity (Tauzin and others 2002). A tryptic hydrolysate of CN generated vasoactive or vasopotentiating peptides, γ-CN f108–113 and f114–121, which displayed a selective potentiating activity on isolated guinea pig ileum for bradykinin (Perpetuo and others 2003). Besides, the γ-CN f114–121 showed an *in vitro* competitive inhibition of ACE and thimet oligopeptidase, and presented opiate-like activity.

The majority of CN-derived ACE-inhibitory peptides do not have ACE inhibitory potencies approaching that of captopril (IC_{50} of 0.006 μmol/L) but are characterized by moderate values of IC_{50} in the range of 100–500 μmol/L. However, being naturally derived, BPs would be expected not to have the side-effects associated with synthetically produced drugs used in the control of hypertension, for example, cough and alterations in serum lipid metabolism (Seseko and Kaneko 1985; Nakamura 1987). They also may be of nutritive/physiological importance in that ACE-inhibitory peptides could be active following oral administration (FitzGerald and Meisel 2000). It is noteworthy that Yamamoto and others (1999) demonstrated that Tyr-Pro, having an IC_{50} of 720 μmol/L, could mediate a significant hypotensive effect in spontaneously hypertensive rats. It should be considered that relatively high amounts (10–60 mg) of bioactive peptides could potentially be produced during proteolysis of 1 g of each of the major CN and whey protein components (Meisel 1998). Nevertheless, very highly active BPs were also found. They corresponded to casokinins such as α_{s1}-CN f23–27 and f1–9, β-CN f60–68 and f177–183, and α_{s2}-CN f174–181 and f174–179 having IC_{50} values lower than 20 μmol/L (Saito and others 2000; Meisel 2001; Tauzin and others 2002).

The antihypertensive potential of BPs is dependent on the ability of these fragments to reach their target site without being degraded and as a consequence inactivated by the action of intestinal or plasma peptidases. Inhibition of ACE in lung, vascular, kidney, and brain tissue by captopril, a drug commonly used in the control of blood pressure, is thought to be central to the antihypertensive effect (Unger and others 1985). Resistance to peptidase degradation is a prerequisite for an antihypertensive effect during the oral ingestion and intravenous infusion of ACE inhibitory hydrolysates/peptides. For instance, α_{s1}-CN f23–27, a potent ACE inhibitor *in vitro*, was shown to have no hypotensive effect *in vivo* (Maruyama and others 1987). The presence of Val-Pro-Pro and Ile-Pro-Pro in heat-treated solubilised aortal fractions of spontaneously hypertensive rat fed with Calpis sour milk demonstrated the resistance of these peptides to intestinal and circulatory peptidases, in addition to absorption of these peptides from the intestine (Masuda and others 1996). Proline-containing peptides are generally resistant to degradation by digestive enzymes (Adibi and Kim 1981).

70.9 PEPTIDES INHIBITORY TO BACTERIAL PROTEOLYTIC ENZYMES

Since the antihypertensive activity attributed to BPs has a mechanism based on the inhibition of target proteolytic enzymes, and since proteolytic enzymes from lactic acid bacteria produce BPs in several dairy products, it may be not surprising if a similar mechanism may influence the microbial and enzyme dynamics in food ecosystems. Indeed, once liberated, BPs or peptides related to bioactive sequences may influence the biochemical activity of the microbial communities. Although, in the absence of a clear *in vivo* evidence of the link between peptides inhibiting microbial enzymes and bioactivity, this fact has probably been underestimated in dairy processing (Gobbetti and others 2002). As an example, β-CN f58–72, containing the sequence of β-casomorphin-7, is released during Cheddar, Jarlsberg, and Crescenza ripening and inhibits noncaseolytic oligopeptidase PepO and aminopeptidase PepN of lactic acid bacteria (Stepaniak and others 1995; Smacchi and Gobbetti 1998). β-CN f193–209 and β-CN f194–209 produced by proteinase of *Lc. lactis* subsp. *cremoris* possess antihypertensive effect and inhibit endopeptidases and aminopeptidases of other lactic acid bacteria. Peptidases of lactic acid bacteria differ in their sensitivity to the same peptides (Gobbetti and others 2002, 2004).

70.10 ANTIMICROBIAL PEPTIDES

It is generally accepted that the total antibacterial effect in milk is greater than the sum of the individual contributions of immunoglobulin and nonimmunoglobulin (lactoferrin lactoperoxidase, and lysozime) defence proteins or peptides. This may be due to the synergistic activity of naturally occurring proteins and peptides, in addition to peptides generated from inactive protein precursors (Clare and Swaisgood 2000). Antimicrobial peptides are observed throughout nature. In mammals, they are found both at the epithelial surfaces and within granules phagocytic cells. They are an important component of innate defences, since in addition to killing microorganisms, they are able to modulate inflammatory responses (Devine and Hancock 2002). With the growing problem of pathogenic

organisms that are resistant to conventional antibiotics, there is an increased interest in the application of antimicrobial peptides in food preservation and in reducing the risk of infection.

During the last decades a number of antibacterial peptides encoded in the primary structure of milk proteins have been described. Antibacterial properties, origin and isolation procedure of such peptides are shown in Table 70.3. Lactenin was probably the first antibacterial factor derived from milk that had been treated with rennet (Jones and Simms 1930). The nature or the origin of this inhibitor of streptococcal growth was not elucidated, the antibacterial activity was found to remain together with the whey protein fraction after rennet treatment, and the active component appeared to be resistant to tryptic hydrolysis. A group of basic, glycosylated, and high-molecular-weight (approximately 5 kDa) polypeptides, called casecidins, are released from chymosin-treated CN (Lahov and others 1971). These peptides were shown to display bactericidal properties against lactobacilli and also against various pathogenic bacteria such as *Staphylococcus aureus*. Another antibacterial peptide derived from α_{s1}-CN treated with chymosin, called isracidin, which corresponded to the N-terminal fragment of this protein (f1–23), was isolated (Hill and others 1974). Isracidin was found to inhibit the *in vitro* growth of lactobacilli and other Gram-positive bacteria, but only at relatively high concentrations (0.1–1 mg/mL). However, *in vivo*, isracidin exerted a strong protective effect against *S. aureus*, *Streptococcus pyogenes*, and *Listeria monocytogenes* when administered at doses as low as 10 μg per mouse prior to bacterial challenge. This peptide also safeguarded sheep and cows against mastitis when injected into the udder at levels comparable to those observed with standard antibiotic treatment. Bovine α_{s2}-CN was also shown to be a precursor of several peptide fragments with antibacterial activity. A positively charged peptide, corresponding to α_{s2}-CN f150–188, which was isolated from boiled and acidified milk and called casocidin-I (Zucht and others 1995), showed inhibitory activity against Gram-negative (*Escherichia coli*) and Gram-positive (*Staphylococcus carnosus*) bacteria. Subsequently, the antibacterial role of α_{s2}-CN was reevaluated with the objective of verifying the existence of an enzymatically induced antibacterial domain (Recio and Visser 1999). Hydrolysis of α_{s2}-CN with the gastric enzyme pepsin rendered two different antibacterial peptides: one, f164–179, which was included in the casocidin-I, and a new antibacterial fragment at the C-terminus of the protein, f183–207. The latter had a consistently higher activity than f164–179, although both peptides showed a comparable hemolytic effect. It has also been proposed that part of the antibacterial activity of human milk resides in the CN fraction, particularly in glycosylated κ-CN and its glycosylated region, the caseinomacropeptide (Stromqvist and others 1995). Two reports (Liepke and others 2001; Malkoski and others 2001) have shown a direct bacterial growth-inhibition effect of κ-CN-derived peptides, this activity being unrelated to the presence of attached sugar residues in their amino acid sequences. One of these peptides, called kappacin, corresponded to nonglycosylated, phosphorylated bovine caseinomacropeptide (κ-CN f106–169), which exhibited growth-inhibitory activity against Gram-positive (*Streptococcus mutans*) and Gram-negative (*Porphyromonas gingivalis*) bacteria. It also showed the capacity to bind enterotoxins and to inhibit viral and bacterial adhesion, for example, the binding of cariogenic bacteria to oral surfaces. Lactoferricin, an antibacterial peptide isolated from a peptic hydrolysate of bovine and human lactoferrin (f17–41 and f1–47, respectively), has shown inhibition against a wide variety of microbial species, including many important foodborne pathogens such as *L. monocytogenes* (Bellamy and others 1992; Malkoski and others 2001). Lactoferricin demonstrated higher bacteriostatic

[6]Cysteine residues with the same superscript (a or b) are linked by a disulfide bridge.

and bactericidal activity than intact lactoferrin. Proteolytic digestion of bovine β-lactoglobulin by trypsin yielded four peptide fragments with bactericidal activity. These peptides corresponded to β-lactoglobulin f15–20, f25–40, f78–83, and f92–100 (Pellegrini and others 2001). The four peptides were synthesized and found to exert bactericidal effects against Gram-positive bacteria only. In order to understand the structural requirements for antibacterial activity, the amino acid sequence of the f92–100 was modified. The replacement of the Asp residue by Arg and the addition of a Lys residue at the C-terminus enlarged the bactericidal activity to Gram-negative bacteria. This study showed a possible antimicrobial function of β-lactoglobulin after its partial digestion by endopeptidases of the pancreas and showed, moreover, that small targeted modifications in the protein sequence could be useful to increase its antimicrobial function. More recently, antimicrobial peptides were designed by using combinatorial libraries (Blondelle and Lohner 2000) and novel antibacterial peptides were expressed *in vivo* in *E. coli* (Walker and others 2001) or purified from a pepsin digest of human milk which corresponded to κ-CN f63–117 (Liepke and others 2001). An antimicrobial peptide, corresponding to β-CN f184–210, was produced by hydrolysis of the human sodium caseinate with the partially purified proteinase of *Lb. helveticus* PR4 (Minervini and others 2003). Inhibition was found against potentially pathogenic bacteria of clinical interest, such as *Enterococcus faecium*, *Bacillus megaterium*, *E. coli*, *L. innocua*, *Salmonella* spp., *Yersinia enterocolitica*, and *S. aureus*. β-CN f184–210 inhibited the indicator culture, *E. coli* F19, at a minimal inhibitory concentration (MIC) of 50 μg/mL, which compares well with the lethal concentrations, 4–10 μg/mL, of the more potent antimicrobial peptides (Hancock and Leher 1998). Water-soluble extracts of nine Italian cheese varieties were assayed for antimicrobial activity towards Gram-positive and -negative bacterial species, including potentially pathogenic bacteria of clinical interest (Rizzello and others 2005). Extensively proteolyzed Parmigiano Reggiano, Fossa, and Gorgonzola cheeses did not show antibacterial peptides. Pecorino Romano, Canestrato Pugliese, Crescenza, and Caprino del Piemonte contained a mixture of antimicrobial peptides with a rather high degree of homology. Pasta filata cheeses such as Caciocavallo and Mozzarella also contained antimicrobial peptides. Peptides showed high levels of homology with N-, C-terminal or whole fragments of well known antimicrobial and/or multifunctional peptides reported in the literature: α_{S1}-casokinin (e.g., sheep α_{S1}-CN f22–30 of Pecorino Romano and cow α_{S1}-CN f23–32 of Canestrato Pugliese); isracidin (e.g., sheep α_{S1}-CN f10–21 of Pecorino Romano); kappacin and casoplatelin (e.g., cow κ-CN f106–115 of Canestrato Pugliese and Crescenza); and β-casomorphin-11 (e.g., goat β-CN f60–68 of Caprino del Piemonte). Crude fractions, containing antimicrobial peptides, were inhibitory at a concentration of 30–120 μg/mL.

The activity of most antibacterial peptides can be broadly defined as a membrane-lytic activity, where they tend to assemble to form channels, with specificity for prokaryotic cell membranes. Many BPs have α-helical structures, are cationic and amphipathic, but hydrophobic α-helical peptides and β-sheet peptides possess antimicrobial activity also (Epand and Vogel 1999). Similar structural characteristics of isracidin and lactoferricin (Yamauchi and others 1993; Lahov and Regelson 1996) concern: length of the amino acid chain (23–26 amino acids), low positive charge, high content of nonpolar hydrophobic residues, and some Pro residues very near the C-terminal end of the peptide which could act to make its degradation by peptidases more difficult (Walker 2001). Most antimicrobial peptides interact with membranes and may be cytotoxic as a result of disturbance of the bacterial inner and outer membranes. Alternatively, a necessary but not sufficient property of these peptides is the capacity to pass through the membrane to reach a target inside the cell (Floris and others 2003). The positive net charge property is proposed to initiate peptide interaction

with the negatively charged bacterial surface, while a certain hydrophobic character would permit the peptides to enter the membrane interior (Wieprecht and others 1997). It is not likely that the diverse groups of peptides has a single mechanism of action, but interaction with membranes is an important requirement for most, if not all, antimicrobial peptides (Epand and Vogel 1999). Most antimicrobial peptides bind avidly to lipopolysaccharides of Gram-negative bacteria and lipoteichoic acids of Gram-positive, and are able to depolarize and permeabilize membranes (Devine and Hancock 2002). Under these circumstances, it is possible that the peptides induce the complete lysis of the microorganism by rupture of the membrane or that they perturb the membrane lipid layer, which allows the leakage of certain cellular components as well as dissipating the electrical potential of the membrane.

Antimicrobial peptides have unusually broad activity spectra compared to other agents, with very few intrinsically resistant bacteria. Although more potent antibiotics are available, antimicrobial peptides show the advantages of being able to kill target cells rapidly and having a broad spectrum of activity, including activity for some of the most serious antibiotic-resistant pathogens in clinics. Since the rate of killing is higher than the rate of bacterial multiplication, this enhances the potential to overcome drug resistance (Bechinger 1997).

70.11 CONCLUSIONS

The use of milk protein-derived BPs for application within food industry looks promising for consumers and producers. An important task for the production of functional foods containing BPs is to enhance their bioavailability from dairy products or to create novel foods by addition/fortification of isolated or enriched fractions of BPs. The production of BPs during food processing by the use of food-grade (GRAS) microorganisms such as lactic acid bacteria is of interest for current and future research work. ACE-inhibitory peptides, CPPs, and immunomodulatory peptides are the most suitable BPs for application in foodstuffs formulated to provide specific health benefits. Antimicrobial peptides have received little attention, but because of their useful intrinsic characteristics, an increased application is warranted. Under these perspectives, it seems crucial for the immediate exploitation of the: (1) *in vivo* mechanism by which bioactive peptides exert their activity; (2) intrinsic resistance to digestive enzymes; (3) adaptability and/or resistance to novel and traditional food technologies; and (4) emerging biotechnology for enriching the yield in bioactive peptides.

71.1 SUMMARY

According to FAO/WHO, fermented cream (sour cream, cultured cream) is the milk product obtained by fermentation of cream, reconstituted cream or recombined cream, by the action of suitable microorganisms that results in reduction of pH with or without coagulation. Where the content of (a) specific microorganism(s) is (are) indicated, directly

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

or indirectly, in the labeling or otherwise indicated by content claims in connection with sale, these shall be present, viable, active, and abundant in the product to the date of minimum durability. If the product is heat-treated after fermentation the requirement for viable microorganisms does not apply.

A process line for production of cultured cream manufacturing includes equipment for standardization of the fat content, homogenization, heat treatment of the cream, and also inoculation, fermentation, and packaging.

Standardized cream becomes heated to at least 80–90°C (at least 5 min holding) before deaeration and homogenization at high pressure (>130 bar) and high temperature (60°C) to improve the texture.

After cooling to mesophilic temperatures (18–25°C) inoculation of 1–4% starter culture takes place in a tank. Fermentation may proceed in a tank or, more commonly, in the final retail pack. The consistency of sour cream might be adversely affected by post-fermentation handling such as stirring, pumping, and filling. Also, the viscosity of the fermented cream might be very high, therefore making it difficult to pack. This is particularly the case with high fat products. Fermentation proceeds for 16–20 h until 0.6% of lactic acid in the fat free phase is reached and is stopped by chilling to around 4–6°C, that is, the packs become transferred to the cold store where they are allowed to rest for 24 h before distribution progresses.

For high-fat sour cream products the homogenization pressure shall be lowered to 100–120 bar only, since there is not enough protein (casein) available to form membranes on the enlarged total surface.

The usage of sour cream is mainly refining dishes. Key criteria defining the quality of the end product are sensorial properties, fat content, and absence of contaminating bacteria. Economically sour cream covers a small but growing segment of the overall fermented milks market.

71.2 INTRODUCTION

71.2.1 History

The history of fermented dairy products including sour cream lies in the dark. According to a legend it shall have been shepherds in the middle east who observed that raw milk permitted to stay for several hours changes in the following ways: (1) Separation of cream from the skimmed milk in a layer on top of the product. (2) Spontaneous fermentation takes place. Hence, since the shepherds appreciated the "new" taste, sour milk products were born such as fermented milk, yogurt, buttermilk, and sour cream.

Other legends claim that an angel delivered yogurt in a pot to earth for the first time, or that a nomad used to carry fresh milk in a container made up of tanned goats skin while riding a camel and recognized that although the product clotted, its sensorial properties were nice and tasty (Klupsch 1992).

Whatever story is true, nowadays fermented dairy products are widely appreciated by the consumers because of their high sensorial properties and nutritional value.

71.2.2 Chemical and Physical Background

Milk basically is made up of water, 4.8% lactose, 3.7% fat, 3.4% protein, mainly the caseins and whey proteins, 0.7% minerals, vitamins, and other so called "minor components."

Native caseins are peptide chains of unfolded threadlike structure with the tendency to form micelles. Within the porous complex the monomers are kept together via hydrophobic bonds, electrostatic bonds (the calcium ion forming bridges between two phosphoro-serin and/or dissociated glutamic acids), and hydrogen bridges. The caseins are widely heat-stable, but coagulate at their isoelectric point of pH 4.6 or via enzymatical cleavage (action of rennet) of the κ-casein. The latter renders the protecting water-soluble glycopeptide to be kept in a dissolved state. The remaining hydrophobic para-κ-casein part of the molecule, however, brings about precipitation and formation of a gel.

Whey proteins such as β-lactoglobulin are globular molecules with three-dimensional structure and are widely pH resistant, however, may unfold under heat treatment conditions (90–95°C for several minutes). The latter property is being used during sour dairy products specific heat treatment conditions of the bulk milk prior to incubation to foster a stable gel formation in the finished good.

Milk may be described as a polydispersed system containing water and dissolved substances in "real" solution, whey proteins and micelles of casein-proteins dispersed in a colloidal state, sometimes small air bubbles, and fat mainly occurring in the form of droplets wrapped by a complex cover of membrane proteins and lipoid substances to keep the droplets dispersed.

Specific mass of raw milk that parameter becomes increased by the dissolved substances, but decreased by the lipid phase in average ending up with a range of 1,029–1,034 g/ml (15°C).

Raw or pasteurized milk may serve as the base for further processing to manufacture different dairy products including consumer milk, fermented dairy products, and others.

Fermented dairy products such as yogurt, sour (clotted) cream, and buttermilk have been manufactured by natural fermentation of the substrate or via the addition of so called starter culture.

Knowledge of the basic chemistry and physics of the proteins and lipids of milk is necessary to understand the processing of fermented milks, yogurt, and sour cream. For further details on chemical, physical, biological, sensory, and nutritive characteristics of milk the reader should refer to Belitz and others (2001), Varnam and Sutherland (2001), and Robinson (2002).

71.3 LEGAL DEFINITIONS

Recommended legal definitions for sweet and sour cream, and cream derived products have been laid down by the FAO/WHO (UN Food and Agricultural Organization/UN World Health Organization) Joint Committee issuing the International Codex Alimentarius (Recommended International Standards for Foodstuffs).

Cream is the fluid milk product comparatively rich in fat, in the form of an emulsion fat-in-skimmed milk (o/w type), obtained by physical separation from milk. The FAO/WHO standard for the fat content of cream is exhibited in Table 71.1.

Fermented cream (sour cream, cultured cream) is the milk product obtained by fermentation of cream, reconstituted cream or recombined cream, by the action of suitable microorganisms that results in reduction of pH with or without coagulation.

Acidified cream is the milk product obtained by acidifying cream, reconstituted cream and/or recombined cream by the action of acids and/or acidity regulators to achieve a reduction of pH with or without coagulation (CODEX STAN A-9-1-Rev. 1-2003).

TABLE 71.1 FAO/WHO Standards for the Fat Content of Cream.

Type of Cream	Min. Fat Content (%)
(Single) cream	18
Half cream	10–18
Double cream	45
Whipping cream	28
Heavy whipping cream	35

More specifically the legal definition for fermented cream in Germany is given as follows:

Cultured cream is the product with a fat content of minimum 10% produced from sweet cream by culturing with lactic acid bacteria. The cream becomes standardized, cooled, and incubated usually with 2–4% butter culture, sometimes also including *Lactobacillus acidophilus*. The cream is fermented at a temperature of 20–27°C until pH of 4.5 is obtained (Pabst 2004).

Labelling criteria are laid down by the Codex General Standard of the Labelling of Prepacked Foods (CODEX STAN 1-1985, Rev. 1-1991; Codex Alimentarius, Volume 1A) and the General Standard for the Use of Dairy Terms (CODEX STAN 206-1999).

In case that nutrition claims are used, labelling needs to be in accordance with the Codex Guidelines for Use of Nutrition Claims (CAC/GL 23-1997, Codex Alimentarius, Volume 1A).

Legal issues concerning ingredients and additives are discussed in different sections below.

71.4 ECONOMICAL SIGNIFICANCE

Throughout the years after World War II until now, the market for fermented dairy products has expanded tremendously. The annual consumption of yogurt per head in Germany used to be 0.95 kg in 1961, however, increased to 12.0 kg in 1991 (Klupsch 1992). As to the cream market, cultured cream covers a small but growing market segment. Table 71.2 provides an idea of the cream market in the United Kingdom

TABLE 71.2 Cream Household Sales and Percentage Change Year on Year (UK 1988).

Name	Volume in 1000 L	% Change Year on Year
Total cream market	40,461	+4.0
Total dairy cream market	36,538	+5.0
Total fresh cream market	24,333	+8.0
Single	6,800	+5.0
Double	10,337	+5.0
Whipping	4,134	+24.0
Clotted	1,541	+13.0
Soured	519	+15.0
Total UHT cream market	6,722	+6.0
Total sterilized cream market	3,676	+1.0
Total frozen cream market	1,807	−12.0
Total synthetic cream market	3,923	−7.0

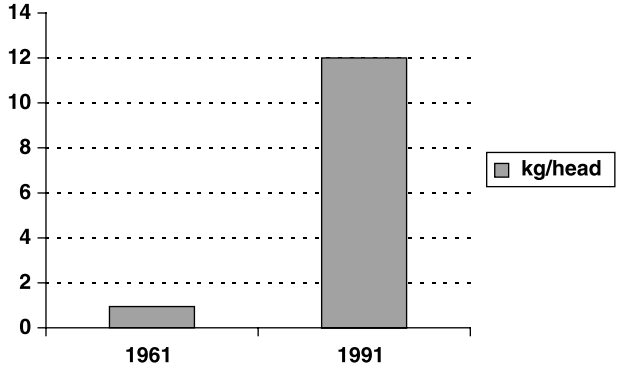

Figure 71.1 *Progress of annual yogurt consumption per head (Germany 1961 versus 1991).*

(Rothwell 1989). Figure 71.1 shows the progress of annual yogurt consumption per head (Germany 1961 vs. 1991).

71.5 INGREDIENTS AND ADDITIVES

Milk and dairy products generally are regarded to serve as basic nutritives in man's diet, therefore, addition of additives is limited to specified technological needs. As to sweet and sour cream FAO/WHO Codex Alimentarius states raw materials as follows (CODEX STAN A-9-1-Rev. 1-2003).

All kinds of cream and prepared cream utilize milk as the main ingredient. Milk for that purpose may have been subjected to mechanical and physical treatments prior to cream processing. According to the Codex the term "cream" is only suitable for products with a minimal butterfat content of 10%.

Only those ingredients listed in the Codex are permitted to be used in the processing of cream, those which are not there are forbidden.

For sour cream only suitable starter cultures are permitted, whereas rennet or equivalent coagulating enzymes and sodium chloride are permitted for fermented and acidified cream.

The additives classes allowed are stabilizers, thickeners, emulsifiers, and acidity regulators if they are needed to ensure the stability and integrity of the emulsion.

Stabilizers and thickeners limited by GMP are alginates, agar-agar, carrageenans, various gums (carob bean, guar, gum arabic, xanthan, gellan), pectin, celluloses, derivatives of celluloses, various native and modified starches. Also functional milk proteins, various milk powders and gelatin are permitted.

Stabilization of cultured dairy products is necessary if natural systems fail to keep the agglomerated casein-micelles (curd) in a three-dimensional network. This is particularly the case for products which become pasteurized (thermization) after filling when undesired flocculation may occur causing sandy mouth feel.

The gel shows a tendency of shrinking which may initiate separation of the whey. This phenomenon is generally called syneresis. Syneresis is often a problem for long shelf-life products.

Factors causing sandiness are as follows:

- No or low denaturation of the whey proteins
- Low fat content

- High thermization temperatures
- Long thermization time.

A natural way to stabilize the system is to increase the product's dry matter by addition of skimmed milk powder before fermentation.

Stabilization by stabilizers is brought about by addition of protective colloids (hydrocolloids). Also gel forming substances, thickeners to increase viscosity, and emulsifiers are being used.

The most common substances which become applied are functional milk proteins (emulsifying properties), native, and modified starches (gel forming and/or thickening properties), and gelatine (gel forming properties). Also carob bean and guar kernel flour (thickening properties) are being used. Sometimes celluloses or carboxy-methyl-celluloses (CMC) are added. Pectin, which is available in a low and in a high-esterified variety, is another hydrocolloid exerting protective-colloid and gel forming properties at low pH values.

Because of the BSE-crisis gelatine has got a poor reputation for European consumers. Thus many dairies replace gelatine by alternative substances as listed above. A combination of pectin and starch, or functional milk proteins probably is most commonly used.

Because of its high fat content sour cream is more stable than yogurt. It is, however, usually desirable to stabilize sour cream too. The substances applied vary with the fat content and the desired viscosity of the product (Fox, Neumann and Popper 2002).

71.6 CULTURES

Lactic acid bacteria (LAB) are Gram-positive facultative anaerobic bacteria fermenting lactose to lactic acid as the main metabolic product. They may be classified according to morphologic criteria (streptococci/lactococci or rods-lactobacillaceae) or according to physiological criteria (homofermentative or heterofermentative). Homofermentative means lactic acid as the more or less single metabolic product (apart from carbondioxide), whereas heterofermentative means that lactic acid is accompanied by other metabolic products such as ethanol or various organic acids.

Taxonomy and physiology of LABs have been reviewed in detail elsewhere (Varnam and Sutherland 2001; Bylund 2003).

In unpasteurized milk, spontaneous fermentation takes place caused by microorganisms (LABs) which are viable within an acid environment, at deep redox-potential, and finally, can utilize lactose as a carbon-source (Klosterneyer 1996).

Commercial sour-milk products use processed milk as the substrate. Acidification is brought about until or below pH values of the isoelectric point of the caseins, coagulation takes place to form the curd.

Nowadays in industrial dairy processing, natural fermentation has been replaced by commercially available blends of specific organisms, which are commonly referred to as "starter cultures." These selected kinds of organisms are responsible to initiate fermentation in the desired way to reach pH of 4.5–4.8 and to generate flavoring substances characterizing the product under concern (Klupsch 1992).

Some strains such as *Bifidobacterium* ssp. are claimed to exert therapeutic, probiotic properties to human health such as maintenance of a normal intestinal microflora,

stimulation of the host's immune system, alleviation of lactose maldigestion, anticarcinogenic activity, or reduction of serum cholesterol levels (Varnam and Sutherland 2001).

A conditio sine qua non for bringing about proper fermentation is that the substrate is free of inhibitory substances, mainly antibiotics originating from veterinary mastitis treatment without complying with minimal waiting periods after the treatment. Thus the processed milk has to be screened for antibiotics prior to fermentation (Brilliant-Black-Reduction test, Delvo test, Charm test or others). Also the milk needs to be free of bacteriophages that might attack the LABs and causes another reason for failure of the starter culture.

The fermentation process is undertaken at mesophilic (sour milk, sour cream) or thermophilic temperatures (yogurt) and, afterwards, stored at cool temperature of 3–5°C, so that it comes to a standstill.

Throughout the last two decades commercially available starter cultures have replaced that ones produced by the creamery itself. Frozen and freeze-dried units have superseeded the liquid cultures. Direct-to-vat inoculation has become the most common feature.

Typical starter cultures contain lactic-acid-bacteria as follows:

1. Sour milk: Mesophilic culture made-up of *L. lactis* ssp. *lactis* and *L. lactis* ssp. *cremoris*. Sometimes *L. lactis* ssp. *lactis* biovar *diacetyllactis* or *Lb. acidophilus* are around too.
2. Yogurt: Thermophilic culture made-up of *Sc. salivarius* ssp. *thermophilus* and *Lb. delbrueckii* ssp. *bulgaricus*.
3. Sour cream: "Butter culture" which is a mesophilic culture similar to that for sour milk.

Frozen DVS (direct to vat set) look like pellets; freeze-dried DVS show a granular shape with a diameter of 2–5 mm. The purity of these cultures as guaranteed by the suppliers (Chr. Hansen 2003; Danisco 2003) is given in Table 71.3.

A "classical" mesophilic mixed-strains culture for fermented milk, sour cream and sour cream butter is specified in Table 71.4 (Chr. Hansen 2003).

Progress of acidification needs to be monitored via pH measurement or titration and becomes plotted against time to indicate potential starter failure and to ensure the desired properties of the product (Figure 71.2).

TABLE 71.3 Microbiological Specification of a Common DVS Culture.

Bacteria sp.	Frozen DVS	Freeze-Dried DVS
Coliform bacteria	<1 MPN/g	<10 MPN/g
Enterococci	<10 CFU/g	<100 CFU/g
Molds	<1 CFU/g	<10 CFU/g
Non-LABs	<500 CFU/g	<500 CFU/g
Yeasts	<1 CFU/g	<10 CFU/g
Staphylococcus aureus	<1 CFU/g	<10 CFU/g
Salmonella sp.	Absent in 25 g	Absent in 25 g
Listeria	Absent in 1 g	Absent in 1 g

Source: Chr. Hansen (2004).

TABLE 71.4 Product Description of a Classical Mesophilic Starter Culture.

Product Description	Concentrated Deep-Frozen Starter Culture Pellets for Direct Inoculation into the Process Milk
Type	*Classical mesophilic mixed strains culture*
Composition	*Lactococcus lactis* subsp. *Lactis* *Lactococcus lactis* subsp. *Cremoris Lactococcus lactis* subsp. *lactis biovar diacetyllactis Leuconostoc mesenteroides* subsp. *cremoris*
Properties	Moderate acidification, formation of mainly L(+) lactic acid, slow citrate fermentation, and thus little carbon dioxide release, moderate diacetyl formation (typical flavor)
Packaging	Polyethylene bags
Shelf-life	12 month at $<45^{\circ}C$
Usage	Open the bag right before inoculation, add the culture aseptically and in a frozen state directly into the procesed milk
Application	Sour cream 1.0–2.0 units/100 l, also applicable for butter- and thick-milk-fermentation and some cheeses as well

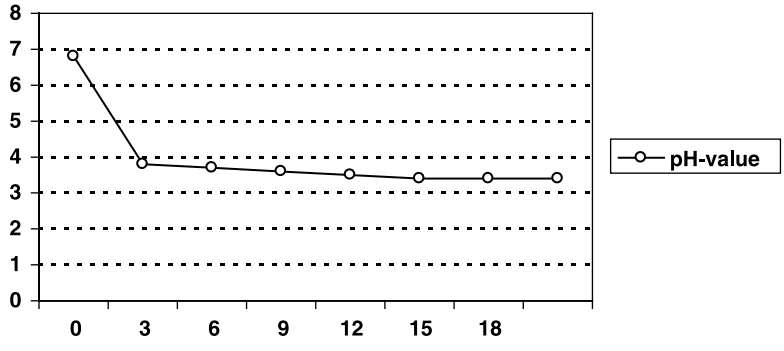

Figure 71.2 *Plotting of pH vs. fermentation time.*

71.7 MANUFACTURING AND PACKAGING

71.7.1 Manufacturing

The basic technology of cream includes separation and standardization, homogenization, pasteurization, and other postseparation processes to obtain creams with differing properties. These basic unit operations have been discussed in relation to cream, its quality, viscosity, stability against syneresis, and other properties by Towler (1987) and Rothwell (1989).

Heat treatment of milk and cream is compulsory to ensure safety of the product, and, in case of sour cream, to bring about denaturation of the whey proteins to achieve a stable curd. Whereas for pasteurized milk applying the HTST (high temperature-short time) process $72^{\circ}C$ for 15 s is regarded to be good enough, because of higher viscosity the heat transfer rate within cream becomes impaired thus more severe heat treatment conditions become arranged such as $85^{\circ}C$ for 30 min or $90-95^{\circ}C$ for 5–10 min to provide two examples.

Usually heat treatment, holding and cooling, but also incubation and addition of fruit preparations become brought about in the same vessel ("multipurpose processing tank") for the stirred type fermented milk, but plate-heat exchangers with an appropriate

holding-tube, incubation in a vessel and fermentation in the final pack is also common for the set type of fermented dairy products.

Commercial sterilization of cream (in the container or UHT-ultra high temperature) requires a reduction rate of 9D (i.e., nine logarithmic cycles) in numbers of endospores-forming bacteria.

Fermented milks may be classified in a number of ways, but a system based on the type of starter microorganism used is generally satisfactory (Table 71.5).

The fat content of cultured (sour) cream is standardized between 10% and 30% depending on the required properties. A process very similar to that used in buttermilk manufacture except that cream of at least coffee cream fat content is used to make sour cream.

Basically sour cream is an extremely viscous product with a gel-like consistency with the flavor and aroma of buttermilk (acetoin as a major flavor component) which is the case because the starter culture is related to that used for cultured buttermilk, that is, mesophilic culture compiled of *L. lactis* ssp. *lactis*, *L. lactis* ssp. *cremoris*, and *L. lactis biovar diacetyllactis.* This is a balanced mixture of acid and flavor producing bacteria (Desrosier 1970).

The process line for production of cultured cream manufacturing includes equipment for standardization of the fat content, homogenization, heat treatment of the cream, and also inoculation, fermentation, and packaging.

Standardized cream becomes heated to at least 80–90°C (at least 5 min holding) before deaeration and homogenization at high pressure (>130 bar) and high temperature (60°C) to improve the texture.

After cooling to mesophilic temperatures (18–25°C) inoculation of 2–4% starter culture takes place in a tank. Fermentation may be brought about in a tank or, more commonly, in the final retail pack. The consistency of sour cream might be adversely affected by postfermentation handling such as stirring, pumping, and filling. Also, the viscosity of the fermented cream might be very high, therefore making it difficult to pack. This is particularly the case with high-fat products.

Fermentation proceeds for 16–20 h until 0.6% of lactic acid in the fat free phase is reached, and is stopped by chilling to around 4–6°C, that is, the packs become transferred to the cold store where they are allowed to rest for 24 h before distribution takes place (Varnam and Sutherland 2001; Bylund 2003).

TABLE 71.5 Classification of Fermented Milks.

Type of Fermentation	Product
Mesophilic lactic fermentation	Cultured buttermilk
	Cultured cream
	Filmjolk
	Scandinavian ropy milks
Thermophilic lactic fermentation	Yogurt
	Acid buttermilk
Therapeutic lactic fermentation	Acidophilus milk
	Yakult products
	Acidophilus-bifidus yogurts
	Proprietary therapeutic products
Lactic/yeast fermentation	Kefir
	Kumis
Lactic fermentation/mold ripening	Viili

Source: Varnam and Sutherland (2001).

For high-fat sour cream products the homogenization pressure shall be lowered to 100–120 bar only, since there is not enough protein (casein) available to form membranes on the enlarged total surface (Bylund 2003).

When properly refrigerated, sour cream should maintain its smooth consistency for several weeks. Exposure to higher temperatures or holding for more then 4 weeks may cause whey separation. The product is still usable after stirring but at this stage it may be somewhat less appealing in flavor. Addition of hydrocolloids may increase the texture stability as discussed above.

Anyhow, the shelf-life of the cultured cream may be prolonged by heat treatment of the fermented product (long-life cultured cream). Stabilizers need to be added usually into the cream before fermentation to improve resistance of the texture against the final heat treatment. The viscosity of the ready product is dependent on the choice of stabilizer, as well as on the design of the particular plant.

A slightly different but also common schedule for the manufacture of sour cream is given in Figure 71.3 (Robinson 2002).

The optional supplementation with milk or whey powders requires additional deareation and filtering steps. Denaturation of the whey proteins via heating to 90°C with subsequent holding is desired to improve the texture and to avoid postprocessing gelatination in the pack.

Sour cream dip is a cultured cream of 12–16% fat containing dry milk solids, sugar, stabilizer, rennet extract, spices, salt or pepper, and sometimes, various cheese condiments.

Crème fraiche is a French denomination for mildly fermented cream of a fat content of $\geq$30%. This is a variety of cultured cream, which is of premium quality usually taken for refinement of dishes. Crème fraiche is popular in Central Europe complying with quality requirements as follows (Klupsch 1992):

- Natural fermentation
- No addition of stabilizers
- No thermal treatment after fermentation
- Stable against syneresis for 5 weeks shelf-life.

Dairy spreads made from sour cream are cultured cream of minimal 28% fat, which show plastical, butter-like rheological properties. The manufacturing process for pasteurized sour cream spreads is given in Figure 71.4 (Klupsch 1992).

Sour cream powders have a variety of applications such as salad dressings, sauces, dips, frozen vegetables, cake mixes, snack blends, and seasoning bases. Containing 21–54% butterfat the products include full-fat, low-fat, high-acid, and high-flavor versions (Anonymous 1994).

Filled sour cream is a product where butterfat becomes replaced by vegetable fat such as palmolein.

Acidified sour cream is a product using sweet cream as the base, but bringing about low pH values by addition of organic acids instead of a natural acidification process. These products obviously lack the typical flavor produced during the fermentation of lactose if not fixed by addition of specific flavoring components.

Sour cream imitates occasionally may appear in the market (Desrosier 1970). Imitation may refer to the way of achieving acidification and/or the nature of the fat phase. These products, however, are not permitted to be used by the WHO/FAO Codex Alimentarius for potential fraud reasons. Specific labeling is required.

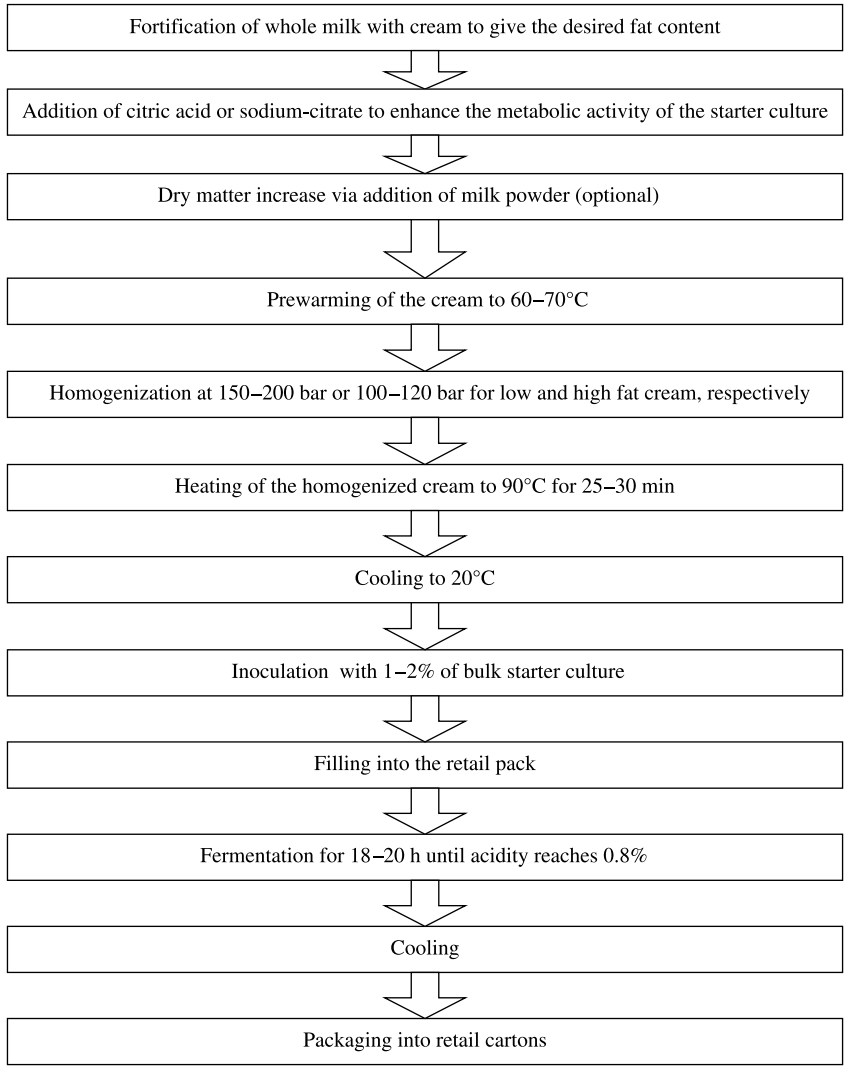

Figure 71.3 *Process flow-chart for sour cream manufacturing acc. to Robinson 2002.*

No fat sour cream is an imitation product where the fat becomes replaced with skimmed milk powder and dairy proteins. The product is claimed to have the full flavor and smooth texture of regular sour cream. This product shall be heat stable within a wide range of time–temperature conditions applied. The unopened shelf life is 4 months in accordance with the information released by the manufacturing company (Anonymous 1995).

Cream yogurts in a way may also be regarded to form a variety of cultured cream. These products are standardized to 10% fat and thermophilic fermentation conditions are applied (40–42°C) using a yogurt starter culture. Fermentation becomes stopped after 4–6 h via cooling to refrigerator temperature. Fermentation might be proceeded in the tank (stirred type) or in the final pack (set type). The process of yogurt making is discussed in more detail by Robinson (2002).

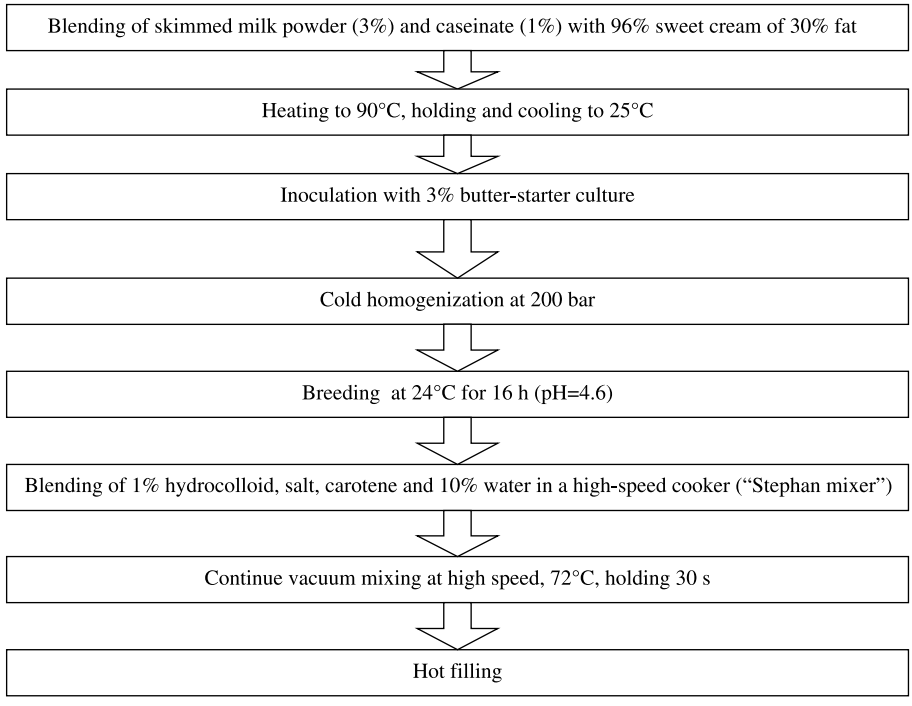

Figure 71.4 *Process flow-chart for pasteurized sour cream spreads.*

Another function of sour cream is to serve as the *raw material of sour cream butter*. Butter is the product gained by dashing concentrated cream to render the fat globules to flow into each other. Thus a phase reversion is achieved from an o/w type emulsion to become a w/o one. Butterfat forms as the continuous phase, small water droplets make up the dispersed particles.

Buttermilk is the liquid low-fat product left over following the separation of the butter grains from the skimmed phase. This by-product of the buttering process is sweet or sour buttermilk, which is usually utilized as feed for cattle and pigs. The commercially available buttermilk, however, is made up by inoculation and fermentation of skimmed milk via usage of a buttermilk starter. The basic types of butter are sweet cream butter and sour cream butter.

Butter made from sour cream has certain advantages over the sweet cream variety. The aroma is richer, the butter yield is higher, and there is less risk of reinfection after temperature treatment as the bacterial culture suppresses undesirable microorganisms. The drawbacks, however, are that it is more sensitive to oxidative fat defects.

Fermentation of sour cream foreseen for the churning process takes place for around 16–20 h at mesophilic temperatures. Sweet buttering cream undergoes a ripening process only to achieve small fat crystals for reducing hardness of the butter.

An excellent review of cream processing and butter making has been provided by Bylund (2003).

71.7.2 Packaging

Material properties requirements for packaging of sour cream are reasonable light and oxygen tightness to avoid light or oxygen induced fat oxidation and thus potential off-flavor, relative impermeability to moisture, proper robustness to avoid mechanical

damage throughout the overall supply chain, tightness to microorganisms and dust particles, and suitability for automatic product filling and packaging at high speed lines. The filled containers must not contaminate the product with flavor-inducing chemical molecules (e.g., styrene monomers). The microbiological contamination of the materials's surface needs to be reasonably low.

Containers to be filled mechanically may usually be polypropylene or polystyrene beakers to be filled hot or cold before fermentation and sealed by aluminum foil. Sometimes glass jars with plastic caps become used. Aseptic filling into polyethylene and metal-layered carton packs is quite common for UHT-cream but less common for sour cream.

Eventually for packaging, the sour cream containers are placed into cardboard cases, which are being moved into the cold store and kept there to rest for 24 h before being ready for distribution. The palettes keeping the cases usually become stabilized by wrapping with polyethylene stretch foil (Rothwell 1989).

71.8 USAGE

Basically there are three main usages of sour cream:

(1) Usage of sour cream in the kitchen to refine various dishes such as addition to sauces and fillings for cakes.
(2) Usage for salad dressings as a comparably low calories replacement of mayonnaise.
(3) Technological usage of high fat cultured cream as the raw material for sour cream butter-making (ref. above).

TABLE 71.6 Sour Cream Salad Dressing.

Ingredients	Quantity
Salt	$\frac{1}{2}$ teaspoon
Sugar	1 teaspoon
Cayenne pepper	$\frac{1}{8}$ teaspoon
Lemon juice	1 tablespoon
Vinegar	2 tablespoons
Sour cream	1 cup

Instruction: Stir together sour cream, vinegar and lemon juice, add sugar and spices, stir again, serve cold.

TABLE 71.7 Recipe Vanilla-Raisin Bread.

Ingredients	Quantity
Golden raisins	1 cup
Vanilla	2 tablespoons
Water	$\frac{1}{2}$ cup
Light sour cream	$\frac{3}{4}$ cup
Honey	3 tablespoons
Salt	1 tablespoon
Bread flour	3½ cups
Cinnamon	1 tablespoon
Active dry yeast	2 tablespoons

Note: Soak the raisins in the vanilla for at least 1 h. Place ingredients 3–9 in a pan, bake on sweet cycle, and add raisins after kneading beep.

TABLE 71.8 Recipe Sour Cream Dip.

Ingredients	Quantity
Shredded hard cheese	2 cups
Sour cream	$\frac{11}{2}$ cups
Sliced black olives	2 small cans
Diced tomatoes	$\frac{11}{2}$ cups

Note: Bake beef or pork meat together with spices almost until done, then add the sour cream in an even layer ontop the meat, then cheese, then olives, bake uncovered until the cheese melts, after taking out of the oven sprinkle tomatoes over the top.

When googling in the internet using "sour cream" as the key words a variety of several hundred URLs appear giving a tremendous amount of recipes of sour cream for cooking purposes. To provide an idea the author selected three examples, which are shown below (Tables 71.6–71.8).

71.9 QUALITY, ANALYSIS, AND CONSUMER SAFETY

For each dairy processing plant, appropriate processes to manage the quality have to be laid down in writing and also to be practically implemented. Such a quality management system may or may not become certified according to the international standard of ISO 9001: 2000 (Peach and others 2000).

Good manufacturing practice (GMP) is a set of basic hygienic rules laid down in SSPs "standard sanitation procedures" or SOPs "standard operational procedures."

A systematic, proactive evaluation of a particular product's process line and its potential usage for consumer safety aspects and afterwards stipulating control points is called Hazard Analyses Critical Control Points (HACCP) (Loken 1995). Critical Control Points to ensure end-product safety (CCPs) for sour cream processing might be: Test for inhibitory substances in the incoming milk, pasteurization, pH values (<4.2) and metal detection.

The analytical chemical, physical, biological, and sensorial methods used in the laboratory or direct at the manufacturing line have to be identified, calibrated properly, and compared with other laboratories via inter-laboratory tests.

Cultured cream is bright, has a uniform structure and is usually viscous. The taste should be mild and slightly acidic with body, creaminess and proper mouth feel. In case of the set type variety of sour cream the texture shall be extraordinary thick and smooth, that is, in a way that a spatula put into the product can stand upright in it.

The rheological features show non-Newtonian flow characteristics, that is, thixotrophic properties. A product is called thixotrophic if exerted shear stress causes decrease of the apparent viscosity (Pa·s) and if the product after being relieved from the shear stress only partly regains its previous structure. This effect observed for viscous-elastic gels is sometimes called shear thinning.

Apparent viscosity may be determined by means of a rotation viscosimeter. The undisturbed gel may become physically investigated for hardness/gumminess, cohesiveness, and adhesiveness to establish a texture profile by using a texture analyzer. Addition of a few ppm of rennet to the sweet cream before adding the starter culture fosters proper gel formation. The gel strength is a maximum at pH values in the area of 4.6, but the

gel strength and firmness decrease at pH < 4.0 because of charge repulsion of the caseins. In case the whey proteins have been denaturated by heat treatment they aggregate with the caseins and hence contribute to a firm gel structure.

Potential reasons for texture problems might be as follows: too high separation temperature ($T > 45^{\circ}C$), too high incubation temperature, insufficient heat treatment so that the whey proteins are not completely denaturated, too low milk solids nonfat (MSNF), too high whey protein to casein ratio, improper selection use and concentration of stabilizers, improper starter cultures (or infection) to cause proteolysis and uncontrolled exopolysaccharide expression of some bacterial strains (Klupsch 1992).

Aspects of syneresis and stabilization of sour cream have been discussed above.

The degree of syneresis may be measured by inverting the product upside down onto a fine sieve and collect and weigh the whey passing through the sieve.

The nutritive value of sour cream of 10% fat is given by 3.1% protein, 10.1% fat, 3.5% carbohydrate (lactose), fat- and water-soluble vitamins, minerals, and trace elements. The energy content of 100 g cultured cream is 510 kJ (122 kCal).

Good raw-milk quality given by low total bacteria count, low somatic cells count, absence of inhibitoring substances, and absence of off-flavor and taste, is essential for the manufacture of a high quality product.

Mechanical damage of the raw or pasteurized milk due to too intensive agitation or pumping needs to be avoided as much as possible, because free fat released from the fat droplets by membrane damage is prone to oxidation. Enzymatic decay may foster a metallic like or rancid off-flavor (Heiler and Schieberle 1996).

Homogenization shall be done at comparably low pressure in two steps to avoid too small droplets corresponding with too large total surface area so that the caseins might not be able to quickly form new intact membranes.

Process control of a sour cream manufacturing line involves fat content measurement of the standardized product, monitoring of the time–temperature conditions applied while heating, monitoring the homogenization pressure applied, testing the activity of the starter culture prior to inoculation, monitoring of fermentation time and temperature, pH or acidity measurement progressing throughout the fermentation, sensorial testing and pH measurement of the fruit preparation, if so applicable.

GMP is confirmed to be attained via sampling for various microbiological tests and implementation of swab tests taken from the milk contacting surfaces or from the environment of the process line.

All operations have to be in accordance with basic hygienic and sanitation rules, particularly postprocessing contamination (PPC) downstream heating needs to be avoided. Any addition of additives or fruit preparation after heating needs also to be monitored. Some authors regard this GMP like process steps to form another CCP (Varnam and Sutherland 2001).

Shelf-life of a sour cream product shall be 4–6 weeks if manufactured in accordance with the hygienic rules described beforehand including constant proper cooling to $4–6^{\circ}C$. After opening the product may remain durable for another 2 weeks. A spoon might remix it in case whey separation occurs (Daisy Dairy Products Ltd. 2004).

An end-product-testing scheme applicable for sour cream and other fermented dairy products widely used in Central Europe has been established by the German Society of Agricultural Sciences (DLG = Deutsche Landwirtschafts-Gesellschaft 2002) as follows.

The fat content of sour cream according to the declaration on the label needs to be at least 10, 20, 30, or 40%. The viscosity of the product in accordance with appropriate

labeling may be liquid, thick, or set. The sensorial properties of the product become evaluated following a 5 points scale for the features appearance, odor, flavor, and texture.

The microbiological quality of the product becomes evaluated with the aid of the parameters coliform germs and molds/yeasts. Coliform bacteria basically need to be less then 10 CFU (colony forming units) in 1 ml samples. Molds and yeasts need to be <100 CFU/mL to achieve the maximal ranking.

The results of sensorial testing and microbiological evaluation become multiplied by a weighing factor, then added up, and finally divided by the overall sum of the weighing factors (i.e., 24 in the DLG scheme) to come up with an overall quality figure, which is in the range of 1–5 points, obviously.

The samples shall have been kept for not more then 2 weeks at 4–8°C. The packs need to be tight. Samples shall have been drawn in accordance with the sampling plan provided by the DLG. The temperature during the conduction of the sensorial tests shall be in the range of 14–18°C. Spoiled samples are to be destroyed.

Analytical methods for examination of dairy products including sour cream have been published by the German Association of Food testing- and Research Institutes (VDLUFA = Verband Deutscher Lebensmittelunter-suchungs- und Forschungsanstalten 1995).

These reference methods are as follows:

(1) Chemical methods
- Fat content: Gravimetric method according to Röse-Gottlieb (Note: In the Anglo-American countries the method usually is called "Mojonnier-method.").
- Protein content: Nitrogen based method according to Kjeldahl.
- Nonprotein-nitrogen: Precipitation of proteins with trichloric-acetic-acid, filtration, nitrogen determination in the filtrate.
- Lactose and galactose content: Enzymatically.
- Mineralic substances: Gravimetric oven-method determining the ash content.
- Sucrose and dextrose content in sweetened dairy products: Enzymatically.
- Number of double bindings in fat: Jodometric titration method ("Jod value"). Routine methods such as IR-spectroscopic determination of fat, protein, and lactose have to be calibrated versus the reference-methods. Nowadays, turbidimetric and IR measurement of fat content have superceded widely the formerly most common butyrometric rapid methods for examination of fat (milcoscan technology).

(2) Microbiological methods
- Total plate count of colony forming units: Koch's petridish method using china blue lactose-agar.
- Coliform germs: MPN (most probable number) method based on sodium laurylsulfate medium or petridish method using violetred-bilesalts-agar.
- Yeasts and molds: Petridish method using maltextract-agar.
- Lipolytic bacteria: Petridish method using tributyrin-agar.

(3) Physical methods
- Apparent viscosity as given above (Adapa and Schmidt 1998).
- Determination of gumminess, adhesiveness and cohesiveness by means of a texture analyzer.

72.1 INTRODUCTION

Protein hydrolysates are produced through hydrolysis (size reduction) of intact proteins to amino acids or mixture of polypeptides, oligopeptides, and smaller peptides and amino acids, depending on the method of hydrolysis. They represent a category of protein

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

ingredients with broad applications in food, nutritional, dietary supplement, medical, and personal care products. Protein hydrolysates have been used since the 1940s for the nutritional management of individuals who cannot digest intact protein (Cuthbertson 1950; Mahmoud and others 1992). The most prevalent use of such hydrolysates, however, has been for feeding infants with food hyper sensitivity (particularly cow's milk) (Mahmoud and others 1992). For the past decade, there has been increasing interest in the utilization of native and hydrolyzed milk proteins for human nutrition and health-related foods (De Wit 1998; Floris and others 2003; Kilara and Panyam 2003; Korhonen and Pihlanto 2003; Playne and others 2003).

Hydrolysis of proteins can be accomplished with enzymes, acids, or alkali, but enzymatic hydrolysis is strongly preferred over strictly chemical methods for producing hydrolysates in nutritional applications (Lahl and Braun 1994). Enzyme-catalyzed processing is very specific and can be controlled to produce protein hydrolysates of defined molecular weight distribution, peptide composition, and degree of hydrolysis (DH). Acid and alkali hydrolysis, on the other hand, can destroy L-form amino acids, produce D-form amino acids, and can form toxic substances like lysino-alanine (Lahl and Braun 1994). Enzymatic hydrolysis is developed mostly under mild conditions of pH (6–8) and temperature (40–60°C), avoiding the extremes usually required for chemical and physical treatments and minimizing side reactions (Clemente 2000).

Hydrolysis of proteins by proteolytic enzymes (often referred to as proteases) is a widely used technique to modify the physicochemical properties (e.g., molecular size, surface activity/hydrophobicity, etc.), functional properties (e.g., gelation, emulsification, solubility, etc.) and sensory properties of food proteins. A review article by Panyam and Kilara (1996) provides several examples where limited proteolysis was used to enhance the functionality of food proteins. After the substrate (i.e., protein) and enzyme(s) selection for enzyme-catalyzed processes, the DH is the principal variable to be used in optimization (Alder-Nissen 1986) to achieve desired protein hydrolysates. One of the major elements in commercial production of hydrolysates is developing the optimal enzyme mixture for producing the desired ratio of amino acids, dipeptides, tripeptides, and oligopeptides (Lahl and Braun 1994). The mechanism, key parameters, and enzyme process control method will be elaborated in Sections 72.2 and 72.3.

Although protein hydrolysates can be derived from vegetable- or animal-based proteins, by acid/alkali or enzyme hydrolysis, the focus of this article is on enzymatic-derived hydrolysates from dairy proteins (whey and casein proteins), henceforth referred to as dairy protein hydrolysates (DPH).

There are considerable interests in DPH, driven by advances in technology, economic incentives (value-added products vs. commodity), potential nutritional and health benefits, and market demand. Today, hydrolysis can be performed by conventional batch hydrolysis or by continuous hydrolysis using ultrafiltration (UF) membranes (Korhonen and Pihlanto 2003), thus providing a technological means to develop products with desired peptide composition. Stepwise UF using low molecular mass cut-off membranes may be useful for separating small peptides from high molecular mass residues and remaining enzymes (Korhonen and Pihlanto 2003). Turgeon and Gauthier (1990) used a two-step UF process and were able to produce a mixture of polypeptides and a fraction rich in small peptides with a molecular mass below 2000 Dalton (Korhonen and Pihlanto 2003). Thus, the UF technology is enabling the development of DPH of selective composition that hitherto was unachievable. The range of new product possibilities and revenues resulting from the application of enzymes and UF technology makes protein hydrolysates

a product category of the future. As value-added products, DPH command higher premium ($>2\times$) than commoditized dairy proteins.

Proteins sources used most commonly in nutritional products containing protein hydrolysates are casein, whey protein, and soy (Lahl and Braun 1994). Cow's milk protein is the most important protein source used in the development of protein hydrolysates designed for nutritional support of patients (references in Clemente 2000). They are produced from isolated casein or from whey protein concentrate by using food-grade proteases (Clemente 2000).

Applications for DPH include (1) the development of special formulations designed to provide nutritional support to patients with different needs (Mahmoud 1994; Boza and others 1995; Clemente 2000); (2) infant formulas (Lahl and Braun 1994); (3) as a source of bioactive peptides (Fox and Kelly 2003; Korhonen and Pihlanto 2003); and (4) in protein supplementation for clinical use (Clemente 2000). Several bioactive peptides are present in hydrolysates of caseins and whey proteins. These include phosphopeptides, caseinomorphines and other peptides with morphine-like properties, immunomodulating peptides, blood platelet-modifying (antithrombic) peptides, angiotensin converting enzyme inhibitors and bactericidal peptides (e.g., from lactoferrin) (Fox and Kelly 2003). Much of the knowledge on bioactive peptides is based on bioactivity by *in vitro* assay protocols; however, more research is needed to understand the pharmacokinetics of peptide production and efficacy *in vivo* (Playne and others 2003; Yamamoto and others 2003). The literature on bioactive peptides from dairy proteins has been extensively reviewed by several authors including Fox and Flynn (1992), Mulvihill and Fox (1994), Shah (2000), FitzGerald and Meisel (2002), Pihlanto-Lappala (2002), and Korhonen and Pihlanto (2003).

While the art of manufacturing dairy protein hydrolysates is well understood by food protein ingredient developers, more work is needed to develop cost-effective, industrial-scale technologies that retain and/or enrich bioactive peptides in DPH. The economic value and growth opportunity in DPH and associated bioactive peptides are enormous considering the various nutritional and potential health benefits and the untapped new applications in several functional foods, dietary supplements, and biotechnology.

The purpose and scope of this chapter is to review general aspects of protein hydrolysis, the technology of DPH, functions and applications of DPH, and provide future perspectives.

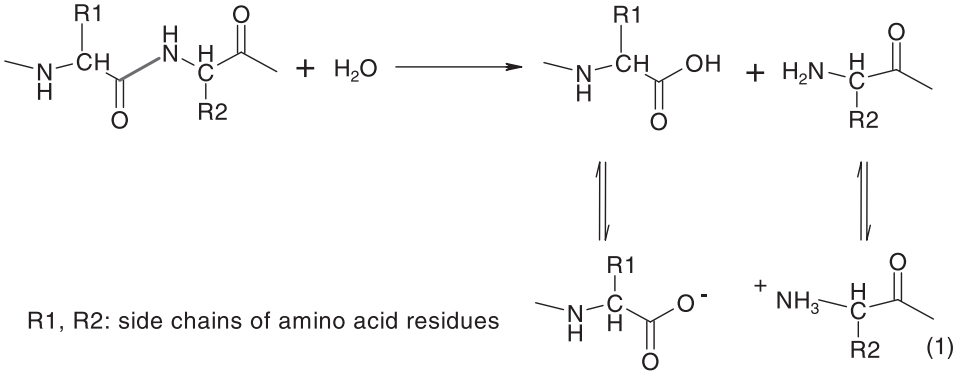
72.2 GENERAL ASPECTS OF PROTEIN HYDROLYSIS

72.2.1 Fundamentals of Protein Hydrolysates

By definition, hydrolysis is a chemical reaction in which a substance reacts with water to be changed into one or more substances. Proteins are made of amino acids linked together linearly by peptide bonds. Hydrolysis of proteins involves the cleavage of these peptide bonds, resulting in breakdown of proteins to peptides and amino acids. The products of protein hydrolysis, which are normally mixtures of peptides and amino acids, are called protein hydrolysates.

Hydrolysis of peptide bonds can be achieved chemically through the use of strong acids or alkalis, or can be achieved enzymatically through the use of proteolytic enzymes (proteases). Equation (1) illustrates an enzyme-catalyzed hydrolysis of a peptide bond. Hydrolysis of each peptide bond generates one free amino group and one free carboxyl

group, which, depending on the pH of the media, can release or take up a proton. At high pH, hydrolysis of peptide bonds results in the release of protons; the up take of protons results at low pH.



Proteases can be categorized into different groups based on their type of action, catalytic mechanism, optimal pH of activity, organisms they are derived from, and so on. The proteases which hydrolyze peptide bonds from the N-terminus or C-terminus, one amino acid residual (sometimes two residuals) at a time, are called peptidases or exopeptidases. The proteases which hydrolyze peptide bonds in the interior of the polypeptide chain are called proteinases or endopeptidases. Based on the mechanism of catalysis, proteinases can be divided into four subgroups: serine proteinases, cysteine proteinases, aspartic proteinases, and metallo-proteinases. Some proteases have a very specific requirement for R1 or R2 to hydrolyze the peptide bond. Such requirements are referred to as the substrate specificity of the protease. For example, trypsin only hydrolyzes the peptide bond when R1 is the side chain of an arginyl or lysyl residue. Therefore, trypsin has a narrow specificity. Some other proteases have broader specificities. An example is Subtilisin A, which hydrolyzes peptide bonds when R1 is the side chain of a hydrophobic amino acid residue.

The rate of protease catalyzed hydrolysis of proteins generally depends on the types of substrates, enzyme and substrate concentrations, pH, and temperature. Increases in temperature generally increase the rate of protease catalyzed hydrolysis until the protease starts to denature and lose its activity. Various proteases have different stabilities to heat denaturation (inactivation). The heat stability of a protease also varies in the presence of different substrate and hydrolysis products. With a given set of conditions, each protease will demonstrate an optimal temperature and optimal pH. The information about proteases' optimal pH and temperature and how they change in the presence of different substrates provide some guidance in developing processes for dairy protein hydrolysates.

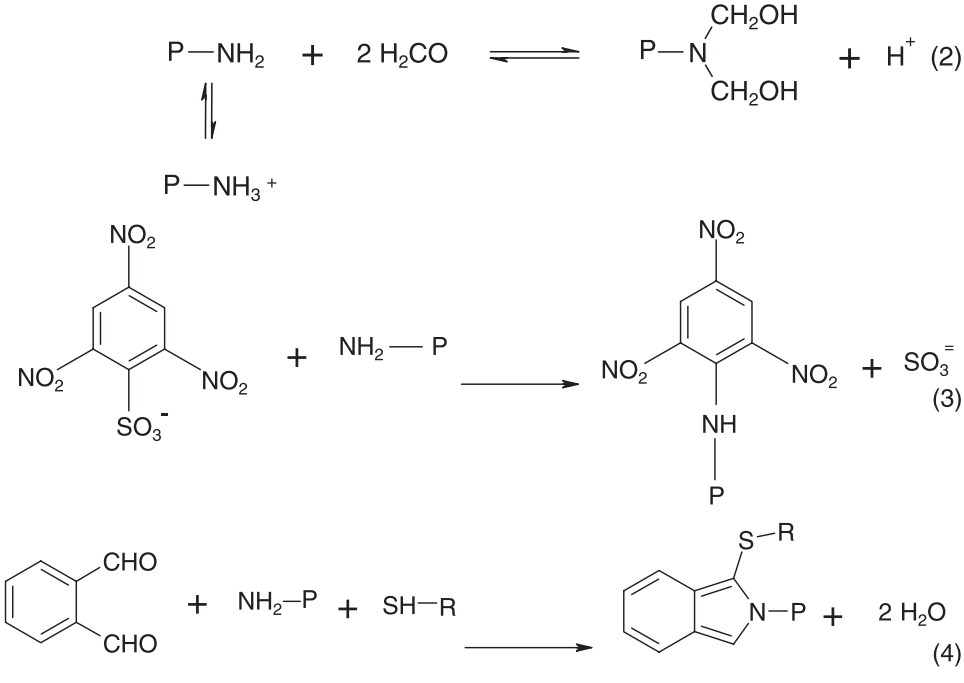
72.2.2 Analysis of Protein Hydrolysates

Depending on the uses of protein hydrolysates, they can be characterized by their level of hydrolysis, peptide profile, functional attributes, and biological activities. Measure of hydrolysis level is the most common form of characterization for any protein hydrolysate. Trichloroacetic acid (TCA) solubility has been used as a measure of hydrolysis level since as a protein is further hydrolyzed, smaller peptides and amino acids, which are more soluble in TCA solution, are formed. Therefore, TCA solubility index has been used as

an indication for the amount of small peptides and amino acids in the hydrolysate products (Margot and others 1994).

Adler-Nissen (1979) has suggested using degree of hydrolysis (DH) as a more quantitative measurement of hydrolysis level. DH is defined as the percentage of peptide bonds hydrolyzed. As shown in Eq. 1, hydrolysis of each peptide bond generates one amino group (and one carboxyl group). By determining the amino groups generated during hydrolysis, one can measure the number of peptide bonds hydrolyzed.

Several methods exist in determining the amino groups in a hydrolysate. Formol titration of amino groups is one of the well-known methods. It is based on the fact that in neutral or alkaline solutions, the amino groups can react with 2 moles of formaldehyde and form a product with much lowered pKa (Eq. 2). If the reaction is carried out at a pH sufficiently lower than the pKa of amino groups, the protons released can be titrated and directly related to the number of amino groups. However, because amino groups in a protein hydrolysate can have different pKa, formol titration usually does not measure all of the amino groups. Reactions of amino groups with trinitro-benzene sulfonic acid (TNBS) or with o-phthalaldehyde (OPA) in the presence of sulfhydryl containing compounds form products which can be measured by absorbance at 340 nm (Eq. 3 and Eq. 4, respectively). These reactions are the basis for the determination of amino groups in protein hydrolysates (Adler-Nissen 1979; Nielsen and others 2001) and ultimately their DH.



Once the amount of amino groups in a hydrolysate is determined by one of the above methods, the ratio of amino nitrogen to total nitrogen (AN/TN) can be readily calculated. AN/TN also reflects the hydrolysis level. For any protein, there is a linear relationship between AN/TN and DH. However, due to the difference in amino acid compositions, hydrolysates from different protein substrates will have a slightly different relationship between AN/TN and DH (Fig. 72.1).

Using size-exclusion chromatography (SEC) on HPLC, the peptide profile (molecular weight distribution) of protein hydrolysates can be determined (Knights 1985; Vijayalakshmi and others 1986; Nakamura and others 1992). Many peptides from hydrolyzed proteins tend to aggregate in aqueous solutions through hydrophobic interaction. When analyzing these hydrolysates by SEC, the mobile phase often contains acetonitrile, trifluoroacetic acid, and salt to disrupt the hydrophobic and ionic interactions. Although HPLC-MS technique can be used to obtain more accurate and specific information about any peptide in a protein hydrolysate, SEC remains the most common technique for general characterization (such as peptide profile) of protein hydrolysates due to its relative ease of operation and availability. Figure 72.2 gives some examples of molecular weight profiles of WPH obtained by SEC on HPLC. The three hydrolyzed whey proteins have calculated DH of 4, 8, and 11, respectively. By proper integration of the areas between different retention times, the percentage of peptide material in various molecular weight ranges can be readily calculated. Another commonly used term to describe the level of hydrolysis is peptide chain length (PCL) (Adler-Nissen 1986). PCL can be directly calculated from DH (Eq. 5) and is a measure of average number of amino acid residues in the peptides. For hydrolysates of dairy proteins, PCL_0 (the number of amino acids residues in a polypeptide chain of an intact protein) is generally in the range of 150–400. Equation 5 will approximate to DH $=$ 100%/PCL (Adler-Nissen 1986).

$$\mathrm{DH} = \frac{\left(\frac{1}{\mathrm{PCL}} - \frac{1}{\mathrm{PCL}_0}\right)}{\left(1 - \frac{1}{\mathrm{PCL}_0}\right)} \times 100\% \tag{5}$$

where PCL_0 is the peptide chain length of the substrate protein.

The need to characterize the functional attributes such as solubility, viscosity, emulsifying properties, and heat stability very often depends on the application of the hydrolysate

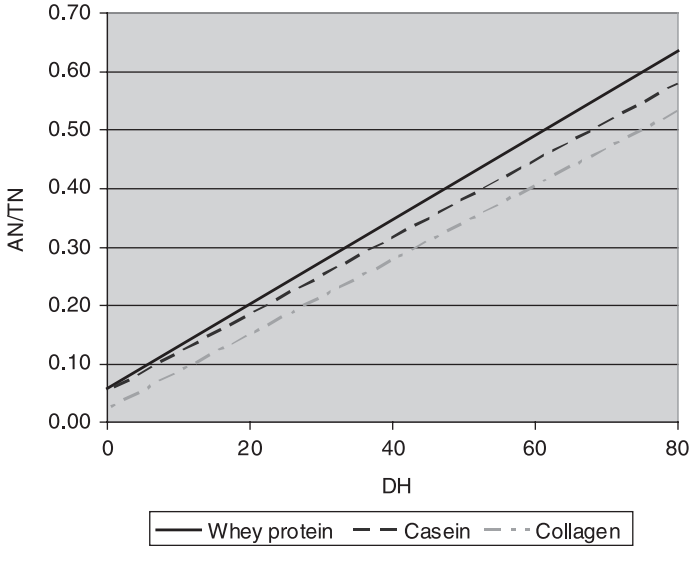


Figure 72.1 *Relationship of AN/TN and DH for hydrolysates of three different types of proteins as calculated based on their amino acid composition.*

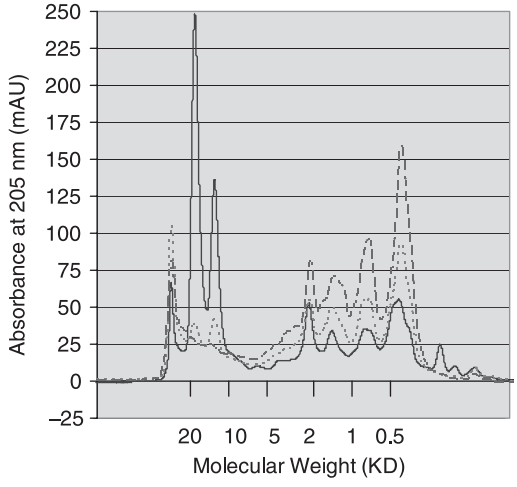

Figure 72.2 *Molecular weight profiles of three hydrolyzed whey protein concentrates with different DHs. The chromatograms were obtained using Tosohass SW2000$_{XL}$ column with aqueous solution of 36% acetonitrile and 0.1% trifluroacetic acid as the mobile phase. products. The techniques used in such characterizations are generally the same as those used to measure nonhydrolyzed protein ingredients (Mahmoud and others 1992; Mahmoud 1994; Boza and others 1995).

In some medical and nutritional applications of protein hydrolysates, the presence of intact proteins and immunoreactive peptides needs to be minimized. Highly sensitive *in vitro* techniques such as enzyme-linked immunosorbent assay (ELISA) and radio allegro sorbent test (RAST) can be used to measure the amount of immunoreactive materials (Otani and Hosono 1987; Asselin and others 1989; Cordle 1994; Van Beresteijn and others 1994). Recently, more attention has focused on various peptides in protein hydrolysates with specific biological activities. Examples include bioactive peptides such as casomorphin peptides, casein phosphopeptides (CPP), angiotensin-converting enzyme (ACE) inhibitory peptides, and so on (Daniel and others 1990; Kitts and Yuan 1992; Schlimme and Meisel 1995). The applications of these bioactive peptides will be discussed later in this chapter. The ability to measure these peptides and/or the bioactivities is often imperative to success of the applications. The measurement of biological activities of protein hydrolysates generally involves enzyme or cell-based assays (Coste and others 1992; Meisel 1997). For instance, ACE inhibitory peptides are measured in an enzyme (ACE) assay using synthetic substrates such as hippnrylhistidylleucine (HHL) or furyllacryloylphenylalanylglycylglycine (FAPGG). ACE catalyzes the hydrolysis of HHL or FAPGG and the activity is measured by the reduction of substrate absorbance or the amount of products formed under standard conditions (Cushman and Cheung 1971; Holmquist and others 1979; Buttery and Stuart 1993). The reduction of ACE activity in the presence of protein hydrolysates reflects the inhibitory activity of the hydrolysates. IC50, the amount of protein hydrolysates which will show 50% of ACE inhibition under the given conditions, is commonly used to represent the measure of the inhibitory activity. Figure 72.3 illustrates data of ACE inhibitor activity assay of two whey protein hydrolysates as compared to the control intact whey protein concentrate.

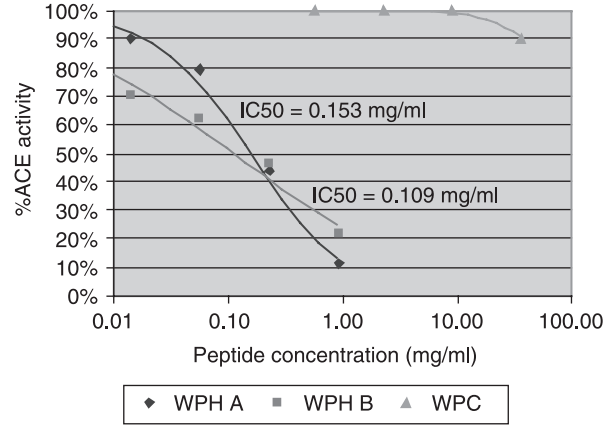

Figure 72.3 *Assay of ACE inhibitor activity of two whey protein hydrolysates and a whey protein concentrate.*

72.3 TECHNOLOGY OF DAIRY PROTEIN HYDROLYSATES

72.3.1 Why Hydrolyze Proteins?

There are many reasons food technologists use hydrolyzed dairy proteins in their food applications. Dairy proteins can be hydrolyzed to modify their functional properties (Panyam and Kilara 1996). For example, hydrolysis of casein can improve its solubility at pH range close to its isoelectric point so that it can be used in applications requiring high solubility in low pH range. Whey proteins, which are normally not very stable to heat treatment in many food processes, can improve their heat stability through enzyme hydrolysis. Much research has been done on the enzymatic hydrolysis of dairy proteins to improve other functional properties such as foaming, gelling, and emulsifying properties (Vojdani and Whitaker 1994; Huang and others 1996; Otte and others 1996). More often, dairy proteins are hydrolyzed for nutritional purposes (Mahmoud 1994; Clemente 2000). Hydrolysis of proteins improves their absorption in our digestive systems (references in Clemente 2000). Hydrolysis is a common approach used to reduce antigenicity and to increase the tolerance of the proteins, especially for infants and patients. Recently, many dairy protein hydrolysates have been produced for the specific peptides or bioactivities released during hydrolysis. Examples of these are CPPs, ACE inhibitory peptides, and so on.

72.3.2 Types of Dairy Protein Hydrolysates and General Production Process

Dairy protein hydrolysates currently fall into three categories based on the types of substrates used: casein hydrolysates, whey protein hydrolysates, and milk protein hydrolysates. With the availability of further fractionated dairy proteins, we can expect to see hydrolysates of fractionated dairy proteins, especially fractionated whey proteins.

Figure 72.4 shows the general process for manufacturing dairy protein hydrolysates. The starting materials are dairy protein solutions or suspensions. They can be reconstituted from dried protein powder and water, or they can be intermediate streams from the dairy protein processes. Examples of the latter are most commonly liquid protein streams before

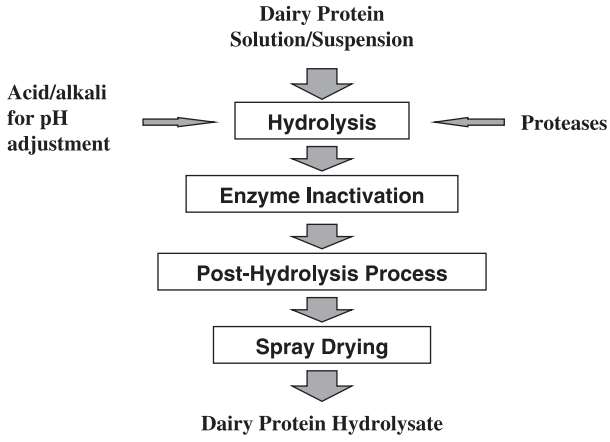

Figure 72.4 *General manufacturing process for dairy protein hydrolysate.*

drying such as liquid whey protein concentrate, milk protein concentrate or converted (neutralized) caseinate solutions.

Although continuous protein hydrolysis in a membrane reaction vessel or in an immobilized enzyme column has been researched (Mannheim and Cheryan 1990; Ge and others 1996), most current commercial operations employ batch hydrolysis carried out in a processing vessel with agitation with the capability to control temperature (heating and cooling), and pH. One of the most critical factors in this step is the selection of the protease or the combination of proteases for a specific substrate. The concentration of the substrate protein, the enzyme to substrate ratio, level of agitation, hydrolysis pH, and temperature are some of the other important factors which will impact the rate of hydrolysis and properties of hydrolysate products. As explained in the last section, protons can be released or taken up depending on pH during protein hydrolysis; therefore, to maintain at the optimal pH for hydrolysis, alkali or acids need to be continuously added. The rate of acid or alkali addition reflects the hydrolysis rate. The total amount of acid/alkali added during constant pH hydrolysis can be used to calculate the degree of hydrolysis (Adler-Nissen 1986).

Because the hydrolysis step in most commercial plants is carried out in batch operation, it is necessary to have an enzyme inactivation step at the completion of the hydrolysis step. The most common way for enzyme inactivation is through heat treatment. The dairy protein substrates still contain some lactose. Reactions of proteins and peptides with reducing sugars such as lactose are promoted at high temperature and are perhaps the most common cause of protein nutritional damage during processing (Hurrell and Finot 1985). The hydrolyzed proteins are more reactive to lactose during the thermal enzyme inactivation step than intact proteins due to increased number of amino groups generated during hydrolysis of the proteins. Therefore, it is undesirable to overheat treat the product during the enzyme inactivation. High temperature-short time (HTST) heat treatment and processing of the product at pH where the proteases are less stable are two approaches that are used to minimize the undesirable side reactions during heat treatment. Not only can different proteases have very different heat stabilities, but a selected protease can show very different stability to heat in a different matrix (substrates, ionic strength, pH, etc.); therefore, the minimal heat treatment to achieve required inactivation very often needs to be experimentally determined. Figure 72.5 shows the effect of different matrices on

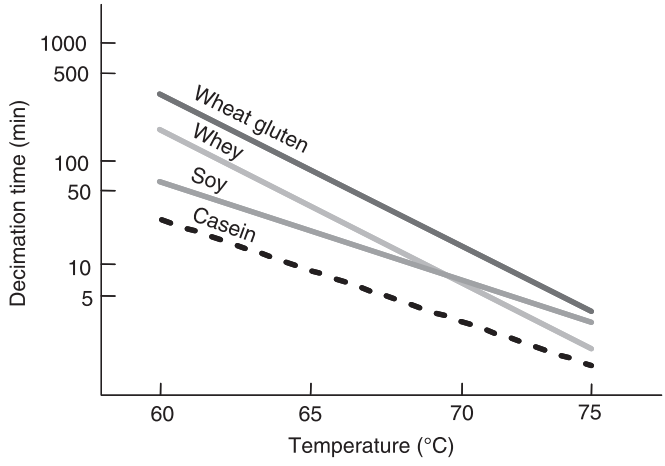

Figure 72.5 *Heat stability of Neutrase in phosphate buffer (pH 6.0) in the presence of various protein substrates. Courtesy of Novozymes North America, Inc.*

the heat stability of a commercial bacterial neutral protease, Neutrase (Novozymes North America, Franklinton, NC). A measure of heat stability of an enzyme is the decimation time (t_D) which is the time required to inactive 90% of the protease activity under a given conditions. Depending on the usage levels of protease in hydrolysis process, heating conditions to achieve more than three to six times of t_D will usually be considered complete inactivation.

Posthydrolysis processes before drying may include many different types of unit operations. These can include a clarification or filtration process to remove insoluble residues, or a fractionation process to separate/isolate peptides of interest and remove peptides with undesirable attributes. Examples of the later include precipitation of certain peptides, membrane separation of peptides based on sizes and adsorption column processes based on various other properties of peptides such as size, charge density, and hydrophobicity.

Sometimes, the hydrolysis is carried out at low protein (or total solids) concentration to achieve the desired attributes of the product. In such a process, the final hydrolysate solution will need to be concentrated through evaporation or membrane processes to maximize the drying efficiency. The drying of concentrated hydrolysates can be carried out by various processes such as roller drying, freeze drying, or spray drying. Spray drying is usually the process of choice for protein hydrolysates due to its efficiency and relatively mild conditions (Lahl and Braun 1994).

72.3.3 Advances in Processing and Analytical Technologies of New Hydrolysate Products

With the advancement of new processing and analytical technologies, it is possible today to develop and produce hydrolysate products with unique properties. An enzyme inactivation step is generally needed in a batch hydrolysis process. Such a process has some inherited limitations especially for proteins which are more heat sensitive such as whey proteins. Therefore, it is difficult to produce whey protein hydrolysate with very low DH in a batch process. Continuous protein hydrolysis processes in an immobilized enzyme column reactor or a membrane reactor not only greatly improves the enzyme

utilization, but also make it possible to produce some bioactive peptides which can be further hydrolyzed and lose activity under batch process conditions (Mannheim and Cheryan 1990; Ge and others 1996). Continuous processing in a column reactor can also produce hydrolyzed whey proteins with very low DH. Such products are reported to have improved gelling, emulsifying, and other functional properties (Chen and others 1993; Huang and others 1996).

Employing various separation technologies, protein hydrolysate products can be fractionated to produce desired peptides. The most commonly used technologies for fractionation of hydrolyzed proteins are membrane processes (Nakamura and others 1992; Pouliot and others 1993). The use of analytical techniques for identifying/quantifying specific peptides, such as HPLC and HPLC-MS, allow the understanding of the kinetics of release and disappearance of the peptides of interest. Such understanding made it possible to develop and produce hydrolysate with specific bioactive peptides (Leonil and Molle 1990; Bouhallab and others 1993). The availability of new commercial proteases with unique specificity also makes it possible to develop hydrolysate products with desired attributes which were previously unattainable. Some of the hydrolysates discussed in the following section are the examples of new generation of protein hydrolysates.

72.4 FUNCTIONS AND APPLICATIONS OF DAIRY PROTEIN HYDROLYSATES

Protein hydrolysates are generally used in enterally administered, nutritionally complete formulas that are given to individuals who have specific nutritional or physiological needs or are used as nutritional supplements for conventional foods (De Wit 1998). Dairy protein hydrolysates have a variety of applications in nutrition (e.g., hypoallergenic infant formula, nutritional/protein supplements, medical foods/enteral formulas), in food (e.g., modifying gelation, emulsion, foam, and flavor characteristics), and in functional foods via bioactive peptides. The term "functional foods" designate foods that provide health benefits beyond nutrition. Functional foods represent an emerging application area for dairy protein hydrolysates with enormous market potential for the health and wellness consumers. It has been indicated that the functional food market is large and in a phase of rapid growth, notably in North America, Europe, and Asia (Playne and others 2003). The global general food market is estimated to be valued at about US$50 billion in 2002 and this market is expected to grow at about 7% per year through 2005 (Sloan 2002). The functional food market in the United States is estimated to be worth about US$18.25 billion, followed by Europe at US$15.4 billion and Japan at US$11.8 billion (Sloan 2002). The global functional dairy food and ingredient market represents a significant segment of this general functional food market, and is also showing strong growth (Playne and others 2003). From a market size of US$4.1 billion in 1998 (excluding Japan market), it is predicted to reach about US$5.3 billion by 2003 (Hilliam 1999; Playne and others 2003). Clearly, dairy protein hydrolysates are functional food ingredients via their potential constituent essential amino acids and bioactive peptides; application opportunities in the functional food market segments are enormous. In the authors' opinion, beverages are uniquely suited as delivery systems for dairy protein hydrolysates. The forecast for functional beverage business growth is strong. According to *Nutritional Business Journal*, functional beverages reached $10.35 billion in sales in

2002, up 10.7%, and are projected to reach $15.9 billion by 2010 (Sloan 2003). Considering the potential opportunities that lie ahead for dairy protein hydrolysates, subsequent discussion in this section will be on emerging new research findings about bioactive peptides from dairy proteins, their potential health benefits and potential applications in functional foods. Also, in this section, key functional properties useful in nutrition products formulations will be discussed.

72.4.1 Selected Functional Properties of Protein Hydrolysates

Functional properties and target applications of dairy protein hydrolysates derived from casein or whey proteins, as with other food protein hydrolysates, are dictated by the extent of hydrolysis, as measured by AN/TN ratio or DH. Mahmoud (1994) suggested a definition for the functional properties of protein hydrolysates to include physicochemical properties that affect the processing, storage stability, organoleptic quality, and nutritional or biological efficacy of the final product. Certain functional properties of the hydrolysates play a more dominant role than others and dictate the choice of the hydrolysate for specific end use (Mahmoud 1994). For example, a hydrolysate targeted for infant formula application will have different process parameters and evaluation criteria than one used for nutritional supplement (e.g., beverage and protein bar applications).

The key physicochemical properties related to functional properties in nutritional products are shown in Table 72.1. Molecular size, commonly designated as molecular weight distribution/profile, has a profound effect on several important functional properties of hydrolysates and thus their application. Osmolality is an important physical characteristic of infant and adult nutritional formulas (Mahmoud 1994). It is a function of the number and size of molecular and ionic particles in the product. In the intact protein-containing

TABLE 72.1 Physicochemical and Functional Properties of Protein Hydrolysates in Nutritional Products.

Chemical and Physicochemical Properties	Functional Properties
Molecular size	Immunogenicity (allergenicity) Solubility Osmolality Viscosity Gelation Emulsification Clarity (turbidity) Flavor

infant formulas and adult nutritional products, the main determinants of this important physical property are electrolytes, soluble minerals, and simple carbohydrates (Mahmoud 1994). On the other hand, amino acids and peptides contribute significantly to the osmolality of protein hydrolysate-based formulas; the extent of hydrolysis of the protein source in the formulas will directly influence the osmolality of the formulations (Mahmoud 1994). It should be noted, however, that achieving and maintaining proper osmolality in a product is critical to the use of hydrolysates. Those knowledgeable in the art of formulating nutritional products know the importance of optimizing and balancing osmolality in products because solutions of high osmolality (i.e., hypertonic or hyperosmolar products) may draw large quantities of water into the small intestine causing severe diarrhea, possible dehydration, and disruption of electrolyte balance that can induce nausea, vomiting, and abdominal distention (MacBurney and Young 1984; Mahmoud 1994).

Many commercially-available hydrolysates possess good to excellent functional properties in addition to their nutritional attributes. For a detailed discussion on functional properties of hydrolysates, the reader is referred to the article by Mahmoud (1994). For the purpose of this chapter, it is important to note that just as DH dictates the end use of hydrolysates, DH can also be controlled to improve heat stability, emulsification, foaming (overrun), and gelation properties of hydrolysates. An example is the effect of DH on emulsion stability in emulsion-based nutritional products. Because infant formula and specialized adult nutritional products are protein-stabilized emulsions, the emulsifying properties of the protein hydrolysates are important (Mahmoud 1994). Singh and Dalgleish (1998) studied a range of hydrolysates in model system to determine their ability to form and maintain stable emulsions. In their study, commercial hydrolysates of whey proteins with DH ranging from 8% to 45% were used to make emulsions with soybean oil (3% wt/wt); and varied hydrolysates concentrations (0.02–5%, wt/wt). The stability of these emulsions was measured by determining the average sizes of the emulsion droplets and their size distribution both immediately after formation and after storage. The effects of heating on the stability of the emulsions were also determined. As determined by the particle size, the maximum emulsifying capacity was obtained from hydrolysates with a DH of 10% or 20%. Higher hydrolysis resulted in peptides that were too short to act as effective emulsifiers. All of the emulsions were unstable when subjected to heat treatment at high temperatures (122°C for 15 min), but emulsions prepared from less hydrolyzed peptide mixtures were stable to heat treatment at 90°C for 30 min (Singh and Dalgleish 1998).

Perhaps the most important functional characteristic that limits the application of protein hydrolysates is bitterness which is a technological problem attributed to the presence of hydrophobic peptides generated during protein hydrolysis. It is sometimes related to the type of enzymes, DH, and/or protein source. Some proteins such as casein are more susceptible to the generation of bitter peptides than others. Judicious use of exopeptidases in combination with endopeptidases in an optimized ratio has been found helpful to minimize the presence of hydrophobic peptides in hydrolysates (Alder-Nissen 1986; Przybyla 1989; Lahl and Braun 1994; Pedersen 1994; Raksakulthai and Haard 2003).

72.4.2 Application of Dairy Proteins in Selected Nutritional Products

For nutritional products applications, protein hydrolysate composition is generally divided into three major groups: (1) formulas for infants with allergies to intact proteins,

(2) elemental diets for patients with impaired gastrointestinal functions, and (3) nutritional supplements to provide nitrogen in an easily assimilated form (Mahmoud 1994; De Wit 1998). In terms of DH, hydrolysates used in nutritional formulations are generally classified into two broad categories: partially or extensively hydrolyzed proteins (Mahmoud 1994). The extensively hydrolyzed proteins (Table 72.2) have substantially reduced immunological reactivities and are primarily used in hypoallergenic infant formulas (Mahmoud 1994). These proteins are usually comprised of free amino acids and very short peptides. Extensively hydrolyzed protein products are available commercially for both nutritional and food flavor development. Commercial hydrolysates are commonly represented by AN/TN ratio and average molecular weight as shown in Table 72.3. To achieve very low average molecular weight (i.e., high AN/TN ratio) use of whey or casein as protein source often requires an optimized mixture of endopeptidases and exopeptidases for controlled hydrolysis to ensure hydrolysates with low bitterness.

Infant formulas are generally based on milk, whey, soy protein, and protein hydrolysates (American Academy of Pediatrics Committee on Nutrition 1989; Lahl and Braun 1994). Infants who are fed formulas based on cow milk proteins may exhibit allergic reactions to these proteins (Van Beresteijn and others 1994). The most effective means to reduce the allergenicity of cow milk is to decrease the molecular mass of the principal cow milk allergens (namely b-lactoglobulin, a-lactoglobulin, bovine serum albumin, bovine

TABLE 72.2 Molecular Weight Profile of Different Classes of Protein Hydrolysates.

	Degree of Hydrolysis		
Molecular Weight Fraction (Dalton)	Slight/Low	Moderate % in Each Fraction	Extensive
<500	3.8	9.8	90.2
500–1000	1.1	13.5	5.5
1000–2000	1.8	13.7	2.9
2000–5000	3.7	16.6	1.4
>5000	89.7	46.4	0

serum immunoglobulin G, and the caseins) by enzymatic proteolysis (Van Beresteijn and others 1994). To this end, much research has focused on preparation of hypoallergenic hydrolysates from casein and whey protein. As a result, "first-generation," casein-based hydrolysates have been marketed for more than 40 years for hypoallergenic infant formula applications (Lahl and Braun 1994). These products are characterized by a greater than 70 mol% composition of amino acids and peptides up to eight amino acids long (Lahl and Braun 1994). Second generation, whey protein-based hydrolysates with 40–60 mol% amino acids and peptides up to 12 amino acids long have been marketed for more than 10 years (Lahl and Braun 1994). Third generation, whey protein-based hydrolysates have become available only in the past few years (Lahl and Braun 1994). These formulas have less than 20 mol% amino acids and peptides up to 15 amino acids long (Lahl and Braun 1994; Siemensma and others 1993). Whey protein hydrolysates have been used as a primary nitrogen source in infant formula with reduced allergenic properties (De Wit 1998). To achieve hypoallergenic hydrolysates, ultrafiltration is a necessary prerequisite (Van Beresteijn and others 1994; Ena and others 1995). Whey protein concentrate has been hydrolyzed using the technical food-grade enzyme Corolase 7092 in order to abolish the allergenicity of whey proteins (Van Beresteijn and others 1994). The minimal molecular mass to elicit immunogenicity and allergenicity of whey protein hydrolysates appeared to be between 3000 and 5000 Da, so the molecular weight cut-off value of the filters required must be in this range (Van Beresteijn and others 1994). The amino acid composition of formulas appears to be a critical factor for the nutrition of newborn infants when intact proteins and protein hydrolysates are used (De Wit 1998).

Cow's milk protein is the most important protein source used in the development of protein hydrolysates designed for nutritional support of patients (Clemente 2000). Uses of such hydrolysates include geriatric products, high-energy supplements, weight-control diets, and clinical applications/medical diets for patients with impaired gastrointestinal function either caused by a reduced absorption surface (e.g., short bowel syndrome and Crohn's disease) or by a reduced digestive capacity (e.g., cystic fibrosis and pancreatitis) (Frokjaer 1994; Clemente 2000).

72.4.3 Bioactive Peptides from Dairy Proteins and Potential Applications

Dairy proteins are known to exert a wide range of nutritional, functional, and biological activities that make them suitable ingredients for health-promoting (functional) foods. These properties are partially attributed to physiologically active peptides encrypted in the protein molecules (Korhonen and Pihlanto 2003). These peptides within the sequence of the intact protein can be released by enzymatic hydrolysis during fermentation, controlled enzyme hydrolysis, or gastrointestinal digestion. Bioactive peptides usually contain three to 20 amino acid residues per molecule; the sequence of amino acids defines the function of a peptide fraction (Korhonen and Pihlanto 2003).

Recently, excellent review articles on the subject of dairy/milk bioactive peptides have appeared in the literature (Shah 2000; Floris and others 2003; Kilara and Panyam 2003; Korhonen and Pihlanto 2003). It is clear from these reviews that dairy proteins are rich sources of bioactive peptides with purported physiological activities (e.g., opioid, immunomodulatory, antimicrobial, hypocholesterolemic, antihypertensive, antithrombotic, mineral binding, and so on). Table 72.4 shows a list of examples of physiological active peptides

TABLE 72.4 Examples of Physiological Active Peptides Derived from Casein and Whey Proteins.

Peptide Group/Specific Peptide	Precursor Protein	Physiological Activity
Opioid peptides		
β-Casomorphin	β-Casein	Opioid agonist and ACE inhibition
α-Casein exorphin	α-Casein	
Casoxins	κ-Casein	Opioid agonist
β-Lactorphin	β-Lactoglobulins	Opioid antagonist
α-Lactorphin	α-Lactalbumin	Opioid agonist and ACE inhibition
		Opioid agonist and ACE inhibition
ACE-Inhibitors		
Casokinins	α- and β-Casein	ACE inhibition
Lactokinins	α-Lactalbumin/ β-Lactoglobulin	ACE inhibition
Lactoferroxins	Lactoferrin	Opioid antagonist
Mineral binding peptides		
Caseinophosphopeptides	α- and β-Casein	Mineral binding
Immunomodulatory peptides		
Immunopeptides	α- and β-Casein, α-lactalbumin β-Lactoglobulin	Modulation of immune system
Antimicrobial peptides		
Lactoferricin	Lactoferrin	Antimicrobial
Casocidin	α-Casein	Antibacterial
Kappacin	κ-Casein (glycomacropeptide)	Antibacterial
Antithrombic peptides		
Casoplatelins	κ-Casein	Inhibition of platelet aggregation
Hypocholesterolemic peptides	β-Lactoglobulin	Reduction of total serum cholesterol

derived from casein and whey proteins. Although, several of these activities are yet to be demonstrated in humans, evidence from *in vitro* and animal studies are encouraging.

A noteworthy novel use of a bioactive peptide derived from casein is the application of casein phosphopeptide CPP in oral care. The calcium-carrier function of caseins has been developed into a functional food ingredient by proteolysis and the extraction of the CPP class of peptides (Playne and others 2003). A commercial food ingredient named Recaldent^{TM} (Bonlac Foods Australia; now Cadbury-Schweppes) fortified with CPP has been demonstrated to protect against the demineralization of tooth enamel (Playne and others 2003; Reynolds 2003). Other examples of commercial products containing bioactive peptides derived from whey proteins or casein via hydrolysis include Biozate 1, cysteine peptide, and lactotripeptide (Ameal S, a dietary supplement), products of Davisco, DMV, and Calpis, respectively. The biozate is a whey protein hydrolysate containing ACE inhibitor peptides, active at 20 g/day in humans. Cysteine peptide is derived from whey protein and is claimed to help in liver detoxification via glutathione enrichment. Lactotripeptide is found in a casein hydrolysate, produced by an extracellular proteinase from *Lactobacillus helveticus* CP790 (Calpis, Japan). The bioactive peptide is

claimed to help maintain a healthy blood pressure and is marketed in the form of fermented milk (i.e., a functional milk beverage) or as an active ingredient in a dietary supplement known as Ameal S. The bioactivity of Biozate 1, cysteine peptide, and lactotripeptide have been tested in animal and clinical trials. ACE inhibitory peptides such as Biozate 1 and lactotripeptide have received more attention in recent years due to the importance of high blood pressure as a major risk factor in cardiovascular diseases.

It is noteworthy to mention the importance of lactoferrin, a minor protein constituent of whey protein. Generally, lactoferrins are single chain polypeptides of about 80,000 Da containing one to four glycans, depending on the species (Spik and others 1994; Steijins and Van Hooijdonk 2000). Bovine lactoferrin consists of about 689 amino acid residues (Steijins and Van Hooijdonk 2000). Lactoferrin not only exhibits both bacteriostatic and bacteriocidal activity against a range of microorganisms (Shah 2000), but also shows significant antiviral activity against both human immunodeficiency virus (HIV) and the human cytomegalovirus (HCMV) (Floris and others 2003), Active peptides named lactoferricin (LF-cin B) can also be derived from it by enzyme digestion (Tomita 1994). Commercial whey protein concentrate will have little ($<0.5\%$) or no lactoferrin. However, owning to advances in chromatography and membrane technology, purified lactoferrin ($>50\%$ purity) products are now commercially available. Lactoferrin and lactoferricin are used in infant formula and dairy foods in Asia. Recently, the Food and Drug Administration approved the use of lactoferrin in fresh meat as a food safety measure. This opens up a new opportunity for lactoferrin-derived products. Using lactoferrin as a starting material, large-scale production of lactoferrin hydrolysate and LF-cin B is readily achievable (Tomita 1994). The product so derived should be uselful as a "a natural" preservative agent in foods and cosmetics and as an ingredient in functional foods.

72.5 FUTURE PERSPECTIVES

The past decade has shown increased interests in the utilization of native and hydrolyzed dairy proteins for human nutrition and health-related foods. The interest in dairy protein hydrolysates and constituent bioactive peptides is expected to remain strong in the future driven by advances in technology, economic incentives (value-added products versus commodity), nutritional and potential health benefits, market demand, and untapped new applications in several functional foods.

While the art of manufacturing dairy protein hydrolysates is well understood by food protein ingredient developers, more work is needed to develop cost-effective industrial-scale technologies that retain and/or enrich bioactive peptides in dairy protein ingredient products. More research is needed in identifying innovative application systems for hydrolysates and bioactive components. Finally, the market success of the future hydrolysate-containing bioactive peptides or isolated bioactive peptides is dependent on the results from well-designed *in vivo* and clinical evaluations.

73.1 INTRODUCTION

Caseins are a unique group of acidic proline-rich phosphoproteins secreted from the mammary glands of mammals. This chapter will focus on bovine caseins which account for approximately 80% of total protein in bovine milk. The most primary physiological function of casein is to provide a calcium source to the neonate in a form that does not cause pathological calcification in the mammary tissue of the mother. Commercially, caseins are used for their excellent nutritional quality, their distinctive functional attributes, and unique physiological properties. The estimated production volumes and major exporters/importers for casein-derived additives are given in Figures 73.1 and 73.2, respectively. It is the current authors' opinion that only a small fraction, 10–15%, of casein-derived products are used in nonfood applications. This chapter will outline what makes caseins so molecularly unique, illustrate how the different caseins derivatives

73.2 CASEIN CHEMISTRY

Caseins are quite exceptional proteins in terms of the enormous variety of applications. This is due to their unique secondary structure. The true extent of applications for caseins can only be realized when the molecular chemistry of caseins is considered. Indeed, each specific functional or nutritional property of casein or casein-derived ingredients can be directly explained by their physicochemical properties.

73.2.1 Molecular Properties of Caseins in Milk

Bovine caseins can be subdivided into four major fractions: α_{s1}-, α_{s2}-, β-, and κ-casein which account for approximately 35, 15, 38, and 12% of total casein, respectively (Swaisgood 1992). Interestingly, human milk does not contain α_s-casein. Within each casein fraction heterogeneity exists due to genetic polymorphism and posttranslational phosphorylation or glycosylation. κ-Casein is the only casein fraction that is glycosylated.

TABLE 73.2 Some Physicochemical Properties of the Different Casein Fractions.

Characteristic	α_{s1}-Casein (B-8P)[a]	α_{s2}-Casein (A-13P)[a]	β-Casein (A^2-5P)[a]	κ-Casein (B-1P)[a]

Trisaccharides or tetrasaccharidies may be attached to threonine$^{131/133/135/136}$ or at serine^{141}. Some molecular properties of the genetically-dominant variants of the casein fractions are listed in Table 73.2. The amino acid composition of caseins are not particularly different from globular proteins except for their relatively high proline content and relatively low cysteine or cystine content. The distribution of hydrophobic and charge amino acid residues into specific domains convey an amphiphatic nature to the 1° structure of the casein. This is particularly evident with β- and κ-casein. As a consequence of their distinct amphiphatic nature of their 1° structure, the high concentration of proline residues (which introduce links in the polypeptide back bone) and low content of cystine residues (which act to intermolecularly bridge proteins), caseins do not have a defined 2° or 3° structure. Caseins have been described as "naturally denatured" and rheomorphic proteins (i.e., can adopt different 2° or 3° conformations depending on environmental conditions such as pH, ionic strength, temperature, concentration, etc.). As a consequence of the "loose" 2° structure of caseins and concomitant exposure of hydrophobic domains, caseins readily associate into macromolecular aggregates.

73.2.2 Associative State of Caseins in Milk

In milk, caseins exist as large macromolecular aggregates in colloidal dispersion known as caseins micelles. Casein micelles have a molecular weight of 10^8 Da, a ζ-potential of −10 to −20 mV, a hydrodynamic radius of approximately 100 nm, and a relatively small size distribution (de Kruif 1988; O'Connell and Fox 2001; Tuinier and de Kruif 2002). There are many theories and models as to the structure of the caseins micelles (Rollema 1992; de Kruif and Holt 2002). Generally, a model will, at best, be a simplification of reality. There is consensus, however, that the calcium-sensitive casein fractions, α_{s1}-, α_{s2}-casein, constitute the micelle interior core which is held together by cohesive hydrophobic interactions and calcium-mediated phosphoserine crosslinks. Conversely, κ-casein is predominantly located at the micelle surface, with its hydrophilic C-terminal protruding into the serum phase creating a "hairy layer." β-Casein exists in temperature-dependent dynamic

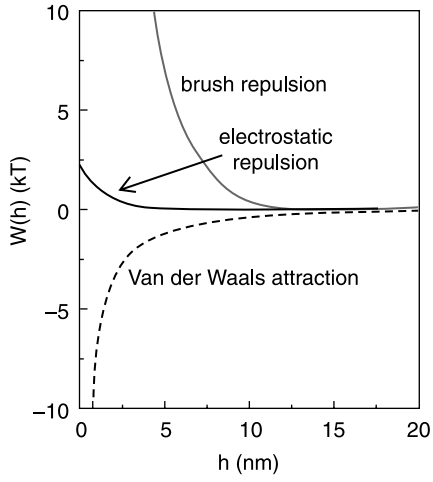

Figure 73.3 *Contributions to the interaction potential between casein micelles at pH 6.7 due to brush and repulsion, electrostatics and van der Waal attractions (Taken from Tuinier and de Kruif 2002).*

equilibrium between the serum and colloidal phases. The principal interactive forces affecting the stability of casein micelles are the van der Waal attractive forces (Eq. 1; Fig. 73.3), polymer brush repulsion forces (Eq. 2; Fig. 73.3) and to a lesser extent electrosatic repulsive forces (Eq. 3; Fig. 73.3). Figure 73.3 shows the relative contribution of the different intermolecular forces on micelle stability.

$$\frac{W_{VdW}{}^{(h)}}{kT} = \frac{-A}{6}\left[\frac{2a^2}{(h+2a)^2-4a^2} + \frac{2a^2}{(h+2a)^2} + \mathrm{Ln}\left\{\frac{(h+2a)^2-4a^2}{(h+2a)^2}\right\}\right] \tag{1}$$

(h: distance separating two micelles; a sphere radius and r is the distance from micelle center to micelle center.)

$$\frac{W_{er}(h)}{kT} = 2\pi a\varepsilon_0 e_r \psi^2 \mathrm{Ln}(1+\exp(kh)) \tag{2}$$

(h: distance separating two micelles; a sphere radius, r is the distance from micelle center to micelle center and Ψ is the surface potential.)

$$\frac{W_{brush}(h)}{kT} = \frac{16\pi a H^2 \sigma^{3/2}}{35}\left(\left(28\left(\frac{2H}{h}\right)^{1/4} - 1\right) + \frac{20}{11}\left(1\left(-\frac{h}{2H}\right)^{11/4}\right) + 12\left(\frac{h}{2H}\right) - 1\right) \tag{3}$$

The "submicelle theory" proposes that casein micelles are made up of hydrophobically-associated submicelles. Submicelles continue to associate, via phosphoserine-calcium crosslinks, until the micelle surface is predominatly located by calcium-resistant κ-casein (see Fig. 73.4). The presence of the "hairy layer" prevents any further association and stabilizes the micelle (Slattery and Evard 1973; Walstra and Jenness 1984).

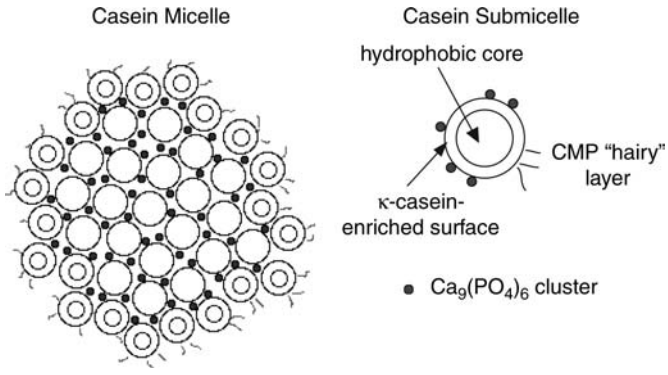

Figure 73.4 *Diagrammatic representation of casein micelle as depicted by the "sub-micelle" theory (from Walstra and Jenness 1984).*

The "nanocluster" theory proposes that calcium-linked phosphoserine residues act as nuclei for the association of casein nanoclusters. Nanoclusters associate until the aggregate surface is predominatly covered with κ-casein, thereby inhibiting any further association (Fig. 73.5; Holt 1992b; de Kruif and Holt 2002).

73.3 MANUFACTURE OF CASEIN DERIVED ADDITIVES

A large variety of casein classes with a milieu of properties exists (Fig. 73.6). Different casein derivatives can be classified according to molecular size or associative state:

- Hydrolysates (glycomacropepetide, surface active hydrolysates, nutritional hydrolysates, physiologically-active hydrolysates)

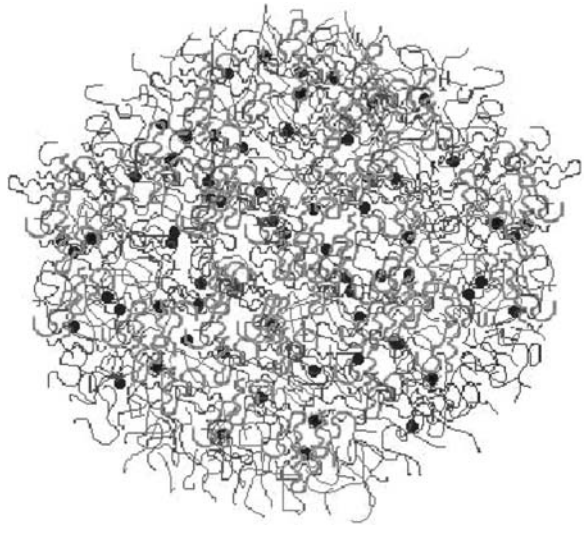

Figure 73.5 *Diagramatic representation of casein micelle structure as depicted by the "nanocluster" theory (taken from Tuinier and de Kruif 2002).*

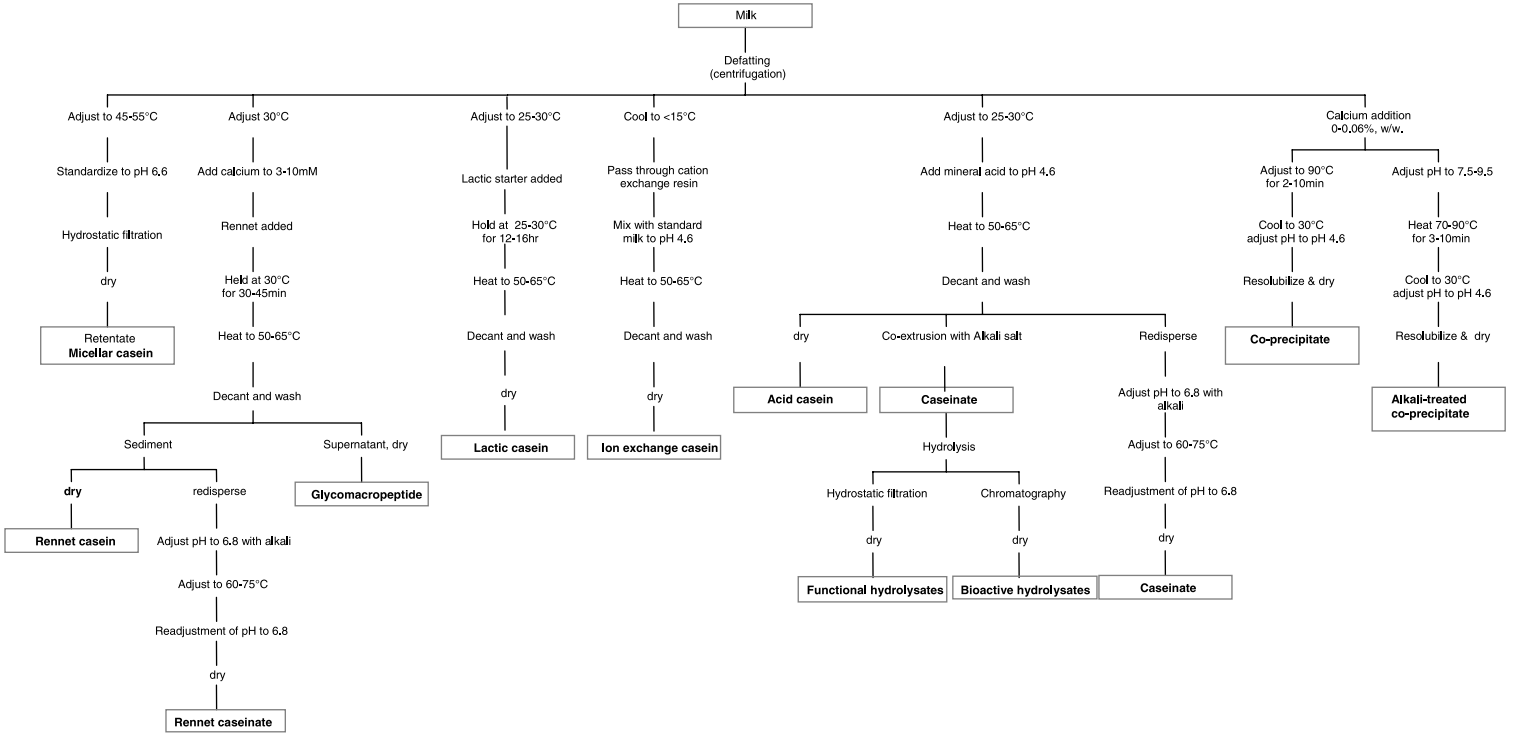

Figure 73.6 *Possible manufacturing processes for a variety of casein classes (data from authors).*

TABLE 73.3 Approximate Degree of Hydrolysis and Free Amino Acid Concentration of Hydrolysates for a Variety of Applications.

Application	Degree of Hydrolysis, %	Free Amino Acid Content, %
Surface active agent	2–12	0
Reduced antigenicity	12–18	Variable
Heat stability/transparency	20	<5
Growth media	30	20–30

- Monomeric caseins (caseinates)
- Colloidal aggregates (micellar casein)
- Macroaggregates (rennet casein, acid casein, coprecipitates)

Regardless of what type of casein-derived product is being manufactured it is imperative that the milk from which it is produced is of good quality. The quality of casein-derived material is affected by the bacterial count of milk, the somatic cell count of milk and the stage of lactation (O'Malley and others 2000). Once delivered to the factory milk is conventionally skimmed and pasteurized. Heat treatments can vary considerably from thermization (60–69°C for 20 s) to pasteurization (LTLT 72°C for 15 s or HTST 85°C for 2 s) to ultraheat (140°C for 1–4 s) treatment.

73.3.1 Hydrolysates

The manufacturing process for casein hydrolysates will differ depending on final use of the hydrolysate. Caseinate or micellar casein is a suitable substrate for functional hydrolysates (i.e., emulsifying agents, foaming agents, reduced viscosity peptides, high transparency-high heat stability peptides), hypoallergenic nutritional peptides or growth media hydrolysates. Downstream processing such as hydrostatic filtration may be used to tailor the molecular weight distribution and free amino acid concentration. Functional or hypoallergenic nutritional hydrolysates are likely to be concentrated by evaporation or reverse osmosis and subsequently dried by spray drying.

The manufacturing process for hydrolysates which are physiologically active or designed for specific nutritional requirements will largely depend on the purity and efficacy the manufacturer aspires to achieve and the quality that the purchaser demands and is willing to pay. At present, hydrolysates which have a low content of active peptides are available (Table 73.3). It should be noted that this area is still in its infancy. As the market matures it is opined that the demand for hydrolysates with a higher content of active peptides will increase. To achieve this end it is likely that more sophisticated fractionation techniques to isolate the substrate or product will have to be used. Non/minimal thermal processing is likely to be employed when concentrating (reverse osmosis, nano/hyperfiltration, freeze concentration) and drying pure hydrolysates (lyophilization).

73.3.2 Rennet Casein

The integral step in the manufacture of rennet casein entails the cleavage of the κ-casein at the Phe^{105}-$Meth^{106}$ sectile bond. Hydrolysis releases the C-terminal glycomacropeptide of κ-casein in the serum phase and consequently destabilizes the casein micelle causing

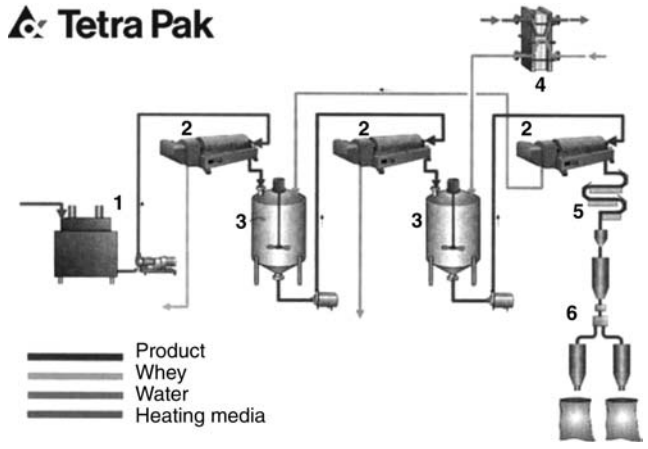

Figure 73.7 *Schematic representation of casein manufacture (1: vat for casein manufacture; 2: decanter; 3: washing tank; 4: drying, milling, sieving, and bagging). (Courtesy of Tetra Pak.)*

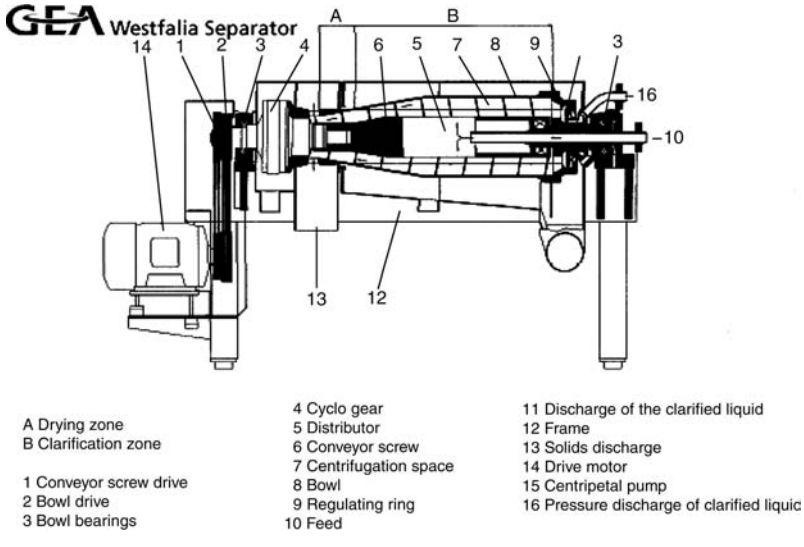

Figure 73.8 *Diagrammatic representation of a centrifugal decanter. (Courtesy of GEA Westfalia Separator.)*

coagulation and gel formation. The enzymes used in rennet casein manufacture are aspartic protinases of animal, vegetable or microbial origin. Once the coagulum has formed it is cooked to 50–75°C and dewheyed. Conventional rennet casein is dewheyed by centrifugal decantation (Figs 73.7 and 73.8). Centrifugal decanters are horizontally-arranged, scroll centrifuges. Feed is pumped using a positive displacement pump into the conico-cylindrical bowl. Under the influence of centrifugal force sediment is deposited onto the wall of the bowl. The casein curd is transported by the scroll while the whey phase is discharged under gravity or with the aid of a centrifugal pump. Rotational speeds for the bowl is in

the order of 4000 rpm with the scroll rotating at approximately 50 rpm faster than the bowl. The curd is then washed to remove residual lactose and whey proteins. Lactose concentrations in the final product should not exceed 0.2% so as to avoid the Maillard reaction and protein crosslinking during drying. Ennis and Mulvihill (1999) reported that the extent of Maillard browning correlated to the hydration characteristics of rennet casein. Residual whey protein can markedly affect the functional properties of rennet casein and should be kept below 2.5%, w/w. Residual lactose and whey proteins, entrapped in the curd matrix, are removed by diffusion through the curd during the washing steps. Countercurrent washing systems are conventionally used and wash temperatures vary considerably between wash cycles (35–75°C). Wash water temperature has a marked effect on the physicochemical properties of the rennet casein properties (O'Sullivan and others 2002). It has been proposed that the effect of wash water temperature is due to whey protein-casein interactions and the concomitant inclusion of whey proteins in the curd (O'Sullivan and others 2002). Generally, a water volume corresponding to 50% of the original milk volume is used during washing. After sufficient washing the casein curd is dewatered; this is achieved by centrifugal decantation producing a curd with a moisture content of 45–55%, w/w. Total casein losses during the dewheying and washing stages should not exceed 1–2% of total casein.

Rennet casein is conventionally dried using an attrition dryer a pneumatic ring dryer (Fig. 73.9*a*), (Fig. 73.9*b*) or a fluidized bed dryer. In ring dryer systems the feed is blown into a high velocity venturi section of the dryer at which stage the bulk of the moisture is flashed off. Conventional inlet temperatures are in the order of 180–250°C. Further evaporation takes place while the sample is being conveyed through the ring duct and enters the manifold where it is classified according to density differences using centrifugal forces. The blade system within the manifold helps to return heavier semidried casein particles back into ring duct for further drying while the dry casein particles are collected using a cyclone system. Typically, curd enters and exits the dryer at approximately 50% and 10–15% moisture, respectively. After ring drying the casein is conventionally milled and/or classified using an impact mill with an air or sieve classifier or fluid energy mill. Some additional moisture loss occurs during milling. Casein is commonly classified according to the USDA ASTM mesh system. Mesh size corresponds to the number of openings across one linear inch of screen. Most common mesh sizes for caseins are 30, 60, 90, and 120 which correspond to openings with a width of about 595, 250, 175, and 125 μm, respectively.

Attrition dryers are also commonly used to dry rennet casein. Attrition dryers are relatively simple units consisting of a mill mounted on a horizontal shaft with bearings on each end. Both halfs of the rotor have static pins while one half has a fixed hammer which generates intense turbulence and concomitant attritional forces. Rotation speeds of approximately 1200 rpm are used, the inlet temperature can be as high as 250°C and residence time is approximately 1–2 s (Muller 1982). Most attrition dryers also have an internal classifier which also grades casein particles according to size and are also fitted with a cyclone or air bag. The most common casein sizes produced using attrition dryers would be correspond to 60, 90, or 120 mesh sizes.

73.3.3 Acid Casein

As the pH of milk is decreases, the caseins' net charge decrease to zero until casein micelles aggregate and a curd is formed at pH 4.6. The pH may be decreased through the addition of mineral acid, *in situ* fermentation (using a mixture of *Lactococcus lactis*

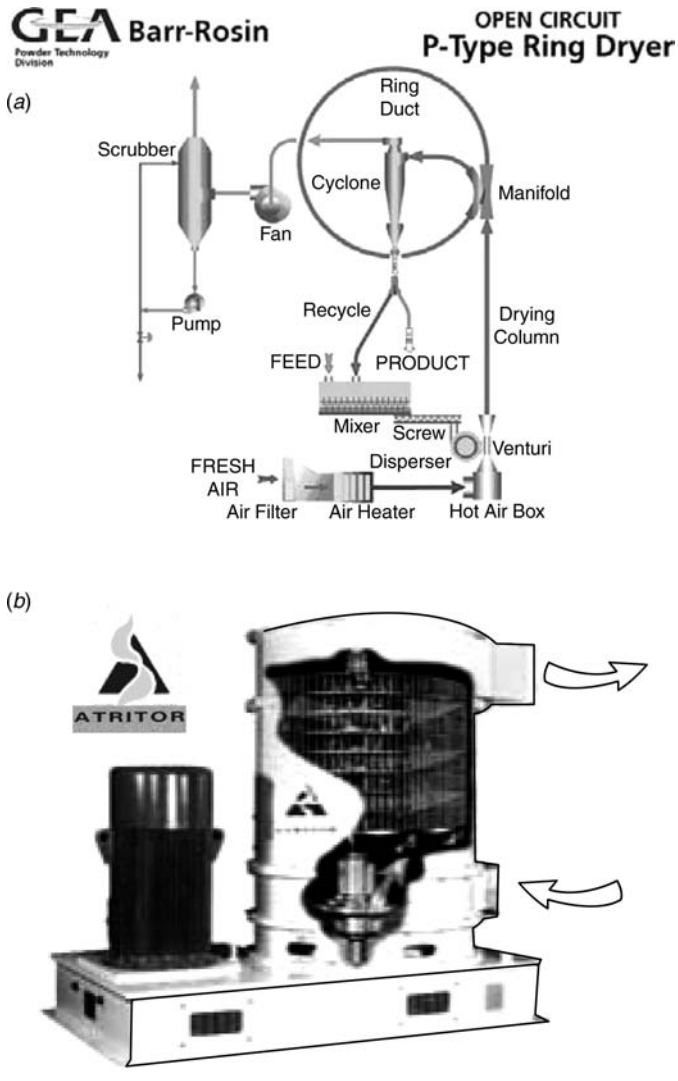

Figure 73.9 *Drawings of ring (a) and attrition (b) dryers. (Courtesy of GEA Barr Roisin and Atritor.)*

and *L. cremoris*), mixing standard milk (ca. pH 6.6) with milk that has been passed through cation exchange resin (ca. pH 2.0; on passing through exchange resin calcium displaces H^+ on the exchange resin with a concomitant release of H^+ into the milk and decrease in pH), or the addition of CO_2 under pressure (CO_2 combines with water to form carbonic acid). Hydrochloric acid is most commonly used since it is relatively inexpensive and produces good quality casein curd. Sulfuric acid is also used to a lesser extent. Acid casein curd is less rubbery than the rennet casein curd, and exhibits a lower tendency to synerese, that is, expel whey (Mulvihill 1992). This is presumably related to the fact that casein micelles in an acid casein curd have a lower tendency to fuse or coalesce. Once the acid curd has formed subsequent treatments are very similar to rennet casein. Great care must be take during the dewheying, washing, and dewateing to remove residual lactose and whey

proteins. Muller (1982) advocated the acidfication of wash water with sulfuric acid so as to reduce wash losses of casein. Casein losses should not exceed 1–2% total casein. Acid casein is conventionally dried using either a pneumatic ring, fluidized bed, or attrition dryer. Epsie and others (1984) reported that acid casein was easier to dry than rennet casein.

73.3.4 Micellar Casein

In the context of this chapter micellar casein is interpreted as casein colloids that are similar in size, surface properties, protein profile, and mineral ion content to native casein micelles in milk. Casein-based, micellar systems such as caseinates and coprecipitates which deviate from these specific characteristics will not behave in a similar manner to native micellar casein from a functional or nutritional perspective.

Tangential hydrostatic filtration which is based on the separation of molecules according to molecular size/associative is a mild, efficient and technologically applicable method for preparing casein micelles. Hydrostatic filtration is classified according molecular weight cut-off of the membrane (Fig. 73.10; Cheryan 1998).

Micellar casein is manufactured by microfiltration. Microfiltration is carried out at temperatures between 20°C and 50°C using spiral-wound synthetic membranes or tubular ceramic membranes and operates at a transmembrane pressure of 1–2 bar pressure. The nominal molecular weight membrane cut off of the membrane is in the region of 0.1–1.0 μm. Casein micelles have a average hydrodynamic radius of 100 nm and as a consequence are retained in the retentate (Section 73.2.2). The retenate is then concentrated by evaporation with or without an ultrafiltration preliminary concentration step. Conventionally, micellar casein is spray dried.

Alternatively, milk protein isolate containing micellar casein and the whey proteins can be prepared by ultrafiltration. Spiral-wound membranes with a nominal molecular weight cut off of 10–20 kDa. are used with the operating temperatures in the order of 20–50°C and a transmembrane pressure of 2–6 bar pressure.

It has also been proposed that micellar casein preparations can be prepared by cryoprecipitation or centrifugaion of milk which has been electrodialysed against acidified whey (see Mulvihill 1994).

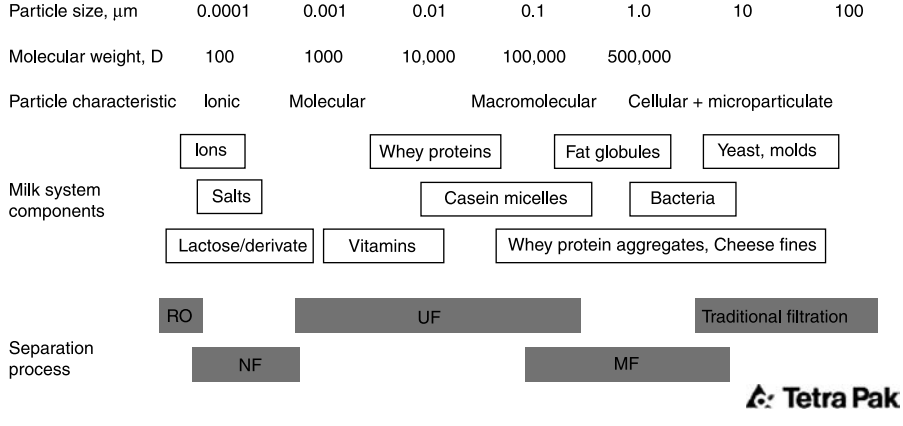

Figure 73.10 *Diagrammatic representation of various hydrostatic filtration processes. (Courtesy of Tetra Pak.)*

73.3.5 Caseinates

Many different forms of caseinate are available, all of which have different functional properties. Caseinates vary with respect to mode of manufacture and the counter ion used. The majority of caseinate is manufactured by mill mixing a minced acid casein curd (50% moisture) with a relatively concentrated alkaline solution. The type of alkali used to manufacture varies considerably. For example, NaOH, KOH, $Ca(OH)_2$, Na_3Citrate, K_3Citrate, NH_3OH are commonly used. The physicochemcal properties of each caseinate class is discussed in Section 73.4. The pH is adjusted to pH 6.6–6.8, and the casein is fully dissolved and dried. Caseinates are conventionally spray dried and to a less degree roller-dried or fluidized bed dried. The general requirements of a spray drier capable of drying caseinate are not very specific. A standard two-stage dryer with integrated fluidized bed would suffice (Fig. 73.11). Centrifugal or hydrostatic atomisation is used. Feed concentrations are generally 25–30%. Inlet and outlet temperatures are in the order of 200–250 and 80–110°C, respectively. Caseinate can also be manufactured by coextruding acid casein with a carbonate (Na_2CO_3 or $CaCO_3$) and then ring or attrition drying.

73.3.6 Individual Casein Fractions

There are a number of reasons why one might wish to prepare individual casein fractions:

- Human milk does not contain α_s-casein and as a consequence there may be some motivation for the development of an α_s-casein-depleted milk protein system for the infant formula industry.
- κ-Casein is a remarkably functional protein with very specific properties. It is quite likely that κ-casein enriched dairy powder preparations would have enhanced physical stability.

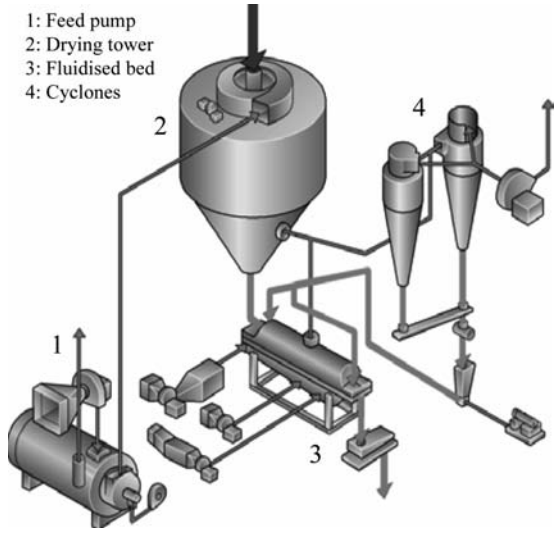

Figure 73.11 *Spray dryer used in the manufacture of caseinate. (Courtesy of GEA Niro.)*

- By isolating individual casein fractions the manufacture of bioactive peptide fractions of high purity may be possible.
- β-Casein is very surface active.

Laboratory scale isolation of individual casein fractions has conventionally used anion exchange chromatography. At low temperatures β-casein readily dissociates as monomers from the casein micelle into the serum phase. The β-casein monomers can then be separated by hydrostatic filtration. Until recently, excellent quality β-casein was available on a commercial scale from a continental European manufacturer.

73.3.7 Coprecipitates

As inferred, coprecipitates consist of casein and whey proteins which are prepared by coprecipitation. Coprecipitation is induced by heat treatment of the milk prior to acidifcation and/or calcification (Table 73.4). Heat-induced covalent crosslinking between the whey proteins and κ-casein through sulfydryl–disulfide interchange reactions play an integral role in coprecipitate manufacture.

73.4 FUNCTIONAL PROPERTIES OF CASEIN-DERIVED INGREDIENTS

The following section deals with the current and potential applications for casein and casein-derived products. The principal factor which qualifies casein as an excellent food ingredient is its pleasant, neutral taste, and soft texture which is neither gritty nor rubbery. This chapter is structured in such a way that functional properties of caseins in general are discussed and specific examples are listed. It should be noted that this list is by no means assumed to be the definitive directory of casein applications (Table 73.5).

73.4.1 Solubility

As solutes, caseins and casein-derived products are a very versatile group of food additives. Caseinates are soluble to high concentrations (20–30% solids) at pH values on the alkaline or acidic side of their isoelectric point. Na-/K-caseinate form translucent solutions which are very heat stable at pH 6.5–7.0 (easily tolerate 140°C for 1 h). The voluminosity of Na caseinate is in the order of 6–9 mL/g (Boulet and others 1998). At acidic pH values Na-/K-caseinate forms thick viscous gel-like systems. Ca-caseinate forms an opaque solution at neutral pH and is not as heat stable as Na- or K-caseinate (Moughal and others 2000). Standard coprecipitates are sparingly soluble in water while variants prepared by heat treating at alkaline pH values are markedly more soluble. In general, caseinates exhibit pseudoplastic rheological behavior but have been

shown to be thixtropic at high shear rates (Mulvihill 1994). The viscosity of Na caseinate solutions is affected by pH, calcium concentration, temperature, and concentration (Fig. 73.12). Soluble caseinates[1] impart a full and satisfying sensation with a clean aftertaste. Caseins are added to coffee creamers, dips, cream liquors, and many other products for their distinctive solubility characteristics amongst other reasons. Rennet casein is insoluble in water below pH 9.0. Phosphates (disodium orthophosphate, disodium pyrophosphate) and/or citrate (trisodium citrate) salts (commonly but incorrectly referred to as emulsifying salts) are often used to solubilize rennet casein during the manufacture of analog and processed cheeses (Ennis 2000). The principal application for rennet casein is in the manufacture of analog and processed cheese products. The main role of rennet casein is to emulsify fat and form the continuous matrix which provides a very characteristic stretch to the final product when cooked. It remains unclear which physicochemical properties are responsible for the stretch of analog cheese.

The development of casein hydrolysates as specific protein solutes has received a lot of research attention recently (Kilara and Panyam 2003). Hydrolysates may be tailored to produce highly transparent and heats stable solutions at acidic pH values (e.g., soft drink applications), or very low viscosity protein solutions (e.g., intravenous nutrition).

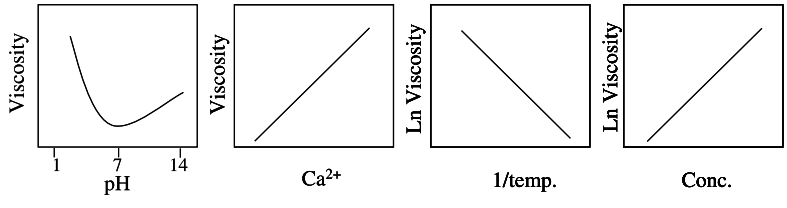

Figure 73.12 *Schematic representation of effect of pH, calcium, temperature and concentration on the viscosity of Na-caseinate solutions.*

[1] Caseinates refers to caseinates and also acid caseins which are resolubilised prior or dring the manufacture of the final product.

73.4.2 Gelation

The gelation of casein in the manner of cheese manufacture dates back to antiquity. Nowadays casein-derived additives are used in many diverse ways to modify gelation properties and/or induce gelation *per se*. The use of micellar casein as an alternative to skimmed milk powder for the standardisation/supplementation of cheese milk has been advocated. The advantage of micellar casein over skimmed milk powder is that there is not a concomitant increase in whey solids that have to be subsequently treated. The application of micellar casein in the development of low-carbohydrate gelled dairy products such as yogurt-like products also warrants research. It has been demonstrated that yogurts prepared using micellar casein have a firmer texture than yogurt prepared using skimmed milk. This is presumably related to the fact that the nonmicellar casein milk constituents, (i.e., whey proteins and lactose) interfere with the continuous gel matrix. Yogurt-like products prepared using micellar casein have to be supplemented with lactose (ca. 0.7%, w/v) to facilitate microbial fermentation. It is opined that the addition of lactose to 0.7%, w/v, would suffice. The ability of mixtures of casein (micellar casein or caseinates) and specific biopolymers (carrageenans and pectin) to interact and gel has been studied extensively (Lynch and Mulvihill 1992, 1994). In our laboratory extensive research has been carried out in the development of low-carbohydrate dessert gels containing mixtures of micellar casein and biopolymers. Acid-induced gelation of caseinates as heterogeneous or mixed systems has also been extensively researched (Dickinson and Casanova 1999; Koh and others 2002). Na-caseinate-gelatin mixtures gel when heated to 30–40°C and redissolve when cooled. Hydrophobic bonding is the principal associative mechanism.

73.4.3 Surface Activity

Emulsions are essentially two phase systems with oil globules dispersed in a continuous aqueous system or *vice versa*. A foam is a system in which air bubbles are dispersed in a continuous aqueous system. Density differences between the aqueous and oil/air phases drive phase separation which is affected by temperature, viscosity and globule/bubble size amongst other factors (Eq. 4).

$$V = \frac{2a^2(\rho_{sol} - \rho_{disp})g}{9\eta} \tag{4}$$

(V: creaming/sedimentation velocity; a: globule/bubble diameter; ρ_{sol} and ρ_{disp} are the density of the continuous and dispersed phases, respectively. g: gravitational constant. η: viscosity of the continuous phase.)

As shown in Eq. 4 globule/bubble size has a marked effect of the rate of creaming or sedimentation. As a consequence, it is imperative to stabilize the globules/bubbles while relatively small and also to prevent subsequent coalesence or growth of globules/bubbles. Surface active agents are amphiphatic molecules (i.e., have distinct hydrophilic and hydrophobic moieties) of varying size and composition capable of decreasing the surface tension at a water-oil or water-air interface and preventing the growth of globules/bubbles. In order for an additive to form and stabilize an emulsion or foam a number of properties are required:

- Nontoxicity;
- Thermodynamic compatability with other constituents in system;

- Sufficient molecular mobility to get to the interface before coalescence of the emulsion or collapse of the foam;
- Capablity to decrease the surface tension at water-air/oil interface;
- Contribution to long term stability at interface.

Casein-derived products are used as emulsifiers and foaming agents in many different food systems. Most low molecular weight surfactants such as phospholipids, mono/diglycerides, sucrose esters, lactylates, and so on, have very clearly defined hydrophobic and hydrophilic moieties. Conversely, casein-derived surface active agents, like all proteinaceous surfactants stabilize interfaces by extending their hydrophilic or hydrophobic moieties into the aqueous or oil/air phases, respectively. Because of their rheomorphic tertiary structure, caseins can easily adapt into the most entrophically stable state (i.e., state of least energy with hydrophilic and hydrophobic amino acid side chains protruding into the aqueous and oil/air phases, respectively). Figure 73.13 illustrates the specific stabilising mode of low molecular weight surfactants, globular proteins and caseins. The stabilizing mode of casein-derived additives is intrinsically linked to the molecular weight of the additive in question. In the current communication we tentatively categorize casein-derived surfactants into three groups (1) hydrolysates, (2) monomeric surfactants, that is, caseinates, acid casein, and (3) colloidal systems, that is, casein micelles. The different molecular weight of each species means that each type will differ with respect to their ability to move to the interface, decrease the surface tension and stabilize the system. Casein hydrolysates are commonly used in conjunction with low molecular weight surfactants to stabilize emulsions and foams. Because of their low molecular weight peptides rapidly migrate to the interface to decrease the surface tension and stabilize the system. Casein hydrolysates are particularly suitable surfactants because of their ability to stretch along the interface and also due to their tendency to engage in hydrophobic associative interactions and hydrogen bonding. Casein hydrolysates are used in a variety of products including ice cream, beverages, nougat, and aerated deserts.

Monomeric casein molecules in the form of caseinates are widely used as emulsifying and foaming agents. Caseinates stabilize interfaces in a manner similar to casein hydrolsates but because of their higher molecular weight are less molecularly mobile and do not migrate to the interface as rapidly as hydrolysates. However, once at the interface caseinates stabilize the interface very well. Enhanced stability is presumably related to the fact the more proteinaceous material has aggregated at the interface which in turn increases the composite density of the oil droplet/air bubble (Eq. 5).

$$\rho_{\text{composite}} = (r^3\rho_{\text{disp}} + [(r+\delta)^3 - r^3]\rho_{\text{inter}})(r+\delta)^3 \tag{5}$$

(r: radius; ρ_{disp} or ρ_{inter}: density of dispersed phase or interfacial material, respectively, δ: interface depth.)

The presence of aggregated protein at the interface leads to the formation of a multilayer structure with a resultant increase in the surface dialational viscosity (Eq. 6) forming a cohesive structure at the interface. The relationship between the associate state of a surface active agent and surface tension is expressed by the surface dialational modulus (Eq. 7). Caseinates are used as emulsifying and foaming agents for many products such as cream liquors, coffee creamers, communited meat products, processed cheese, confectionary, and bakery products. The foaming ability of caseinate is dependent

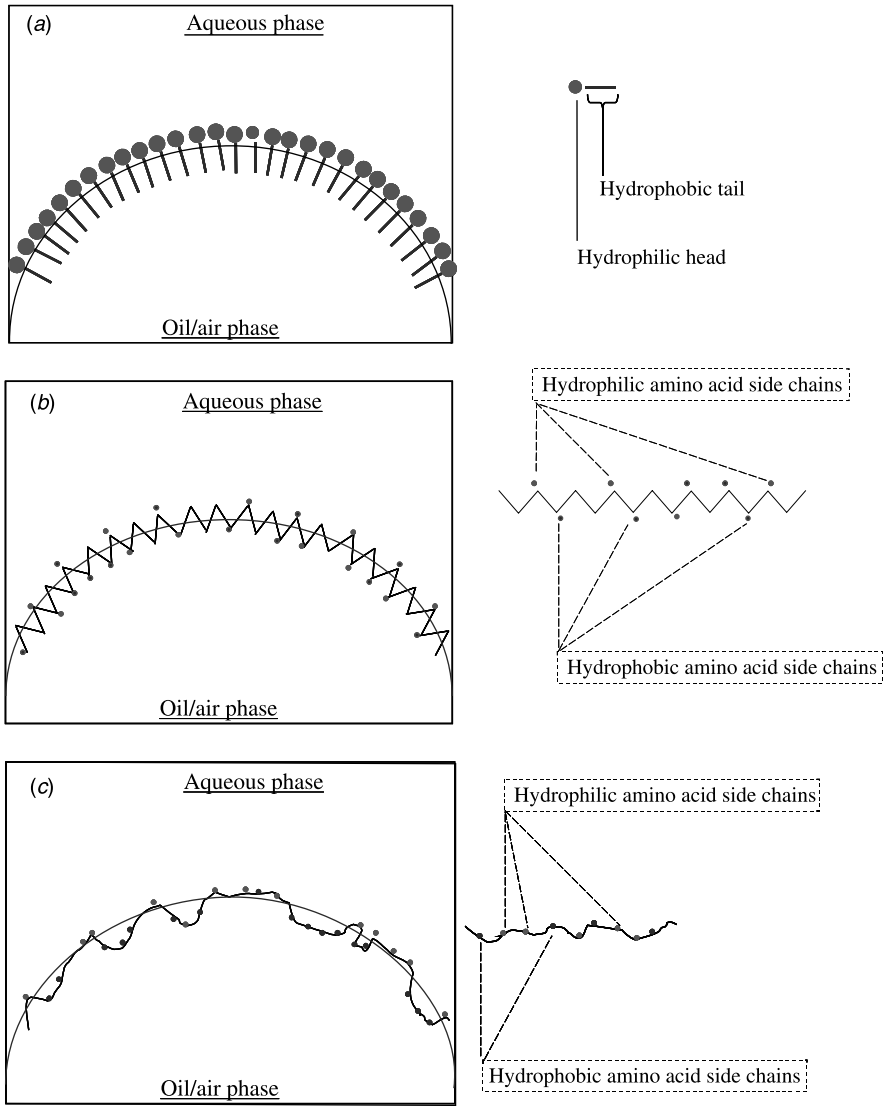

Figure 73.13 *Schematic representation of alignment of low mol. weight surface active agents (a), globular proteins (b), or caseins (c) at a water-oil/air interface.*

on ionic strength, calcium concentration, pH, and so on (Fig. 73.14; Mohanty and others 1984). It would appear that in Na caseinate systems monomers migrate to the interface (Fang and Dalgleish 1993) while in Ca caseinate systems, aggregates move to the interface (Srinivasan and others 2001). As

$$\eta = \Delta\gamma(\mathrm{dLn}\,A/\mathrm{d}t)^{-1} \tag{6}$$

(η: surface dialational constant; γ: surface tension; A: surface tension, and t: time.)

$$\varepsilon_d = \frac{1}{2}(d\gamma/dLnr) \tag{7}$$

(ε: surface dialational modulus, γ: surface tension, and r: radius.)

Casein micelles, in the form of skimmed milk powder or as purified micellar casein systems are widely used as emulsifying and foaming agents. The larger hydrodynamic size of casein micelles (200 nm) (O'Connell and Fox 2001) compared to monomeric casein units (e.g., β-casein ca. 8 nm) (O'Connell and others 2003) means that casein micelles move to the interface very slowly, but it as been shown that micellar systems confer high stability to emulsions. Examples of the use of micellar casein to stabilize emulsions include ice cream (3–5%), dairy whiteners (2–15%), cream liquors, beverages (0.5–3.0%), frozen deserts (0.2–1.0%), and mousses (1–5%), and so on. Chang and others (1995) reported that light hydrolysis of micellar casein markedly improved low fat ice cream.

73.4.4 Hydration

The tendency of caseins and casein-derived additives to bind water is of great significance to many applications. In general caseins are highly hydrated proteins. Interestingly, the water-binding ability of caseins varies considerably within casein fractions (Hong and others 1997):

$$(\text{Hydration } \beta\text{-casein} \gg \alpha_{s1}\text{-casein} > \alpha_{s2}\text{-casein} > \kappa\text{-casein})$$

Na caseinate binds water more readily than Ca caseinate with the differences being more pronounced at high pH and high A_w values (Rüegg and Morr 1984). Rüegg and others (1974) reported that micellar casein is more hydrated than rennet casein. Diamante and others (1992) recorded the sorption profiles of rennet, lactic, and mineral casein. All three casein variants had sigmoidal type II sorption isotherms according to BET classification and had hysteresis loops in their water sorption profiles (Fig. 73.15). Hysteresis loops are common features of sorption profiles of protein systems and have been attributed to the structural rearrangements of the protein upon the uptake of water. The equilibrium moisture content of caseins differed significantly. The following order in extent of

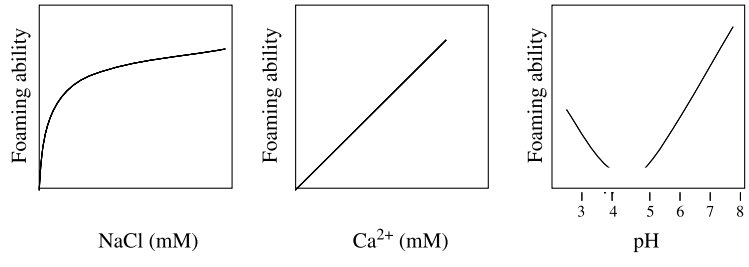

Figure 73.14 *Diagrammatic representation of effect of NaCl, calcium, and pH on the foaming ability of casein.*

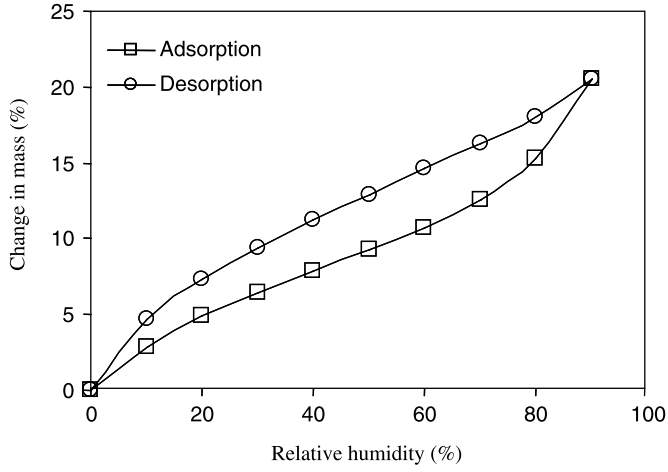

Figure 73.15 *Diagrammatic representation of hysteresis loop in the sorption profile of acid casein (O'Connell and Flynn, unpublished data).*

hydration was evident:

(Mineral casein < rennet casein lactic casein)

Rennet and acid casein differ considerably compositionally (acid casein has much lower mineral content while rennet casein has lost the hydrophilic C-terminal of κ-casein in the form of the GMP) which explains the why rennet casein has a low water binding capacity compared to acid casein. An explanation for the low water binding ability of lactic casein is less obvious but may be related to the fact that starter culture cells are incorporated in the casein matrix. The monolayer moisture content of different casein variants correspond to their overall water binding ability (Diamante and others 1992) which implies that compositional differences rather than structural arrangements are responsible for the different equilibrium moisture content (EMC) of casein variants. Processing factors also affect the water binding capacity of caseins. Espie and others (1984) investigated the effect of milk pasteurization (72 vs. 78°C), precipitation pH (pH 4.50 vs. 4.75), cook temperaure (45, 50, or 55°C), wash water ratio (0.3–0.5), hot wash temperature (60 vs. 80°C), drying mode (no drying, lyophilization, or pneumatic ring drying), or drying temperature (150, 180, or 220°C) and concluded the EMC of casein was only significantly effected by the latter two factors. O'Sullivan and others (2002) also reported that increasing drying temperature within the range of 80–140°C increased the hydration time of rennet casein when dispersed in a disodium orthophosphate solution and attributed this to differences in the fracturabiity of the powders rather then any heat-induced chemical changes.

Voluminosity studies of casein micelles have reported hydration values in the order of 4–6 mL/g protein. Sorption studies report hydration values of caseinates in the order of 0.4–0.6 g H_2O/g protein (Curme and others 1990; Mistry and others 1990). Caseinates and soluble coprecipitates are used as water binding agents in an array of products. Caseinates are added, at of 1–10%, w/w, to communited meat products to emulsify, gel, and bind water. Casein products are also added to whole meat joints, such as cured hams, through brine injection. Pasta formulations containing from 1% to 30% casein have

also been developed to enhance the nutritional quality, freeze-thaw stability, and water binding ability of this food. The performance of casein-derived additives in bakery applications is also markedly dependent on their water binding ability. It should be noted that the water binding ability of a milk protein preparation will depend on a number of factors including (1) protein composition (pure casein vs. whey-casein mixture), (2) predrying processing (heat treatment), (3) drying mode (ring dryer vs. spay dryer) and many other factor such as storage time/conditions, food matrix, formulation conditions, and so on.

There are also applications for casein preparations which have little tendency to bind water, that is, coprecipitates. Breakfast cereal or biscuit formulations containing hydratable proteins become soggy when mixed with water/milk. Conversely, breakfast cereal prepared with insoluble casein coprecipitates remains crunchy when mixed with water/milk, and so on. Related applications include frostings for donuts, nutrition bars, and aerated confectionary products. When selecting suitable coprecipitates it is also important that the product has the appropriate sensory attributes as some coprecipitates have very distinctive and deleterious Maillard and disulfide sensory undertones.

73.5 CASEIN DERIVATIVES AND HEALTH

The recommended daily protein intake is thought to be approximately 0.6–0.9 g/kg body weight (Renner 1983; Manninen 2002). In Western society, it is estimated that milk proteins account for up to 20–30% or 55–65% of total or animal protein intake, respectively (Renner 1983; Hambraeus 1992). The quality of casein and casein-derived products in meeting general and specific nutritional requirements is discussed and some proposed salutary health effects of casein-derived biologically active peptides are introduced (Fig. 73.16).

73.5.1 General Nutrition

Qualifying the nutritional value of proteins is a complicated process as one has to consider the nutritive value of protein in relation to many factors:

- Growth requirements
- Maintenance requirements
- Nitrogen content of protein
- Biological availability
- Value of a particular protein within a certain basal diets.

As shown the amino acid requirements of humans vary considerably (Table 73.6), as does the nitrogen and amino acid contents of different proteins (Table 73.7 and Table 73.8). The amino acid profile of casein is relatively similar to most proteins except for the comparatively low concentration of cysteine residues. The ratio of essential amino acids to nonessential amino acids of milk protein, egg protein, and soy protein is 3.22, 3.20, and 2.58, respectively (Blanc and Sieber 1978). Within the casein fractions β-, α_s-, and κ-casein contain 48.4, 43.3, and 41.1 g essential amino acids per 100 g protein, respectively (Renner 1983). The biological availability of casein (protein digestibility-corrected amino acid score (PDCAAS = 1) is very high compared to meat (PDCAAS = 0.92),

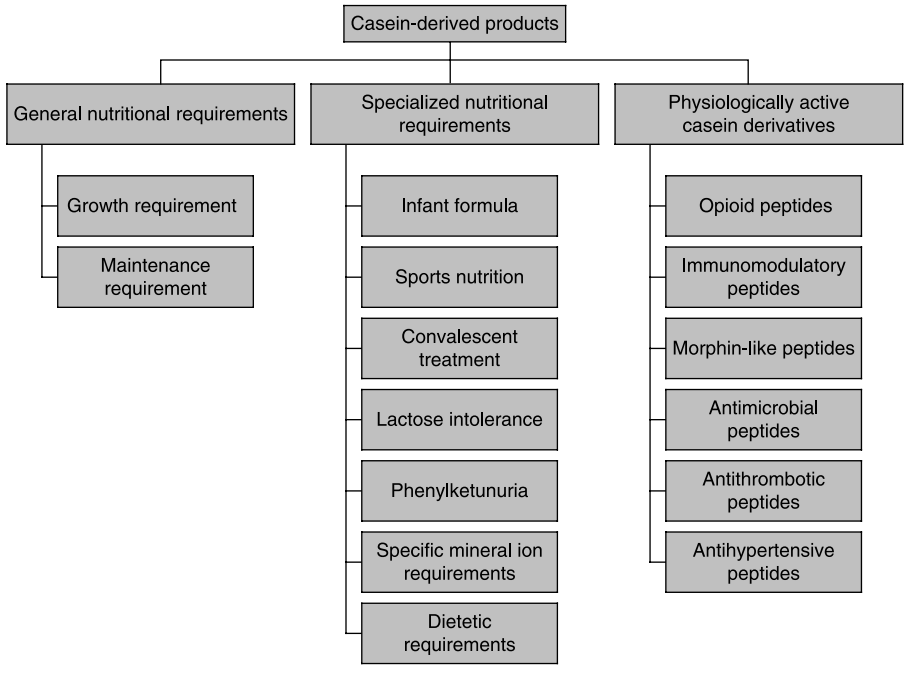

Figure 73.16 *Nutritional applications of casein-derived ingredients.*

wheat (PDCAAS = 0.40), or beans (PDCAAS ~ 0.60). This is due to the high digestibility of caseins and the high levels of essential amino acids. The nutritive value of a particular protein must also be considered in context of its value as part of a diet. For example, the lysine content of caseins is high while its sulfur-containing amino acid content is relatively low. However, when caseins are consumed in a diet containing cereal proteins (low lysine content but high in sulfur-containing amino acids), the amino acid requirements are easily

TABLE 73.6 Daily Amino Acid Requirements (mg/kg^{-1}/day) of Men, Women, Children, and Infants.

met. A protein intake consisting of 76% milk protein and 24% cereal protein is deemed ideal in terms of protein requirements. Similarly when milk proteins and egg proteins are combined in a diet, the composite dietary value of the combination exceeds that of either protein individually (Fig. 73.17).

73.5.2 Specialized Dietary Requirements

73.5.2.1 Infant Nutrition. Milk is intended to be the exclusive source of nutrition to the neonate during a delicate period which combines pronounced growth, development of critical tissue (i.e., liver, kidney, etc.) and reduced tolerance due to the immaturity of the aforementioned tissue. The use of bovine milk in infant formula manufacture is widespread. However, bovine and human milk differ considerably (Table 73.9). Unmodifed bovine milk is not recommended for at least the first 6 months post partum and as a consequence slight adjustments are required (Poskitt, 1994; Table 73.8). The protein fraction of human milk supplies 6–8% of the available energy from milk which is lower than bovine milk (Morrow 1994; Poskitt 2004). The protein : carbohydrate : fat ratio similar to human milk (1 : 2 : 4) is conventionally formulated. The protein content of commercial infant food formulations is in the region of 1.3–4.0 g/100 mL. The casein : whey fractions

of human and bovine milk are markedly different at 40 : 60 and 80 : 20, respectively. As a consequence the ratio is conventionally adjusted through the addition of whey protein concentrate. The net protein utilization (NPU) of infant food formulation is lower than that of human milk but higher then infant food formula manufactured using soy protein.

73.5.2.2 Dietary Requirements of Convalescent Patients. The importance of meeting the nutritional requirements of convalescent patients before and after operations can not be over emphasised. Enteral feeding procedures are an ideal way of meeting this requirement. As a consequence the development of high quality, easily digestible, casein derived products has received a lot of research attention. Micellar casein and casein hydrolysates with very specific free amino acid concentration and molecular weight profiles have been developed and are commercially available. The specific advantage of casein-derived material is that it is easily digestible and that the viscosity of such systems can be easily controlled. Milk protein preparations are used for patients suffering from gall

bladder diseases, hyperlipidaemia, diabetes, cirrhosis, impaired kidney functions, gastric ulcers, and so on.

Micellar casein and casein hydrolysates are also widely used as nutritional supplements in protein based, powdered beverage products. The specific coagulation properties of caseins in the stomach also appears to aid digestion. It is unclear whether this effect is related to the micellar properties of caseins or the molecular properties in all casein monomers, that is, precipitation at isoelectric point (Renner 1983; Hambraeus 1992).

73.5.2.3 Lactose Intolerance. Lactose intolerance can be a congenital or secondary condition but in the majority of occasions is developmental, that is, genetically programmed to develop after about 2 years. Lactose intolerance is very common amongst some ethnic or racial groups, that is, incidence in black Africans, black Americans, and Asians is in the order of 75, 90, and 95%, respectively, and relatively low amongst other groups, that is, Caucasians (ca. 10%). Lactose intolerance is caused by the lack of β-galactosidase which is responsible for the breakdown of lactose in dairy products to glucose and galactose. In the case of individuals suffering from lactose intolerance, the unmetabolized lactose moves from the small intestine into the colon where its is catabolized by the endogenous gas-producing colon microflora. Symptoms include abdominal pain, flatulence, cramps, and to a lesser degree, abdominal distension and nausea. Symptoms usually manifest 30–120 min after the consumption of lactose. Common dietary adjustments adopted are to take β-galactosidase supplements or to avoid dairy products. The problem with the latter option is that dairy products are also a major dietary source of calcium and phosphate. The use of micellar casein or milk protein isolate to meet this requirement has been advocated. Caseinates or coprecipitates do not meet this

mineral supply requirement because they do not contain the endogenous colloidal calcium phosphate of native casein micelles. Supplementation of caseinate or precipitate preparations with calcium phosphate is not seen to be of the same nutritional value as micellar caseins as this source does not match the mineral profile of the minor mineral constituents.

73.5.2.4 Galactosaemia. Galactosaemia is a rare genetic condition resulting in the deficiency of one of three galactose metabolising enzymes (gal-1-P uridyltransfease, galactokinase, or UDP galaose-4-epimerase). When lactose is consumed it is metabolized to glucose and galactose which results in a build up of galactose in the brain and eyes causing severe mental retardation and eye cataracts. The replacement of standard skimmed milk protein with micellar milk protein would eliminate any potential problems associated with galactosaemia.

73.5.2.5 Phenylketonuria. Phenylketonuria (PKU) is a autsomal recessive condition where there is little if any ability to metabolize phenlyalanine due to a near complete deficiency of phenylalanine hydroxylase. High phenylalanine and tyrosine levels in blood may cause brain damage such as profound and irreversible mental retardation, microcephaly, or epilepsy. Unless phenylalanine levels in food are tightly controlled, especially during childhood, some mental impairment is inevitable. Standard food preparations for individuals suffering from PKU include amino acid mixtures and synthetic peptide systems. The use of the κ-casein glycomacropeptide as stable source of amino acids for individuals suffering from PKU has also been advocated (Renner 1983; Nielsen and Tromholt 1994; Brody 2002). The lack of essential amino acids such as cysteine, histidine, tryptophan, tyrosine necessitates that some other source of amino acids be consumed in addition to GMP.

73.5.2.6 Hyperuricaemia and Related Conditions. It would appear that milk proteins are an ideal source of protein for individuals suffering from hyperuricaemia and gout. Both conditions are caused by the build up and subsequent deposition of uric acid in the muscle and tissue. Dietary purines are the principal precursors for uric acid. Casein-derived products are a very suitable source of purine low protein (Renner 1983).

73.5.2.7 Sports Nutrition. The dietary requirements of athletes are very specific. It is required that sufficient protein is consumed to provide amino acids for synthesis of body protein during growth and replace body proteins irreversibly catabolized during exercise. Physical exercise regardless of its specific nature (high intensity/short time vs. endurance exercise) has a similar acute response (decrease in protein synthesis and increased rate of protein degradation) but the time course and magnitude of the changes differ. Endurance exercise causes an increase in mitochondrial protein with minimal effect on the myofilbrillar proteins, while weight lifting causes an increase in catabolic response and decrease in anabolic response. It has been proposed that the recommended daily protein intake of athletes is approximately 1.3–1.6 g/kg/day (Gontzea and others 1974, 1975; Friedman and Lemon 1989). Caseinates, coprecipitates and casein hydrolysates are commonly used with whey protein (whey protein isolate or whey protein concentrate) in protein supplement beverage powder mixes.

It has also been proposed that "slow release proteins" such as micellar casein could be used by athletes to prevent muscle catabolism during periods of dieting or prolonged fasting. The basis of the "slow release proteins" claim is that casein coagulates and

aggregrate in the stomach causing slow degradation of proteins with a concomitant slow release of amino acids. This in turn decreases the rate of muscle degradation (Boirie and others 1997; Beanfrere and others 2000; Manninen 2002).

73.5.2.8 Weight Reduction Diets. Casein and casein-derived products have two specific applications within weight reduction diets. Pure casein products, particularly micellar casein preparations, could be viewed as carbohydrate-free variants of skimmed milk powder. The benefit of micellar casein over coprecipitates/caseinates is that the former system is rich in calcium, phosphorus and other minerals and as such mimics skimmed milk more closely than coprecipitates or caseinates. The applications of micellar casein as an alternative to skimmed milk solids include low carbohydrate ice cream, low carbohydrate yogurt, dairy smoothies, and so on.

The κ-casein glycomacropeptide has been demonstrated to increase the sensation of satiety and induces an appetite-reducing effect. Satiety is loosely defined as the feeling of fullness. It has been proposed that ingestion of κ-casein glycomacropeptide causes a increase in the release of cholecystokinin (CKK) in the duodenum and jejunum with a concomitant increase in CKK concentration in the blood. CKK stimulates the production of insulin and slows the rate of gastric emptying which in turn contributes to a long lasting sensation of fullness. It would appear that the sialic acid and sugar moieties of GMP play a paramount role in this physiological effect (Beucher and others 1994; Corring and others 1997; Monnai and Otani 1997; Froetschel and others 2001).

73.5.3 Biologically Active Peptides

73.5.3.1 Opioid Peptides. Casein-derived biologically active peptides have received a lot of research attention recently and this trend is likely to continue. Casein-derived bioactive peptides have a range of physiological effects (Fig. 73.16 and Table 73.10). Opioid-like peptide are the most studied biologically active casein peptides and can be subdivided into opioid agonists and opioid antagonists. Opioid agonists are prepared from α_s-/β-casein hydrolysis and act by binding to naloxone receptors (Kilara and Panyam 2003). The proposed physiological effects of casein opioid agonists are modulation of social behavior, lengthening gastrointestinal transit duration, antidiarrheal action, stimulating secretion of insulin, and somatostatin and simulating intestinal transport (Takahashi and others 1997; Meisel and FitzGerald 2000; Floris and Alting 2003). Casein antagonists suppress the action of humoral peptides enkephalins and block the action of agonists. It should be noted that the specific effect of casein-derived opioid peptides may depend on the mode of administration (parenteral feeding vs. oral administration). A lot of research is required to elucidate the actual physiological effect of ingesting biologically active peptides.

73.5.3.2 Immunoregulatory Peptides. Several casein derived peptides have been shown to have defined imunoregulatory properties. Casein-derived peptides may directly inhibit the growth of bacteria (*Encherichia coli*, *Straphyococcus aueus*, or *Klebsiella pneumoniae*), yeasts (*Candidia albicans*), or viruses (Epstein Barr virus), or alternatively enhance the existing immune system by increasing antigen T cell proliferation, lymphocyte proliferation, neutrophil locomotion, phagocytosis, peritoneal macrophage activity, murine activity, or natural killer cell activity (Coste and others 1992; Lehov and Regelson 1996; Otani and Monnai 1996; Otani and others 1996; Brody 2000) FitzGerald and Meisel

TABLE 73.10 List of Selected Biologically Active Peptides Derived from Casein.

Role	Peptide	Comment	Ref.
Mineral binding	α_{s1}-CN F43–59	Binds Fe, Mn, Cu, Se, Ca,	[a]
	α_{s1}-CN F43–58	Binds Fe, Ca; two phosphoserine residues, net charge of −7	[a]
	α_{s1}-CN F43–79	7 Phosphoserine residues, binds Ca	[a]
	α_{s1}-CN F59–64	2 Phosphoserine residues, binds Ca	[a]
	α_{s1}-CN F59–79	Binds Ca and Fe; 5 phosphoserine residues, net charge of −9	[a]
	α_{s2}-CN F1–21	4 Phosphoserine residues	[a]
	α_{s2}-CN F46–70	4 Phosphoserine residues; charge of −11	[a]
	α_{s2}-CN F66–74	3 Phosphoserine residues; binds Ca	[a]
	β-CN F1–25	Binds Ca and Fe; 4 phosphoserine residues, net charge of −9	[a]
	β-CN F1–28	Binds Ca; 4 phosphoserine residues; charge of −8	[a]
	β-CN F33–48	Binds Ca; charge of −6	[a]
Antithrombotic	κ-CN F106–116	Inhibits thrombin-induced aggregation and ADP-induced platelet aggregation	[b]
	κ-CN F106–112	ADP-induced platelet aggregation	[b]
	κ-CN F113–116	ADP-induced platelet aggregation	[b]
	κ-CN F103–111	Inhibits thrombin-induced aggregation and ADP-induced platelet aggregation	[b]
	κ-CN F112–116	Inhibits thrombin-induced aggregation and ADP-induced platelet aggregation	[b]
Immunoregulatory peptides	α_{s1}-CN F194–199	Increases antibody formation, increases phagocytosis, decreases proliferation of lymphocytes, ACE inhibitor	
	α_{s1}-CN F1–23	*Isracidin*; Protection against *Straph. aureus*, *E. coli*, and *Candidia albicans*	[c]
	α_{s1}-CN F90–96	Decreases lymphocyte proliferation, increases natural killer activity and increases neutrophil locomotion	[c]
	α_{s1}-CN F90–95	Decreases lymphocyte proliferation, increases natural killer activity and increases neutrophil locomotion	[c]
	α_{s1}-CN F23–34	ACE inhibtor, increases phagotosis, protects against *Klebsiella pneumoniae* infection	[c]
	α_{s1}-CN F23–37	ACE inhibtor	[f]
	α_{s1}-CN F28–34	ACE inhibtor	[f]
	α_{s1}-CN F104–109	ACE inhibtor	[f]
	α_{s1}-CN F142–147	ACE inhibtor	[f]

(*Continued*)

TABLE 73.10 *Continued.*

Role	Peptide	Comment	Ref.
	α_{s1}-CN F143–148	ACE inhibtor	*f*
	α_{s1}-CN F157–164	ACE inhibtor	*f*
	α_{s1}-CN F194–199	ACE inhibtor	*f*
	β-CN F193–209	Decreases lymphocyte proliferation, increases phagocytosis	*c*
	β-CN F63–68	Increases antibody formation, increases phagocytosis	*c*
	β-CN F191–193	Increases antigen dependent T cell proliferation	*c*
	β-CN F60–70	Decreases lymphocyte proliferation; protects against *Klebsiella pneumoniae* infection	*c*
	β-CN F60–66		*c*
	β-CN F74–76	ACE inhibitor	*f*
	β-CN F57–64	ACE inhibitor	*f*
	β-CN F84–86	ACE inhibitor	*f*
	β-CN F108–113	ACE inhibitor	*f*
	β-CN F169–175	ACE inhibitor	*f*
	β-CN F177–183	ACE inhibitor	*f*
	β-CN F193–198	ACE inhibitor	*f*
	β-CN F193–202	ACE inhibitor	*c*
	β-CN F77–183	ACE inhibitor	*c*
	κ-CN F106–169	*Glycomacropeptide*; inhibits splenocyte proliferation	*g*
	κ-CN F106–169	*Glycomacropeptide*; binds cholera toxin	*g*
	κ-CN F106–169	*Glycomacropeptide*; binds *E. coli* heat labile enterotoxins LT-I and LT-II	*g*
	κ-CN F106–169	*Glycomacropeptide*; adhesion and protection against Epstein-Barr virus	*g*
	κ-CN F106–169	*Glycomacropeptide*; inhibition of cariogenic bacteria such as *Streptococcus mutans*, *S. saguis*, *S. sobrinus and Actinomyces viscosus*	*h*
	κ-CN F106–169	*Glycomacropeptide*; Decreases lymphocyte proliferation	*c*
	κ-CN F17–21	Decreases lymphocyte proliferation	*c*
	κ-CN F38–39	Decreases lymphocyte proliferation	*c*
	κ-CN F58–59	ACE inhibitor	*f*
	κ-CN F108–110	ACE inhibitor	*f*
Opioid	β-CN F 60-64	β-*Casomorphin 5*; Opioid agonist	
	β-CN F	β-*Casomorphin 5*; Opioid agonist	*g*
	β-CN F	*Morphiceptin*; Opioid agonist	*g*
	α_{s1}-CN F	α-*Casein exorphin*; Opioid agonist	*g*
	α_{s1}-CN F	*Casoxin D*; Opioid antagonist	*g*
	κ-CN F	*Casoxin 4*; Opioid antagonist	*g*
	κ-CN F35–42	*Casoxin A*; Opioid antagonist	*h*
	κ-CN F58–61	*Casoxin B*; Opioid antagonist	*h*

(*Continued*)

TABLE 73.10 *Continued.*

Role	Peptide	Comment	Ref.
	κ-CN F25–34	*Casoxin C*; Opioid antagonist	[h]
DNA synthesis stimulating	β-CN F177–183		[f]
	β-CN F105–69		[f]
	κ-CN F106–169	*Glycomacropetide*	[f]
Antithrombotic activity	κ-CN F106–116	Inhibits ADP-treated platlet aggregation	[f]
	κ-CN F39–42		[f]
	κ-CN F103–116		[f]
	κ-CN F106–169	*Glycomacropetide*, Antithrombotic activity	[f]
	κ-CN F106–110	*Casopiastrin*	[f]
Suppress gastric secretions	κ-CN F106–169	Acidity of gastric secretions lowered and motions in gastric fundus and duodenum reduced.	[g]
Bfidobateria stimulating	κ-CN F106–169	*Glycomacropeptide*; only glycosylated form is active	[g]
Antitumor	Casein	Prevention of DHM-induced intestinal cancer	[i]

[a]Vegarud and others 2000; [b]Rutherfurd and Gill 2000; [c]Gill and Cross 2000; [d]Shah 2000; [e]Meisel and FitzGerald 2000; [f]FitGerald and Meisel 2000; [g]Brody 2000; [h]Nesser and others 1988; [i]Gill and Cross 2000.

2000; Gill and Cross 2000; Harsharnjit and others 2000; Floris and Alting 2003; Kilara and Panyam 2003). The specific immunoregulaory activity of casein hydrolysates are presumably due to the distinct surface properties of casein peptides. It has also been demonstrated that κ-casein promotes the growth of Bifidobacteria. It would appear that glycosylated forms of GMP are the active variants (Zbikowski and Ziajkas 1986; Yvon and others 1994; Brody 2000).

The use of GMP as an anticariogenic agent for the protection of teeth has also been proposed. It has been reported that GMP inhibits the adhesion of cariogenic bacteria such as *Streptococci mutans*, *S. sorbinus*, *Actinomyces visosus*, to teeth (Schupbach and others 1996; Vacca Smith and others 2000).

73.5.3.3 Antihypertensive Peptides. The ability of casein-derived peptides to inhibit angiotensin-I-converting enzyme has received a lot of research attention. Angiotensin-I-converting enzyme (ACE), a dipeptide liberating carboxypeptidase (peptidydipepide hydrolase; EC 3.4.15.1) converts angiotensin I to octapeptide angiotensin II and also hydrolyses brandykinin (FitzGerald and Meisel 2000; Grosiak and Muller 2000; Shah 2000). Angiotensin I is a potent vasoconstrictor. Casein-derived ACE inhibitors (casokinins) have charged amino acid moieties at their C-terminal and are thought to inhibit ACE by electrostatically binding to the catalytic site of ACE (see FitzGerald and Meisel 2000). A specific feature of casokinins is their resistance to digestive hydrolysis which may be related to their relatively high proline content.

73.5.3.4 Mineral Binding Peptides. The ability of casein to bind and enhance the delivery of minerals is the intrinsic biological role of casein (Holt 1992a). It has also been demonstrated that casein-derived peptides can bind and enhance the adsorption of mineral ions (Scholz and Schrezenmeir 2000; Vegarud and others 2000; Floris and Alting 2003). The binding mechanism of casein can be specific through phosphserine residues or nonspecific. The use of casein derived peptides as mineral binding agents in dental care products (to counteract decalcification of dental enamel), breakfast cereal products and dry flour mixes has also been advocated (Reynolds 1987).

73.5.3.5 Antithrombotic Peptides. Several κ-casein derived peptides have been demonstrated to have antithombotic properties. This effect is presumably related to the high degree of homology between the human fibrinogen γ-chain and κ-casein peptide fraction F106–116. Collectively antithrombotic κ-casein derived peptides are called casoplatelins and are thought to work by (1) physically inhibiting platlet aggregation, and (2) inhibiting the fibrinogen γ-chain binding to the platlet surface (Jolles and others 1986; Fossett and Tome 1998; Tome and Ledoux 1998; Pfeuffer and Schrezenmeir 2000; Rutherford and Gill 2000; Floris and Alting 2003; Kilara and Panyam 2003).

74.1 INTRODUCTION

Despite of the myths surrounding the origins of ice cream, we do not know for sure how the evolution of ice cream resulted. Snow and ice have been popular during warmer seasons because of the cooling properties of these materials. Perhaps first snow and ice were mixed with fruit juices and later with milk or yogurt, and this resulted in a gradual evolution of these products as we know them. Until the nineteenth century, harvesting ice and storing it for use during summer was a labor intensive process and therefore, ice cream was a food for the rich only. With the invention of the hand cranked freezer and a ready availability of ice, ice cream moved down the social ladder, and towards the end of the nineteenth century it was sold on the streets of metropolitan areas.

Ice cream and frozen desserts are popular throughout the world. Although ice cream is a popular frozen dessert in all parts of the world, the major consumer countries of ice cream are New Zealand, the United States, Canada, Australia, Belgium, Finland, and Sweden. In some areas of the world, unavailability of appropriate ingredients, lack of refrigerated distribution chain, economics, or other cultural factors may deter the manufacture (and

therefore consumption) of ice cream. There are several different names for ice cream in the world. In Norwegian it is *iskrem*, in Portuguese *sorvettes*, in Spanish *healdos*, in French *glacé*, in Italian *gelato*, in Hebrew *glidah*, in German *eis*, in Finnish *jatelo*, in Greek *pagoto*, and in Chinese *bing qi lin* or *sou go*.

The popularity of ice cream results from several characteristics such as partial freezing, cooling, and refreshing sensation produced when the product is consumed, its sweet taste and the lack of a preconditioning aroma. In all these products a sugar solution is the common denominator. The characteristics of the syrup are manipulated by the addition of other materials to obtain desired taste, texture, consistency, and appearance.

Ice cream is manufactured as regular, custard/French, reduced fat, light, low, and no-fat versions. Other frozen desserts include frozen yogurt, sherbet, water ice, mellorine, frozen dairy dessert, frozen confection, frozen dairy confection, milk shake, smoothies, shake, and slush. The nomenclature varies from country to country depending on the prevailing legislation. Two manufacturing practices that affect the characteristics of frozen desserts are the freezing technique and degree of freezing. The freezing technique may involve stirring (agitation) during freezing, or without stirring (quiescent), or a combination of the two. Similarly, the degree of freezing results in products that are hard frozen, or designed for dipping or scooping, or used as soft serve or a milkshake.

The characterizing materials that are added to the sugar syrup are dairy ingredients, sweeteners (other than sucrose), body and texture modifiers, flavors, and colors. Most of the legal terms used in this chapter are based on the authors' experience in the United States and it is recognized that this information varies considerably due to geography.

74.1.1 Classification of Frozen Desserts

74.1.2 In the United States, FDA Standards

The Code of Federal Regulations (21 CFR135.110) specifies both compositional and manufacturing requirements for a product to be called ice cream. The compositional requirements state that the product cannot contain less than 20% total milk solids including 10% milk fat. No more than 25% of the nonfat milk solids can be derived from whey, and caseinates may be used only after reaching the 20% milk solids minimum. Some allowances are made for bulky flavors such as chocolate and certain fruit flavors, and the requirements for milk solids level is reduced by 20%. For a product to be called frozen custard (or French ice cream), the product must contain at least 1.4% egg yolk solids. Last but not the least, a minimum total solids and weight per gallon are also specified. Ice cream must weigh a minimum of 4.5 lb/gallon or 540 g/L. This requirement specifies the maximum amount of air (a maximum of 100% overrun) permissible in the product. However, for reduced fat, low fat and nonfat ice cream, the minimum weight requirement is reduced to 480 g/L. Total food solids must be at least 1.6 lb/gallon or 192 g/L. A serving of ice cream is considered to be one half cup or 4 fl. oz, or 120 mL (a volumetric measure). To conform to the weight requirement of 4.5 lbs/gallon, 1/2 cup corresponds to 63.8 g.

The manufacturing requirements defined in law are that the freezing should occur under agitation; the mix should be pasteurized, may contain safe and suitable nonmilk derived ingredients, may be sweetened with safe and suitable sweeteners, and may be flavored.

With the introduction of the Nutritional Education and Labeling Act (NLEA) in 1993 several modifying terms could be used with standardized foods. Thus descriptors such as reduced fat, light, low fat and nonfat, or no fat could be used in conjunction with the word ice cream. Reduced fat ice cream is a nutritionally altered product (compared to ice cream)

which contains 25% less fat as compared to conventional ice cream. Light or Lite ice cream is a product that has one-third fewer calories or half the amount of fat of that found in regular ice cream. Low fat ice cream is a product that contains less than 3 g fat per serving. Fat free, no fat, or nonfat ice cream is a product that contains less than 0.5 g fat per serving. With these changes in descriptors, the total milk solids requirements of 20% still apply and all other aspects of ice cream described above still apply.

There are other frozen desserts that also have a standard of identity. These are sherbet, mellorine, and water ice. Sherbet should contain not less than 1% milk fat and no more than 2% milk fat; milk solids-not-fat content should be not less than 2% and no more than 5%. The minimum weight requirement is 6 lb/per gallon. A fruit flavored sherbet should have a minimum acidity of 0.35%. Sorbet and water ices have the same standards as sherbet except no milk or egg ingredient is allowed (except egg white). Frozen yogurt are has no federal standard of identity, but it consists of a mixture of dairy ingredients, sweeteners, stabilizers, and flavors. Usually, frozen yogurt mix contains 10% cultured yogurt component and the titratable acidity of the mix is 0.3%. Novelties are packaged in single servings. They may be juice bars, fudge sticks, or ice cream sandwiches. Gelato is served in a semifrozen state resembling soft serve ice cream. It is more dense (contains less air) than ice cream.

Mellorine is a product made with fats other than milkfat. These fats can be animal or vegetable derived. Mellorine should contain a minimum of 1.6 lb of food solids per gallon, a fat content of not less than 6%, a minimum protein content of 2.7% (the protein has to be of equal nutritional value of milk protein) and a gallon of mellorine should weigh not less than 4.5 lb per gallon.

When a pasteurized ice cream mix is frozen without stirring the product is labeled as a quiescently frozen dairy dessert. If the product contains no milk solids or less than a total of 20% total milk solids and is frozen without agitation it has to be labeled as quiescently frozen dairy confection. On the other hand, if the product does not contain any dairy ingredients and is frozen without agitation then it is called a frozen confection.

74.1.3 Trade Classification

The chemical composition of ice cream differs mainly with regard to the fat content and three grades of ice cream can usually be found in most market areas. One grade just meets the minimum fat content, often has an overrun that approaches the maximum allowed by law, and usually contains relatively inexpensive flavor ingredients. At the other extreme are the so-called premium ice creams that are high in fat, low in overrun, and usually contain natural flavors. A third grade of ice cream, designed as a compromise between the minimum cost and premium products, is the type that has dominated the market for many years. Newer developments have introduced a fourth grade referred to as super premium ice cream that is characterized by higher fat contents and lower overruns than premium varieties. Cost of the product is directly proportional to the grade of the ice cream.

74.1.4 Trends in Ice Cream Market

The volumes of ice cream and other frozen dairy desserts produced in the United States in 2003 and 2004 are shown in Table 74.1.

According to U.S. Department of Agriculture statistics, 1.58 billion gallons of ice cream and frozen desserts were manufactured in 2004. Of this total, 60% was ice

TABLE 74.1 Production Statistics of Various Frozen Desserts in the United States.

Frozen Dessert	2003 (Million Gallons)	2004 (Million Gallons)
Ice cream, regular, total	992.9	943.7
Ice cream, regular, hard variety	875.4	844.7
Ice cream, low fat, total	398.3	415.5
Ice cream, low fat, hard variety	101.4	114.1
Ice cream, low fat, soft variety	296.9	301.4
Ice cream, nonfat, total	20.4	22.7
Ice cream, nonfat, hard	18.8	19.1
Water juices and ices	60.6	63.9
Frozen yogurt, total	70.4	67.7
Frozen yogurt, low fat, hard	21.4	19.7
Frozen yogurt, nonfat, hard	12.1	11.1
Other frozen dairy desserts	7.2	8.1

cream, 28% was reduced fat, low- fat and nonfat ice cream, 4% frozen yogurt, 4% water and juices, 3.5% sherbet, and 0.5% other frozen products. It is estimated that 444.2 million gallons of soft serve ice cream products were produced in 2004. In the United States, per capita sales in 2004 were 26.4 quarts and the market value exceeded 21 billion dollars.

74.2 FORMULATION

In order to make an ice cream mix, three categories of ingredients are necessary. A concentrated source of milk fat is the first category, the second is a concentrated source of milk solids-not-fat (aka serum solids) and the third is called a balancing ingredient.

Representative formulae for commercial grades of ice ream are shown in Table 74.2. Composition of other variants of ice cream and frozen desserts are shown in Table 74.3. The prioritization of ingredient selection can be said to approximate the hierarchy as follows:

1. *Select Milk Fat Content*: Since milk is bought and sold on the basis of fat content and quality grade of ice cream is also reflected by the fat content, the amount of milk fat will determine the cost and grade of the product.

TABLE 74.2 Representative Formulae for Ice Creams of Different Grades.

			Super Premium %		
Constituent	FDA Standard %	Premium %	1	2	Super %
Milk fat, min.	10.00	12.00	14.00	16.00	18.00
Milk solids–not-fat, min.	7.50	9.00	10.00	10.50	9.50
Whey solids, max.	2.50	2.00	–	–	–
Sucrose	–	7.60	12.00	15.00	15.00
Corn syrup solids	–	9.00	6.80	5.00	–
High fructose solids	–	4.50	2.60	–	–
Stabilizer	–	0.35	0.25	0.13	0.12
Emulsifier	–	0.25	0.25	0.15	0.10
Total solids	–	40.50	41.28	41.72	42.50

TABLE 74.3 Composition of Other Frozen Desserts.

Constituent	Ice Cream			Sherbet	Water Ice
	Nonfat	Low Fat	Reduced Fat		
		Abundance (%)			
Milk fat	0.5	3.0	6.0	1.5	0
MSNF	13.5	13.0	12.5	3.5	0
Sucrose	10.0	9.0	10.0	23.0	23.0
Corn syrup solids	10.0	9.0	8.0	7.0	7.0
Stabilizer/emulsifier	1.0	0.8	0.6	0.4	0.4
Total solids	35.0	34.8	37.1	35.4	30.4
Water	65.0	65.2	62.9	64.6	69.6
Total solids	35.0	34.8	37.1	35.4	30.4

2. *Select Nonfat Milk Solids Level* to complement the fat content. Too much of nonfat milk solids can cause sandiness.
3. *Sweetener Ingredient*: Type and amount of sweetener are in turn dependent on the fat and total solids content and also by economic considerations. Higher fat mixes need high sweetener levels. Type of sweetener used depends on demands and supply which in turn controls the cost of the ingredients.
4. *Stabilizer and Emulsifier*: The amount and type are affected by fat and total solids levels, manufacturing processes, and storage and distribution factors.
5. *Label Considerations*: If specific nutritional or other claims have to be made (e.g., "all natural," or "reduced calorie," or "reduced fat") then the above hierarchy of ingredient selection is slightly modified and cost of ingredients plays a lesser role than the functional aspects.

For the manufacture of good ice cream there is no secret or magic formula. Difference between good and not-so-good ice cream is controlled management. By controlled management is meant such things as using good ingredients for every batch, maintaining the same composition every time, proper and controlled mix making, freezing, packaging, hardening, storage, distribution, and minimal turnover time.

These representative subclasses vary not only in the proportion of ingredients but also in the types of ingredients used to furnish a required component. For example, in the "economy" subclass of ice cream serum solids may be derived from nonfat dry milk (skim milk powder), or condensed skim milk and can also include the maximum allowable amounts of whey solids. The maximum allowed amount of whey solids is 25% of the milk solids-not-fat content. Therefore the 10.0% of serum solids may be derived from condensed skim or nonfat dry milk up to a total of 7.5% and whey solids may be added to the level of 2.5%. Since whey solids cost considerably less than milk solids, thereby the overall costs of the formulation can be reduced. Similarly, sweeteners may also be substituted to reduce costs of formulations. High fructose corn syrup has approximately the same sweetness intensity as sugar but cots less than sugar. In some formulations, approximately 50% of the sugar solids can be substituted with high fructose corn syrup solids. In general, the "economy," "regular," and "premium" subclasses of ice cream also contain higher overrun while the "super premium" subclass contains less overrun. Additionally, the "super premium" subclasses are packaged in smaller containers of 468 mL (1 pint) whereas

the other products are packaged in 1.874 L (half U.S. gallon) containers. Lastly, the distribution and points of sales of the different subclasses of products can also vary considerably.

74.2.1 Concentrated Sources of Milk Fat

Fat in milk is secreted as tiny droplets called globules. A drop of milk contains millions of such globules. Each globule is surrounded by a membrane called milk fat globule membrane. This fat is made up of triglycerides, traces of di- and monoglycerides, cholesterol, and phospholipids among many other substances. In fact milk fat is composed of some 3600 different compounds. The triglycerides which are the main component are synthesized by the cow by linking three molecules of fatty acids to one molecule of glycerol, hence the name triglycerides. These fatty acids consist of carbon, hydrogen, and oxygen atoms. Fatty acids can have as few as four carbon atoms or as many as 26 carbon atoms. In milk fat, we have a number of different fatty acids including those containing four, six, and eight carbon atoms. This is significant because the characteristic flavor of milk fat is in large part due to the presence of these lower chain fatty acids butyric, caproic capryllic, and capric acids, carbon numbers 4, 6, 8, and 10, respectively. Further there are fatty acids that are unsaturated and thus we have fatty acids with one double bond (monoenoic) fatty acids, two double bonds (dienoic) or with three fatty acids (trienoic). The unsaturated fatty acids with multiple double bonds are functional, healthy, and essential for human beings.

Milk fat melts and crystallizes, is unctuous, depresses the cold sensation, contributes desirable flavor, is a solvent for added flavors, adds structure to ice cream and is of great importance in extrusion properties of ice cream. Extrusion helps shape ice cream in novelties.

Milk and cream constitute the most important components because they furnish the basic ingredients for a good quality ice cream. Variables related to dairy ingredients exert a profound influence on the flavor, body, and texture of the frozen product.

The nature and intensity of ice cream flavor is a function of the flavor quality of the individual constituents and subsequent processing treatment of the ice cream mix. Flavor defects in ingredients cannot be alleviated during ice cream making. Actually, flavor problems could be compounded as a consequence of negligent processing procedures.

The body or consistency of ice cream is related to the mechanical strength of the mix and its resistance to melting. Heat shock resistance is dependent on the nature and concentration of the stabilizer-emulsifier system used. The texture of ice cream depends upon the size, shape, number, and arrangement of fat globules, ice crystals, and the ratio of liquid and frozen water in the ice cream.

Balancing quality and cost is a major challenge to frozen dessert manufacturer. Satisfactory composition produces ice cream having an optimum combination of cost, flavor, body, and texture, cooling effect, viscosity, whipping ability, and freezing characteristics. In summary, factors responsible for overall ice cream quality are: raw material quality, sanitary care during mix preparation, processing parameters, flavoring used, freezing techniques, and storage conditions.

Formulation of frozen dessert mix involves utilization of both the fat and solids-not-fat components of milk. The functions and preferred sources of major ice cream ingredients are summarized in Table 74.4.

TABLE 74.4 Role and Sources of Various Components of Ice Cream.

	Role and Functions	Limitation	Sources in Order of Preference
Milk fat	Imparts desirable creamy rich flavor Source of fat-soluble vitamins Improves body texture Improves melting resistance	Calorie-dense. Too much fat (17%) gives too much viscosity to mix and hinders whipability Source of oxidized, rancid, and fishy flavor defects	Fresh sweet cream Fresh milk Frozen cream
Milk-solids-not-fat	Improves texture Imparts better body Source of protein, minerals, and vitamins	Improper levels cause "sandiness" defect Source of desirable cooked flavor	Dry milk Fluid whole milk Fluid skim milk Condensed skim milk Skim milk powder, whey products
Sweeteners	Impart sweet flavor	Too much sweetener, especially corn syrup impedes freezing process	Cane sugar, corn syrup solids, high fructose corn syrup

74.2.1.1 Sweet Fresh Cream and Fresh Milk. Whole milk may be used primarily as a source of milk solids. Without question, there is no better source of fat than sweet cream because of its desirable flavor, convenience of handling, and good whipping characteristics. Fresh cream is judged by flavor, acidity, and bacterial count. The titratable acidity should be low and show no evidence of developed acidity. When fresh cream is not available at a favorable cost, alternative sources of fat should be considered.

74.2.1.2 Frozen Cream. The high price of sweet cream during certain seasons of the year makes storage of cream during the months of surplus economically attractive. All known precautions must be used to ensure prevention of the development of off-flavors in stored cream. Only the best cream should be processed for storage, and it should contain no developed acidity. Off-flavors likely to develop in frozen cream are rancid, fishy, oily, and tallowy. Hydrolytic rancidity is due to free butyric acid from the partial hydrolysis of butter fat brought about by enzymatic activity of lipase on the butterfat or by certain bacteria of the enzymes they produce. A proper heat treatment regime, an essential phase for the preparation of cream for freezing, consists of heating cream at 76.7°C for 20 min, or 82.2°C for 10 min, or 87.8°C for 5 min. This treatment not only inactivates the lipase enzyme naturally present in milk but also destroys 95–99% of the bacteria present.

Heat treatment of cream also increases the resistance of the cream to oxidation. A fishy flavor in dairy products results from the formation of trimethylamines by the hydrolysis and oxidation of lecithin, naturally occurring phospholipids in milk. Factors that promote development of this flavor are high acidity and the presence of proxidants (iron or copper salts). Evidently, heat treatment at these times and temperatures "activates" or uncoils the proteins so that sulfhydryl groups are exposed and become oxidized by atmospheric oxygen in preference to the unsaturated fatty acids. Apparently, these sulfhydryl groups function as antioxidants in the liquid system. In addition they may complex with proxidant minerals.

Following heat processing, the cream is quickly frozen. Proper packaging and handling of frozen cream are also important. Preferred packages include stainless steel or plastic

containers. Quick-frozen cream is held at −20°C. Disadvantages of frozen cream include the necessity or thawing before use and the fact that it is messy to handle.

Due to fluctuating supplies and price of cream and the disadvantages of frozen cream some manufacturers rely on unsalted sweet cream butter. Butter is manufactured by agitating or churning cream. Cream is oil-in-water emulsion. The aqueous phase is skim milk. Agitation of cream results in a phase inversion converting oil-in-water emulsion to water-in-oil emulsion. The serum is separated and is called buttermilk. This buttermilk is not to be confused with cultured buttermilk which is a different product. Buttermilk is dried into a powder form and can be used as a source of serum solids in ice cream formulations. Unsalted butter is packaged in 25 kg (56 lb) blocks. Butter for immediate use should be stored refrigerated. For extended shelf life, butter should be stored frozen. To use butter as a concentrated source of milk fat, it requires melting and is considered a processing inconvenience.

In some parts of the world where refrigerated storage is at a premium, butteroil may be used by ice cream manufacturers as a concentrated source of milk fat. Butteroil is manufactured by removing moisture and residual serum solids from unsalted butter. Butteroil is sold in 55 gallon drums and is stored under ambient conditions. During storage, however, milk fat crystallizes and this may necessitate the warming of the oil prior to use in mix making. Butteroil is packed under nitrogen to delay the onset of rancidity.

All other things being equal, the preferred sources of concentrated milk fat (from most to least) are cream, unsalted butter, and butteroil. Choice depends upon availability, economics, local preferences, regulatory factors, and quality of the ingredients.

74.2.2 Concentrated Sources of Serum Solids

Milk solids-non-fat (MSNF) is skim milk solids and these are made up of lactose, protein, and milk salts. Proteins play an important role in emulsification of the fat. Milk proteins also help in developing overrun (aeration). The combination of emulsification and foaming create desirable texture. Proteins also contribute to the viscosity of the mix. Proteins are surface active agents (surfactants). Surfactancy of proteins results in desirable interfacial behavior.

74.2.2.1 Fluid Whole and Skim Milk. Both are excellent sources and should be used in the mix. However, because of their low serum solids content in contrast to the serum solids desired in ice cream mix, their use is limited. Skim milk should be purchased on the basis of a definite MSNF content in order to guard against dilution with water.

74.2.2.2 Plain Condensed Skim Milk. Fresh condensed skim milk is easy and convenient to use, has an excellent flavor. The concentrate may be paid for on the basis of the solids content, which runs around 25–30%. The heat treatment given fluid skim milk is usually the same as the regular pasteurizing range. The keeping quality of condensed skim milk is better than that of cream. It should be stored at 0–1°C and used while fresh and sweet (usually for 7–10 days).

74.2.2.3 Plain Condensed Whole Milk. This is concentrated about two and a half times and contains 8% fat and 20% serum solids.

74.2.2.4 Superheated Condensed Skim or Whole Milk. The use of superheated condensed milk may substitute the use of heat concentrated milk. The already-condensed product is slowly heated to a high temperature, usually in the range of 82.2°C. When properly done, a concentrate of much greater viscosity is obtained, which improves the whipping ability of the ice cream mix and contributes a smooth texture, which then binds more free water. Accordingly, less water is available to form ice crystals during freezing and shelf-life, and the smooth texture of the ice cream is maintained throughout its shelf-life. Superheating, therefore, functions like a stabilizer.

74.2.2.5 Sweetened Condensed Whole or Skim Milk. A sweetened condensed product may sometimes be used as a source of MSNF. This ingredient provides 8.5% fat and 28% total milk solids. The added sugar (40–44%) improves the keeping quality over that of plain condensed milk. With this concentration of sugar, the osmotic pressure of the solution is high enough to suppress the growth of practically all microorganisms. The product will keep at room temperature.

The titratable acidity test should be applied to all condensed milk products. When diluted so as to contain the same MSNF concentration as skim milk, the acidity should be approximately that of fresh skim milk (0.18%).

74.2.3 Balancing Ingredients

In order to balance a formula and make a mix, ingredients such as milk, skim milk, or water may be necessary. This is because a concentrated source of milk fat such as cream will contribute serum solids along with the fat. Similarly concentrated sources of MSNF may also contribute fat to the mix, for example, condensed whole milk. In instances where liquid sugar is used, water in the ingredient may dilute the solids. Therefore a balancing ingredient is necessary.

74.2.4 Sweeteners

Ice cream is a sweet frozen dessert. Its sweetness is due to the presence of sugars and other sweeteners. Sweeteners are classified either as nutritive or nonnutritive.

74.2.4.1 Nutritive Sweeteners. They provide four calories per gram of the sweetener and include sugar (sucrose, saccharose), lactose (milk sugar), dextrose (glucose), fructose (fruit sugar, levulose), corn syrup solids (glucose syrup solids), and high fructose corn syrups, sugar alcohols (xylitol, maltitol, sorbitol, and glycerol). A comparison of the properties of nutritive sweeteners is given in Table 74.5.

Sugar (sucrose). It provides sweetness, depresses freezing point, affects freezing performance, affects body and texture, enhances flavor, and contributes bulk or total solids and impacts on economics. Generally the equivalent of 15% sucrose is considered optimal sweetness in ice cream. In making no-sugar added ice cream and frozen desserts, the bulk contributed by sugar is absent and therefore bulking agents, such as polydextrose, are used. Sugars depress the freezing point of the ice cream mix.

TABLE 74.5 Comparison of Properties of Nutritive Sweeteners.

Sweetener	Relative Sweetness	Solubility (g/100 g) at 25°C	Chemical Type
Sucrose	1.0	67	Disaccharide
Glucose	0.6	51	Monosaccharide
Fructose	1.2–1.8	81	Monosaccharide
Invert sugar	1.0	–	Glucose and fructose
Lactose	0.3	16	Disaccharide
Sorbitol	0.6	72	Sugar alcohol
Mannitol	0.7	18	Sugar alcohol
Xylitol	1.0	64	Sugar alcohol
Corn syrup solids (36 DE)	0.45	70	Mixtures
Corn syrup solids (42 DE)	0.45	70	Mixtures
High fructose corn syrup	1.2	67	Mixture

Liquid Sugar. Liquid sugar is sugar syrup containing 67% sugar and 33% water. It is used by high volume ice cream manufacturers and is sold in rail tank cars or truck load quantities. It can be easily pumped and metered into ice cream mix making operations.

Monosaccharides. Glucose and fructose are simple sugars called monosaccharides. They depress the freezing point of water to a greater extent than disaccharides (sucrose, lactose). They are added as a part of the high fructose corn syrup mixture. High fructose corn syrup contains 45% fructose and 55% glucose and has the same sweetness as sugar. By further refining the proportion of fructose can be increased to 55% fructose, 45% glucose. The resulting product called high fructose corn syrup 55 is slightly sweeter than sugar. An additional refining step can increase the fructose content to 90%. This product is called high fructose corn syrup 90 and is approximately 1.8 times sweeter than sugar.

Sugar Alcohols. Sorbitol and xylitol are examples of sugar alcohols. They depress freezing point to an extent greater than disaccharides and similar to monosaccharides. Glycerol depresses the freezing point to a greater extent than sugar alcohols and ethanol (alcohol) depresses the freezing point to an extent greater than glycerol. These are illustrated in Table 74.6.

Corn Sweeteners. Often corn syrup solids or maltodextrins are added to ice cream mix formulations. Corn sweeteners are derived from the modification of corn starch. Low

TABLE 74.6 Effect of Nutritive Sweeteners on Freezing Point Depression.

Sweetener	Relative Effect
Sucrose	1.0
Lactose	1.0
Dextrose	1.82
Fructose	1.82
55% High fructose corn syrup	1.85
Sorbitol	1.90
Glycerol	3.70
Alcohol	7.40

conversion corn syrups are 23–38 dextrose equivalents (DE). DE is a measure of the extent of hydrolysis or modification of starch. Regular conversion syrups are 38–38 DE, intermediate conversion syrups are 48–58 DE, and high conversions are 58–68 DE. These products are not as sweet as sugar but they contribute total solids to the mix. By increasing total solids to the mix heat shock protection is provided.

Other Nutritive Sweeteners. Honey is used as a sweetener. Honey is like invert sugars. It is made up of glucose and fructose, both monosaccharides, therefore it depresses freezing point to a greater extent than sugar at equivalent concentrations.

Maltodextrins. In certain low fat and no fat mixes as well as no sugar added mixes, maltodextrins of 5 or 10 DE are used to provide solids in the mix without adversely affecting the freezing point of the mix. These products are also derived from corn starch and the modification of the starch is to a much lesser extent than with maltodextrins. Typically the DE ranges from 5 to 15 for maltodextrins.

74.2.4.2 Nonnutritive Sweeteners. No sugar added products are ice cream and frozen desserts in which no sugars are added to achieve sweetness. Such formulations rely on the addition of intense nonnutritive sweeteners. The intense sweeteners that do not provide any significant calories at use levels. They include sucralose, aspartame, saccharin, cyclamates, Acesulfame-K, and many others. As little as 0.07% aspartame can provide the sweetness equivalent to 15% sugar. By reducing the mass of the formulation by 14.93% we have more water in the formulation to control. In order to make up this difference bulking agents are used. One common bulking agent is polydextrose. Additionally, removal of sugar increases the freezing point of the mix. Therefore, to lower the freezing point sugar alcohols are used. A third adjustment necessary for no sugar added formulations is the increased levels of stabilizers in the formulation. A comparison of the non-nutritive sweeteners is provided in Table 74.7.

A typical formula for a no sugar added low fat ice cream would contain 3% fat, 12% MSNF, 8.0% polydextrose, 5% 10 DE maltodextrin, 1.2% microcrystalline cellulose, 0.35% stabilizer and emulsifier, 0.07% aspartame, and 2.0% sorbitol. The total solids would be 36.62%. This mix would freeze at 27°F (2.7°C).

74.2.5 Stabilizers and Emulsifiers

Apart from sweeteners, stabilizers, and emulsifiers are also important nondairy ingredients. The term stabilizer is used for a group of substances that help stabilize the structure

TABLE 74.7 Comparisons Among Nonnutritive Sweeteners.

Sweetener	Relative Sweetness	Solubility (g/100g) at 25°C
Saccharin	250–550	125
Cyclamate	30–50	Not known
Aspartame	120–200	1
Acesulfame-K	100–130	27
Alitame	2000	17
L-sugars	1.0	67
Sucralose	500–700	30

of ice cream. Other names include colloids, hydrocolloids, and gums, which indicate that these substances are large molecules (macromolecules) that are capable of interacting with water. By interacting with water also lets some of these compounds interact with proteins and lipids in the mix. A variety of materials are used as stabilizers. These include gelatin, guar gum, sodium carboxymethylcellulose, microcrystalline cellulose, locust bean gum (carob), and carrageenan. During mix processing, presence of gums affects mix viscosity and homogeneity, during freezing gums exert secondary effects in dryness and stiffness of ice cream and in the finished frozen desserts, it controls the properties of the water that is unfrozen. This last point means that ice cream is smoother and ice crystals take longer to grow in the presence of stabilizers especially during storage and distribution of these products. Usually, stabilizers are used at 0.1–0.5% levels in the mix but the actual amount depends on the type of stabilizer, strength of the stabilizer, total solids and fat level of the mix, duration and temperature of storage of ice cream and the method of pasteurization. High fat and high total solids mixes require lesser level of stabilizers. More stabilizer is needed for ice cream that is stored for a long period of time or if the temperature fluctuation during storage is frequent. If the mix is pasteurized by the high temperature short time method, more stabilizer may be needed than if the same mix were pasteurized by the batch method or by ultra high temperature method.

74.2.5.1 Stabilizers. A good stabilizer should be non toxic, readily disperse in the mix, not cause excessive viscosity, separation or foam in the mix, not clog strainers and filters, provide ice cream with good meltdown, be economical, and not impart off-flavor to the mix. Some of the common stabilizers and their characteristics are listed below.

Gelatin. It is an animal protein derivative and is effective at high concentrations of 0.3–0.5% and is expensive and therefore rarely used in the United States. It may not prevent the effects of heat shock. It is also not acceptable to certain religious and vegetarian segments of the population. If gelatin is used as a stabilizer, a long aging period for the mix is necessary. Gelatin disperses easily and does not cause wheying off or foaming.

Guar Gum. This stabilizer is derived from the seeds of a tropical legume called guar. It is the least expensive of the stabilizers and effectively mitigates the undesirable changes in ice cream due to heat shock. It readily disperses in the mix and does not cause excessive viscosity in the mix. Typically 0.1–0.2% is required in a mix and therefore this substance is considered to be a strong stabilizer.

Sodium Carboxymethyl Cellulose (CMC). This is a chemical derivative of cellulose. Cellulose is the most abundant carbohydrate in nature. CMC causes mix separation and therefore it is often blended with carrageenan to prevent wheying off. It is a strong stabilizer. Only 0.1–0.2% is need in a mix. It imparts body and chewiness to ice cream.

Locust Bean Gum. This is also derived from a plant seed and is also known as carob seed gum. It is a strong stabilizer and is used at 0.1–0.2% levels. Mix containing locust bean gum separates or wheys off during storage. It also does not fully hydrate in high temperature short time pasteurized mixes.

Carrageenan. This stabilizer is derived from a sea weed *Chondritis crispus*. It is used in many stabilizer blends at levels of 0.01–0.02%. This stabilizer reacts with milk proteins and thereby prevents wheying off in mixes.

74.2.5.2 Emulsifiers. As opposed to stabilizers, emulsifiers exert their action on the fat phase of ice cream. Emulsifiers are surface active agents (surfactant). Fat and water do not mix. Emulsifiers facilitate the mixing of fat and water because these molecules have two domains, one that likes water (hydrophilic), and another that likes fat (hydrophobic). When the hydrophobic part of a surfactant interacts with the fat, the water-loving part of the molecule can interact with water, thus facilitating the suspension of fat in water. Generally mono- and diglycerides and ethoxylated esters of sorbitol (polysorbates) are the commonly used emulsifiers. Mono - and diglycerides are derived from fatty acids and glycerol. Therefore, emulsifiers are fatty substances. They also show fat like properties of melting point, crystallinity, and they can be composed of saturated or unsaturated fatty acids. Presence of emulsifiers in ice cream leads to smoother texture and better shape retention, while improving the ability of the mix to incorporate air.

Mono- and Diglyceride Mixtures. These compounds are obtained by the chemical treatment of fats such as lard, palm kernel or soybean oil. Most of the mono- and diglycerides are solid at room temperature and are added to the mix prior to pasteurization at a level of 0.1–0.2%. Emulsifiers with high monoglyceride content are also effective drying agents.

Polysorbates. Polysorbates are polyoxyethylene compounds. These synthetic chemicals are the most effective drying agents. Polysorbate 80 is an oleic acid derivative. It is very powerful drying agent and is used at 0.04–0.07% levels. Polysorbate 65 is helpful as a whipping agent, that is, it helps in air incorporation. To obtain comparable stiffness, more polysorbate 65 has to be used than polysorbate 80. At high levels, polysorbate 80 imparts off-flavors whereas polysorbate 65 does not. Polysorbates are generally liquids and cause churning of the mix.

Egg Products. Dried or frozen egg yolks are used to produce dry, stiff ice cream. Dried egg yolks are harder to incorporate into a mix than frozen and sugared egg yolks. The general use level of egg yolks is 0.3–0.5%. If a French-style or custard is required, a minimum of 1.4% egg yolk solids are necessary. Lecithin, a phospholipid present in egg yolks is thought to act as the emulsifier. Lecithin can also be derived from soybean oil.

Buttermilk Powder. Buttermilk powder provides phospholipids which can act as emulsifiers.

74.3 MIX CALCULATIONS

Once a formula has been finalized, a recipe has to be created. Formulas specify composition of the desired mix in terms of percentages of fat, MSNF, sweeteners, stabilizers, and emulsifiers. A recipe calculates the weight and/or volumes of ingredients needed to meet the formula requirements. These calculations are called mix calculations.

Mix calculations are essential for manufacturing consistent quality finished products. When composition of raw materials varies or the economics of ingredients changes, the recipe for making an ice cream mix has to change. Further this change has to occur in a manner that the finished product composition is not altered. In some instances changing regulatory definitions and health claims may necessitate manufacture of products to carefully defined specifications. Mix calculations are important in standardizing mixes prior to

freezing. Ice cream plants now use computer software programs to calculate the amounts of various ingredients to conform to required specifications of composition of ice cream mix. However, for basic understanding, we will discuss below the fundamentals of the mix calculations.

Mix calculations can be performed by Pearson's Square, algebraic methods, and arithmetic methods. Pearson's Square is of limited utility, algebraic methods are complicated and involve the use of simultaneous equations and matrices. Arithmetic calculations are simpler and require fewer computations than algebraic method. In this section all three methods will be discussed. Prior to calculating a mix, certain preliminary steps have to be completed.

Several factors are important in mix calculations.

1. Composition of the mix has to be specified. Mix composition clearly states the percentage of fat, MSNF, sugar, other sweeteners, stabilizers and emulsifiers, and alternate ingredients. For example a typical mix composition would be milk fat 10.1%, MSNF 10%, sugar 8.0%, high fructose corn syrup 4%, corn syrup solids (36-DE) 5.0%, stabilizer, 0.3%, emulsifier 0.2%. The total solids of this mix are 37.6%. Although not specified explicitly, the water content of this mix is $100 - 37.6 = 62.4\%$.
2. The source of the ingredients should also be specified. For example milk fat will be derived from cream, MSNF from condensed skim milk, and so on.
3. The amount of mix to be made must also be determined. Generally if volumetric amounts are known (e.g., 100 L or 100 gallons), these quantities have to be converted to weight equivalents of kilograms or pounds. Specific gravity or density of the mix would have to be known.
4. In order to make an ice cream mix, three categories of ingredients are essential. These are (a) a concentrated source of milk fat, (b) a concentrated source of MSNF, and (c) a balancing ingredient.
5. In order to perform mix calculations, determine the composition of the mix to be made, list the available ingredients and their compositions, and list the amount of mix to be made in weight equivalents. Then perform calculations.
6. After performing calculations verify or validate the calculations by constructing a proof sheet.
7. Make the mix according to calculated amounts of the ingredients and test to make sure that the desired composition has been attained. If required, standardize the mix to obtain the desired composition.

74.3.1 Terms Used in Mix Calculations

Serum in dairy ingredients (milk, skim milk, cream, condensed skim milk, condensed whole, etc.) is the fat-free portion of that ingredient.

$\%$ Serum $= 100 - \%$ milk fat
$\%$ Serum $= \%$ MSNF $+ \%$ moisture
If fat is considered to be 0 in skim milk, serum in skim milk is $100 - 0 = 100$
Serum in 3.5% fat milk is $100 - 3.5 = 96.5$
Serum in nonfat dry milk (skim milk powder, assuming 0% fat) is $100 - 0 = 100$
Serum in sweetened condensed skim milk with 0% fat, 25% sugar is $100 - 25) = 75$

Serum in sweetened condensed whole milk with 8% fat and 40% sugar is $100 - (8 + 40) = 52$

Serum in ice cream mix is calculated slightly differently than serum in milk ingredients.

Percent serum in ice cream mix = 100 − (% milkfat + % sweeteners + % stabilizers/emulsifiers + other nondairy solids).

Serum in an ice cream mix with 10.1% fat, 10% MSNF, 8% sugar, 4% high fructose corn syrup, 5% corn syrup solids, and 0.3% stabilizer, and 0.2% emulsifier is: $100 - (10.1 + 8 + 4 + 5 + 0.3 + 0.2) = 100 - 27.6 = 72.4$.

Weight of product multi % of constituent as a decimal = weight of a constituent.

Example 1. Make 100 lb mix to contain 15% sugar, 0.35% stabilizer, 0.5% egg yolk solids, 12.5% fat, and 11% serum solids. Available ingredients are 40% fat cream, 3.5% fat milk, 8% fat, and 20% serum solids condensed milk.

Solution 2: For 100 lb mix, 15 lb sugar, 0.35 lb stabilizer, and 0.5 lb egg yolk solids are needed. Therefore $100 - (15 + 0.35 + 0.5) = 84.15$ lb has to be derived from cream and condensed milk.

Let $x = 40\%$ cream, $y = 3.5\%$ milk, and z = condensed milk. It follows that

$$x + y + z = 84.15 \tag{1}$$

We know that the total fat content must be 12.5 lb Therefore,

$$0.4\,x + 0.035\,y + 0.08\,z = 12.5 \tag{2}$$

Also we know that serum solids needed is 11% so

$$0.053\,x + 0.085\,y + 0.20\,z = 11 \tag{3}$$

Thus, we have three simultaneous equations for three unknowns. Eliminate an unknown by expressing in terms of other unknowns.

$$x + y + z = 84.15 \tag{1}$$

$$x = 84.15 - y - z \tag{1a}$$

Substituting this value for x in Eq. 2 we get.

$$0.40(84.15 - y - z) + 0.035\,y + 0.08\,z = 12.5 \tag{2a}$$

Simplifying Eq. 2a, it converts to

$$36.5\,y + 32\,z = 2116 \tag{2b}$$

Similarly Eq. 3 becomes

$$0.053(84.15 - y - z) + 0.085\,y + 0.20\,z = 11 \tag{3a}$$

Conversion of Eq. 3a results in

$$3.2\,y + 14.7\,z = 654.005 \tag{3b}$$

If we wish to eliminate one of the equations in (2b) and (3b) it is necessary that the multiples of unknowns which we wish to eliminate be the same in both equations. If we wish to eliminate y, then the multiples of y must be the same in both equations. This condition is obtained as follows:

Multiply Eq. 2b by 3.2 to obtain Eq. 2c and multiply Eq. 3b by 36.5 to obtain Eq. 3c.

$$116.8\,y + 102.4\,z = 6771.2 \tag{2c}$$

$$116.8\,y + 536.55\,z = 23871.18 \tag{3c}$$

Subtract Eq. 3c from Eq. 2c and the result is:

$$434.15\,z = 17099.98 \tag{4}$$

$z = 17099.98$, $434.15 = 39.39$ lb of condensed milk.

Solve for y by substituting this value for z in either Eq. 2b or Eq. 3b. Substituting in Eq. 2b we get:

$$36.5\,y + (32 \times 39.39) = 2116$$

$$36.5\,y = 855.52$$

$y = 855.52$ 36.5 = 23.44 lb 3.5% fat milk.

By substituting found values of y and z in Eq. 1 we get:

$$x + 23.44 + 39.39 = 84.15$$

$x + 84.15 - (23.44 + 39.39) = 84.15 - 62.83 = 21.32$ lb cream.

To validate the calculation let us construct a proof table.

Weight	Ingredient	Fat	Serum Solids
15.0	Sugar	0.00	0.00
0.035	Stabilizer	0.00	0.00
0.50	Egg yolk solids	0.00	0.00
21.32	Cream	8.5280	1.1299
23.44	Milk	0.8204	1.9924
39.39	Condensed milk	3.1512	7.8780
100.00	Total calculated	12.4996	11.0003
100.00	Total desired	12.5000	11.0000

74.3.2 Arithmetic Method

This method relies on two main types of equations. One is called the serum point formula and is useful when fat is derived from only one ingredient. The other is called milk and cream formula and is used when multiple sources of fat are involved.

74.3.2.1 Serum Point Formula.

This equation is used to calculate the amount of concentrated source of serum solids need for a mix recipe.

$$\frac{\text{lb serum solids needed} - (\text{lb serum of mix}) \times 0.09}{\text{lb serum solids of 1 lb condensed} - (\text{lb serum of 1 lb condened}) \times 0.09}$$

The terms serum solids needed are given in mix composition, the word condensed simply means concentrated source of MSNF. This equation contains both terms *serum* and *serum solids*.

74.3.2.2 Milk and Cream Formula

$$\frac{\text{lb fat needed} - (\text{lb milk} + \text{cream needed}) \times (\text{lb fat of 1 lb milk})}{\text{lb fat of 1 lb cream} - \text{lb fat of 1 lb milk}}$$

The milk and cream formula is used in instances where fat is supplied by more than one source in the same recipe.

1. A 1000 lb ice cream mix is composed of the following ingredients:

Ingredient	*Lb*
40% fat cream	237.3
4% fat milk	376.9
29% SS/MSNF condensed skim milk	222.8
Sugar	160.0
Stabilizer/emulsifier	3.0

   (a) Enter the pounds of each ingredient into a proof table.
   (b) Calculate the pounds of each constituent contributed by each ingredient. Constituents are fat, MSNF, sugar, stabilizer/emulsifier.
   (c) Total the pounds in each of the constituent columns of the proof sheet and calculate the percentage composition to the nearest hundredth percent of each of the mix constituents.

Answers:

a. Pounds of milk fat from cream = 237.3 × 0.40 = 94.92 lb
b. % Serum solids in cream = 100 − 40 = 60 × 0.09 = 5.4%
c. Pounds of serum solids in cream = 237.3 × 0.054 = 12.81 lb
d. Pounds of total solids in cream = 94.92 + 12.81 = 107.73 lb
e. Pounds of fat from milk = 376.9 × 0.04 = 15.08 lb
f. % Serum solids in milk = 100 − 4 = 96 × 0.09 = 8.64%
g. Pounds of serum solids in milk = 376.9 × 0.0864 = 32.56 lb
h. Pounds of total solids in milk = 15.08 + 32.56 = 47.64 lb
i. Pounds of milk fat in condensed skim milk = 0.0
j. Pounds of serum solids in condensed skim milk = 222.8 × 0.29 = 64.61 lb
k. Pounds of total solids in condensed skim milk = 64.61 lb
l. Pounds of sugar = 160 lb

m. Pounds total solids of sugar = 160 lb
n. Pounds of stabilizer/emulsifier = 3 lb
o. Pounds of total solids of stabilizer/Emulsifier = 3 lb
p. Total pounds of mix = 237.3 + 376.9 + 222.8 + 160 + 3.0 = 1000
q. Total pounds of milk fat = 94.92 + 15.08 = 110.0
r. % Milk fat = 110/1000(100) = 11.0%
s. Total pounds of serum solids = 12.81 + 32.56 + 64.61 = 109.98
t. % Serum solids = 109.98/1000(100) = 10.998 or 11.0%
u. Total pounds of sugar = 160
v. % Sugar = 160/1000(100) = 16%
w. Total pounds of stabilizer/emulsifier = 3
x. % Stabilizer/emulsifier = 3/1000(100) = 0.3%
y. Total pounds of solids in mix = 382.98
z. % Total solids of mix = 382.98/1000(100) = 38.298 or 38.3%

74.3.3 Mix Proof Sheet

Desired Formula		Available Ingredients
___% Milk fat	237.3 lb	40% fat cream
___% Milk solids not fat	376.9 lb	4% fat milk
___% Sucrose	222.8 lb	Condensed milk 29% MSNF (SS)
___% Corn syrup solids	160.0 lb	Sugar
___% Stabilizer	3.0 lb	
Stabilizer/emulsifier		
___% Emulsifier		
___% Total solids		
___Lb of mix		

Ingredient	Quantity (lb)	Milk Fat (lb)	Serum Solids (lb)	Sucrose (lb)	Corn Syrup Solids (lb)	Stabilizer (lb)	Emulsifier (lb)	Total Solids (lb)
40% fat cream	237.3	94.92	12.81					107.73
4% fat milk	376.9	15.08	32.56					47.64
29% MSNF condensed milk	222.8	0.0	64.61					64.61
Sugar	160.0			160.0				160.0
Stabilizer/ emulsifier	3.0					3.0		3.0
Total	1000.0	110.0	109.98	160.0		3.0		382.98
Percent	100	11.0	11.0	16.0		0.3		38.3

Example 2. Calculate the amount of ingredients needed to make 100 lb of an ice cream mix:

Desired Composition	Available Ingredients
10.00% Milk fat	30% fat cream
12.00% MSNF	Skim milk
15.00% Sugar	Condensed skim milk (27%MSNF)
0.30% Stabilizer/emulsifier	Sugar
37.3% Total solids	Stabilizer/emulsifier

Fill in the attached proof sheet and provide all calculations supporting your solution.

a. Pounds of serum solids needed $= 100 \times 0.12 = 12.0$
b. Pounds of serum of mix $= 100 - (10 + 15 + 0.3) = 100 - 25.3 = 74.7$
c. Pounds of serum solids of 1 lb condensed $= 27/100 = 0.27$

$$\frac{\text{lb serum solids needed} - (\text{lb serum of mix}) \times 0.09}{\text{lb serum solids of 1 lb condensed} - (\text{lb serum of 1 lb condened}) \times 0.09}$$

d. Pounds of condensed skim needed $= \{12 - (74.97 \times 0.09)\}/\{0.27 - (1.0 \times 0.09)\} = (12 - 6.723)/(0.27 - 0.09) = 29.32$
e. Pounds of cream needed $= 10/0.3 = 33.33$
f. % serum in 30% cream $= 100 - 30 = 70$
g. % Serum solids in cream $= 70 \times 0.09 = 6.3$
h. Pounds serum solids in cream $= 33.33 \times 0.063 = 2.09979$ or 2.10
i. Pounds of skim milk required (by difference) $= 100 - (33.33 + 29.32 + 15.0 + 0.3) = 22.05$
j. Pounds serum solids in skim milk $= 22.05 \times 0.09 = 1.9845$ or 1.98
k. Pounds of sugar needed $= 100 \times 0.15 = 15$
l. Pounds of stabilizers/emulsifiers needed $= 100 \times 0.003 = 0.3$

Desired Formula	Available Ingredients
10.0% Milk fat	30% fat cream
12.0% Milk solids not fat	Skim milk
15.0% Sucrose	27% MSNF condensed skim
0.0% Corn syrup solids	Sugar
0.3% Stabilizer/% emulsifier	Stabilizer/emulsifier
37.3% Total solids	
100 Lb of mix	

Ingredient	Quantity (lb)	Milk Fat (lb)	Serum Solids (lb)	Sucrose (lb)	Corn Syrup Solids (lb)	Stabilizer (lb)	Emulsifier (lb)	Total Solids (lb)
30% fat cream	33.33	10.0	2.10					12.10
Skim milk	22.05		1.98					1.98
27% MSNF condensed skim	29.32		7.92					7.92
Sugar	15.0			15.0				15.00
Stabilizer/ emulsifier	0.3					0.3		0.30
Total	100.0	10.00	12.00	15.00		0.30		37.30
Percent	100	10	12	15		0.3		37.30

74.4 PROCESSING

Figure 74.1 shows various steps involved in the manufacture of ice cream. Knowing a mix specification, mix calculations are performed to determine the amounts of desired ingredients needed to formulate the mix. Mix processing begins with the assembly of the necessary ingredients in the desired amounts. Generally this assembly requires weighing the ingredients or if liquid ingredients are used they are metered. Meters rely on knowing the density or the specific gravity of the ingredient and these values are highly temperature dependent. In most small scale operations weighing is the method of choice.

74.4.1 Blending

In the next step the ingredients are blended together. Mix blending can be performed at refrigeration temperatures 40°F (4°C) or at warmer temperatures 113°F (45°C). Cold batching is preferred method when cream, liquid milk, condensed skim are the ingredients. Warmer temperatures are generally used when the ingredients include butter, butteroil/ anhydrous milkfat in combination with nonfat dry milk. Batching begins by placing a liquid ingredient in a vat. Generally this ingredient is skim milk (balancing ingredient), or water. The dry ingredients such as corn syrup solids, maltodextrins, sugar, stabilizers, and emulsifiers are incorporated into this liquid and finally cream is added. When cream is subjected to excessive shear it can be churned to butter. This should be avoided. Incorporation of the dry ingredients is aided by one of two types of devices, namely, (a) powder horn, and (b) high shear mixers. The powder horn is the easiest device and consists of a funnel with a valve placed in line with a pump and capable of recirculating the liquid in the vat (Fig. 74.2).

With the valve closed, the dry ingredient is placed in the funnel, the pump is started and once the fluid is recirculation, the valve under the funnel is opened. As the liquid flows past the funnel it inspires (sucks in) the powder. The mixture of the powder and the liquid hits the impeller of the centrifugal pump which facilitates the dispersion of the powders. The dispersed powder enters the vat and is recirculated. This process continues until such time

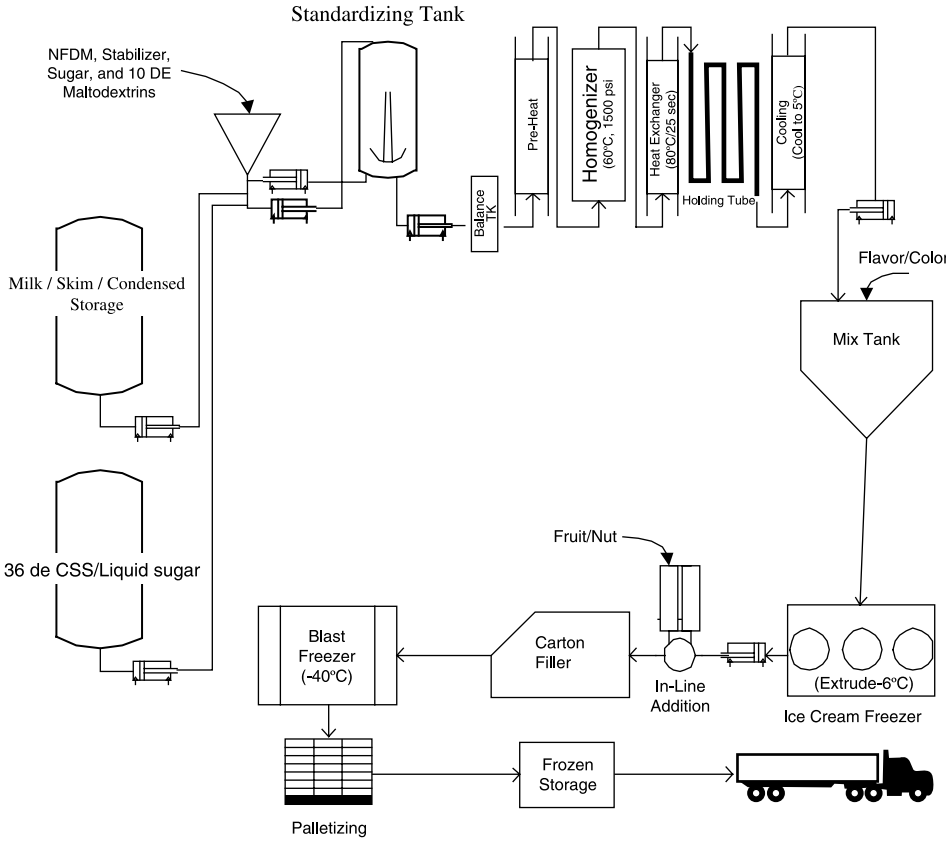

Figure 74.1 *Flow sheet diagram for the manufacture of ice cream.*

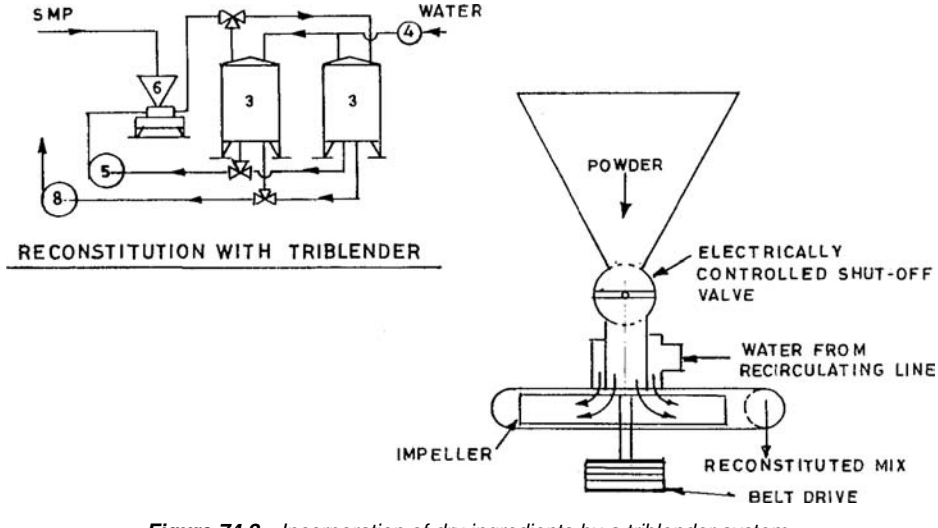

Figure 74.2 *Incorporation of dry ingredients by a triblender system.*

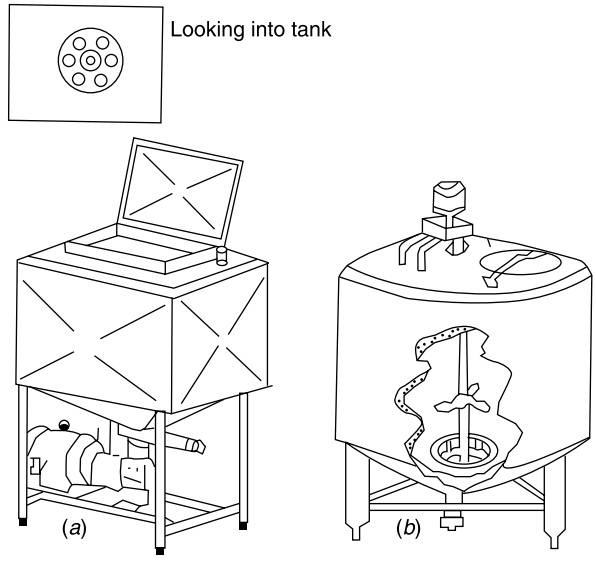

Figure 74.3 *High shear mixing devices (a) Likwifier and (b) turbine blender.*

that all of the powder has been incorporated into the process fluid and then the valve beneath the funnel is closed. If this valve is not closed a large amount of air can be inspired into the mix creating foam which is undesirable.

In the second process (Fig. 74.3) a high shear mixer that functions like a giant Waring blender is used.

Here the process fluid is filled to three-quarters of the volume of the blender. The motor is turned on and under vigorous agitation the dry ingredients are incorporated into the mix. Once all the dry ingredients are incorporated, the mixture is discharged into a vat. The hardest ingredients to incorporate are the stabilizers and emulsifiers. If they are not properly handled they form lumps and are not uniformly dispersed in the mix. Excess agitation is undesirable in suspending these ingredients. Generally, mixing stabilizers with dry sugar and corn syrup solids aids in a uniform hydration and suspension of these ingredients.

74.4.2 Pasteurization

The hydrated ingredients are pasteurized and homogenized. Pasteurization is a heat treatment given to food products to destroy pathogenic (disease causing) microorganisms. According to the U.S. Public Health Service and its Pasteurized Milk Ordinance, pasteurization of an ice cream mix requires that every drop of mix be heated to 155°F (68.3°C) and held at that temperature for 30 min. Alternately, every drop of mix should be heated to 175°F (79.4°C) and held at that temperature for 25 s. Pasteurization can be performed either as a batch operation or as a continuous operation.

The batch pasteurization is carried out in a specially designed and approved vat. A batch of mix is placed in the vat and pasteurized by heating the mix to a minimum of 68.3°C (155°F) and once that temperature is attained, it is held for 30 min prior to homogenization and cooling. This process is also known as the low-temperature-long-time (LTLT) method of pasteurization.

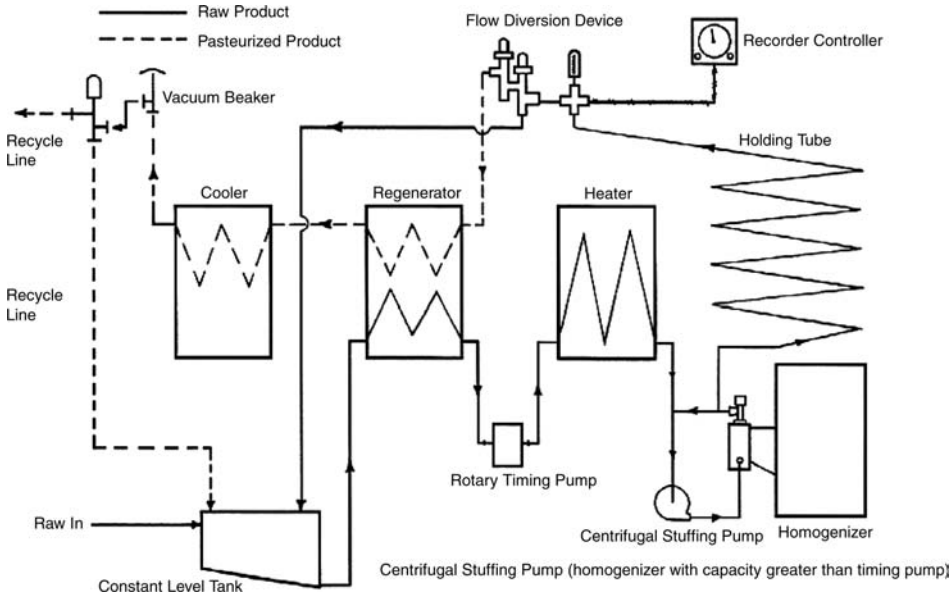

Figure 74.4 *Schematic of a high temperature short time pasteurizer with timing pump and homogenizer.*

In the continuous process, a plate heat exchanger is used. This heat exchanger has three sections called (a) regeneration, (b) heating, and (c) cooling sections. In this process the mix is heated to a minimum temperature of 79.9°C (175°F) and held for 25 s; raw cold mix enters the regeneration section where it is heated by the hot pasteurized mix. The warm raw mix is then homogenized and heated by hot water to 79.9°C (175°F). The heated mix flows through a tube called the holding tube for 25 s. Then it has to pass through two controls known as the flow diversion devices. If the mix is cooled to below 79.9°C (175°F) during the holding, these flow diversion devices sense this and send the mix to be repasteurized. Once the mix successfully flows past the flow diversion devices, it enters the regeneration section where it gives off some of its heat to the incoming raw mix. Thus the regeneration section is an energy saving device. The pasteurized side of the plate is maintained at a minimum pressure differential of 2 psi so that raw mix cannot contaminate the pasteurized mix. The partially cooled mix then goes to the cooling section where it is cooled to 4°C (40°F). One schematic of a continuous pasteurizer also called a high temperature short time (HTST) is shown in Figure 74.4.

74.4.3 Homogenization

The process of homogenization has been referred to during the pasteurization step. Homogenization of an ice cream mix results in a smoother eating ice cream. It is a process whereby fat droplets in the mix are reduced to a uniform size. In unhomogenized ice cream mix, the average fat droplet size would be around 2–4 μm. Homogenization breaks down the fat globules to an average size of 1 μm or less. One micrometer is 1/25,000th of an inch, a size not visible to the naked eye. In order to homogenize the ice cream mix, all the fat must be in the liquid state. Therefore homogenization is performed

on hot mix. In a LTLT (batch) pasteurization system, the homogenization is done after the heating and holding of the mix at a temperature of around 68.3°C (155°F). In the HTST system of pasteurization, homogenization can be performed either after the mix is warmed up in the regeneration section where mix temperature is around 62.7°C (145°F) or after the mix is pasteurized prior to entering the regeneration section when the temperature is 79.9°C (175°F). It is preferable to homogenize prior to pasteurization. The typical pressures for homogenization are 2000 psi first stage and 500 psi second stage. In high fat mixes, high acid mixes, chocolate mixes, and mixes with high amounts of egg yolk, homogenization pressures are reduced to 1200 psi first stage and 500 psi second stage.

74.4.4 Aging

The pasteurized, homogenized mix then is aged in a refrigerated vat. Aging is a process of quiescent storage of the mix with intermittent agitation for a period varying from 3 h to 16 h. During the aging process, the fat crystals that melted during pasteurization recrystallize, the gums or stabilizers also complete their hydration process and the proteins complete their adsorption at the fat/water interface. In the days when gelatin was used as the primary stabilizer in ice cream, aging times of 12–20 h were recommended. Modern day stabilizers do not use gelatin and require far less time to complete their hydration. A minimum aging time of 2–4 h is recommended.

74.4.5 Flavors

Flavor is the most important esthetic attribute of a food and ice cream is no different. Ice cream differs from other food products in that it has no preconditioning flavor like some other foods do. The flavor of ice cream will only become apparent when the product is in the mouth and undergoes melting. You can smell ice cream and not be able to discern the flavor of the frozen product. The term flavor is composed of two important attributes, namely, taste and aroma. In the tasting of ice cream, all five senses are used. The sense of sight is used to determine the color of the product, homogeneity of the product and sometimes one may observe ice crystals at the surface. The sense of touch is employed because when ice cream enters the mouth one can sense its temperature that it is cold and smooth. The sense of hearing may also be employed as the ice cream is moved around in the mouth and masticated sound travels along the jawbone to the ear canal and such things as crunchiness of ice crystals can actually be heard. The other two senses, smell and taste are the basis of flavor experience. The flavor of ice cream can be treated analogous to the ubiquitous computer. Sensory evaluation involves an input in the form of stimulation. The brain is the microprocessor that transforms these sensations and the out put is the reaction of like, dislike and so on. Since the subject has psychological and physiological variations, the response is not as reproducible as that of an instrument. Therefore, statistical techniques are employed to understand the consistency of reactions of the fickle instrument called the human brain. This chapter will not delve into the intricacies of sensory evaluation.

Flavor is an important attribute of a food. It is a sensory response that has three components, olfaction (odor/smell), gustation (taste), and tactual (mouthfeel). Ice cream is cold, creamy, refreshing, and sweet, and releases aroma upon melting in the mouth. When the word "flavor" is used in everyday parlance we imply taste and olfaction. Taste compounds are sweet, salty, bitter, and sour. Generally compounds imparting

these tastes can be detected at levels of 0.01–0.5. Olfactory compounds (smelly stuff) are volatile and have thresholds in the parts per million to parts per trillion range. Threshold is defined as the minimum concentration that at least 50% of the population can detect. Threshold of aroma compounds are 10 to 10 million times less than taste compounds.

Perception of aroma is affected by the composition, physical structure and temperature of the food. Undesirable flavors are called off-flavors. Off-flavors affect the overall flavor qualities of the food. Deteriorative reactions are time dependent and cumulative. Therefore, the length and conditions of storage has a profound influence on the perception of overall flavor. These deteriorative reactions occur in ingredients used in ice cream manufacture. Therefore, careful attention should be paid to the quality of ingredients used in ice cream manufacture.

In eating ice cream, whether you lick, bite, or chew, ice and fat melt. Melting of these two constituents leads to the collapse of the air cell. Upon collapse of the air cell, flavor volatiles are released. Flavor volatiles traverse the palette and enter the olfactory membrane. The brain then recognizes the signal and processes it. An ice cream mix is compounded and processed to obtain a neutral flavored base. This base has the ability to acquire any characterizing flavor added to it. This neutrality of flavor also means that if the mix is mishandled it can easily absorb off flavors. The ice cream mix contains fat, MSNF, sweeteners, stabilizers, and emulsifiers, and in some instances other additives. The preferred source of fat is milk fat and the flavor quality of cream and milk should be carefully monitored. If milk fat is improperly handled, off-flavors can easily result. When the source of fat is other than milk, other flavors may be present. Most flavor compounds are fat soluble. Milk solids-not-fat sources contribute a slightly salty note but can also contribute to stale, caramelized, old ingredient flavor notes. Off-flavors from whey solids and buttermilk solids should be avoided by using fresh supplies of these ingredients. The most common sweetener used is sugar. Sugar helps augment certain flavors. Corn syrup solids and high fructose corn syrup solids are also used as sweeteners. These could contribute a syrupy flavor and may mask the delicate flavor notes of some other ingredients. Mix processed in batch processors is particularly prone to this syrupiness. Stabilizers rarely pose flavor problems but by increasing the viscosity may slow the release of delicate flavors. Emulsifiers rarely pose flavor problems unless they are old. Rotating stocks and inventory control can avoid these problems.

Determining how much flavoring to add is always important. Know what your customers like. There are regional preferences for flavors and intensities of flavors. As a rule of thumb, higher the fat content of the mix, more the flavoring required. Also batch pasteurized mixes, especially if they contain egg yolk solids, require more flavoring HTST pasteurized mixes. Always test the effectiveness of the added flavor in the ice cream and not by judging the quality of flavored mix.

Flavors are added in at least three different ways, namely, (1) directly to the mix prior to freezing (e.g., vanilla, chocolate, mint), (2) immediately post freezing (fruit pieces, nuts, candy, and confectionery pieces); or (3) postfreezing prior to packaging (ripples and variegates). Modern flavoring systems are complicated and may use all three of these modes of flavoring in the same ice cream. The most popular flavors are vanilla, chocolate, fruits, nuts, bakery goods, confectionery items, and ripples or variegates. Nearly 30% of the ice cream manufactured is vanilla.

Vanilla is a standardized food. It is the only flavoring substance to be so classified. According to the Food and Drug Administration, single fold vanilla extract must contain 13.8 oz vanilla bean material in 70 proof alcohol. Ice cream made with pure

vanilla extract is labeled Category I as vanilla ice Cream. Ice cream flavored with a mixture of vanilla extract and vanillin (a mixture of natural and artificial with the natural predominating) is labeled as Category II ice cream or vanilla flavored ice cream. The third type is called Category III and consists of any vanilla that is not Categories I and II. Such a product is labeled as artificially flavored vanilla ice cream.

Vanilla is the bean of the only edible orchid *Vanilla plantifolia Andrews*. The bean only grows around the equatorial belt. Mexico, Madagascar, India, Indonesia, and The Comoros are all good growing areas for the vanilla orchid. The beans produced from the orchid are cured and shipped to countries where the flavor is extracted using alcohol and water.

Chocolate is another popular flavor. Chocolate is derived from the beans of a plant called *Theobroma cacao*. This plant also grows in the equatorial regions of the world and countries. Ghana, Ivory Coast, Brazil, Cameroon, Indonesia, Malaysia are all noted for the production of cocoa beans. Beans contain fat and other materials. Once fat is extracted cocoa powder is the residue. Cocoa powders can either contain 10/12% fat or 22/24% fat. Cocoa powders still contain fiber which can be removed by alkalizing the powder. This process is also known as "Dutch Cocoa." The most common flavoring material is 10/12 cocoa for light, low and no fat ice creams whereas 22/24% cocoa is used for regular ice cream.

Fruit flavors are popular and can be added as extracts, essences often with other natural flavors (WONF). Fresh fruit of good quality can also be added and slightly overripe fruits are preferred for this purpose. However fruits are seasonal horticultural products. The allure of fruit flavored ice cream is to eat it when the fruits are not in season. To accomplish this fruits are sliced and packed with sugar and frozen. Generally one part of sugar is added to three parts of fruit (three plus one pack) or one part of sugar per four parts of fruit (four plus one pack). Sugar is added to protect the fruit during the freezing process. The frozen fruits have to be thawed prior to adding to ice cream. Some fruits such as, strawberries, cherries, and pineapple can be heat treated and the flavor improved due to the heat treatment. Stabilized packs need not be refrigerated and some stabilized fruits may have a jam-like flavor rather than that of the fresh fruit.

Nuts like pecans, almonds, walnuts, cashews, hazelnuts, peanuts, macadamia, and pistachios are also used to flavor ice cream. Nutmeats must be free of shells, clean, fresh (free of rancidity) and should have low microbial counts. Nuts are generally roasted and salted to keep them fresh. Nuts contain a large amount of unsaturated fatty acids which are susceptible to rancidity. The best results are obtained by using fresh roasted and salted good quality nuts.

Ripples or variegates are a method of flavoring ice cream which incorporates unusual appearance and flavor into ice cream. A good ripple is soft flavorful and distinctive. Sugar present in the ripple may affect the freezing and storage characteristics of ice cream. Most ripples have stabilizers to impart viscosity. Ripples are introduced into the product by one of two methods: (a) freezer whipping or (b) pumps other than the freezer. Whipping in the freezer involves double duty for the equipment. The freezer first freezes the ice cream and is then slowed down to incorporate 10–12% of variegating sauce. Air actuated pumps are also used to pump the ripple sauce into the ice cream just prior to packaging. Variable speed controls on such pumps allow different amounts of ripple sauce to be deposited into the product. Ripples can have been of such varied flavors as chocolate, marshmallow, peanut butter, butterscotch, caramel, fudge, raspberry, blueberry, or other fruits.

Candy and confectionery pieces have become popular flavoring materials in ice cream. Toffees and hard candies are popular flavors. Hard candies have a moisture content of $<2\%$ and need to be stored properly in order for them to be added without difficulty into ice cream. In the ice cream these pieces should have a clean bite rather than a sticky, tacky one. The candy pieces must be sufficiently large to retain their piece identity in ice cream.

Baked pieces like cookies, cookie dough, cakes, pie crusts, and so on, are also used as flavorings. Over a period baked goods absorb moisture from the ice cream and become soggy and lose their freshness. Some baked items are fragile and end up as dust in the product. This is not desirable.

The final point about flavorings is that it is the first bite or lick that hooks the consumer if the flavor is good. Therefore flavor is one of the most important attributes of ice cream. When purchasing flavors, do not be influenced by the cost per unit of the additive but rather by the impact and quality of the impact that results from this ingredient. Calculate the cost of the flavoring on a use basis rather than the cost of the ingredient per se.

74.4.6 Freezing and Hardening

When freezing of ice cream is discussed, it is important to remember that it concerns the creation of ice from water in the mix. Therefore, the only constituent of the mix being frozen is water. During the freezing process the equilibrium between water and ice is altered. Freezing is facilitated by the removal of heat from a substance. In the old salt and ice machine, used prior to mechanical refrigeration, ice served as the refrigerant and addition of salt lowered the freezing point of water. The brine extracts heat from the mix. The mix temperature is lowered and the brine temperature increases. Brine is not a good refrigerant. With the advent of mechanical refrigeration, the use of ice and salt for freezing ice cream was relegated to a hobby status.

74.4.6.1 Refrigeration. Sensible heat is the heat which when added or removed causes a change in temperature of the product. Sensible heat can be measured by observing the temperature of the substance. Latent heat (hidden heat) is the heat required to bring about a change of state. For example to convert water to ice at $0^{\circ}C$ ($32^{\circ}F$) requires the removal of a large amount of heat and latent heat cannot be observed by temperature changes.

Mechanical refrigeration relies on fluids that have a low boiling point and a high latent heat of vaporization. In the vapor phase the refrigerant must be dense, nontoxic, low flammability, immiscible with oil, and low cost. Ammonia is the commonly used refrigerant in large installations.

Mechanical refrigeration units rely on four elements: (1) evaporator, (2) compressor, (3) condenser, and (4) expansion valve. The refrigerant circulates between these four elements and changes state from liquid to gas to liquid. In the evaporator the liquid refrigerant evaporates under reduced pressure and in doing so absorbs latent heat of vaporization and cools the medium being frozen. The other parts of the refrigeration recycle the refrigerant. Refrigerant vapor passes from the evaporator to the compressor where the pressure is increased. The high pressure vapor then passes to the condenser where it is condensed to a high pressure liquid. The liquid passes through an expansion valve where pressure is reduced and the cycle starts again.

74.4.6.2 Freezing Ice Cream. This refrigeration cycle is responsible for freezing water in an ice cream mix. Latent heat of crystallization for water is 1 kilocalorie per kilogram or 144 British Thermal Unit (BTU) per pound. The freezing point of a food is the temperature at which a minute crystal of ice exists with the surrounding water. However, before an ice crystal can form, a nucleus of water molecules must be present. Nucleation therefore precedes ice crystal formation. In the freezing of an ice cream mix the freezing point is determined by the amount and types of solutes present. The important solutes are sugars and milk salts and any other dissolved low molecular weight materials. In this regard, it must be borne in mind that monosaccharides depress freezing point to a greater extent than disaccharides and salts depress freezing point two to three times greater than an equal concentration of sugars.

As the refrigeration is turned on and the mix is agitated, it soon reaches its freezing point and nucleation takes places, followed by freezing of some water. Once some of the water is converted to ice, the concentration of the solutes increases and a new freezing point is established. The refrigerant removes some more heat and the new freezing point is reached, nucleation occurs and some more water is frozen. Once again, the concentrations of the solutes increase and yet another freezing point is established and the process is continued until the desired amount of water is frozen. Because this water is frozen rapidly and under agitation small ice crystal nuclei are formed. In the freezing of an ice cream mix, approximately 50% of the water in the mix should be frozen as quickly as possible (matter of minutes). The freezing of half of the water in the mix in a rapid manner results in a large number of small ice crystals. This is desirable in creating a smooth textured ice cream.

74.4.6.3 Overrun. In addition to the freezing process agitation helps in the incorporation of air into the ice cream. Incorporation of air leads to a volume expansion of ice cream. The term overrun is used to describe the increase in volume of the ice cream. Thus if 1 gallon (3.75 L) of mix is converted to 2 gallons of ice cream (7.5 L) we have effectively doubled the volume of the mix. This is termed 100% overrun. Overrun can be calculated on a volume basis or on a weight basis as follows:

On a volume basis

$$\text{Percent overrun} = \frac{\text{Volume of ice cream made} - \text{Volume of mix used}}{\text{Volume of mix used}} \times 100$$

On a weight basis

$$\text{Percent overrun} = \frac{\text{Weight of unit mix} - \text{Weight of equal volume of ice cream}}{\text{Weight of equal volume of ice cream}} \times 100$$

Example 1: 500 gallons of mix were used to produce 850 gallons of ice cream. The overrun would be calculated as follows: $\{(850 - 500)/500\} \times 100 = (350/500) \times 100 = 0.7 \times 100 = 70\%$.

Example 2: A mix weighs 8.9 lb to a gallon and the finished ice cream weighs 4.5 lb to a gallon. The overrun would be calculated as follows: $\{(8.9 - 4.5)/4.5\} \times 100 = (4.4/4.5) \times 100 = 0.978 \times 100 = 97.8\%$.

In practical ice cream operations, a target overrun is chosen for the product and then package weights are calculated. For example, it is desired to make 85% overrun ice cream and a gallon of mix weighs 9.1 lb the gallon of 85% ice cream is calculated by the formula:

$$85\%\ \text{overrun} = \frac{9.1 - x}{x} \times 100$$

Or

$$\frac{9.1}{1.85} = 4.92\,\text{lb}$$

from this calculation the weight of a half gallon of this ice cream can be set at 2.46 lb and a quart of this ice cream should weigh 1.23 lb and a pint of this ice cream should weigh 0.61 lb or 9.8 oz.

74.4.6.4 Types of Ice Cream Freezers

Batch Freezer. Generally ice cream can be frozen in a batch or a continuous mode. Batch freezers are commonly used by small ice cream shops that make ice cream on the premises. In batch freezers a predetermined amount of mix is charged into the freezing chamber, refrigeration is turned on as is the agitation. Generally the mix will occupy half of the barrel. The mix is agitated and whipped while being cooled. After some time the mix begins to freeze and when it achieves a certain consistency it begins to incorporate air. Incorporation of air in conjunction with the freezing stiffens the ice cream. At this point the refrigeration should be turned off and agitation continued for some additional period of time. When the desired overrun is achieved, the ice cream is discharged from the barrel with the agitator mechanism still on. Just prior to discharge of the ice cream, fruits and nuts can be added to the barrel but the preferred method of addition of particulate inclusions is to fold it in to the ice cream as it is being discharged from the barrel. Once this process is complete, the next batch of mix can be charged into the freezer barrel and the process repeated. The important variables are the composition of the mix, temperature of the mix, desired overrun, refrigerant temperature, the type and model of the freezer, and condition of the scrapper blades in the agitation mechanism (dasher). Under ideal conditions a batch of mix should be frozen in 8–10 min. There is some skill to operating such a freezer and batch to batch variations are routine in such products.

Continuous Freezer. Continuous freezers are commonly used in larger ice cream manufacturing plants where more than 500 gallons (1875 L) of ice cream per day may be manufactured. Continuous ice cream freezers have larger capacities, can be operated continuously, ingredients can be added in-line and packaging can be also automated. Also, continuous freezers make it possible to produce ice cream of different shapes through extrusion devices. Novelty extrusions such as sandwiches, prefilled cones and cups, cakes, and so on, are possible through the use of continuous freezers. The ice cream from a continuous freezer is smoother and creamier than a product from a batch freezer. This is because the ice crystals formed in a continuous freezer are smaller and the air cells may also be more uniform. The ice cream exiting a continuous freezer is also generally colder than that coming out of a batch freezer. There are a number of different types of continuous ice cream freezers, some are vertical freezers, especially for

smaller scale operations, others are horizontal ice cream freezers. Regardless of whether the freezing cylinder is horizontal or vertical all continuous freezers have a set of blades for scrapping the walls of the freezers. In a continuous freezer a mixture of air and mix is introduced at one end and is progressively frozen until ice cream is discharged at the other end. The conveyance of the mixture of air and mix and the discharge of the ice cream may be facilitated by coordinated pumps in some models. Also the newer models of freezers are equipped with microprocessor controls that monitor and control the discharge temperature of the ice cream, the viscosity of the ice cream and the overrun of the ice cream. Further these microprocessors can work in tandem with other downstream equipment such as ingredient feeders and packaging lines.

In continuous freezers the air for the overrun has very little effect in the freezing cylinder because it is compressed. In a freezer operating with 4 atm cylinder pressure, the air required to give 100% overrun occupies only 15% of the volume of the total mix. The density of the mixture in the freezer is not altered enough by the air to affect the rapid internal heat flow to the cylinder walls. When the semifrozen ice cream exits the freezer barrel, it expands as the pressure is lowered to atmospheric and when this expansion has been completed maximum overrun is achieved.

Continuous freezers enable production of ice cream of high overrun and low drawing temperatures. Air for overrun of up to 130% at draw temperatures of $-7.2^{\circ}C$ ($19^{\circ}F$) can be achieved with cylinder pressures of 3.5–5.5 atm (50–80 psig) depending upon the dasher and blade design and the condition of the blades. For overrun in excess of 130%, cylinder pressures may have to be increased further. When draw temperatures is lower than $-7^{\circ}C$ ($19^{\circ}F$) cylinder pressures may have to be increased by 2–3 atm.

The temperature of the mix entering the freezer is very important to freezer performance. If the temperature of the mix is uniform throughout the run, the overrun control and freezing rate are predictable, provided that the refrigerant supply and suction conditions are uniform. Temperatures of $0^{\circ}C$ ($32^{\circ}F$) will optimize freezer performance. However, to achieve such a low temperature of the mix a scraped surface heat exchanger may have to be used. Normal pasteurized mix temperatures are around $3–4^{\circ}C$ ($40^{\circ}F$). Newer freezer designs make it possible to extrude ice cream at $-18^{\circ}C$ ($0^{\circ}F$) creating some interesting and desirable texture characteristics.

The consistency of ice cream as it is drawn from the freezer is often referred to as "wet," "dry," or "stiff." The terms dry and stiff are used interchangeably in parts of the world. This consistency is influenced more by formulation than by any other factor. Mix that produces a characteristic wet ice cream can be reformulated to produce a dry product. Stiffer drier ice cream is advantageous when manufacturing novelties where the ice cream is manipulated to form different shapes. Flowable wet ice cream is preferred when filling containers of various sizes because such a product results in a uniform fill with no empty pockets. Stiff, dry ice cream when filled in containers can leave voids that consumers interpret as companies cheating them.

The capacity of continuous freezers is difficult to rate since frozen desserts have differing characteristics which in turn affect refrigeration requirements. There is no generally adopted standard among equipment manufacturers for rating freezer throughput. However, if the machines are new or in excellent operating conditions, refrigerants are oil free, the ice cream mix is approximately 10% fat, 15–16% sugar, 37–38% total solids and the mix enters the freezer at $4^{\circ}C$ ($40^{\circ}F$) and exits at $-5^{\circ}C$ ($23^{\circ}F$) and the refrigerant evaporating temperature is $-5^{\circ}C$ ($23^{\circ}F$) or 2 psig pressure a valid comparison can be made for ice cream throughput at 100% overrun. It is critical to have all conditions

illustrated above to be the same to make valid comparisons between manufacturers of equipment. The rating is a nominal value and it is a given that the ice cream manufacturer will rarely approach these ratings in day to day production.

74.4.6.5 Hardening. The aim of freezing ice cream is to convert approximately 50% of the water in the mix to ice. This is done by rapid freezing in the continuous freezer which also results in small ice crystals. The remainder of the water in the mix is frozen on to these newly created ice crystals as rapidly as possible in an operation called hardening. In order to harden ice cream the package of ice cream is placed in a very cold environment where large volumes of very cold air sweep the surfaces of the packages for a period of time. In such instances freezing of the remaining water on the already existing nuclei takes place from the outside towards the center of the package. As more water gets converted to ice it acts as an insulator. Therefore it takes considerable amount of time for the center of the package to reach $-18^{\circ}C$ ($0^{\circ}F$). It is recommended that the center temperature of a rectangular half gallon of ice cream reach $-18^{\circ}C$ ($0^{\circ}F$) in 3 h or less. In order to achieve the air temperature has to be at least $-28.9^{\circ}C$ to $-34.4^{\circ}C$ (-20 to $-30^{\circ}F$). A larger package, such a as 11.25 L (3 U.S. gallon) tub, will take a longer period of time to reach a center temperature of $-18^{\circ}C$ ($-0^{\circ}F$). Ideally a core temperature of $-18^{\circ}C$ ($0^{\circ}F$) should be reached in 9–10 h. Hardening rooms can batch or continuous. Batch hardening rooms consist of a very cold room with the ability to move large volumes of air about in this room. The products should arrange in such a manner that this cold air is able to sweep all surfaces of the packaged ice cream. This requires air spaces all around the cartons of ice cream. In a continuous hardening system the ice cream package traverses a box in which cold air is circulated. The ice cream enters this box on a conveyor belt at one end of the box and is conveyed in a repeating zigzag manner back and forth until the required residence time is attained. Then the hardened ice cream exits from this hardener and can be stored. Continuous hardening systems are called hardening tunnels.

Hardening apparatus configurations can be a room, tunnels, spiral tunnels, straight through tunnels, contact plate freezers, and special tunnels used in novelty manufacture.

In all hardening systems frost builds up in the room over time. In humid environments, this process may be quicker than in arid environments. The room or tunnel has to be defrosted. Avoiding or minimizing frost build up is desirable. It is important to keep the evaporators and other parts of the room or tunnel frost free. Defrosting entails raising the temperature enough to melt and remove the frost. It consumes energy to defrost and additional energy is required to cool the room or tunnel back down to operating temperatures.

Hardened ice cream is stored at $-28^{\circ}C$ ($-20^{\circ}F$) prior to distribution. The time to harden is affected by the package size and geometry, air temperature, air velocity and turbulence, package surface exposure to cold air and over wrapping, bundling, and so on.

74.5 PACKAGING

A good package must contain the product, protect it, provide convenience and provide information on the product to the consumer. Food packages provide protection against physical, chemical and biological damage. It also provides information useful to the consumer, for example, ingredient label, nutritional label, net contents, serving suggestion, and methods of preparing the product. Besides these attributes, a good food package

keeps the food at nearly the same quality as when it was manufactured. During distribution packages are subjected to physical abuses such as shocks, vibrations, compression, and in the case of ice cream and frozen desserts, heat shock.

For frozen dessert packaging three main factors have to be considered. First, the package has to protect against temperature fluctuations, photooxidation, dehydration, and odor transmittance. Second, it has to take into consideration distribution related factors such as package integrity, thermal shock and cube efficiency. Third, municipal solid waste management factors have also to be considered.

In a consumer study performed prior to the passing of the Nutritional Labeling and Education Act NLEA, 90% of the consumers polled wanted tamper evident packaging and nutritional information (particularly calories and sodium contents). The latter is now mandated in a defined format by NLEA and has adequately addressed that concern. Almost 80% of the consumers desired ice cream packages that hold up better and not get soggy. Also noted were resealable rectangles and cartons that shrank as product was used.

Ice cream was packaged in the 1920s in paperboard tapered pails with handles with easy open tabs and was of small size for total consumption. In the 1930s various configurations of packages which were small enough to fit into the ice cube tray compartments of home refrigerators paperboard containers appeared. Such containers were no larger than a quart and were reclosable tab lids. In the 1940s and 1950s the package size increased to half gallon with appropriate strength to be filled automatically and had reclosable tabs at either end. In this era round containers were positioned as premium products. In the 1960s through 1970s plastic rounds, two piece cartons coated for higher quality graphics, zippered tab opening and hooded hinged lids were introduced. In the decades of 1980s through 1990s tamper evident shrink film and bands, two place containers in a wide range of materials, transparent and translucent packages, membranes inside packages to reseal, and rectangular packages with rounded corners were some of the notable developments. These evolutionary patterns follow the penetration of domestic refrigerators and the changes in sociological and demographic factors.

Regardless of the container shape and material of construction, ice cream packages are often shrinkwrapped and then sleeved in singly or in pairs prior to entering the hardening systems. The shrink wrap is an indication of tampering but it also provides an additional layer of protection. It is a two-edged sword in the sense that in addition to providing an extra layer of protection the heat applied to seal may cause heat shock and more importantly, reduce heat transfer rates during the hardening phase of manufacture. This can result in longer times for hardening ice cream and act as a capacity constraint.

As far as protecting the product from heat shock goes, there a number of variables which have an impact on this. The cold chain which consists of the steps involved in moving ice cream from the factory to the consumer is a major variable. The number of steps involved may be as simple as moving the ice cream from the hardening room to point of sale as may be the case in a small shop to as complex as moving ice cream from the factory to a factory warehouse, then to retailer's distribution center and from there to the store freezer, display freezer, transport home, and finally consumption. Transportation is involved in this chain and distance and altitude of travel may also play a role. Because of these variables it is often hard to arrive at a reliable sell-by date for ice cream. The problems may be exacerbated in the case of novelties because generally these products are smaller in volume and therefore more susceptible to melting and refreezing. In many instances manufacturers do not know the extent of temperature variation in their distribution system.

TABLE 74.8 Effects of Packaging Materials, Display Cabinet Style, and Temperature of Storage on Shelf-life of Ice Cream.

Package Material	Time Until Product is Not Fit for Sale (Weeks)			
	Vertical Cabinet			*Open display*
	−12°C	−15°C	−18°C	−15°C
	Cartonboard Packages			
Hot melt coated	8–10	11–16	22	Nd
PE-coated	6–8	11–16	13–17	10
Aluminum foil laminated	Nd	Nd	Nd	16–18
	Plastic Packages			
PS-box	16	16–22	>30	Nd
HDPE-box	16	19	22–26	Nd

Abbreviations: PE = polyethylene; PS = polystyrene; HDPE = high density polyethylene; Nd = not determined.

In a Finnish study conducted in 1984 compared different package types stored at different temperatures in both chest and upright freezer cabinets. Product acceptability was evaluated using a sensory panel (Table 74.8).

74.5.1 Storage and Distribution

Frozen and hardened product is stored and often distributed prior to the enjoyment by the end consumer. The intermediate steps involved in storage vary depending upon scale of manufacture, market share, point of sale, and consumer preferences. In the simplest case of a retail ice cream manufacturer, the product is made fresh in the store and sold very soon after manufacture and this requires relatively few controls. In an extreme case, the product made on one of the coasts of the United States is transported for sale to the opposite coast. Here, time, transport conditions, altitude, temperature, humidity, refrigeration conditions, and so on, have to be carefully controlled in a manner that the frozen dessert maintains its quality when the consumer eats the product.

Ice cream is unique in that it is the only product that is consumed in the frozen state. Therefore, once it is manufactured it has to be stored, transported, distributed, and sold in the frozen state. In the United States, frozen foods are distributed in a separate chain than ice cream is because the cold chain for frozen foods is −18°C (0°F) and is inadequate for ice cream. Ice cream cold chain maintains −23°C (−10°F). The distribution chain is called the cold chain and varies from manufacturer to manufacturer. Regardless of the variations one thing is certain. The cold chain is imperfect. This imperfection affects the quality of the product at the point of purchase and impacts consumer satisfaction. Factors affecting the shelf-life of ice cream are manufacturing procedures, warehouse equipment, warehouse handling practices, transportation, storage at retail premises, retail display equipment, and retail handling practices.

74.5.1.1 Manufacturing Procedures. Mix formulation, the adequacy, functionality, and quality of ingredients are all important parameters that receive careful attention. This is followed by proper blending to achieve intended functionalities of the added ingredients. Next pasteurization and homogenization, freezing, packaging, and hardening

have also to be carefully monitored and controlled. Packaging and outer case for products should be of good quality to prevent contamination, ensure integrity of product during normal storage and transportation, minimize dehydration and also but not the least package coding should be adequate for effective identification. Outer coding is useful for proper stock rotation and phrases such as "store at $-29^{\circ}C$ ($-20^{\circ}F$) or colder" should appear on outer cases. Lot pallet or unit load identity is useful in proper stock rotation while maintaining lot identity.

74.5.1.2 Warehouse Equipment. Warehouse should be of adequate capacity, suitably refrigerated to maintain a steady air temperature of $-29^{\circ}C$ under peak loading conditions and maximum ambient temperature. Storage areas must be equipped with accurate temperature recording devices. Daily checks of temperatures of each area in the warehouse should be maintained and recorded. Automated recorders are preferable and data should be retained for a 2-year period. Warehouse operator should record the product temperature of each lot of product received and should accept custody only in accordance with good commercial practice. Records for arrival lot temperatures should be retained for a period of 1 year.

If products are received above $-29^{\circ}C$ the operator should immediately notify the owner or consignee and request instructions for special handling. Product received above $-29^{\circ}C$ had incurred heat shock and may pose quality problems. Before placing the shipment in storage it should be code marked for effective identification. Every effort should be made to minimize exposure to elevated temperatures and humidity conditions.

During defrosting operations cover products beneath areas of accumulated frost. Products going in to the staging areas for order assembly must be moved out of the area promptly unless the staging area is maintained at $-29^{\circ}C$. As many of the operations should be carried out in the cold if possible. Allow the bottom of the stack to have air passage and leave adequate room between stacks for proper air circulation.

74.5.1.3 Transportation. Vehicles used for transporting ice cream products should be clean, free of dirt, offensive odors, debris, and so on They should also be insulated and equipped with adequate refrigeration. The vehicle must have tight-fitting doors without air leaks and should be precooled for 25 min prior to loading. Transport vehicles must also have accurate, visible, and readable temperature recording devices. The thermostat on the truck should be set to maintain an air temperature of $-29^{\circ}C$ with proper airflow or circulation. During loading and unloading operations the refrigeration unit must be off.

74.5.1.4 Storage on Retail Premises. Storage on retail premises must have adequate refrigeration capacity to maintain a product temperature of $-29^{\circ}C$ and of sufficient size to maintain proper stock control and rotation. Storage facility must have adequate circulation of cold air all around the products. Storage facilities must be equipped with an accurate, readable temperature recording device which is easy to calibrate. Facility should be defrosted regularly as necessary to maintain refrigeration efficiency.

74.5.1.5 Retail Display Equipment. Display cabinets should be capable of maintaining $-29^{\circ}C$ and should be situated away from drafts, direct sun, heat producing equipment, or any other factor likely to reduce its efficiency. The display case should have a calibrated easy to read thermometer at a location representative of the average temperature

of the cabinet. Display cabinets should have a properly marked load limit on the cabinet walls. To facilitate air circulation cabinets should have sufficient dividers, separators, and grids. Cabinets must be defrosted when necessary to assure proper operation. It should be kept free of debris, signs, and tags which deflect refrigerated air flow.

74.5.1.6 Retail Handling Practices. Ice cream and frozen novelties should be delivered in a frozen condition at $-29^{\circ}C$. Warmer products should be rejected or if accepted examined for quality and put up for quick sale. Once unloaded at the retail end, the products must be moved quickly to the freezer. Inventory must be rotated on a first-in, first-out basis. Any cases not bearing a code or date should be dated upon receipt. When loading ice cream into display cabinets rotate inventory already in the cabinet. New products should be placed beneath the existing stock. Items should not be placed outside of the designated load limit lines and care should be taken not to block air flow. Store personnel should be aware of maintenance and sanitary upkeep of the freezers.

For the operation of efficient and optimal cold chain educational programs for all personnel handling ice cream must be implemented. This will insure that the customers receive products in the best possible condition.

74.5.1.7 Heat Shock. Heat shock is a term used to describe temperature fluctuations that occur during the storage and distribution of ice cream. The aim is to minimize heat shock and its deleterious effects. Rise and fall of temperatures affect the water–ice equilibrium in frozen desserts. During the freezing and hardening of ice cream extreme care is taken to create the largest number of small ice crystals. Ice crystal nucleation is initiated in the ice cream freezer where the objective is to freeze approximately 50% of the water in the formulation as quickly as possible. The remainder of water that can be frozen changes state in the hardening process. No new ice nuclei are created in the hardening process. Following the laws of thermodynamics large ice crystals grow at the expense of small ice crystals. Every time the temperature rises some of the ice melts and when the temperature goes down it refreezes. The refreezing takes place on existing ice nuclei and thus the number of small ice crystals decreases while that of larger ice crystals increases. The amount of ice thawing and water refreezing is dependent on the extent of temperature fluctuation and the frequency of this fluctuation. When ice crystal sizes reach 150 μm the coarseness begins to get apparent to the tongue. Other effects of heat shock are the loss of shape and eye appeal of novelties and if persistent loss of market share for the manufacturer.

Depending upon the solute composition of the ice cream mix a freezing and thawing curve for that mix can be constructed (Fig. 74.5). Such a curve can provide the amount of ice and water changing state for defined temperature change. At very low temperatures relatively little water/ice changes state.

As the temperature warms more, water/ice change state. If a greater amount of water/ice changes state the shelf life of the product will shorten considerably when compared to a much smaller change in temperature. An example of the field data of temperature changes during storage and distribution of ice cream is provided (Fig. 74.6).

In this illustration the ice cream was “all natural” with no added stabilizers or emulsifiers. The overrun was approximately 100%. Whenever the product was in transit the temperature fluctuations were large. When the warehouse was under the management of the manufacturer product handling was good. Whenever warehouse control was

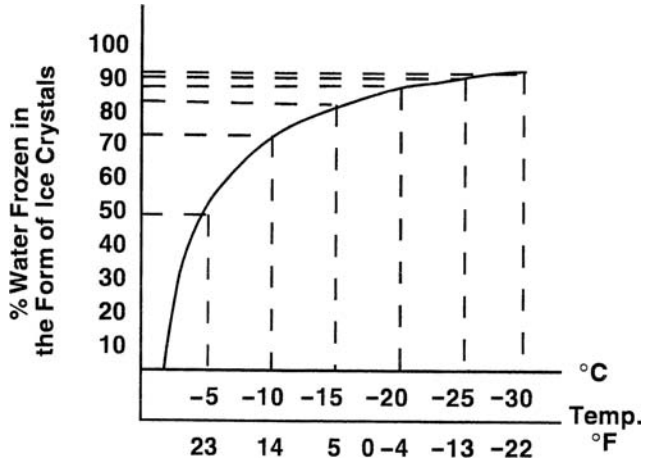

Figure 74.5 *Freezing / thawing curve for a typical ice cream mix.*

relinquished by the manufacturer the temperature fluctuations increased. In this example the product was coarse within 90 days.

Display cabinets at the retail point of sale are also notorious for causing heat shock to the product. The common types of display cabinets are open top merchandisers (also known as coffin style) and upright with glass doors. Consumers also keep doors open while making their choices leading to frost build up and necessitating frequent defrost cycles, which in turns adds heat shock. A survey of ice cream manufacturers in the United States revealed that physical defects were more frequent than flavor defects.

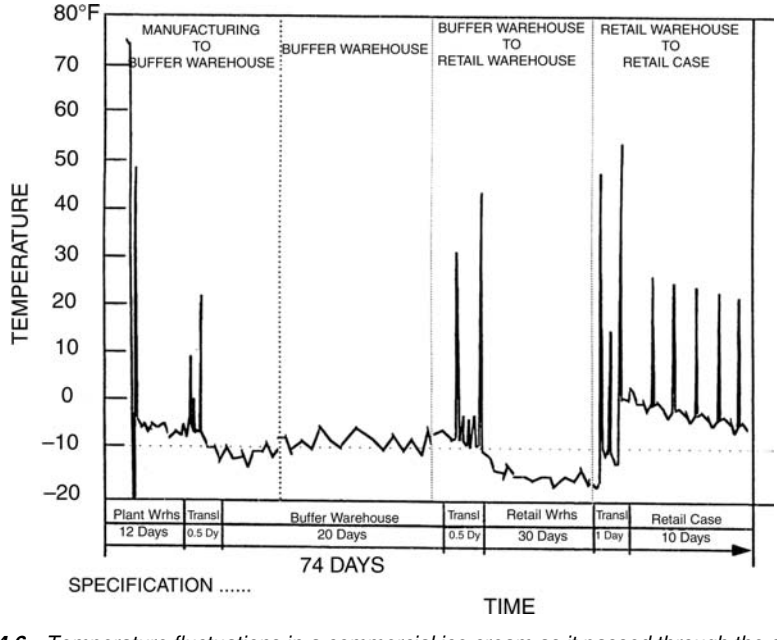

Figure 74.6 *Temperature fluctuations in a commercial ice cream as it passed through the cold chain.*

Customers reacted unfavorably to physical defects. Defects occurring often were reported to be icy texture, shrinkage, gummy/sticky texture, and evidence of previous melt. Customers were more tolerant of icy or coarseness than other physical defects. These defects objectionable to the consumers are all a result of heat shock.

If rectangular 1.88 L (U.S. 0.5 gallon) containers of ice cream are placed in an open top merchandiser packed three deep and the merchandiser undergoes two defrost cycles per 24 h the temperature fluctuations are as depicted in Figure 74.7.

As expected, the carton on top undergoes the greatest fluctuation and the cartons on the bottom of the pile undergo the least fluctuations. In such cartons the product contained in the outside 2 cm represents 60% of the total ice cream in the container while the center 2 cm portion represents only about 15% of the volume of the container. In approximately 4 days the amount of water that is formed and converted to ice is equivalent to the total water that was originally present in the mix.

74.6 NUTRITIONAL VALUE OF ICE CREAM

Table 74.9 gives an example of nutritional label of ice cream. It is evident that ice cream furnishes vital constituents and nutrients of milk, such as protein, calcium and other minerals, as well as vitamins.

74.7 MANUFACTURE OF ICE CREAM NOVELTIES

Novelties are products that have unique characteristics such as shape, color, and packaging. Typically novelties offer convenience, portion control (individual serving), unique forms (shape, size, color, flavor, and package). These are value added products conducive to impulse purchase. Novelties can be classified as sticks, bars, slabs, bite size, cups, and cones. These products can be molded that is, shaped by pouring and freezing mix in a mold or extruded. The products can be ice cream, water ice, sherbet, or a combination of these.

74.7.1 Molded Novelties

Novelties that acquire their shape from a mold or form are called molded novelty items. In such products a mold is filled with a mix or ice cream and then frozen further. The product is then demolded (removed from the mold) and enrobed in or coated. Most often molded products are stick products. Sticks are inserted into the semifrozen product in a mold and

TABLE 74.9 Comparisons Between Molded and Extrusion Processes.

Characteristic	Molded	Extruded
Ice cream temperature	−3 to −4°C	−6 to −7°C
% Water frozen	25–35	55–60
Texture from freezer	Fluid	Stiff
Flow	Intermittent	Continuous
Shape defined by	Mold	Orifice
Texture after hardening	Coarse	Smooth

then the freezing process is completed. When such a product is demolded the stick serves as a means of holding the product while eating. Equipment that manufactures molded novelties can be straight line or rotary machines. In a straight line machine there is a linear array of molds. Molds can be easily changed. Straight line machines occupy more floor space, are easier to clean and sanitize but the water use is greater as is the waste generation. In rotary machines molds are arranged radially on a large circular wheel and this configuration uses less floor space than straight line machines. There is less product lost in the molds but cleaning is more difficult and mold changes are time consuming. Molds are made of special alloys that have good heat transfer capacity, mechanical durability, resistance to brine, and resistant to corrosion from cleaning and sanitizing solutions. Molds can also be made from plastics which have particular advantages in three-dimensional effects. Generally molds are 0.22 mm (0.75 in) thick and volumes of molds vary from 50 mL (1.8 fl oz) to 75 mL (2.8 fl oz). Molds are held in place several molds wide on a rotating conveyor belt. In a straight line machine the molds traverse from one end of a cold brine trough to the other. Various operations are conducted in stages during this travel from end to end. There are also rotary machines in which the molds rotate around a drum containing cold brine and various operations can be staged at different points in this rotation. In either case the novelty making process starts with charging the molds with ice cream and ends with the demolded product transferred to packaging stations.

The steps in molded novelty manufacture involve filling the mold with partially frozen mix. The filled molds are frozen to a consistency that can support a stick upright and then the stick is inserted. Freezing proceeds further until a stiff consistency is obtained. Then the product is demolded. Demolding takes place by passing the molds through a warm brine zone where the outer layer of the product is softened enough so that the product can be removed from the mold. The product is removed from the mold by lifting it from the mold. The removed product can then be dipped in water, chocolate coating, and so on. The coated products can then be dipped in nuts, candy, sprinkles, and so on, prior to packaging. Some coatings may require a refreezing of the product. This refreezing can be accomplished by immersion in liquid nitrogen. This step may be repeated several times to build up a thick layer of the coating. The packaged product are put into multipacks or cartons and sent for hardening. The terms used in molded novelty manufacture are as follows: "wide" refers to the number of individual molds in a row of the machine, for example, eight wide means eight molds in one row or 12 wide means 12 molds in a row. "Strokes" means number of pieces produced in one synchronous movement. It is a measurement of speed. Typical strokes are 16–24 per min. So an eight wide machine operating at 16 strokes per min produces 128 pieces per min or 7680 pieces per h.

Several variations can be made in the manufacturing process. For example, one-third of the mold can be filled with one flavor, partially frozen, and a second flavor added to make two-thirds of the volume, and finally another third of a different flavor can be layered on top prior to stick insertion. A second instance of variation is what is called shell and core freezing. In this type of stick novelty the outside has a different flavor and product than the inside. This is achieved by filling the mold with one flavor and allowing that flavor to freeze along the inner edges of the mold; the unfrozen mix is aspirated from the mold followed by the filling of a second flavor or type of product. Freezing, sticking, demolding, and packaging then continues after these stages. By controlling the extent of product frozen in the mold prior to aspiration of the unfrozen mix different thicknesses of flavors can be achieved.

74.7.2 Extruded Novelties

In the manufacture of this type of novelty ice is extruded through an orifice and then separated into individual portions (frequently by a heated wire). Extruded novelties can be stick or stickless products. Sticks are inserted immediately after extrusion and prior to cutting. Extrusion can be horizontal or vertical. Horizontal extrusion is also called band extrusion. Coextrusion is also possible where more than one type of ice cream is extruded through the orifice. Cups, cones, and other filled products can be made by extrusion. Extruded portions are then hardened in a spiral freezer. Since the volume of the extrudates is small hardening can be achieved rapidly. Hardened products can then be coated/enrobed and packaged. The types of extruded novelties include cups, cones, sandwiches, cakes, bite size miniatures (e.g., bon bons), and candy bars style products. Extruded items can be decorated during extrusion. A small orifice in the shape of a star is often used to create a rosette and up to eight such devices can be used simultaneously to decorate an ice cream cake. The true expertise in the manufacture of molded novelties is in the design of the extrusion nozzles and in conceiving unique shapes or forms. Comparisons of molded and extruded novelties are described (Table 74.10).

This chapter has provided an overview of the manufacture of ice cream and other frozen desserts. There obviously are many more facets to this complex process. Changes occurring at a molecular level, the physicochemical basis for structure formation, sensory evaluation methods, proper cleaning, and sanitation procedures and new developing trends in the industry are not discussed in this article. Their omission here must not be misconstrued as the lack of importance of these topics. Additionally, the demand for ice cream and frozen desserts is increasing globally. With this global demand newer flavors, nutritional concerns, and cost-effective manufacture and delivery of these tasty treats gains greater importance.

75.1 INTRODUCTION

Fully, a quarter of the frozen dessert products sold in the United States are in the novelty category and this proportion has been growing (IDFA 2003). Vending machine sales of frozen novelties exceeded 8.5 million units in 2004 (IDFA 2005). The total retail value of the novelty category was 5.2 billion dollars in 2004, which accounted for 24% of the ice cream industry for that year (IDFA 2005). Supermarket sales of frozen novelties accounted for 2.3 billion dollars in 2004 (IDFA 2005). The highest sales, by volume share in 2000, were frozen ices (26%), ice cream bars (19%), ice cream sandwiches (13%), and fruit juice bars (9%) (IDFA 2001).

Items made by freezing a mix of flavor and other ingredients with water were developed much earlier than ice cream. It is likely that a sweet food froze serendipitously at some point in the past (perhaps even with an embedded stick), and someone found that they liked the result. Mankind tends to take advantage of chance occurrences like this. Perhaps initially artisans and chefs made these products for their affluent customers. It has been reported that the emperor Nero imported ice form the mountains to be combined

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

with fruit juices in the 4th century BC (Bellis 2005). In recent times, after the development of refrigeration, mass production of novelty products could be distributed to more and more people. Today there are vast numbers of these products sold in huge quantities in virtually every country on earth.

On a basic level, this enormous variety of different frozen novelties can be broken into three groups. Novelties that are frozen by placing the fluid ingredients into a mold and then freezing that product without further stirring are classified as quiescently frozen. An example of this kind of product is the conventional ice pop or ice-lolly. Products that are placed into a mold after being partially frozen in a conventional ice cream freezer are classified as stirred products. Ice cream frozen to a slurry consistency, deposited into a mold to finish freezing, removed from the mold and coated with chocolate is an example of this genus. The third group comprises those products that are frozen in a conventional ice cream freezer, extruded and cut to form the shape of the final product. These are called extruded novelties. Perhaps the most common example of this type of novelty is the ice cream sandwich. Extruded novelties can be much more complicated than this. They include products like ice cream on a stick shaped like a cartoon character with colored ice cream embedded in the extrusion to represent the various parts of the character.

75.2 QUIESCENTLY FROZEN PRODUCTS

Quiescently frozen novelties can either be simple or complex. They may have a single flavor/color or many colors and flavors layered, swirled, or otherwise cast within the product. Since the shape of the novelty is determined by mold geometry (Fig. 75.1), the number of possible shapes is infinite, though shapes that lend themselves to easy removal from the molds are most common. Perhaps the simplest novelty in this genus is the ice pop. This product is basically a frozen solution of water, sugar, flavor, and color, mounted on a stick.

The two most common quiescently frozen products are ice pops and fudge bars. An ice pops is basically a frozen syrup containing sugars, flavor, and color. The ingredients in ice pops can be partially substituted for by fruit juice, to make juice pops. Similar to the ice pop, but slightly more complex, is the fudge bar. Fudge bars often include some fat and have a higher solids content than ice pops. Fudge bars and similar products

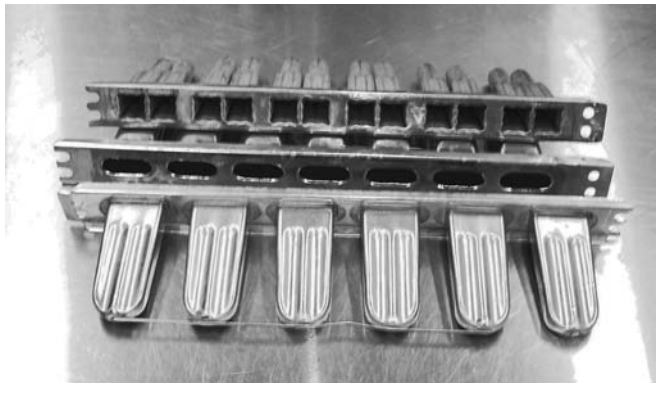

Figure 75.1 *Various molds for quiescently frozen novelties.*

TABLE 75.1 Formulations for Quiescently Frozen Products.

Component	Ice Pop (%)	Sugar Free Ice Pop (%)	Fudge Bar (%)	Nonfat Fudge Bar (%)
Milk fat	—	—	3.0	—
Milk solids nonfat	—	—	9.5	8.5

Artificial sweetener	—	0.01	—	—
Stabilizer	0.4	0.45	0.3	0.3

have a smoother texture than ice pops, attributable to smaller ice crystals and a higher content of unfrozen solution at consumption temperature that result from formulations that contain higher solids and fat. Pudding bars have similar formulations, without cocoa. Table 75.1 contains some representative formulations for ice pops and fudge bars.

During the freezing process, the fluid mix is deposited into the mold. The mold is suspended in a temperature exchange medium. This medium can be a calcium chloride brine, glycol, forced air, liquid nitrogen, or any other safe medium that can carry away heat from the product as rapidly as possible. Each of the media has advantages and disadvantages and it is best to consider the situation and consult equipment suppliers as to which is best for a specific product. As the product is not stirred, the solution in contact with the sides of the mold will cool more quickly than it will near the center of the pop. This fact is critical to both the texture of the pop and to its manufacture. When the solution becomes cold enough, the water in the solution begins to crystallize. The actual temperature at which this happens is dependent on the formulation of the product. Dendritic (needle shaped) crystals begin to form on the surface of the mold. Ice crystals are formed of pure water (Korber and others 1992). Because of this, the other components in the mix are mechanically swept out ahead of the growing ice crystals. This results in a concentration gradient forming in the vicinity of the ice crystals. The number of crystals forming and the eventual size of the ice crystals in the product are affected by this concentration gradient. The concentration gradient in the mix forms, during freezing, with the highest concentration near the ice crystal and the lowest in the areas not yet containing ice crystals. The viscosity in the gradient near the growing crystals increases as a result of this concentration (Bronstien and others 1991). Also as a result of this physical process, the freezing point of the liquid close to the ice crystals is depressed. Because the freezing point of the solution in the gradient is low relative to the bulk solution, and because the viscosity of the mix near the growing crystal is relatively high, the formation of new ice on the existing crystals is impeded in this area.

Since heat continues to be removed by the cooling medium, there is a tendency for new ice crystals to form where the solution is less concentrated. The result is the generation of smaller ice crystals. The sugars and other small molecules in the mix control the effect on freezing point. The effect on viscosity is due to both the sugars and to the hydrocolloids used in the stabilizer. Solutes can more easily diffuse away from the forming ice crystals during slow freezing than during rapid freezing. The reason for this is that there is more time for diffusion to take place. Larger ice crystals are, therefore, the result of slow

freezing. Larger ice crystals are perceived as a more course texture that, depending on the product, may not be desirable. Equipment, processes, and formulations can be designed to produce a variety of textures by manipulating the rapidity of the freezing process.

During the freezing process, all the solutes are concentrated in the spaces between the ice crystals (Korber and others 1992). At some point (depending on formulation and rapidity of the freezing process) the unfrozen solution becomes so viscous that water is prevented from reaching the forming ice crystals. Because of this, additional ice cannot form. The ultimate concentration of the material surrounding the ice crystals depends on the temperature of the product and on the number of individual molecules present in a unit volume of the solution. With small ice crystals, this concentrated material is more uniformly distributed throughout the product than it would be if large crystals predominated. This difference in distribution can be detected in the mouth and is interpreted as smoothness/coarseness.

During freezing the general direction of ice crystal formation is towards the geometric center of the novelty (towards the center of the mold). At the point when the ice crystal front has nearly joined at the center, the stick is inserted. Stick inserting mechanisms are placed at this point in the freezing process line. The actual position is determined by eye (manual or mechanical). This allows the stick to remain vertical until the completion of freezing. The exclusion of solutes including flavoring and coloring from the growing ice crystals forces theses materials toward the center. In extreme cases the stick can become covered by a viscous layer of concentrated sugar, flavor, color, and stabilizer, resulting in potential customer complaints.

After the product has been completely frozen the apparatus advances the molds into a warm bath (the temperature and duration of this bath are determined by the equipment and the product formulation). At this time the mold is heated just enough to permit the removal of the bars. In the case of elaborate molds like spirals, the withdrawal procedures can be quite complex, involving twisting, mold disassembly or other operations. After withdrawal the bars are wrapped and boxed and sent to the distribution freezer.

In formulating novelties, and for that matter all frozen products, it is necessary to take into account the freezing point of the unfrozen mix. Too high a freezing point yields a product with a hard texture at serving temperature and too low a freezing point will yield a product that melts and drips at serving temperature. The freezing point of any solution is determined by the solutes. For frozen desserts these are primarily in the carbohydrate content of the mix. Salts and other small molecules like ethanol can also affect the freezing point and must also be accounted for in formulations that contain them. It is the number of molecules present that determines the degree of freezing point depression, not the type of molecule. Since there are more molecules in a unit weight of a small molecule like fructose, the freezing point will be depressed more than would be the case if the same weight of a larger molecule like sucrose were used. Likewise, huge molecules like hydrocolloids and protein, have little effect on the freezing point of mixtures that contain them. Table 75.2 contains a list of common carbohydrates found in frozen desserts, their molecular weight, and effect on freezing point as compared to sucrose. Figure 75.2 shows this relationship in general.

At storage temperature (below $-18^{\circ}C$) the product will contain ice crystals and an amount of unfrozen solution that depends primarily on the solute content. The unfrozen solution is very viscous, if not glassy, at storage and consumption temperatures. This viscosity, along with the type and size of the ice crystals imbedded in it, will contribute to the eating quality of the dessert. In addition to the simple carbohydrates in the product, the

TABLE 75.2 The Relationship Between Molecular Weight and Freezing Point Depression for Some Common Carbohydrates.

Carbohydrate	Average Molecular Weight (Daltons)	Change in Freezing Point Relative to Sucrose[a]
Sucrose	342	1.0
Fructose	180	1.9
Glucose	180	1.9
Lactose	342	1.0
Sorbitol	182	1.9
Lactitol	362	1
Xylitol	152	2.3
Maltitol	362	1.0
Erythritol	122	0.9
Glycerin	99	3.7
Polydextrose	>22,000	Negligible
High fructose corn syrup (42%)	190	1.8
36DE corn syrup solids	472	0.7

[a]Factor used to calculate the reduction in freezing point on an equal weight basis as compared to sucrose. For example, the reduction in freezing point for a given weight of fructose is nearly twice (1.9) as much as the reduction for the same weight as sucrose.

hydrocolloid content affects the texture of the products. The hydrocolloid content primarily affects the viscosity and gel like nature of the concentrated solution. Manipulating the hydrocolloid type and content can achieve many variations in texture. For example a slimy texture for children's novelties can be achieved using xanthan gum. The addition of modified food starch can give a pudding-like texture. Even gelled textures, where the dessert does not drip but becomes a gel upon melting, are possible. There is no ideal texture for novelties; often a defective quality in one novelty is the desired result in another.

While the desired texture and flavor of novelties may require a low freezing point, this low freezing point can make novelty products susceptible to damage at storage temperatures and temperatures during distribution. At storage and distribution temperatures producers want products to be as hard as possible, in order to survive distribution. In order to make products more resistant to damage a coating of frozen water or fat is often

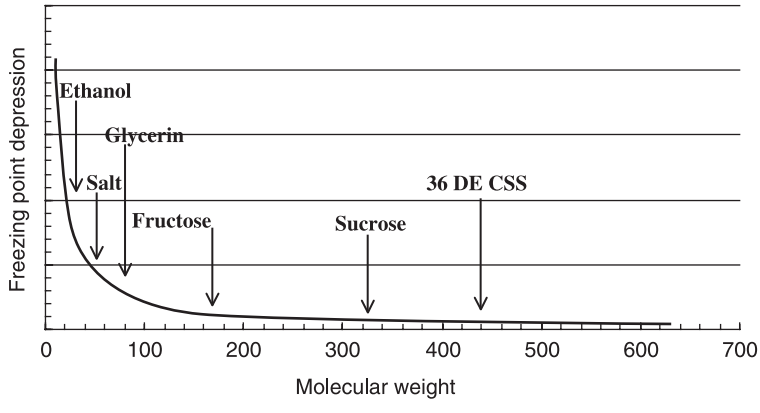

Figure 75.2 *The relationship between molecular weight (Daltons) and freezing point depression relative to sucrose on an equal weight loss.*

applied to the novelty (Frank 2000). This gives a more rigid exterior to the novelty that helps maintain shape when temperatures are above or near the melting point of the interior. A layer of frozen water coating the bar also helps prevent the paper wrapper from adhering to the bar during storage.

Including fat contributes to the body and texture of quiescently frozen products. Fat provides points of discontinuity within the structure of the product. Fat obstructs the formation of long needle-shaped crystals within the product. Further, the advancing ice front is slowed or blocked by large solid particles like fat. The result of the presence of fat or other colloids is a smaller ice crystal average size and therefore a smoother texture. Fat also coats the mouth and lubricates during mastication, further altering the perceived texture of the product. This lubricity is largely a function of the melting profile of the fat. In cases where fat is desired in the formulation, the melting profile of the fat should be considered. Fats with a high melting point will not melt as quickly in the mouth in a frozen product as they might in a product served at room temperature. Sometimes this can be perceived as a sandy or gritty texture.

75.3 STIRRED NOVELTIES

In the stirred novelties group of molded novelties, the mix is partially frozen in an ice cream freezer prior to depositing it into molds. Within the freezer the product begins to form ice crystals and air is whipped in (overrun), though the product is still quite fluid in texture. On reaching the desired temperature (-2 to -3°C depending on the product formulation) this partially frozen aerated slurry is then pumped into a hopper, deposited into molds, and frozen quiescently. The final texture of stirred novelties is much creamier and smoother than those that are simply frozen quiescently. The presence of air, partially agglomerated fat and more numerous ice nucleation sites produced in the ice cream freezer results in smaller, less continuous ice crystals forming during the quiescent freezing step. This results in a smoother, creamier texture in the final product. Recently, filling technology has been introduced where high viscosity (frozen to a lower temperature -5 to -6°C) ice cream and similar products are introduced under pressure to the bottom of the mold (bottom filling) (Hansen 2004). This allows a much higher quality to be achieved in stirred novelties. Because the ice cream in bottom filled novelties is more viscous, the product is able to suspend inclusions like fruit and nuts (Hansen 2004), This makes possible many more products.

Stirred novelties are often coated with chocolate and sold as ice cream on a stick. There are many coatings that can be applied to the outside of the bars after they have been removed from the molds. Chocolate is one of the most prevalent coatings. Although pure "chocolate" can be used as a coating it is often not appropriate for frozen novelties. Pure chocolate contains cocoa fat that is very hard and brittle at low temperatures. A softer vegetable oil is often more suitable for these applications (Marshall and Arbuckle 1996). The fat content (55–70%) of coatings is often higher than for pure chocolate (Frank 2000). Lecithin is added to coating compounds to prevent thickening of the mixture due to moisture build-up during prolonged dipping (Turnbow and others 1992). The uniformity of the coating and its thickness after dipping is a function of the viscosity of the coating. Careful control of the composition and temperature of the coating mixture is critical to this control. The temperature of the dipping mixture is dependent on the composition of the coating and the desired thickness. It is important that coated bars be removed to a freezer quickly after dipping to remove the heat absorbed during dipping. Table 75.3 contains some examples of chocolate coating formulations.

TABLE 75.3 Chocolate Coating Formulations.

Ingredients, %	Dark	"Milk" 32% Fat
Fat	26–34%	28–34%
Cocoa powder	15%	6%
Skim milk powder	6%	15%
Sugar	45–53%	45–51%
Lecithin	0.4%	0.4%
Vanilla flavoring	0.2%	0.2%

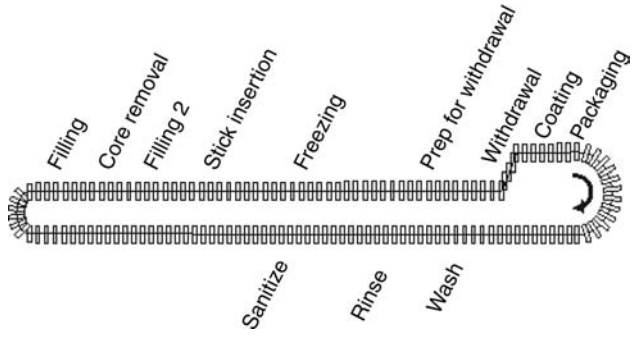

Figure 75.3 *Diagram of a typical quiescently frozen novelty process showing positions for mold filling, stick insertion, withdrawal, packaging and sanitation.*

Another stirred novelty product is made by first adding a fruit flavored sherbet or sorbet mix to the molds and allowing this to subsequently become partially frozen. The unfrozen core of the fruit mixture is removed by suction. In most equipment designed for this kind of product, the position (time) at which the core is removed is adjustable. This position is set usually by eye or by weight of the remaining shell. Ice cream is deposited into this shell and the freezing process is completed. The result is a bar with a fruit flavored shell on the outside and ice cream on the inside. A schematic for this process is shown in Figure 75.3. Close control of viscosity, temperature, and mix composition for all the components of these novelties must be made in order to assure uniform and predictable results.

By combining shells, fillings and coatings, a great many novel products can be created. Novelty equipment suppliers have designed a numerous different molds and equipment for extracting the novelties from the molds, which has enabled seemingly impossibly-shaped novelties to be easily formed. Interesting examples include spirals and animal forms in a rainbow of colors and flavors.

75.4 EXTRUDED NOVELTIES

Another basic group of novelties are extruded products. These can include shaped novelties, ice cream sandwiches and enrobed ice cream bars. Ice cream, sherbet, sorbet, and water ices can all be extruded. Extruded products are produced by first freezing a mix in an ice cream freezer to about -6°C. The product is then passed through a shaped nozzle or orifice. The product is then cut into slices using a blade or electrically heated

Figure 75.4 *Shapes possible using extrusion techniques.*

wire cutter (Marshall and Arbuckle 1996). If necessary, a stick is inserted and the product is hardened in a blast freezer (−30 to −40°C). Enrobing and decorating can occur after the product has been completely cooled to at least −15°C (Marshall and Arbuckle 1996). Equipment has been designed to produce virtually any shape and pattern. Some potential examples are shown in Figure 75.4.

One of the simplest novelties made in this manner is the ice cream sandwich, which consists of two flat cookies with a layer of ice cream between them. The ice cream is continuously extruded in a ribbon sized to fit width of the cookies and the desired thickness of the sandwich. Simultaneously, the cookies are placed on either side of the ice cream ribbon by the filling machine. The mechanism advances and the trailing cookie cuts off the ribbon of ice cream. (In some cases a wire cutter is employed in this step.) This advance sets the mechanism for the formation of the next sandwich. The sandwich then advances to a mechanical wrapper. The equipment is timed to deliver the correct amount of ice cream between the cookies without any undesired overhang. After wrapping, the ice cream sandwiches are boxed, palletized, and blast frozen. This whole process is a complex and precisely timed operation with the ice cream ribbon being extruded, the cookies being inserted the sandwich being formed, advanced (cutting the ice cream ribbon), and wrapped in paper. It is critical that the ice cream extrude uniformly and be cut cleanly for the process to work effectively.

A common problem that the ice cream sandwich manufacturer faces is tailing. This happens when the ice cream does not cut cleanly as the cookies advance. The result is a trail of ice cream being deposited on the wrong side of the cookies. In extreme cases the problem can cause the filling equipment to malfunction, causing down time. The reason for tailing can be as simple as incorrect temperatures from the freezer or as complex as a seasonal change in the fat used for the ice cream.

A good stable structure that is semirigid is necessary for the ice cream to cut cleanly and flow without mixing. Proper extrusion qualities are in large part a result of the state of the fat in the ice cream. Air bubbles in the ice cream are stabilized by agglomerated fat. The air cells are embedded in a semirigid structure formed by partially agglomerated fat (Goff 1997), ice crystals, and the freeze concentrated serum. In non-fat products, this structure is weakened by the absence of this fat structure. In reduced fat novelty applications one must rely upon ice crystals and the unfrozen serum to stabilize the structure. Since the fat in frozen products is concentrated by freezing along with the other components, it is only necessary for a small amount of fat to be present to have a large effect on the extrusion properties of the mix. Emulsifiers and hydrocolloid stabilizers can help build back the structure of frozen desserts when the fat is removed.

In products containing fat it is important to formulate and process the mix to maximize the structure in the extruded mix. Part of the structure in these products is formed from partially agglomerated fat. The emulsion state of the mix is a result of a complex interaction between fat globules and protein and other substances on the surface of the fat globules (Arbuckle, 1986). In the unfrozen mix, it is desirable for the fat to be stable enough to be pumped and agitated during storage and delivered to the freezer without churning. It is also desirable for the fat to resist creaming during storage. During the freezing process it is necessary for the fat particles to interact to form a semirigid structure (Arbuckle 1986). This structure is the result of the partial agglomeration of the fat particles forming three-dimensional structures surrounding the air in the mixture (Bollinger and others 2000). The ingredients used to control this are emulsifiers. In this application emulsifiers are not used to promote the formation of an emulsion but to partially destroy it. As with most phenomena in foods, the situation is not as simple as one would suppose at first. In this case the protein in the mix interacts with the fat globule, and it is this complex interaction that makes the products possible (Barfod and others 1991). It should be remembered that proteins, especially the caseins, have emulsifying properties (Walstra and Jenness 1984). Emulsifiers chosen for ice cream must have the ability to slowly displace the protein from the fat globule (Turnbow and others 1992). If this displacement occurs too fast, the mix will churn during processing. If it is too slow, excessive aging must take place. With too much protein on the surface of the fat globule, the globules will be prevented from agglomerating properly in the freezer and a weak structure will result. With too little protein on the surface of the fat globules the fat will churn and form large fat deposits in the freezer and pipelines from the freezer to the filler. Chunks of fat can be found in the ice cream in extreme cases of churning. Since extruded novelties are subject to extra stress during extrusion into shapes, it is especially important that proper fat agglomeration be achieved. Close control of the protein levels and type, and emulsifier selection will aid in achieving proper structure.

It is impossible, on a practical level, to observe the state of fat emulsions during processing. One characteristic that is observable however, is the surface appearance of the ice cream at the filler. The desired quality is called “dryness.” A dry, flat or eggshell like appearance on the extruding ice cream is desirable. The “dry” appearance is related to the amount of fat agglomeration (churning) that occurs in the ice cream freezer. Light is scattered by agglomerated fat. This light scattering causes the surface to take on the flat appearance. The amount and type of fat present, emulsifier system, freezer design and settings, mix aging, and formulation of the ice cream mix in general all contribute to the dryness quality. Often a small change in the fat source (seasonal changes in milk fat for instance) can cause a process that had been functioning well to fail completely. In these cases a change in emulsifier system is necessary to return to a good extrusion. Polysorbate 80 can often improve the extrusion qualities of a mix in this case. Where warranted, stabilizer suppliers can produce stabilizers that are specifically designed to produce good extrusion qualities. Table 75.4 contains formulas for ice cream-based extruded novelties.

The crystal structure of a dessert that is frozen, extruded, and cut into bars, more closely resembles a premium ice cream than similarly shaped novelties made by quiescently freezing a similar mix. Products made this way can command a premium price in the market. Extruded novelties need not be limited to simple rectangular bars. It is possible to coextrude several streams of frozen product using complex extrusion heads. Using this technology, many fanciful designs are possible. There are some limiting factors, however. Designers should avoid having a stream of frozen product where small

[a]Use manufacturer's recommendations.

narrow areas and larger areas are within the same flow. It is difficult to maintain uniform flow in this situation. Equipment manufactures have been able to design equipment for this application with multiple flowstreams or cleverly designed extrusion heads that have largely overcome these problems.

One new technology that has made possible very detailed novelty products is cold extrusion (Hansen 2004). Cold extrusion technology involves following a conventional freezer with another heat exchanger, where the temperature is brought down to levels 7–10 degrees lower than the conventional freezer. This heat exchanger often takes the form of an extruder similar to that used to produce shaped cereal. The difference is that heat is removed from the product. This produces a very firm ice cream with a very fine structure and a low temperature (Danisco 2003). Using molds that can be split into several sections and injecting the ice cream into the mold enables incredibly detailed molded novelties to be made (Hansen 2004). Liquid nitrogen-cooled molds can help prevent product form sticking (Hansen 2004). The stiffness and lack of the need for extensive hardening using cold extrusion has made this possible. These solutions can be costly and the novelty developer will need to balance this cost with the desired complexity of the product.

75.5 THE CHANGEABLE NATURE OF NOVELTIES

Volatility is the nature of products like frozen novelties, as the demand for specific types of novelties will vary over time. Cartoon characters and the popularity of shapes and flavors come and go. A stroll down the aisle of any grocery store in the developed world will confirm this. It is one of the advantages of frozen novelties that the equipment is designed to be flexible. Molds can be changed, flavors and colors can be altered, and completely new products can be designed. It is important to keep closely allied with equipment and ingredient suppliers and to keep a close eye on the marketplace so that products can be developed as demand is generated and maintained.

76.1 INTRODUCTION

This chapter will provide a brief overview of the science and technology of yogurt manufacture with particular emphasis on commercial practices in the United States. Information in this chapter will include a definition of the product category as well as methods for production and quality control, chemical, and biological changes during yogurt production, yogurt microbiology, and nutritional aspects of yogurt. An excellent source for more detailed information about yogurt is the comprehensive book by Tamime and Robinson (1999).

Yogurt is a traditional fermented milk food that has shown strong sales growth in the United States dairy grocery category during the past two decades. Production in the United States more than tripled between 1980 and 2002 (from 540 to 2100 million pounds) and per capita consumption has increased steadily (Fig. 76.1).

In the United States, the refrigerated yogurt category is segmented by nutritional value of product (full fat, low fat, nonfat, artificially sweetened, low calorie), by packaging format (single cup, large size, multipack cups, tubes, and bottles) and by the type of product (cup set, fruit on bottom, blended or stirred style, and beverage). The category may also be segmented by consumer benefit with offerings for snack yogurt, dessert or indulgent yogurt, drinking yogurt, and specific health benefit yogurt, among others. Yogurt for children introduced in the 1980s is a rapidly growing segment in the U.S. market. In particular, beverages based on yogurt, and yogurts with specific health benefits (such as low lactose or probiotic) are areas of tremendous current growth.

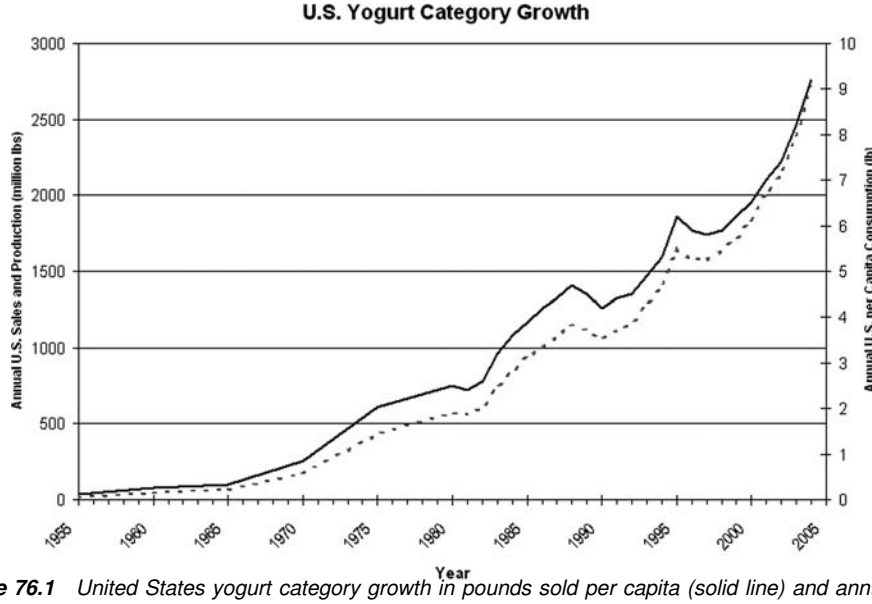

Figure 76.1 *United States yogurt category growth in pounds sold per capita (solid line) and annual dollar sales (dashed line) (International Dairy Foods Association 2005, Milk Industry Foundation 1980).*

76.2 DEFINITION OF YOGURT

The U.S. definition of yogurt can be found in the Code of Federal Regulations (CFR), Title 21, Volume 2, Parts 131.200, 203, and 206 (21 CFR 131.200–206 2003). In Europe, yogurt is defined by Codex Alimentarius Standard 243-2003 (Codex Alimentarius Standard 243-2003 2003). Generally, the definition of yogurt requires that it be a milk product that is fermented by the action of both *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. Different countries have different regulations regarding acceptable additives, minimum required quantity of live organisms, and final pH or acidity. In the United States the CFR does not require specific numbers of viable bacteria to meet the identity of yogurt. However, the National Yogurt Association (NYA), a trade association of yogurt manufacturers, offers a "live and active" culture seal. Commonly found on refrigerated yogurt products, the presence of the "NYA live and active seal" guarantees 10^8 colony forming units per gram at the time of manufacture, and activity of the cultures at the end of shelf-life of the product. The milk fat content of yogurt is regulated by the CFR with definitions for yogurt, low fat yogurt, and nonfat yogurt (21 CFR 131.200–206. 2003).

76.3 YOGURT MANUFACTURE

The Grade A Pasteurized Milk Ordinance, enforced by the Food and Drug Administration (FDA), is the primary regulation guiding the manufacture of milk products in the United States (U.S. Department of Health and Human Services 2002). In Europe, each country defines its own standard yogurt manufacturing practices. Although there are traditional methods of yogurt manufacture, this chapter will cover only the commonly used practices for commercial yogurt production. The basic steps required for manufacture of yogurt include:

1. Raw ingredient receiving and quality inspection
2. Milk standardization
3. Culture handling
4. Yogurt mix blending
5. Mix homogenization and pasteurization
6. Inoculation, fermentation, and cooling
7. Fruit, flavor, and/or color addition
8. Packaging and storage

The general goal of yogurt production is to create a semisolid, long shelf-life food from perishable, fluid milk. Development and retention of the appropriate texture is critical to good yogurt quality. Yogurt mix preparation (particularly heat treatment and fortification), fermentation conditions (particularly culture type), and postfermentation handling all have a great impact on product texture. Each of these will be covered briefly in this chapter. For more detailed information, consult recent review articles (Jaros and Rohm 2003; Lucey 2004; Sodini and others 2004). A general scheme for the production of yogurt indicates that the process differentiation between cup set yogurt, stirred yogurt, and yogurt drinks generally occurs after pasteurization

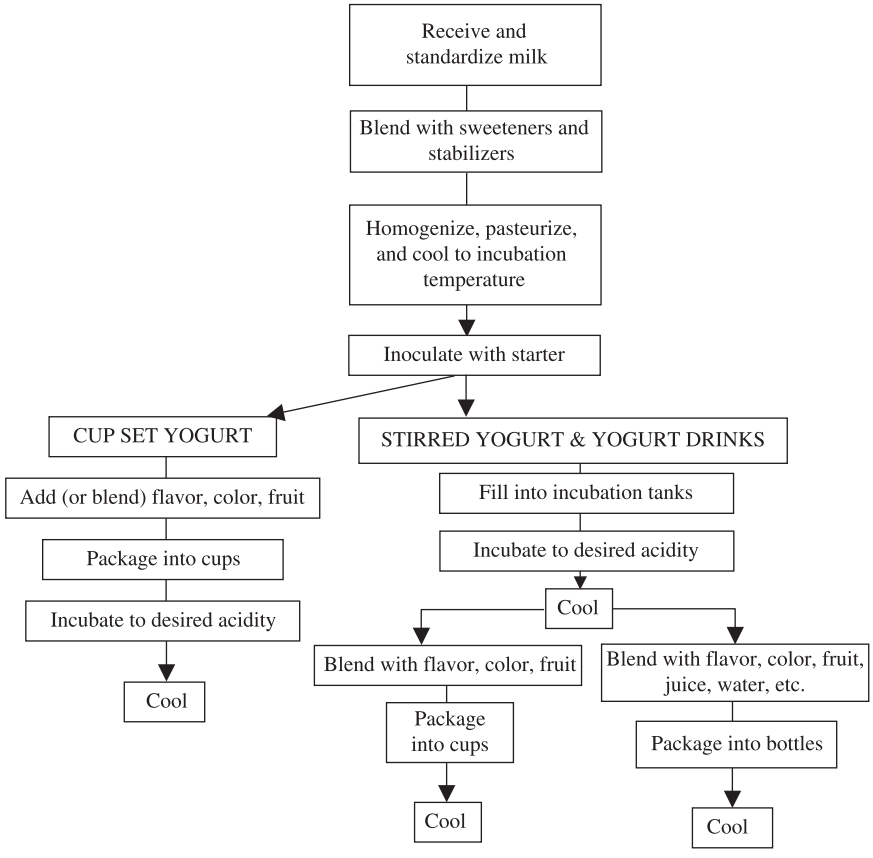

Figure 76.2 *A general scheme for yogurt manufacture. (Adapted from: Robinson and Tamime 1975, Lucey 2004, and Chandan 1982.)*

(Fig. 76.2). Typical equipment installations for stirred style and cup set yogurt can be found in Figures 76.3 and 76.4.

76.3.1 Raw Ingredient Receiving and Quality Inspection

According to U.S. regulation, incoming raw milk must be tested for antibiotics. This is usually done by a commercially available rapid method specific for a certain antibiotic or class of antibiotics or by a microbial inhibition method (Bishop and others 1993; U.S. Department of Health and Human Services 2001a). It is critical that milk be free of antibiotics as even low levels can inhibit the yogurt culture. The fat, protein, and total solids content can be determined by a standard method or calibrated rapid method (Bishop and others 1993). Compositional information is important when standardizing the yogurt mix. Raw milk is often clarified to remove dirt and unwanted materials such as somatic cells (Humphreys and Plunkett 1969; Puhan 1988). Clarification is commonly done in a centrifugal separator during milk fat content standardization, but is also sometimes accomplished with a dedicated clarifier. Clarification can induce rancidity in raw milk, so its use should be followed immediately by heat treatment (Humphreys and Plunkett 1969).

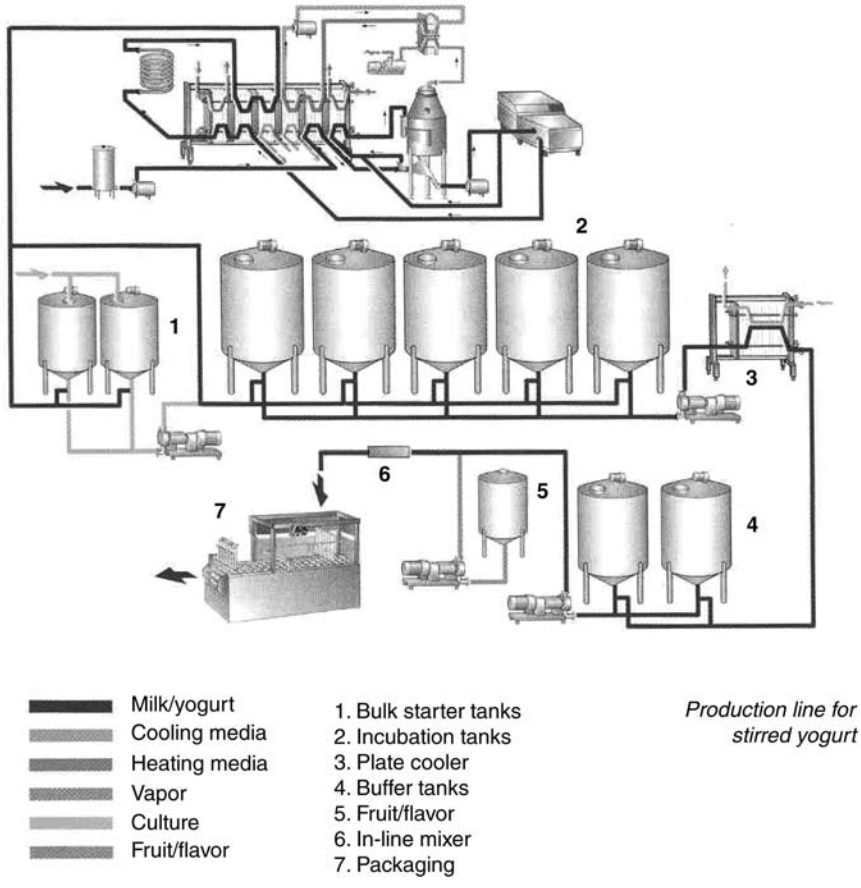

Figure 76.3 *Typical stirred style yogurt manufacturing installation. Reprinted with permission from Tetra Pak (Tetra Pak 1996).*

76.3.2 Milk Standardization

Milk is often separated into skim and cream components to allow standardization to the desired milk solids and fat content in the yogurt mix. A Pearson square calculation can be used to easily calculate the necessary mix of dairy ingredients to achieve a desired milk solids or fat level (Tamime and Robinson 1999). A dairy will generally utilize the most economical blend of ingredients to achieve the target composition. However, allowable milk sources may be limited by applicable regulations. Milk sources commonly used worldwide in the yogurt industry include raw milk, condensed milks, dry milk powders, milk protein concentrates, and caseinates. Because ultrafiltration (UF) removes lactose and some minerals, UF retentate is useful for making lower lactose, high protein products (Glover 1985; Puhan 1988).

Concerns important when utilizing raw milk include proper separation of raw and pasteurized stages, strict adherence to sanitary measures to prevent contamination from milk trucks entering the dairy plant, safe handling of raw milk to prevent microbial

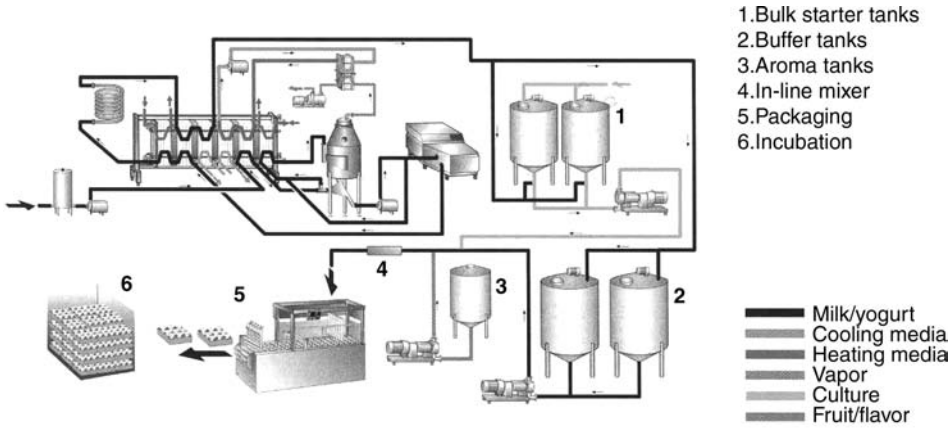

Figure 76.4 *Typical cup set yogurt manufacturing installation. Reprinted with permission from Tetra Pak (Tetra Pak 1996).*

growth, and gentle handling of raw milk prior to heat treatment to prevent lipase induced rancidity. If raw milk is agitated prior to heat treatment, the milk fat globule membranes can become disrupted and allow the active milk lipases to act on the fat, creating rancid off-flavors (Harper 1976; Bodyfelt and others 1988).

Yogurt mix is usually fortified with milk protein to increase gel strength and decrease susceptibility to syneresis (Davis 1975; Tamime and Deeth 1980; Harwalker and Kalab 1983; Kalab and others 1983; Modler and others 1983; Puhan 1988; Kesseler 1998; Schokoda and others 2001; Bhullar and others 2002; Remeuf and others 2003; Sodini and others 2004). Fortification can be accomplished by the addition of skim milk powder (often 1–3%), whey protein concentrate (often 1–2%), or ultrafiltration retentate. Alternatively, the mix may be concentrated by evaporation or ultrafiltration (10–15% concentration) (Puhan 1988; Lucey and Singh 1997). If total solids are higher than 22%, fermentation may be slowed due to increased osmotic pressure of the milk blend (Tramer 1973; Tamime and Robinson 1999). The method of fortification will impact finished product quality. For example, fortification with caseinates increases gel strength more than fortification with skim milk powder (Guinee and others 1995). Yogurt will generally contain 9–20 g total milk solids (including fat) per 100 g with the lower end typical of low fat yogurt (Tamime and Deeth 1980).

76.3.3 Culture Handling

Both *Streptococcus thermophilus* and *Lactobacillus bulgaricus* are required to make yogurt. Few dairies maintain their own culture collection because of the expense associated with culture maintenance. Rather, yogurt cultures are generally purchased from culture manufacturers as deep-frozen concentrates or freeze dried powders, and stored at −40 to −57°C (−40–71°F) until use (Mocquot and Hurel 1970; Sellars 1989). Cultures may be the direct set type, or culture concentrates may be used at the dairy to create a bulk starter culture. Direct set (DS) cultures are a convenient way for manufacturers to maintain the target rods to cocci ratio, while also delivering desired counts of

adjunct microorganisms, such as *Lactobacillus acidophilus* or *Bifidobacterium* species. Freeze-dried or frozen DS cultures contain 10^7 to 10^9 colony-forming units per milliliter (Sellars 1989; Tamime and Robinson 1999). For DS cultures, the dairy might utilize a small tank for thawing and dilution of the culture prior to addition, or they may choose to add frozen culture to each batch in the fermentation tank. DS cultures generally exhibit slower fermentation than bulk starter cultures due to an extended lag phase (Tamime and Robinson 1999).

Dairies may create a mother culture in the laboratory that is used to inoculate milk to produce bulk culture. Although freeze dried cultures require subculturing to regain activity prior to bulk culture production, deep frozen cultures do not, and may be used for direct inoculation of bulk culture milk. Bulk cultures must contain sufficient viable organisms in the correct ratio, be free from yeast, molds, coliforms, bacteriophage, or other contaminants, and be capable of growth in the yogurt mix (Tamime and Robinson 1999).

Milk for bulk culture production is generally nonfat dry milk reconstituted to 9–12% milk solids not fat (MSNF) which has been heated to 85–95°C (185–203°F) for 30 min, then cooled to 37–43°C (99–110°F). This can occur in one vat that is jacketed with both steam and cold water lines. Thawed, concentrated culture is added to the milk, which is then incubated to the desired endpoint, commonly pH 4.4–4.6 or titratable acidity of 0.8%. The resulting bulk culture is agitated while being cooled to 40°F (Sandine 1979; Chandan 1982; Chandan and Shahani 1995). Milk that is used for bulk starter growth should be pasteurized at a high temperature with a long hold time in order to release growth factors, destroy pathogenic and competing organisms, reduce the oxygen content, release sulfhydryl compounds, lower the pH, denature whey proteins, and destroy inhibitory compounds (Humphreys and Plunkett 1969; Davis 1975; Sandine 1979).

It is most important that cultures be handled aseptically to prevent the introduction of unwanted contaminants that may grow in the milk. Although not a common problem, bacteriophage can attack yogurt microorganisms. Therefore, strain selection, strain rotation, and strict adherence to good sanitation practices are necessary to prevent culture failure due to bacteriophage attack (Chandan 1982; Sanders 1989).

76.3.4 Yogurt Mix Blending

Other ingredients are mixed with the standardized milk in a blending step. For sweetness, sugar is often added at this stage. Common sweeteners include crystalline or liquid sucrose, crystalline fructose and high fructose corn syrup. Sugar addition greater than 12%, and sometimes as low as 9%, will noticeably slow fermentation by changing the osmotic potential of the mix (Tramer 1973; Davis 1975; Puhan 1988; Chandan and Shahani 1995; Tamime and Robinson 1999). Stabilizers, though not required, are often added to reduce the susceptibility of the yogurt to spontaneous whey separation (syneresis) and to provide reset viscosity in stirred-style products. In addition, stabilizers add body and viscosity, create a firmer gel, and increase the ability of the gel to withstand refrigerated distribution (Humphreys and Plunkett 1969; Chandan 1982; Puhan 1988; Chandan and Shahani 1995; Tamime and Robinson 1999). Common stabilizers, and their typical use rates in the yogurt mix, include gelatin (0.2–0.4%), starch (1.2–2.0%), pectin (0.05–0.2%), agar (0.8–1.12%), carageenan (0.05–0.2%) (Puhan 1988), and (less commonly) locust bean gum, xanthan gum, and guar gum (Lucey 2004).

Hydrocolloids in yogurt can affect elasticity, viscosity, and stability of the coagulum. Some stabilizers will react with charged milk proteins. This can create phase separation,

graininess, and interfere with gel formation. These problems are sometimes evidenced by a less shiny, slightly grainy surface appearance (Dickinson 1998; Olson 2002). These stabilizers (pectin, guar, locust bean gum, sodium carboxymethylcellulose, gum arabic, and carageenan) should, therefore, be added only after fermentation and in small amounts (Puhan 1988; Dickinson 1998; Poppe 1999; Tamime and Robinson 1999) or in combination with other ingredients that minimize their reactivity. Caseinate addition will increase yogurt viscosity and reduce syneresis, but can result in a grainy texture at higher levels (greater than 0.3%). Modified starches (resistant to acid and shear) can provide yogurt viscosity. Stabilizers often require special handling, such as premixing with other dry ingredients, or hydration prior to sugar addition to ensure full functionality. High-methoxy pectin is recommended for acidified dairy beverages due to its ability to stabilize milk proteins at low pH, while low-methoxy pectin is recommended to add viscosity to yogurt (Puhan 1988; Dickinson 1998; Leskauskaite and others 1998; Olson 2002). Pectin can interact with exopolysaccharides produced by yogurt cultures to increase viscosity and reduce syneresis (Olson 2002). Some stabilizers (such as some types of pectin or alginate) are calcium reactive and, therefore, should be added only in small amounts or with chelators. Gelatin is effective both at reducing syneresis and adding body to finished yogurts (Modler and Kalab 1983; Modler and others 1983; Modler and Kaleb 1983; Guinee and others 1995). Typically, a 100–150-bloom gelatin is used (Imeson, Thickening and Gelling Agents for Food 1997).

Reduced calorie yogurts are generally nonfat and use high intensity sweeteners such as aspartame or sucralose to replace sugar. Aspartame is not heat stable, so it is generally added post-fermentation, often via the fruit preparation.

Preservatives, such as potassium sorbate or sodium benzoate are sometimes added to yogurt to inhibit yeast and mold growth, but may not be allowed by local regulation (Tamime and Robinson 1999).

Ingredient addition is most often accomplished by use of a high-speed mixer, such as Multiverter or Liquiverter made by APV (APV, Denmark). In smaller operations, dry ingredients may be added gradually through an inline mixer, such as a Tri-blender (Alfa Laval, Sweden). Proper mixing ensures sufficient hydration of dry milk solids and stabilizers while minimizing incorporation of air.

76.3.5 Mix Homogenization and Pasteurization

Homogenization reduces fat globule size to prevent creaming of fat in the finished product, improves yogurt texture and stability, denatures some of the whey protein, affects stabilizer incorporation and functionality, and can increase the viscosity of higher fat yogurts (Humphreys and Plunkett 1969; Puhan 1988; Tamime and Robinson 1999). Some yogurts are made with unhomogenized milk to intentionally provide a cream layer on top of the yogurt. Homogenization can improve the body of lower solids yogurt, but has less effect on higher solids yogurt, so homogenization pressures should be tailored to the specific yogurt mix (Puhan 1988). Typically, yogurt mix is heated to 55–80°C (131–176°F), then homogenized in one or two stages at 7–20 mPa (1000–2900 psi) (Puhan 1988; Lucey and Singh 1997; Tamime and Robinson 1999). Homogenization after pasteurization can improve yogurt consistency, but is generally carried out before pasteurization in order to minimize the risk of contamination (Puhan 1988). Pasteurization must occur either prior to or immediately after homogenization to destroy lipases that would

otherwise create rancid off-flavors in the raw homogenized mix (Puhan 1988). Homogenization also increases product susceptibility to light activated off-flavor (Puhan 1988).

Pasteurization is carried out to destroy any pathogenic bacteria in the mix. An extended heat treatment is applied to yogurt milk to denature the whey proteins. The heat treatment also serves to reduce the number of competitive microorganisms, inactivate natural milk enzymes such as lipases, hydrate stabilizers, reduce the oxidation-reduction potential (favoring microaerophilic growth), and produce growth factors for lactic acid bacteria (Davis 1975; Puhan 1988; Chandan and Shahani 1995; Tamime and Robinson 1999). The extended heat treatment ensures 80–95% whey protein denaturation in the yogurt mix (Puhan 1988; Lucey and others 1997), which enhances yogurt texture and reduces susceptibility to syneresis (Grigorov 1966b; Dannenberg and Kessler 1988) as discussed later in this chapter.

Yogurt mix is typically heated to 80–85°C (176–185°F) for 30 min or 90–95°C (194–203°F) for 5 min (Humphreys and Plunkett 1969; Davis 1975; Lucey and Singh 1997). Homogenized, pasteurized milk blends can be held chilled until ready to use, providing an opportunity to check mix total solids and composition (Humphreys and Plunkett 1969). Insufficient heating will lead to a weak gel structure after fermentation, while excessive heating can lead to decreased viscosity and graininess (Sodini and others 2004).

Pasteurization as well as the extended heat treatment are most often carried out in a plate heat exchanger equipped with a long holding tube. However, in multiproduct plants the extended heat treatment is often accomplished following HTST pasteurization directly in the fermentation tank. After pasteurization, the mix is cooled to the fermentation temperature, typically 43–45°C (109–113°F) (Lucey and Singh 1997).

76.3.6 Inoculation, Fermentation, and Cooling

Fermentation can take place directly in the yogurt cup (set-style or cup-set) or in a fermentation tank resulting in a stirred style yogurt. Bulk starter is added to the warm yogurt mix at 2–3% (Davis 1975; Lucey and Singh 1997), while DS starter culture is added at a much lower rate, typically 0.02%. Starter culture can be injected inline as the base mix is pumped or added batchwise to a tank. After thorough mixing to incorporate starter, it is important that the mix be incubated quiescently during fermentation as agitation could result in graininess, lumpiness, or catastrophic precipitation of the proteins.

The fermentation temperature will affect product quality. A lower fermentation temperature favors the growth of *Streptococcus thermophilus* while a higher temperature favors the growth of *Lactobacillus bulgaricus* resulting in a different texture and flavor in the finished product (Mocquot and Hurel 1970; Tamime and Robinson 1999). Favoring the growth of *Lactobacillus bulgaricus* will usually result in a more acidic yogurt. Some yogurt cultures are characterized as "ropy" due to their production of exopolysacchrides. A lower break pH (final fermentation pH) will lead to a higher rods : cocci ratio (Kneifel and others 1993). Maintaining the fermentation temperature between 40–45°C (105–115°F) promotes growth of both cultures. The two cultures grow associatively, each benefiting from the growth of the other, which is discussed in more detail later in this chapter. The generally recommended temperature for optimal growth of the two cultures together is 42.5°C (108.5°F) (Mocquot and Hurel 1970), with slower growth at both higher and lower fermentation temperatures (see Fig. 76.5).

When the yogurt reaches the desired endpoint, as measured by titratable acidity or pH, the yogurt is cooled. The fermentation endpoint (fermentation break) will be reached in

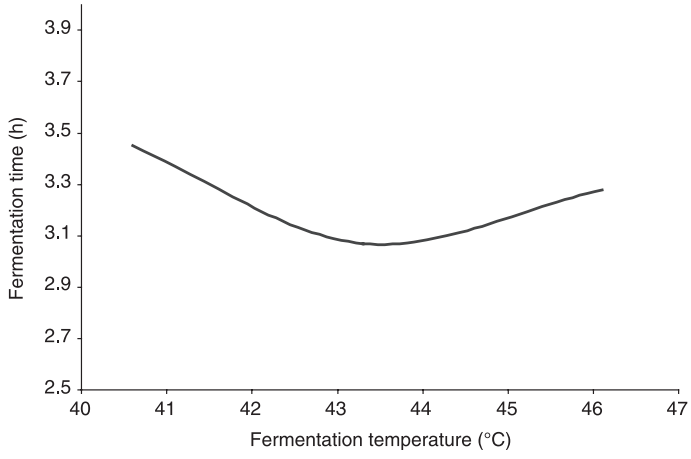

Figure 76.5 *The effect of temperature on fermentation time of a proprietary mixed culture of S. thermophilus and L. bulgaricus in milk. The optimum temperature for this culture blend is approximately 43 °C. Printed with permission from General Mills, Inc. (Maeve Murphy and Kyle Long, unpublished data).*

2–5 h, depending on the culture used and the mix composition. Because acidity will continue to develop as the yogurt is cooled, the endpoint must be adjusted to compensate for this continued fermentation (Tramer 1973). Depending on the rate of cooling, this process should begin when the yogurt reaches pH 4.4–4.8 in order to reach a final pH of 4.3–4.5 at the end of cooling. For cup set yogurt, sampling is important, as cups on the bottom of a pallet may have cooled more during pallet stacking, leading to a different fermentation rate compared to cups on the top of the pallet.

To cool cup set yogurt, pallets of cased product are either passed through cooling tunnels or placed in front of large cooling fans. Cases should have holes in them to facilitate the flow of cold air through the packaging and accelerate cooling. Bulk set yogurt can be cooled in the tank, if the tank is jacketed with chilled water and equipped with an agitator. However, cooling through a plate heat exchanger is more common. In the United States, yogurt must be cooled to less than 45°F (7°C) prior to shipping to meet standards of the Pasteurized Milk Ordinance (U.S. Department of Health and Human Services 2001).

Typically, bulk set yogurt is cooled to 10–21°C (50–70°F) to slow culture activity and, therefore, acid production. Fruit and flavor is added, the product is packaged and then cooled to 2–5°C (36–41°F). This two-step process helps increase yogurt viscosity by minimizing damage to the protein coagulum (Tamime and Robinson 1999; Olson 2002) (see Fig. 76.6).

In some instances, yogurt is cooled to 2–5°C (36–41°F) prior to the addition of fruit and flavor, and is then packaged and warehoused without need for further cooling. The coagulum is more likely to suffer textural damage when pumped at these lower temperatures (Vedamuthu 1991b; Tamime and Robinson 1999; Sodini and others 2004). The gel can recover some viscosity, but recovery is not full (Guinee and others 1995; Sodini and others 2004). For maximum viscosity and the most stable product, Maiocchi (2003) recommends a three step cooling process whereby yogurt is cooled to 25–30°C (77–86°F) prior to cup filling, then quickly cooled in the package to 10–15°C (50–59°F) in a blast cooler followed by slow cooling to 4°C (40°F) over 24–48 h.

In the case of stirred style yogurt, the coagulum is pumped or gravity fed from fermentation tanks to packaging fillers, and is mixed with fruit, flavor and color during the

Filling temperature	Description of yogurt
10°C 	Relatively low mouthfeel Watery consistency Tendency to whey separation Looser protein structure
15°C 	Still relatively low mouthfeel Still watery consistency Reduced tendency to whey separation Looser protein structure
20°C 	Higher mouthfeel Higher viscosity Very little tendency to whey separation
25°C 	Even higher mouthfeel Even higher viscosity Very little tendency to whey separation

Figure 76.6 *Effect of filling temperature on yogurt structure (Olson 2002). Printed with permissioin from Danisco USA Inc.*

process. Stabilizers can make the coagulum more robust by contributing to the gel recovery. To minimize the mechanical stress on the yogurt gel, positive displacement pumps such as lobe-type rotary pumps, wing type rotary pumps, or screw type pumps (Tamime and Robinson 1999) are utilized. Choosing the right pump, running a lower pump speed, minimizing the distance of pumping, utilizing special plate heat exchangers with larger gaps between plates, as well as avoidance of pipe diameter reductions and 90° elbows in piping all help to minimize mechanical damage (Tamime and Deeth 1980; Vedamuthu 1991b; Tamime and Robinson 1999; Maiocchi 2003). Pumps optimally should be run at 60 rpm, and no more than 100 rpm to preserve yogurt texture (Maiocchi 2003). When a smoother texture is desired in the yogurt, shear can be applied by using a smoothing screen or shear valve (Tamime and Deeth 1980; Lucey 2004). Typical shear valves are throttling valves which may be adjusted to constrict the flow of yogurt through the line, creating back pressure. Screens may be as a simple as a filter/strainer made of perforated metal inserted into the piping. Both shear valves and screens smooth the yogurt by increasing mechanical shear on the coagulum.

76.3.7 Fruit, Flavor, and/or Color Addition

For cup set yogurt, fruit, flavor, and color are added prior to fermentation. Fruit is filled directly into cups for fruit on the bottom yogurt. For blended or stirred style yogurt, these ingredients are added to the yogurt after cooling either continuously via inline injection or batchwise by direct addition to the tank. Heat treatment of fruit for addition will help ensure product safety and minimize the possibility of contaminating the yogurt with yeast and mold. Pectins in fruit preparations can sometimes lead to product defects due to interactions with the calcium in the yogurt. The interface between the fruit and the yogurt in fruit on the bottom products, is particularly problematic. Water activity differences between the fruit and yogurt layers can lead to water migration issues.

Fruit preparations for yogurt are typically comprised of fruit (15–60%), sweetener (0–40%), stabilizers (3–5%), flavor, color, preservatives (potassium sorbate and/or sodium benzoate), acid, and water (Chandan 1982; Hegenbart 1990). The preparation is heat treated, and aseptically filled into stainless steel totes or smaller packaging. Final fruit prep is usually 60–65% solids and 40–50 degrees Brix (Hegenbart 1990; Chandan and Shahani 1995). Viscosity is critical for fruit on bottom style yogurt to provide clear delineation between fruit and yogurt, and to prevent fruit from floating to the top of the unfermented base. Stability against microbial spoilage is provided by the high solids, the low pH (less than pH 4) and any preservatives in the preparation. Heat treatment should be severe enough to decrease microbial load and activate gums or cook starch, but as gentle as possible to preserve fruit quality. Fruit preparations typically have a 1-year shelf life when stored refrigerated, although 6 months is a common limit to ensure higher quality. Fruits used in preparations are usually frozen with sugar, because straight-pack (frozen without sugar) fruits tend to be less firm in the preparation. Viscosity is often measured using a Bostwick consistometer with a target of 5 units (cm) in 30 s at 24°C (75°F) being typical (Chandan and Shahani 1995). Fruit preparations must have a pH that is compatible with yogurt (generally pH 4), color that will show no or minimal migration to the yogurt, desired viscosity, and meet strict microbiological standards (generally less than 10 CFU per gram for yeast, mold, and coliforms) (Chandan 1982; Hegenbart 1990; Klink 2003).

Flavor and color ingredients also need to conform to strict microbiological specifications. Typically, the requirement is <10 CFU/mL yeast, mold, and coliforms. Ingredients added after pasteurization need to be handled in a sanitary manner to prevent possible contamination of the yogurt.

Accurate addition of fruit, color, and flavor is important for consistent yogurt quality. Mass flow meters are often used to provide a controllable process. To minimize damage to fruit, positive displacement pumps are generally used to pump fruit preparation. Pumps that accurately dispense small amounts, such as peristaltic (or hose type) pumps, are required for flavor and color addition (Tamime and Robinson 1999).

76.3.8 Packaging and Storage

Plastic is the packaging material of choice for yogurt with polypropylene and polystyrene cups being the most common. Yogurt packaging material must be durable, allow a hermetic seal, protect the product from moisture loss, and be easy for the consumer to use.

Oxygen transmission rates are also an important consideration, both for survival of sensitive cultures and for stability of added vitamins. Both thermoformed and injection molded plastic containers are used. Antistatic coatings should be included in packaging material to minimize the likelihood of dust or airborne microbes being attracted to the cups (Humphreys and Plunkett 1969). Filling into packaging should take place with a minimum of air incorporation to maintain best product quality. In the United States finished products must be stored at less than 45°F to meet the requirements of the Grade A Pasteurized Milk Ordinance (U.S. Department of Health and Human Services 2001).

76.3.9 Finished Product Quality Control

Quality control must ensure the finished product is safe, meets all regulatory requirements, provides the desired organoleptic qualities, and maintains those qualities through the product shelf life.

76.3.9.1 Safety and Regulatory Quality Control. Closely monitoring the pasteurization step and all postpasteurization ingredient addition points, as well as regular environmental monitoring for pathogens and undesirable organisms are key to ensuring product safety and quality. To meet applicable regulatory requirements, the milk blend or product should be tested for total solids and fat content. The finished product should be tested for yeast, mold, and coliform contamination, as well as for lactic acid bacteria. Methods for these are outlined in *Standard Methods for the Examination of Dairy Products* (Marshall 1993).

76.3.9.2 Organoleptic Quality. Texture, Flavor, Color. Monitoring product quality is important for maintaining consumer satisfaction. Evaluation of texture, flavor, and color are typically done at the time of production by the processor.

Product texture is closely monitored. Measurement of gel firmness is usually with a penetrometer, a heliopath rotational viscometer with a t-bar spindle (Brookfield, USA), or a Haake type viscometer (Thermo Electron Corp., USA). Apparent viscosity of blended yogurts is measured with a rotational viscometer usually at a single, predetermined shear rate (Tamime and Robinson 1999; Jaros and Rohm 2003).

Failure to ferment is characterized by a lack of acid production and failure to form a protein gel. This can be caused by the presence of inhibitory substances such as antibiotics or sanitizers, by the presence of bacteriophage, by the use of mastitic milk, or by the presence of short chain free fatty acids (Humphreys and Plunkett 1969; Tramer 1973; Davis 1975; Sanders 1989; Tamime and Robinson 1999). *Streptococcus thermophilus* and *Lactobacillus bulgaricus* are very sensitive to antibiotics, particularly the former (Kosikowski and Mocquot 1958). Mixed strains used in yogurt manufacture may show slowed fermentation, rather than stopped fermentation after bacteriophage attack (Sanders 1989). While bacteriophage is traditionally less of a problem in yogurt plants than cheese plants (probably because yogurt plants are not separating and storing large amounts of whey (Davis 1975), bacteriophage will attack both *Streptococcus thermophilus* and *Lactobacillus bulgaricus*. Therefore, proper selection of phage resistant strains, proper sanitation and a culture rotation program will help prevent phage attack (Chandan 1982; Sanders 1989; Tamime and Robinson 1999). Sanitation to prevent phage attack must include sanitizers effective against phage, such as chlorine-based compounds.

Lumpiness and graininess are two common textural defects in yogurt. Lumpiness is characterized by large protein aggregates in yogurt, often visible as white lumps, and graininess is smaller particles. Both defects can be caused by excessive acid produced too quickly, the use of rennet, excessive amounts of starter culture, agitation, or vibration during fermentation, incorrect use of stabilizers or having an excessive whey protein to casein ratio (Humphreys and Plunkett 1969; Davis 1975; Lucey and Singh 1997; Remeuf and others 2003; Lucey 2004; Sodini and others 2004). Lumpiness can be corrected by pumping the yogurt through a screen or mesh filter; graininess is an irreversible defect.

Ropiness is a defect characterized by a stringy, mucilaginous texture. This is most often a result of excessive production of exopolysaccharides by the yogurt culture, a culture characteristic that may be desirable in moderation (Davis 1975). This defect can be avoided by proper strain selection and maintenance of the optimum fermentation temperature (Davis 1975).

Weak gel in the finished product cannot be corrected, so it must be prevented. Common causes of a weak yogurt gel are low milk solids, improper selection or batching of hydrocolloids, low pH of yogurt mix during processing, overly high homogenization pressure, insufficient hold time during heat treatment, improper fermentation temperature, high break pH, improper starter culture ratio or excessive shear after fermentation. Monitoring total solids prior to yogurt mix processing can help prevent batching or dilution errors. Improper sampling during fermentation can lead to inadvertantly breaking the yogurt at a high pH. Sampling to monitor fermentation should be collected in the center of the fermentation vessel and not in a previously sampled location.

Although acid enhances fruit flavors, it can detract from nonfruit flavors which are currently gaining popularity in yogurt. Acidity is measured by either titratable acidity or pH measurement (Marshall 1993). Typical yogurt flavor is characterized by acetaldehyde (23–55 ppm), with little or no diacetyl produced by yogurt cultures (Humphreys and Plunkett 1969; Tramer 1973; Rašić and Kurmann 1978; Chandan 1982). Over acidification results in a flavor defect characterized by a sour taste, syneresis, lower viable bacterial counts, and the accumulation of D(−) lactic acid. It may be caused by high storage temperature, incorrect starter strain, delayed cooling after fermentation or excessive starter culture (Humphreys and Plunkett 1969; Kneifel and others 1993).

Finished product flavor should be checked regularly. Some yogurt flavor defects are bitter (can be caused by incorrect strains, sporeformer growth, excessive stabilizers), unclean (can be related to poor sanitation or off-flavors in milk supply), and flat (can be caused by low incubation temperature, under fermentation, or inhibition of fermentation) (Humphreys and Plunkett 1969).

Yogurt, like milk, is susceptible to light activated off-flavor (sunlight flavor), and product should, therefore, be protected from light (Humphreys and Plunkett 1969; Bosset and others 1995; Tamime and Robinson 1999).

Color may be measured using a colorimeter (such as a Hunter Colorimeter, HunterLabs, USA) or by comparison to color standards such as Pantone or Munsell.

76.3.9.3 Shelf Life Quality Control. Yeast and mold control are critical to product quality because the growth of one or both of these is the usual cause of product failure at the end of shelf life. These microorganisms can originate from airborne or surface contamination, the latter being the more common source (Tamime and Robinson 1999). Regular testing of equipment and building surfaces will help identify potential problem areas early. Positive air pressure and high efficiency particulate air (HEPA) filtration in

the filling room will minimize airborne mold and yeast contamination. Contaminated starter culture, poorly cleaned filters, and ingredients added postpasteurization can also contribute yeast and mold (Vedamuthu 1991c). Yeast problems can be minimized by thoroughly heating milk and fruit preparations, avoiding reopening of fruit containers, thorough cleaning of equipment, sanitary ingredient handling and thorough sanitization of equipment prior to use (Davis 1975).

Gassy defects are most likely caused by yeast contamination and growth (Humphreys and Plunkett 1969). Yogurt cultures are homofermentative and the introduction of heterofermentative lactic acid bacteria can also lead to defects such as non-characteristic flavor and gassiness (Rašić and Kurmann 1978).

Whey separation is a defect caused by syneresis, a contraction of the coagulum that leads to exudation of whey. This may by minimized by applying sufficient homogenization, increasing the milk solids, adding a stabilizer (if allowed by applicable regulations), avoiding excessive or insufficient acid production, heating sufficiently to denature whey proteins, avoiding excessive starter addition, and avoiding containers with sloping walls (Humphreys and Plunkett 1969; Harwalker and Kalab 1983; Lucey and Singh 1997; van Vliet and others 1997; Tamime and Robinson 1999; Pereira and others 2003). Susceptibility to whey separation is often measured by gravitational methods (Jaros and Rohm 2003).

76.4 MANUFACTURE OF SPECIALTY YOGURT PRODUCTS

76.4.1 Yogurt Drinks

Yogurt drinks can either be yogurt that has a low viscosity, or a blended product that is a mixture of yogurt, and/or water, milk, and fruit juice. For drinkable yogurt, an intentionally thin yogurt is created by lowering milk solids, decreasing stabilizer content and/or applying extra shear after fermentation. To manufacture yogurt drinks, other ingredients (such as fruit juice) are mixed with yogurt typically followed by a blending step that may introduce significant product shear (such as homogenization) (Tamime and Deeth 1980; Berry 2002; Leporanta 2002).

Yogurt drinks often show whey separation and require shaking prior to consumption. Higher viscosity beverages show less separation than lower viscosity beverages. The use of high methoxy pectin to stabilize the proteins can help minimize the separation and create beverages that do not separate and have a smoother texture (Leskauskaité and others 1998; Danisco Cultor 2001; Olson 2002). Generally, other stabilizers such as modified starch or gelatin are used in combination with pectin.

Kefir is processed similarly to yogurt drinks, but fermented with a combination of yeast and bacteria. Cultures identified from traditional kefir include *Saccharomyces kefir*, *Torula kefir*, *Lactobacillus caucasicus*, *Leuconostoc* spp., and lactic acid streptococci, with yeasts representing 5–10% of the culture present (Kosikowski 1977). The presence of yeasts traditionally leads to a slight carbonation and different flavors. Products currently found in the U.S. marketplace rarely show carbonation.

76.4.2 Aerated Yogurt

This product is created by aerating the yogurt after fermentation and cooling (Klink 2003). Aerating equipment such as Oakes (E.T. Oakes, Inc., USA), Tanis (Tanis Food Tech, M.J. Meijer Aeration B.V., Netherlands) or Mondo (Haas-Mondomix BV, Netherlands) may be

used with the injection of an inert gas such as nitrogen or carbon dioxide to minimize oxidation potentially caused by the incorporation of air. The amount of gas added, calculated as overrun, ranges from 20% to 100% and can be adjusted to reach desired product attributes. To create a stable foam, stabilizer systems are required and can contain an emulsifier.

76.4.3 Frozen Yogurt

Frozen yogurt is a product that is a hybrid between ice cream and yogurt. Typically a frozen yogurt will contain 1.5–2% milk fat, 13–15% MSNF, 7–10% sucrose, 4–5% corn syrup solids (24–26 DE) and 0.15–2% stabilizers (Chandan 1982). A portion (generally 10–20%) of the frozen yogurt mix is fermented to pH 3.9 or a titratable acidity of 0.3%. This mix is blended with fruit, sugar, flavor, color, and frozen like ice cream (Chandan 1982; Marshall and others 2003). More information about frozen yogurt will be found in the ice cream chapter of this text.

76.4.4 Greek Yogurt

Greek style yogurt is traditionally thick, like a sour cream, and is produced by removing a portion of the whey from yogurt to increase the solids to 22–26% (Stringer and Dennis 2000). Usually a paterurized cream is added back to the strained yogurt to adjust the final fat content. Commonly, a small amount of sheep's milk may be added to provide characteristic aroma.

76.5 CHEMICAL AND BIOLOGICAL CHANGES DURING YOGURT PRODUCTION AND SHELF LIFE

76.5.1 Heat Treatment and Homogenization

Milk for yogurt production is subjected to a longer heat treatment than required to pasteurize the milk in order to denature the whey proteins. Denatured whey proteins, particularly beta-lactoglobulin, interact with the kappa casein or other whey proteins (Zittle and others 1962; Kalab and others 1983; Mottar and others 1989; Vasbinder and de Kruif 2003). This influences the pH of gelation, the size of the micelles and the strength of the resulting yogurt gel (Lucey and Singh 1997; Horne 1999; Anema and others 2004; Femelart and others 2004). Yogurt created with added whey protein has fewer fused micelles, more intermicellar spaces, and less syneresis than that made without added whey protein (Modler and Kalab 1983). The association of whey proteins with kappa casein is very pH dependent with more association at pH 6.5 vs. pH 6.7 (Anema and others 2004). This surface adherence shows up in electron micrographs as a fuzzy or spiky micelle surface (Kalab and others 1982; Lucey and others 1998) and leads to a more complex network with more interstitial spaces, and, therefore, increased water holding capacity (Pereira and others 2003). In unheated milk, micelles form coarse clusters during fermentation with larger interstitial spaces creating a gel more susceptible to syneresis (see Fig. 76.7) (Kalab and others 1983).

Because casein micelles exhibit a pH of maximum heat stability (pH 6.6), manufacturers of yogurt need to maintain the pH of the yogurt mix in an area of heat stability (pH 6.5–6.7) (Singh and Creamer 1992). If the mix pH is higher or lower than optimal, the caseins can

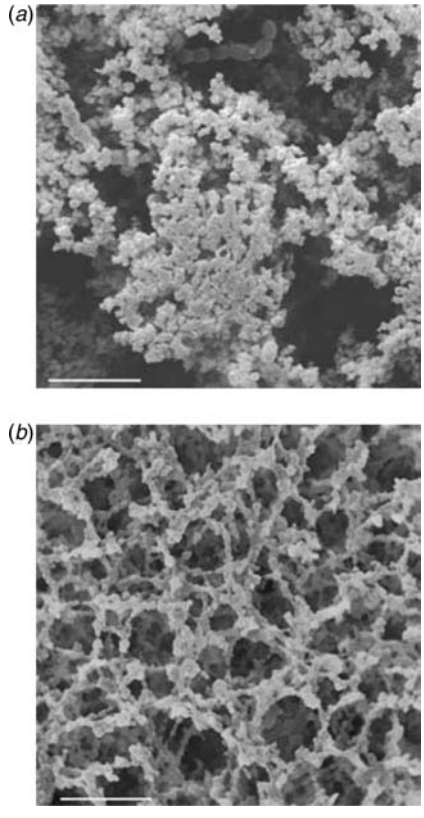

Figure 76.7 *Structure of yogurt gels from heated and unheated milk. Reprinted with permission from M. Kalab. Unheated milk, A. Heated milk, B. Bar shown is 5 micrometers in length. (From series taken at the time of Kalab and others 1983.)*

preprecipitate. This will be evidenced as high viscosity out of the heat exchanger, and will produce an inferior coagulum during fermentation (if coagulation is achieved at all).

Casein micelles are also sensitive to the calcium phosphate balance of the milk. Added ingredients that affect this balance, including water with a high mineral content, added calcium containing ingredients, or calcium chelating ingredients such as sodium citrate, will affect the stability of the micelle to heating (Singh and Creamer 1992).

The homogenization step during heat treatment also effects the final properties of the gel by increasing firmness. It appears that the effect is predominantly due to the reduction in size of the fat particle. While this results in an increase in the fat surface area and an increase in the amount of protein at the fat interface, the mechanism for the increased firmness is thought to be due to the formation of a finer gel network (i.e., one that is not disrupted by large fat globules) (Kesseler 1997).

76.5.2 Fermentation

During fermentation, the lactic cultures digest lactose and produce lactic acid. This gradual acid production lowers the pH. As the pH is decreased from about 6.7 to 5.3, the calcium phosphate balance changes as more colloidal (micellar) calcium phosphate

becomes soluble (Guinee and others 1993). The charge on the casein micelle starts to change becoming less negatively charged. As the milk reaches pH 4.6, the isoelectric point of casein, the micelles have a net neutral charge, losing the electrostatic interactions that helped prevent micelles from aggregating (Tamime and Robinson 1999). In heated milk, micelles start forming clusters and short chains at about pH 5.3. Whereas rennet gels are formed from clumps of casein micelles, acidified milk gels such as yogurt are formed from short chains or clusters of casein micelles and whey proteins. This is partly due to the interference of the denatured whey proteins on the surface and partly due to the differences in the coagulation mechanism.

The presence of denatured whey proteins shifts the gelation pH upward (Grigorov 1966a; Kalab and others 1983; Lucey and others 1997, 1999; Vasbinder and others 2001; Graveland-Bikker and Anema 2003). In model systems of casein and heated whey protein, gelation started at pH 5.8–6.2 with rapid gel strength increase at pH 5.3 (O'Kennedy and Kelly 2000). This leads to gel formation when only a portion of the colloidal calcium phosphate is solubilized.

76.5.3 Postfermentation Cooling and Storage

During refrigerated storage the cultures, particularly the lactobacilli, continue to produce acid (Tramer 1973). The majority of the acid is produced in the first seven days (Beal and others 1999). As yogurt ages, cultured dairy flavors increase, fruit flavor decreases, and sourness increases. Mold and yeast may grow if present. Whey separation may occur. All of these changes will accelerate as the temperature increases, so cold storage is important for maximizing the shelf life of yogurt. In the United States yogurt has a shelf life of 14–90 days from manufacture to the "sell by" date. This broad range is partly due to the fact many yogurts in the United States contain potassium sorbate to prevent yeast and mold growth. In the absence of yeast and mold growth, yogurt shelf-life is limited by flavor or appearance changes. Pasteurized or heat treated yogurt, which is heated after fermentation, will have a longer shelf life, but no live and active cultures.

76.6 YOGURT MICROBIOLOGY

Streptococcus salvarius subsp. *thermophilus* (also called *Streptococcus thermophilus*) and *Lactobacillus delbrueckii* subsp. *bulgaricus* (also called *Lactobacillus bulgaricus*), are both thermophilic, homofermentative lactic acid bacteria (Hardie 1986; Kandler and Weiss 1986). *Lactobacillus acidophilus* is also included in many commercial yogurts sold in the United States. Other microorganisms are sometimes added to yogurt for nutritive effects, and will be discussed separately in the nutrition section of this chapter.

Because lactobacilli have complex growth requirements, growth media used for plating these organisms must be carefully chosen. Lactobacilli require low oxygen, fermentable carbohydrate, protein, protein breakdown products, nucleic acid derivatives, fatty acids, minerals, and some B-vitamins (Mital and Garg 1992). MRS broth and M-17 agar are the usual enumeration media for lactobacilli and streptococci, respectively (de Man and others 1960; Terzaghi and Sandine 1975; IDF 1983; Sellars 1989; Vedamuthu 1991a; Frank and others 2003). However, MRS agar is not useful for differentiating between *Lactobacillus bulgaricus* and *Lactobacillus acidophilus* (Speck 1978).

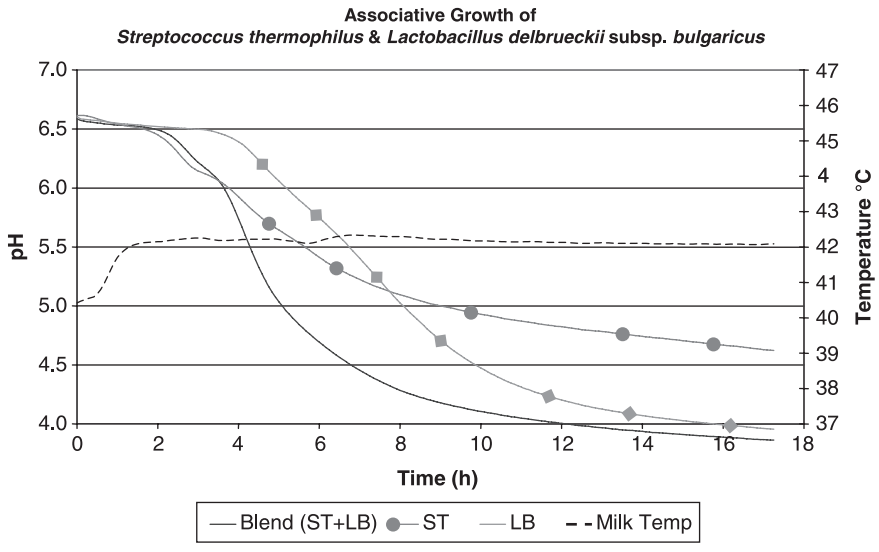

Figure 76.8 *Acidity development in a mixed culture of Streptococcus thermophilus and Lactobacillus bulgaricus. Mixed culture in a 50:50 ratio (solid line), Streptococcus thermophilus alone (circles), Lactobacillus bulgaricus (diamonds), milk temperature (dashed line). Reprinted with permission from Danisco USA Inc.*

Streptococcus thermophilus and *Lactobacillus bulgaricus* exhibit associative growth, the combination of the two leading to faster milk fermentation than either singly, as shown in Figure 76.8 (Davis 1975; Moon and Reinbold 1976; Tamime and Robinson 1999). When the two are fermented together, *Lactobaccillus bulgaricus* starts the fermentation, producing amino acids that promote streptococci growth. *Streptococcus thermophilus* continues the fermentation, rapidly producing lactic acid from lactose to about pH 5.0, after which *Lactobacillus bulgaricus* growth dominates (Tramer 1973). As it grows, *Streptococcus thermophilus* releases substances which promote the growth of *Lactobacillus bulgaricus*. The most important of these are carbon dioxide and formic acid (Tramer 1973; Driessen and others 1982). As growth factors for *Lactobacillus bulgaricus* increase in milk, *Lactobacillus bulgaricus* growth increases. As the pH decreases, *Streptococcus thermophilus* growth diminishes, because *Streptococcus thermophilus* is less acid tolerant than *Lactobacillus bulgaricus*. *Lactobacillus bulgaricus* is more proteolytic than *Streptococcus thermophilus*, and produces amino acids that promote *Streptococcus thermophilus* growth (Bautista and others 1966; Rašić and Kurmann 1978; Tramer 1973). Whereas *Streptococcus thermophilus* is responsible for the bulk of acid production at the start of fermentation, *Lactobacillus bulgaricus* is responsible for the bulk of acid production at the end of fermentation (as well as postfermentation acidification in the finished product during storage) (Kneifel and others 1993; Beal and others 1999). Fermentation rate depends on a balance of fermentation temperature, total solids in the mix, and inoculation rate for any given starter (Kristo and others 2003). The optimum temperature for growth of the two cultures together is 42.5°C (108.5°F) (Mocquot and Hurel 1970).

Starter cultures are chosen on the basis of flavor produced (whether mild or traditional is desired), resistance to phage and antibiotics, rapid acid development in milk, tolerance to sugar, ability to grow in mixed culture, minimal postfermentation acidification, production of exopolysaccharides, adaptability for large scale production, stability in finished product,

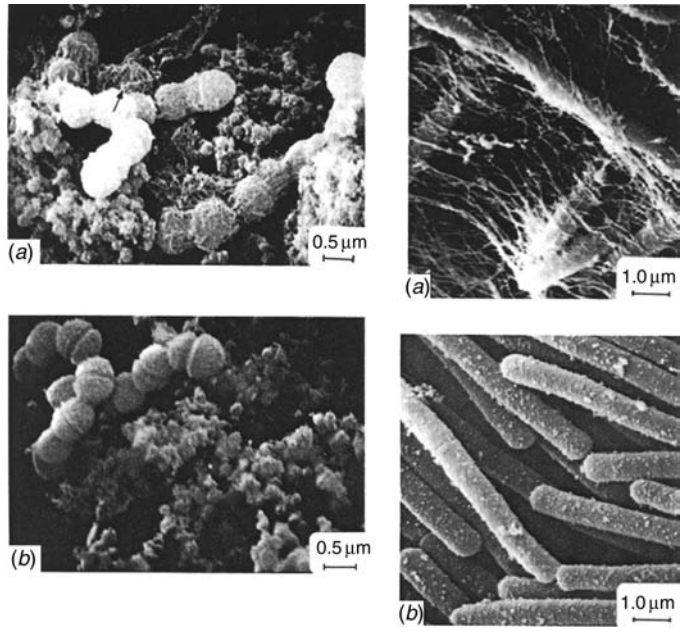

Figure 76.9 *Micrographs of ropy and non-ropy bacteria. Streptococcus thermophilus (left) (ropy top, non-ropy bottom) and Lactobacillus bulgaricus (right) (ropy top, non-ropy bottom). (Schellhaass and Morris 1985). Reprinted with permission from S. Schellhaass.*

stability during cryogenic preservation, frozen storage, and distribution (Mocquot and Hurel 1970; Tramer 1973; Davis 1975; Sellars 1989). Traditionally, *Lactobacillus bulgaricus* and *Streptococcus thermophilus* have been used in a rods to cocci ratio that is 1 : 1 to 1 : 15 (Humphreys and Plunkett 1969; Davis 1975; Chandan and Shahani 1995), with one streptococci actually often corresponding to a clump of 5–10 cells (Tamime and Deeth 1980). The ratio used will be primary in determining the final product pH (Torriani and others 1996). Typical specifications for starter cultures are described by Sellars (1989).

Ropy, or exopolysaccharide (EPS) producing strains of yogurt cultures can improve yogurt texture by producing either capsular or filamentous polysachharide exudate (see Fig. 76.9) (Tramer 1973; Davis 1975; Rašić and Kurmann 1978; Schellhaass 1983; Schellhaass and Morris 1985; Hess and others 1997; Duboc and Mollet 2001; Olson 2002). Exopolysaccharides can increase stirred viscosity and decrease syneresis (Schellhaass and Morris 1985; Tamime and Robinson 1999; Duggan and Waghorne 2003). The effect of EPS on texture is less noticeable in stirred yogurts, suggesting that these bonds do not reknit after mechanical stress (Duggan and Waghorne 2003), and is greatest for low solids yogurts (Maiocchi 2003). The type of exopolysaccharide produced, the composition of the milk, the break pH, the growth phase of the organisms and the fermentation temperature all impact the influence of ropy strains on yogurt texture (Duboc and Mollet 2001; Laws and Marshall 2001). Because lower fermentation temperature can favor *Streptococcus thermophilus* which is more commonly "ropy," lower fermentation temperatures can lead to greater exopolysaccharide production (Davis 1975). However, EPS can be produced by both *Lactobacillus bulgaricus* and *Streptococcus thermophilus* (Davis 1975).

Acetaldehyde (mainly produced by *Lactobacillus bulgaricus*) and to a lesser extent diacetyl (mainly produced by *Streptococcus thermophilus*) are important to yogurt

flavor (Davis 1975; Rašić and Kurmann 1978). Sugar at levels greater or equal to 8% in the yogurt mix can decrease acetaldehyde production (Davis 1975).

Lactobacillus acidophilus is added to yogurt for health properties, but can exhibit poor survival in yogurt (Sodini and others 2002) due to its acid intolerance (Mital and Garg 1992) and slow growth attributed to lack of proper growth factors in milk (Tramer 1973). It is not advisable to add *Lactobacillus acidophilus* after fermentation; rather *Lactobacillus acidophilus* should be grown with yogurt starter or added to the milk blend at the time of culture addition since it can be inhibited by hydrogen peroxide produced by *Lactobacillus bulgaricus* (Mital and Garg 1992). Growth of *Lactobacillus acidophilus* with yogurt cultures may increase the survival of the acidophilus in yogurt by increasing the hydrogen peroxide tolerance of the organisms (Lourens-Hattingh and Vijoen 2001). Addition of cysteine can improve the survival of *Lactobacillus acidophilus* in yogurt, possibly by increasing the redox potential (Dave and Shah 1997). Selection of the starter culture strains can greatly influence the survivability of adjunct strains such as *Lactobacillus acidophilus* or *bifidobacterium* (Lourens-Hattingh and Vijoen 2001).

Streptococcus thermophilus is easily identified among the lactics by its unique high temperature tolerance. *Lactobacillus bulgaricus* is less easy to distinguish from other

TABLE 76.1 Distinguishing Characteristics.

Characteristic	*Streptococcus salvarius subsp. thermophilus (Streptococcus thermophilus)*	*Lactobacillus delbrueckii subsp. bulgaricus (Lactobacillus bulgaricus)*	*Lactobacillus acidophilus*

Source: Kandler and Weiss (1986); Hardie (1986); Davis (1975); Tamime and Robinson (1999); Mocquot and Hurel (1970); Chandan and Shahani (1995); Mital and Garg (1992); Chandan (1982).

lactobacilli and is often confused with *L. lactis*. Distinguishing characteristics of *Streptococcus thermophilus*, *Lactobacillus bulgaricus*, and *Lactobacillus acidophilus* are outlined in Table 76.1. Environmental conditions can alter lactic morphology, and the presence of antibiotics, high solids or repeated culture transfers can lead to *Streptococcus thermophilus* that are elongated cocci (Rašić and Kurmann 1978).

Storage time, fermentation temperature, final fermentation pH, yogurt formulation, and strain selection affect the bacterial concentration to be found in the finished yogurt (Beal and others 1999; Kneifel and others 1993). *Streptococcus thermophilus* is the predominant microorganism found during storage (Vinderola and others 2000; Kristo and others 2003; Gueimonde and others 2004). Two weeks after production yogurts typically contain $10^7 - 10^9$ CFU/mL (Kneifel and others 1993).

76.7 YOGURT NUTRITION

Yogurt is a nutritious food that can deliver multiple health benefits to consumers (McKinley 2004). Yogurt, like milk, can be a good source of high quality protein, and important vitamins and minerals. The level of protein and calcium varies in commercial products, depending on the level of milk solids and nutrients that are added above the required minimums. In the United States, whey protein concentrates are often added as a protein source, but these concentrates usually have less calcium and lactose on a protein equivalent basis than skim milk powder.

Fermented dairy products have long been thought to confer special health benefits. Professor Elie Metchnikoff in 1908 (Metchnikoff 1908) reported research being conducted on the use of fermented products by indigenous cultures. He suggested that the cultures in fermented dairy products, especially Bulgarian *bacillus* species, helped to prevent intestinal putrefaction, thereby prolonging life. Research into the health benefits of yogurt have focused on the traditional yogurt cultures, and on adjunct cultures that are often added for their health benefits.

In the United States, the National Yogurt Association (NYA) has developed a program whereby manufacturers of yogurt with live and active cultures are permitted to pay for the right to display a seal on their packaging. The seal allows manufacturers to clearly identify to consumers which yogurts contain active cultures. The use of the symbol requires that the yogurt must contain 10^8 colony forming units at the time of manufacture, and the organisms must be capable of a one log increase in growth after culturing into milk at the end of the product's shelf-life (National Yogurt Association 2004).

Yogurt is generally an excellent source of calcium, a nutrient important for development and maintenance of strong bones and teeth. Recently, a link between weight loss and sufficient calcium intake was established. Consumption of calcium from dairy foods such as yogurt has been shown to contribute more fat loss and better retention of lean body mass during weight loss while following a restricted calorie diet (Zemel 2004; Zemel and others 2004).

Scientific documentation of the benefits of ingestion of yogurt cultures has focused on the benefit to lactose intolerant individuals. During fermentation, the lactose content of milk is reduced by up to 30% (Chandan 1982; Tamime and Robinson 1999; Adolfsson 2004). Approximately 80% of adults in the world have lost the ability to split the β-glycosidic bond in lactose (Barth 1996). This is very much dependent on the race of the individual. Only 20% of caucasians have problems with lactose maldigestion, while

levels approaching 100% of Africans and Asians lack the necessary enzyme (Barth 1996; Adolfsson 2004). When undigested lactose is fermented in the colon uncomfortable symptoms of gas and diarrhea can result. The reduction of lactose by fermentation and the active enzymes released from the yogurt cultures when cells burst have been shown to improve the digestibility of the milk and yogurt for lactose intolerant individuals (Martini and Savaiano 1988; Saavedra and others 2002). Although the two yogurt cultures, *Streptococcus thermophilus* and *Lactobacillus bulgaricus*, cannot colonize the human intestine, they have been found to remain viable in the small intestine for 3 to 6 h after yogurt consumption (Robins-Browne and Levine 1981) and can be detected, along with accompanying beta-galactosidase activity, in the duodenum for 1 h after ingestion (Pochart and others 1989). However, Pedrosa and others (1995) could not isolate yogurt cultures from the stomach after ingestion.

In addition to the required yogurt cultures, probiotic cultures are increasingly being added to yogurt. Probiotics are live microorganisms that exert health benefits when ingested in adequate amounts. The most common probiotic in the United States is *Lactobacillus acidophilus* which is added to most yogurts sold in the United States. However, survival of *L. acidophilus* can be poor in fermented milk products, so unless culture counts are declared, the consumer will not know the dose of *L. acidophilus* ingested. Other cultures commonly added to yogurt are *L. acidophilus*, *L. lactis*, *L. casei*, *L. helveticus*, and *Bifidobacterium* species (*longum*, *bifidum*, *infantis*) (Ming and others 1989; Sellars 1989).

Many factors affect the survival of probiotic organisms in yogurt and after ingestion. Probiotic survival is influenced by yogurt composition, oxygen content, and pH (Vinderola and others 2000; Chen and others 2004; Talwalkar and Kailasapathy 2004). Prebiotic ingredients incorporated into the base or coencapsulated with the organisms can enhance survival of some probiotics (Varga and others 2003; Akalin and others 2004; Anjani and others 2004). Screening for organisms that are acid and bile tolerant is essential to ensure that they survive transit through the GI tract and contribute to the intestinal microflora (Saarela and others 2002). Encapsulation can improve survivability of acid and bile sensitive probiotics (Goodward and Kailasapathy 2003; Sridar and others 2003).

Some health benefits that have been postulated for yogurt and probiotics are:

- Lower serum cholesterol
- Stimulate the immune system
- Reduce risk factors for colon cancer
- Reduce lactose intolerance
- Increase calcium absorption
- Synthesize vitamins and predigest proteins
- Normalize the intestinal microflora (i.e., help with irritable bowel syndrome, inflammatory bowel disease, resistance to colonization by pathogens)
- Improve digestive regularity.

Streptococcus thermophilus and *Lactobacillus bulgaricus* have been shown to confer some of the above benefits which are thought to include aiding with lactose intolerance, stimulation of immune function, and reduction in tumor formation (Meydani and Ha 2000; Saavedra and others 2002). There are also other nonbacterial components of

yogurt that have been shown in some studies to stimulate immune function. These include peptides produced during fermentation, cysteine from whey proteins, conjugated linoleic acids and soluble minerals (specifically calcium) (Meydani and Ha 2000).

There are many excellent references summarizing studies of yogurt and probiotic cultures and their effects on health (Chandan 1989; Robinson 1991; Fernandez and others 1992; Havenaar and others 1992; Barth 1996; National Dairy Council 1997; Meydani and Ha 2000; Mattila-Sandholm and others 2003; Adolfsson 2004). A problem with some studies is the inability to derive firm conclusions due to failures in study design that involve controls, administration of the probiotic to the organism, the use of in vitro indicators, and the short duration of treatment (Meydani and Ha 2000). Because of the difficulties in interpreting results and in understanding which organisms are most beneficial, the European Union has undertaken the PROEUHEALTH initiative. The goals of this program are to maintain and build confidence in probiotic products and to improve the health and quality of life of EU consumers. The research institutions involved are working to develop appropriate research tools, understand the mechanisms of probiotic action, investigate the effects on health in humans, and develop the technological properties of the organisms (Saarela and others 2002).

77.1 INTRODUCTION

Human milk is widely accepted as the ideal nutrition for infants: it does supply all necessary nutrients for rapid growth in sufficient amounts, without overloading the functional capacity of the not yet developed gastrointestinal tract or metabolism. This is especially achieved by the high bioavailability of the nutrients, so that relatively low concentrations ensure a sufficient supply (Oddy 2002).

In addition, human milk contains a lot of components, which have a functional importance rather than a nutritive one. In Table 77.1 the most relevant compounds are summarized. However, the list of these components is very long and the specific functions of a lot of these components present in human milk are still not fully understood (Oddy 2002).

When taking growth and development of the breastfed infant as a starting point, instead of considering the composition of human milk, new approaches for infant nutrition arise that could not have been won from the composition of human milk alone. In a lot of respects, breastfed infants develop differently compared to infants with artificial feeding (Davis 2001). Apart from a reduced incidence of allergic or atopic diseases (Garofalo and Goldman 1999; Kelly and Coutts 2000; Halken and Host 2001) as well as a reduced incidence of infections (Hanson and Korotkova 2002), the varying incidence of diabetes mellitus type 1 (Wasmuth and Kolb 2000) or the better cognitive functions of breastfed infants in later life are also worth mentioning (Morley and Lucas 1997). If – compared to breastfed infants – the same capacity for development should be offered to artificially fed infants, functional components have to be found that are able to compensate for the differences still present.

Another important functional aspect is the possibility that in the long term the homeostasis of important metabolic processes can be programmed in infancy by the diet. The aspect of programming homeostasis mechanisms is of ever-growing importance with regard to judging the security of functional components in infant nutrition (Koletzko and others 2002). Theoretically, components newly introduced into infant nutrition might have a negative influence on the process of programming, thus preparing the ground for later diseases, without causing negative side effects during application in infancy.

Out of the many functional components in human milk, some have already gained admission to the practice of infant nutrition. Thus, it has always been a fundamental consideration to use important functional components of human milk in infant formula as well. This is managed in the minor part by isolating such components from other sources than human milk or by searching for alternatively available components, which at a different structure have comparable effects to human milk. In the present chapter, especially lipids and food

TABLE 77.1 Bioactive Components of Human Milk and Their Functions.

Bioacitve Component	Described Function
ACTH and cortisol	Stimulate the maturation of enterocytes and intestinal barrier, modulation of the intestinal immune system
Prolactin	Regulate the maturation of the neuroendocrine and the reproductive system
Gastrointestinal hormones	Influence the function, growth, and maturation of the gastrointestinal tract
Erythropoetin	Stimulates formation of red blood cells
Growth factors IGF, EGF, TGF	Stimulate growth and maturation of the gastro-intestinal tract
Growth factor TGF β	Modulate directly immune system
Growth factor NGF	Influence neuronal maturation and cognitive functions
Cytokines	Infleunces the postnatal development of the immune system
Vitamines A, C, E; prostaglandins, inhibitors of enzymes	Reduce inflammatory reaction
Colony-stimulating factors (CSF)	Stimulate cell growth
Immune globulin sIgA	Defences against pathogens, protects intestinal mucosa
Living cells (macrophages, neutrophils, lymphocytes)	Protect against infections by bacteria and fungi
Nucleotides	Influence intestinal flora, might be involved in postnatal modulation of the immune system
Glutamine	Influences metabolism of enterocytes, possibly protective against infections
Lactoferrine, lactoferricine	Protects against infections by bacteria, viruses, and fungi, antioxidative
Long chain polyunsaturated fatty acids (LCPUFA)	Stimulate neuronal and cognitive development, modulatory effects on immune system and inflammation response
Cholesterol	Supports the enterocytes with cholesterol, has programming effect on cholesterol synthesis, and influences bile acid metabolism
Oligosaccharides	Stimulates the development of a beneficial intestinal flora (prebiotic effect of neutral oligosaccharides), modulate the immune system, and decrease the adhesion of pathogens on the surface of intestinal epithlial cells (mainly acidic oligosaccharides)

components that have an influence on the intestinal flora are reviewed. Although not present in all products, such components are on the market as part of infant formulas.

77.2 LIPIDS

Lipids are the main energy source in breast milk (>50% of energy). At birth, the infant's gastrointestinal tract is immature. In particular, the capacity to digest fat is limited mainly due to a low activity of the pancreatic lipase (Boehm and others 1995a,b) but also due to a low concentration of bile acids in the duodenal juice (Boehm and others 1996a). In breast milk, a bile acid stimulated lipase is present that helps the infant to digest the high amount

of lipids. Additionally, the critical palmitic acid is preferentially in the n-2 position of the lipid which protects the fatty acid for soap formation and subsequently low absorption. In infant formula, the addition of lipase has not been used in mass products but there are some products on the market containing artificial lipids that contain palmitic acid preferentially up to 60%) in the n-2 position (Schmelze and others 2003).

The unsaturated and monosaturated fatty acids up to a chain length of 18 carbon atoms are mainly used as energy source. The polyunsaturated fatty acids are mainly used to be incorporated into biological membranes. Therefore, for functional aspects the long chain polyunsaturated fatty acids are in the focus of the discussion.

77.2.1 Long Chain Polyunsaturated Fatty Acids (LCPUFA)

Long chain polyunsaturated fatty acids (LCPUFA) are important components of all biological membranes in the form of phospholipids. Thus, sufficient availability is an important prerequisite for practically all cell functions. In addition, some LCPUFA serve as precursors for eicosanoids, thereby influencing the immunological development and the inflammatory response of the infant. LCPUFA are defined as fatty acids with more than 18 carbon atoms. Corresponding to the position of the double bindings, one distinguishes between the n-3 and the n-6 LCPUFA-family (Fig. 77.1). Like all animals, human beings have the necessary enzyme system to synthesize these fatty acids from their essential precursors α-linolenic acid (C18 : 3 n-3) and linoleic acid (C18 : 2 n-6). Higher plants only contain fatty acids with a maximum chain length of 18 carbon atoms.

77.2.1.1 Preformed Dietary LCPUFA as Components of Biological Membranes. Human milk contains LCPUFA in relatively high concentrations, quantitatively most important are arachidonic acid (C20 : 4 n-6) and docosahexaenoic acid (C22 : 6 n-3) (Koletzko and others 1992). During intrauterine and postnatal development, there is a considerable accumulation of these two fatty acids in the brain and other tissues.

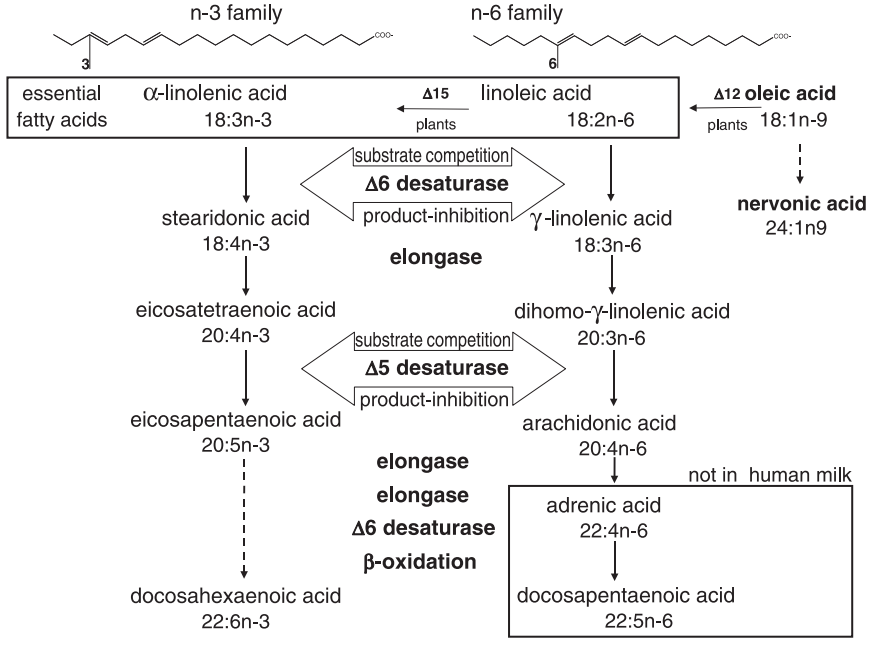

Figure 77.1 *Pathways of the two fatty acid families from the essential precursor fatty acids.*

As a result, the hypothesis arose that in addition to the essential fatty acids α-linolenic acid and linoleic acid, LCPUFA should be supplied with the diet in infancy as semiessential fatty acids. Since the beginning of the 1990s and based on the respective state of knowledge, various committees expressed recommendations for the supplementation of infant formulas with LCPUFA (ESPGAN 1991; BNF 1992; FAO/WHO 1994; ISSFAL 1994; EEC 1996; Koletzko and others 2001; SCF 2003) (Table 77.2).

It has been demonstrated in a lot of studies that in breastfed infants proportionately more LCPUFA were found in plasma lipids as well as in erythrocyte membranes, compared to infants fed a formula without LCPUFA. Besides, the content of essential precursor fatty acids was always sufficient in the respective study formulas. However, if these formulas are supplemented with LCPUFA, comparable fatty acid patterns in plasma lipids or erythrocyte membranes can be achieved as in breastfed infants (Koletzko and others 1995; Makrides and others 1995; Boehm and others 1996b).

When measuring the LCPUFA synthesis by means of [C^{13}] labeled fatty acids, it was clearly shown that both term and preterm infants are already able to synthesize LCPUFA from precursor fatty acids with 18 carbon atoms right after birth (Carnielli and others 1996; Szitanyi and others 1999). The already mentioned examinations of phospholipids in plasma and erythrocytes clearly show that the capacity for synthesis obviously does not match the huge requirements of the rapidly growing organism (Koletzko and others 1995; Makrides and others 1995; Boehm and others 1997b). Recent baboon studies performed with [C^{13}] marked arachidonic acid showed that LCPUFA from milk are actually not transferred to the general carbon cycle, that is, the dietary arachidonic acid was not xoydised, but was preferably used as structural components of biological membranes (Wijendran and others 2002a). From a metabolic point of view, this shows very clearly the importance of preformed LCPUFA for the nutrition during the first months of life.

In Table 77.3 the most important recommendations for the supplementation of infant formula with LCPUFA for preterm and term infants are summarized. They are all based on the assumption that infant formulas should contain LCPUFA at the same concentration as in human milk. Although influences of the maternal diet on the composition of human milk have been described, the pattern of LCPUFA in the lipid fraction of human milk seems to be relatively constant (Koletzko and others 1992; Jensen and others 2000). This is mainly due to the fact that the majority of LCPUFA in human milk derive from maternal stores, while only 10–15% derive from current nutrition (Sauerwald and others 2000).

Human milk contains all n-3 fatty acids up to docosahexaenoic acid and all n-6 fatty acids up to arachidonic acid. There are further fatty acids in the tissue that derive from arachidonic acid by elongation and desaturation (Fig. 77.1). These fatty acids are not present in human milk. Thus, arachidonic acid seems to be an important dietetic precursor for these fatty acids, which are especially important to the myelinization in neuronal tissues (Martinez and Mougan 1998; Wijendran and others 2002).

The present data allow the conclusion that in spite of a sufficient supply with essential fatty acids, preformed dietary LCPUFA from human milk are preferably incorporated into biological membranes. This can be similarly achieved by supplementing formulas with LCPUFA-containing lipids.

77.2.1.2 Physiological Importance of LCPUFA in Infant Formulas

Effect of LCPUFA on Brain Development. The putative significance of LCPUFA for the development of the rapidly growing brain of the newborn was already a matter of

interest at an early stage, since the neuronal tissue is very rich in LCPUFA (Martinez and Mougan 1998). This was supported by the investigations of the study group of A. Lucas, which very early pointed to the significance of nutrition for brain development (Lucas and others 1992). Additionally it could be shown to show that the fatty acid composition of erythrocytes is concomitant to that of the brain indicating that the measurements of fatty acid pattern of red blood cell membrane are relevant also for the neuronal tissue (Makrides and others 1994). As a consequence, breastfeeding is associated with improved neurological conditions (Bouwstra and others 2003b) as well as cognitive functions (Hadders-Algra 2005). Based on these data it is widely accepted that a supplementation of infant formulas could support the development of the brain.

Infant formulas that are supplemented with LCPUFA are commercially available in Europe since 1992. However, the debate about a possible benefit of LCPUFA in infant formula is not over yet. There is only a fairly good consensus that preterm formulas should contain LCPUFA. The attitude towards the benefit of LCPUFA for healthy term infants is by far less unanimous. The most important reason for that it is difficult to measure brain function. Internationally recognized neurological tests have been developed, in order to differentiate between a normal development from a disturbed one. Due to the enormous ability of the brain to compensate for harmful effects during development (so-called "plasticity" of the brain (Beaulieu 2002), it is, however, very difficult to prove positive effects of a supplementation with LCPUFA during the first months of life with these methods at a later age as well (Koletzko and others 2001; Bouwstra and others 2005). Thus, first studies have been started to develop new neurological tests, which are able to measure differences of the development within the normal variations.

Recently, it was found that the fatty acid status at birth has an important impact on the postnatal development of brain functions indicating that the fatty acid supply to the pregnant woman is also important. High intake of trans fatty acids was accompanied by lower levels of docosahexaenoic and arachidonic acid in the infant's tissue (Desci and others 2002). The fatty acid status at birth had significant influence on the neurological behavior immediately after birth (Dijck-Brouwer and others 2005), on general movement quality at three months of age (Bouwstra and others 2003a, 2006a) and on cognitive functions at 18 months of age (Bouwstra and others 2006b).

Since still many aspects of the LCPUFA metabolism are under investigation, there are no final statements with regard to the necessity of a supplementation of infant formulas for

healthy term infants. However, there is increasing evidence that LCPUFA are helpful for supporting brain development during the first months of life (Khedr and others 2004; Hadders-Algra 2005).

Effect of LCPUFA on the Development of the Immune System. LCPUFA are an important link between fat metabolism and the immune system. On the one hand, they are precursors of important mediator-substances, the so-called eicosanoids, which play an important role in inflammations (Calder and Grimble 2002; Calder 2003). The most important fatty acids, which serve as precursors for eicosanoids are eicosapentaenoic acid (C20 : 5 n-3), docosahexaenoic acid (C22 : 6 n-3), dihomo-γ-linolenic acid (C20 : 3 n-6), and arachidonic acid (C20 : 4 n-6). On the other hand, some LCPUFA regulate the formation of eicosanoids from their respective precursors (Guichardant and others 1993; Keichler and others 1995; Ringbom and others 2001) by inhibition of the enzymes cyclooxidase and lipoxigenase indicating a very crosslinked regulative system which can be influenced by dietetic measures (Kelley and others 1997; Calder 1999). While there is considerable, clinically relevant evidence for older children and adults regarding the dietetic application of specified lipid mixtures in chronic-inflammatory diseases (Suter 1994; James and Cleland 1997; Belluzi and Miglio 1998; Ziboh 1998), there are practically no studies in newborns. This is partly based on the LCPUFA requirements of the newborn, which are essentially determined by the requirements for growth. In addition, the specific constellation of the immune system of newborns does not allow a direct comparison to the immune systems of adults with regard to the effect of fatty acids. At birth, the immune system is dominated by Th2-reactions. This is necessary until the end of pregnancy, in order to suppress cytological reactions of the Th1-type, which would result in an immunological conflict between mother and fetus (Langrish and others 2002; Morein and others 2002).

However, there are recent studies showing that there is a relationship between LCPUFA supply during infancy and postnatal development of the immune system. The fatty acid profile of the milk of atopic mothers is characterized by relatively low concentrations of important LCPUFA. This is also reflected in the fatty acid status of the newborn (Beck and others 2000; Kankaanpaa and others 2001). If the human milk contains relatively high amounts of n-6 and low amounts of n-3 fatty acids, breastfed infants also show atopic symptoms even during the first year of life (Duchen and Björksen 2001). Field and others (2000) were able to show that by supplementing an infant formula with LCPUFA, the lymphocyte population and cytokine production were comparable to breastfed infants.

It is known from animal studies that LCPUFA can promote the growth of the thymus gland (Guimaraes and Curi 1991; Fernandez and others 1997). Thus, LCPUFA are directly linked to the postnatal development of a central organ of the immune system. So far, there are no systematic studies in human newborns on this subject. However, it was shown by sonographic measurement of the thymus size that in breastfed infants during the first three months of life, the thymus tissue growths much better than in infants fed formula without LCPUFA (Hasselbalch and others 1999). Results of studies showing in how far the difference between breastfeed and formula fed infants can be corrected by LCPUFA supplementation are not available yet.

In summary, it may be said that LCPUFA in human milk have an important immunomodulating task. Therefore, the supplementation of infant formulas with LCPUFA should not exclusively be considered on the basis of structures and function of membranes of the brain.

Further Physiological Effects of LCPUFA. Due to the various effects of eicosanoids, which are not only limited to the immune system, and the far-reaching importance of LCPUFA for the function of biological membranes, impacts on a variety of physiological processes are possible.

Thus, it was reported that the blood pressure in 6-year-olds, who where fed an LCPUFA supplemented infant formula for 3 months as infants, was significantly lower compared to infants fed a formula without LCPUFA (Forsyth and others 2003). This could be of considerable importance with regard to the development of cardiovascular diseases later in life.

Experimental results are plausible with regard to the influence of LCPUFA on the development of bone tissue (Bodin and others 2003). Clinical studies in infants on this subject are not yet available.

As it is too early for a clinical evaluation of such results, they have not been considered yet in the production of fat blends for infant formulas. The results also show that with the progressive state of knowledge new applications are possible.

77.2.1.3 Side Effects. *In vitro* and animal experiments have shown that apoptosis was induced by a high concentration of eicosapentaenoic acid (Heilmi and others 2001; Sweeney and others 2001), while high doses of arachidonic acid led to a reduction in thrombocyte aggregation.

Due to the sensibility of LCPUFA towards oxidation, it was examined whether an additional dose of LCPUFA would have an impact on the peroxidation of lipids. This was not the case (Stier and others 2001).

LCPUFA-supplemented formulas are on the market since 1992 and with regard to the concentrations all manufacturers comply with the recommendations. There have been no reports so far about direct side effects in this concentration range. Therefore, there has been no safety advice accompanying the recommendations (ESPGAN 1991; BNF 1992; FAO/WHO 1994; ISSFAL 1994; EEC 1996; Koletzko and others 2001; SCF 2003).

77.2.1.4 Recommendations for the Supplementation of Infant Formulas. With extracts of egg lipids, the whole range of LCPUFA in form of phospholipids is available as a raw material. Fish oils can be used as an excellent source for all n-3 LCPUFA. Arachidonic acid and docosahexaenoic acid are available in form of triglycerides as so-called single-cell oils. These raw materials have already been used in infant formulas in Europe and the United States in various mixtures. Thus, the technological requirements exist, in order to manufacture every possible combination with regard to the fatty acid profile as well as the form of the lipids.

All LCPUFA in human milk are assigned to have a physiological role. Therefore, one has to assume that a well-balanced ratio of the individual fatty acids is important for the supplementation of infant formulas (SCF 2003).

In all published recommendations so far, the absolute amount of the single LCPUFA but not the form of lipids in which they appear played an important role. However, recent animal studies have shown that the form of the lipid influences the efficiency of the incorporation of LCUFA from milk into structural lipids. For instance, LCPUFA that are offered as phospholipids are incorporated in a significantly more efficient way into lipids, compared to LCPUFA that are administered in the form of triglycerides (Wijendran and others 2002a). This can be partly explained by the fact that LCPUFA from phospholipids are more efficiently absorbed compared to those from triglycerides (Boehm and others 1997; Carnielli and others 1998). In human milk, LCPUFA are

practically not available as free fatty acids, but can be found as 85% triglycerides and 15% phospholipids (Jensen 1996). Due to the influence of the lipid form on the bioavailability of LCPUFA, they should ideally be supplemented in infant formulas as in human milk consisting of both, triglycerides and phospholipids.

The necessary duration of a supplementation is still an unsettled issue. There are no systematically conducted clinical trials with formula-fed infants. Investigations with healthy term infants have shown that with regard to the neurological development, a breastfeeding period of more than six weeks does offer advantages compared to a shorter duration. As the LCPFUA supplementation follows the "ideal" human milk as far as possible, a duration corresponding to the breastfeeding recommendations seems to be useful.

77.2.2 Gangliosides

Gangliosides are a group of sialic acid containing glycosphingolipids. They consist of a lipophilic ceramide moiety and a hydrophilic oligosaccharide chain. Ceramide is comprised of a sphingoid base and an amide bond fatty acid. The oligosaccharide chain is linked to the sphingoid base at the hydroxyl-group at carbon atom 1 (Fig. 77.2).

Gangliosides are vital components of neural membranes first described in ganglia cells by Klenk in 1935 (Klenk 1935). Since then gangliosides could be detected in a diversity of other tissues.

Gangliosides in human milk are part of the membrane fraction of the milk fat globule (Jensen 1996).

The quantitatively most important milk gangliosides are the disialogangloside GD_3 and the monosialoganglioside GM_3 (Huang 1973; Hauttecoeur and others 1985). Moreover, the ganglioside composition of human and bovine milk was shown to be different. While GD_3 is the main ganglioside in bovine milk, GM_3 dominates in human mature milk. The fatty acid composition of GM3 and GD3 differs between human and bovine milk (Bode and others 2004). Because bovine milk is the main basis for infant formula attempts have been made to chance the fatty acids composition of bovine gangliosides toward the composition found in breast milk (Beermann and others 2005).

Human milk possesses a specific pattern of gangliosides dependent on the state of maturation. Bovine milk based IMF ganglioside levels are lower. However, butter milk is a interesting source of milk born gangliosides. Approximately 1–2% of the total lipid content of bovine buttermilk are gangliosides. In human colostrum GD_3 is the main ganglioside whereas in mature human milk GM_3 and several highly polar gangliosides are predominant, dependent on the maturation status (Rueda and others 1998). In addition the fatty acid composition of gangliosides is species specific. In bovine milk, it has been shown that the fatty acid pattern of triacylglycerols, phospholipids and gangliosides depends on the stage of lactation and may be an adjustment to specific metabolic demands (Martin and others 2001). A critical analysis showed that infants fed starter formulas have only 20% ganglioside sialic acid intake of those fed human colostrum or transitional milk. Follow on formulas (4–5 months) provide more or less the same amount ganglioside (also total sialic acids) as mature human milk. A supplementation with sialic acid containing glycoconjugates of infants especially for the first days after delivery is recommended (Sanchez-Diaz and others 1997).

As sialic acid is an important component of the brain tissue, gangliosides have been considered essential for CNS growth and development since many years. There

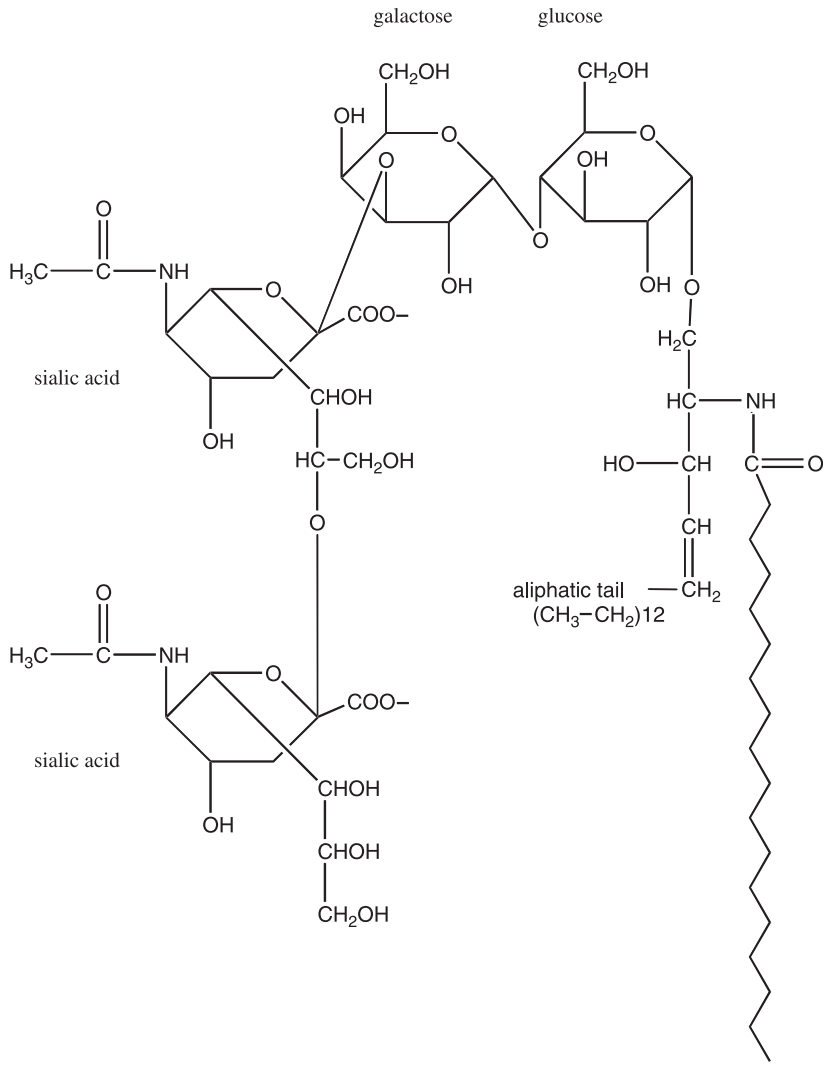

Figure 77.2 *Chemical structure of gangliosides (example: GD_3).*

is evidence that gangliosides are essential for synaptogenesis, and neurotransmission, brain growth and maturation (Wang and others 2003). Human milk is very rich source of sialic acid relative to infant formulas and breast fed infants have two-fold higher concentration of salivary sialic acid. It is conceivable that documented developmental advantages of breastfeeding might be partly explained by higher ganglioside content in brain gray matter, which resulted from a higher intake of exogenous sialic acid like in human milk (Mendez-Otero and Santiago 2003; Khedr and others 2004). Additionally it could be demonstrated that a strong correlation exists between the LCPUFA and ganglioside metabolism of the brain (Wang and others 2003). Consequently, a combination of both ingredients could be a further step of improvement of infant formulas.

77.2.3 Analytical Techniques

Although not completely understood, there is a strong relationship between the biological functions and the molecular structure of lipids. This relation between physiological function and molecular structure of milk lipids efforts an analysis strategy with a systematic process implementing target specific extraction, chromatographic separation and fractionation techniques up to mass-spectrometry methods for molecular structural characterization.

Human or animal milk as a native matrice contain a complex composition of lipids with different polarities and a broad range of different types of integrated fatty acids.

For the structural/qualitative and quantitative analysis extraction methods focusing on the main lipid classes neutral lipids and polar lipids are helpful. Aside this, a rapid method for the determination of total fat in milk products using a supercritical fluid extraction has been developed (Wolf and others 2003).

To separate lipids into the different polarity classes varying in polarity from cholesterolesters up to lysophosphatidylcholine a HPLC method with a triple gradient (hexane, isopropanol, water) with a polyvinyl-alcohol diol/reversephase column techniques is the next step.

This technique is also suitable for the quantitative analysis of major lipid classes. For the optimal quantification of lipophilic molecules and lipid species of the different polarity classes, independent of absorption properties of the eluent and probes and without any derivatization labeling an evaporative light scattering detection is used. With reference to standard calibrations it is possible to quantify separated lipid components derived from milk and other native matrices.

Further neutral- and glycolipids could be separated via HPCL with a binary gradient (acetonitrile, isopropanol) and reverse phase (C18) column technique. Concerning glycolipid-extrations analysis a binary gradient (acetonitrile, phosphate buffer) with a aminopropyl anion-exchange technique is available. The combination of this HPLC lipid class separation combined with an automatic fractionation and completed with gaschromatographic analysis or mass spectrometry allows a rapid and complete lipid structure explanation (Sebedio and Pevkins 1995).

Depending on the question it is possible to analyze the sampled fractions from HPCL separation on fatty acid composition via methyl ester derivatisation and gaschromatography. And using mass spectrometry often coupled with gas or liquid chromatography the exact molecular structure deduced from the molecular mass could be characterized.

The combination of different extraction-methods, chromatography and mass-spectrometry techniques can be used for the determination of the lipid composition of a great variety of source materials and to describe the molecular structure of isolated components.

77.3 CARBOHYDRATES

The main carbohydrate in breast milk is lactose and consequently, the majority of infant formulae contain lactose. Lactose is an easy digestible source of energy. Although the lactase activity of the brush border membrane appears relatively low most infants tolerate lactose well. The tolerance is less developed in Asian populations.

Apart from lactose, breastmilk contains considerable amounts of so called oligosaccharides (OS). These OS are not digestible and have several biological functions (Boehm and Stahl 2003a). Since 1980 OS are defined as carbohydrates with a degree of polymerization up to 10. However, as there is no physiological reason for this definition,

oligosaccharides have been variously defined later on ranging from a degree of polymerization of 2 up to 20 and more (BNF 1990; Kunz and others 2000). Recently the IUB-IUPAC Joint Commission on Biochemical Nomenclature stated that the borderline between oligo- and polysaccharides cannot be drawn strictly. However the term oligosaccharide is commonly used to refer to defined structures as opposed to a polymer of unspecified length (IUPAC and IUBMB 1997).

Free oligosaccharides are naturally a constituent of all placental mammals' milks and can also be found in bacteria, fungi, plants, and so on. Further they derive from hydrolysis of dietary polymers during digestion. Technologically, they can be extracted from natural sources, can be synthesized from monomers and/or small oligosaccharides or derived from hydrolysis of natural polymers.

Human milk contains up to >1 g OS/100 mL indicating that, at least during postnatal development, they play an important physiological role. It is widely accepted that human milk oligosaccharides contribute to the establishment of a particular intestinal flora (dominated by bifidobacteria), the postnatal stimulation of the immune system, to the defence effect of human milk against viral and bacterial infections, and the enhancement of the bioavailability of minerals. Although human milk is the specific diet during the postnatal period, there is evidence that effects of oligosaccharides observed during the postnatal period can also be found in later life.

77.3.1 Carbohydrate Components that Influence the Intestinal Microflora

The intestinal flora of the infant is developed in a stepwise process after birth, which can be influenced by many factors. Modus of birth, extrinsic factors such as medication or nutrition, but also bacterial interactions lead to a very complex flora with about 400 species within the first few weeks of life (Orrhage and Nord 1999). Breastfed infants develop an intestinal flora in which bifidobacteria dominate, while formula-fed infants develop very quickly an intestinal flora comparable to that later in life without a dominating bifidus flora (Harmsen and others 2000).

The physiological significance of the intestinal flora for the host has been the focus of many scientific studies in the past few years. The intestinal flora reacts with the intestinal epithelial cells as well as with the immune system (Köhler and others 2003). The influence of the postnatal development of the immune system is of considerable importance for infancy. First results come to the conclusion that there are tight relations between the intestinal flora during infancy and the development of atopic or allergic diseases later in life (Böttcher and others 2000; Björksen and others 2001; Kalliomaki and others 2001; Woodcock and others 2002). During the past few years, allergic diseases have increased considerably in developed countries. Therefore, there is a huge scientific interest in the possibility to reduce the frequency and severity of such diseases by positively influencing the intestinal flora.

There are basically two concepts to selectively change the intestinal flora by dietetic interventions (Saavedra and Tscherina 2002): living bacteria (so-called probiotic bacteria) are administered into the gastrointestinal tract or the diet is supplemented with components (so-called prebiotics) that positively influence the intestinal flora by selectively promoting specific bacteria. When taking the effects of human milk on the intestinal flora of the infant as an example, the prebiotic way can be considered as the natural way to develop the intestinal flora.

77.3.1.1 Oligosaccharides as an Important Prebiotic Factor in Human Milk. The bifidogenic effect of human milk is known since more than 100 years (Tissier 1900). Various bifidogenic substances have been identified in human milk. Oligosaccharides have been recognized as an especially effective prebiotic in human milk (Newburg 2000).

Oligosaccharides appear in human milk at a concentration of up to >1 g/100 mL, while they are virtually absent in infant formulas. The structure of oligosaccharides in human milk is very complex (Boehm and Stahl 2003) and the functional consequences of these very different structures remain to be elucidated.

Oligosaccharides in human milk are virtually resistant to digestion (Engfer and others 2000; Moro and others 2005). Therefore, they reach the colon, where they can develop their prebiotic effect. Thus, the nondigestibility during the passage through the small intestine is a prerequisite for a prebiotic effect. Structural requirement for the resistance towards digestive enzymes is the beta-glycosidic bonding of galactose in the basic molecule (Fig. 77.3). In fact, the digestive enzymes of the human gastrointestinal tract are only able to split off galactose from an alpha-glycosidic bonding. In contrast, the intestinal bacteria have the enzymes available to utilise these compouds.

77.3.1.2 Effects of Prebiotic Oligosaccharides of Nonmilk Origin. Due to the complexity of OS in human milk and the lack of natural raw materials with identical structure, it was necessary to search for alternative structures with prebiotic effect for the application in infant formulas.

When searching for alternative substances, criteria such as availability, safety of the source and biological efficacy play an important role.

Several oligosaccharides from different sources have been identified as prebiotic components. The most relevant compounds for the use in infant nutrtion are summarized in Table 77.3.

The most extensive experience is available for fructo-oligosaccharides gained from chicory extract and galacto-oligosaccharides gained from enzymatic synthesis of lactose. Initially used for adults, they are the basis for the prebiotic concept for infant formulas since the mid-1990s (Gibson and Roberfroid 1995; Boehm and others 2003).

So far, especially fructo-oligosaccharides and galacto-oligosaccharides were used in infant formulas. The most intensive studies exist for fructans and, to a lesser extent, for

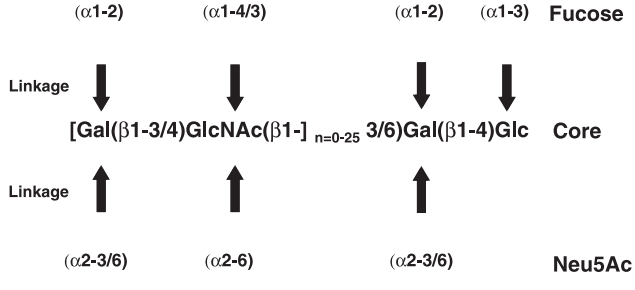

Figure 77.3 *Basic structure of human milk oligosaccharides. The arrows mark the possible location of the glycosidic linkages of the respective fucose and sialic acid residues. Please note that not all possible linkages might occur in a distinct oligosaccharide.*

galactooligosaccharides (Loo and others 1999). Fructans are linear or branched fructose-polymers, which are either mainly β2-1-linked inulins or mainly β2-6-linked levans. Because the inulin type fructans can be easily extracted from plant sources (e.g., asparagus, garlic, leek, onion, artichoke, chicory roots, etc.) they have been widely used as ingredients of dietary products.

Galactooligosaccharides are synthesized from lactose via enzymatic transgalactosylation using β-galactosidases mainly of bacterial origin (e.g., *Bacillus circulans*) (Tanaka and Matsumoto 1998). The commercial use of β-galactosidase in food processing is extensively reviewed elsewhere (Kinsella and Taylor 1995) Galacto-oligosaccharides consists of a chain of galactose molecules with mainly a glucose molecule at the reducing terminus, varying in chain length (degree of polymerization range 3–8) and linkages.

A mixture of these two oligosaccharides has been proven to be particularly effective. The bifidogenic effect was shown in formula-fed preterm (Boehm and others 2002) and term (Moro and others 2002; Schmelze and others 2003) infants. The effect depends on the dosage. At a concentration of 0.8 g/dL (this corresponds to the concentration of neutral oligosaccharides in human milk), the number of bifido bacteria was tantamount to that found in the feces of breastfed infants. The bifidogenic effect was associated with a reduction of the stool Ph (Moro and others 2002) as well as a reduction of pathogenic bacteria (Knol and others 2005a).

Short-chain fatty acids are of considerable importance to the physiological effect of the intestinal flora. They are the fermentation product of bacteria in the colon and are therefore an important characteristic feature of the intestinal flora (Siguur and others 1993). Compared to formula-fed infants, the profile of short-chain fatty acids differs considerably from that of breastfed infants. On supplementing an infant formula with a mixture of galacto-oligosaccharides and inulin, there was a pattern of short-chain fatty acids in feces that corresponded to the pattern found in the faeces of breastfed infants (Knol and others 2005b). The short chain fatty acid pattern reflect the metabolic activity of the entire flora.

Thus, the similarity of fecal short chain fatty acids between breastfed infants and infants fed a formula supplemented with galactooligosaccharides and inulin indicate that the given prebiotic mixture stimulate the entire flora towards the flora of breastfed infants (Boehm and others 2004a).

There is accumulating evidence that the bacteria stimulated by the prebiotic ingredients as well as by their metabolites play an important role in the postnatal developemnt of the immune system (Boehm and others 2004b). The effect could be proven in animal experiments. Feeding galactooligosaccharides and inulin as mixture to mouse a significant stimulation of the cellular (e.g., Th1/Th2) immune balance and reduced the allergic inflammation after antigen exposure (Boehm and others 2004b).

In summary, the conclusion can be drawn that such prebiotic oligosaccharides are able to positively influence the immunological development (Boehm and others 2005).

77.3.1.3 Side Effects of Prebiotic Oligosaccharides. There are no known side effects when applying up to 1 g/100 mL of galacto-oligosaccharides. In theory, higher dosages could display osmotic effects. In clinical trials, concentrations higher than 1 g/100 mL have not been applied. Therefore, such side effects have not been described in infants.

At higher concentrations (>0.5 g/100 mL) fructo-oligosaccharides can cause flatulence. This applies especially to short-chain fructo-oligosaccharides (chain length of up to 10 monomers). As a consequence, some commercially available infant formulas with prebiotic oligosaccharides use especially inulin with a chain length of more than 10 monomers at a relatively low concentration. The Scientific Committee on Food of the EU did not have any safety concerns with regard to a total concentration of 0.8 g/100 mL and a mixture of 90% galacto-oligosaccharides with 10% long-chain fructo-oligosaccharides (ECSCF 2001).

77.3.1.4 Recommendations for the Supplementation of Infant Formulas with Prebiotic Oligosaccharides. Provided that alternative oligosaccharides are similarly effective as neutral oligosaccharides in human milk, the concentration range of supplemented oligosaccharides should be between 0.4–0.8 g/100 mL. This is supported by the results of clinical studies: at a concentration of 0.8 g/100 mL of a galacto-oligosaccharide/fructo-oligosaccharide mixture, the concentration of bifidobacteria in feces was similar to that of breastfed infants (Moro and others 2002; Schmelze 2003).

The effect of prebiotic oligosaccharides depends on a constant supply. Therefore, the duration of the supplementation should follow the recommendations for breastfeeding.

77.3.2 Analytical Methods

Depending on the type, size and structure, as well as the (biological) source of oligosaccharides a variety of separation techniques and methods have to be applied for the characterization of the molecules of interest. The milk oligosaccharides are described in detail by Newburg and Neubauer (1995) and Kunz and others (2000).

For general analytical techniques and methods in the field of glycobiology the reader is referred to Lennarz and Hart (1994) and El Rassi (1995).

Briefly, the major techniques for the analyses of glycans (pure carbohydrates) and glycoconjugates (such as glycoproteins and glycolipids) are chromatography, mass spectrometry (MS), spectroscopy, electrophoretic methods and separation techniques like crystallization, and filtration. Chromatography plays the major role in separation and analyses of oligosaccharides. Besides ion exchange chromatography, affinity chromatography (by lectins or antibodies) and gel permeation GPC, high performance liquid chromatography (HPLC) is the most frequently used technique. As stationary phases normal phase (e.g., amino phases), reversed phases (e.g., C-18) as well as graphitized carbon columns are used. Refractive index, UV and fluorescence, and radioactivity are used as detection principles with evaporative light scattering detection as a technique with a great potential. High pH anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) is a powerful method widely used for carbohydrate analysis (Lee 1996).

For structural analyses of distinct oligosacharides nuclear magnetic resonance spectroscopy (NMR) is a very powerful method but if only minute amounts of samples are available, mass spectrometry plays an important role for sequencing of molecules. Methylation analyses and GC-MS of monosaccharide compounds are widely used for determination of structural features of oligosaccharides. Fast atom bombardement (FAB-MS) enable the structural analyses of mainly derivatized oligosaccharides and more recent techniques like matrix assisted laser desorption/ionization mass spectrometry

(MALDI-MS) and (nano) electrospray ionization mass spectrometry enable the characterization of native (underivatized) carbohydrates. MALDI-MS of glycans and glycoconjugates is excellently reviewed by Harvey (1999). Nano-ESI-MS is especially well suited for analyses of oligosaccharides, glycoproteins, and other glycoconjugates (Karas and others 2000).

As an alternative to PSD MALDI the negative ion nano-ESI-ion trap MS of native underivatized oligosaccharides is even a more powerful technique, since in the MS^n-mode of fragmentation the real sequence from the reducing end of the molecules can be generated with additional information on position of the glycosidic linkage of the released fragment (Pfenninger and others 2002a). The use of MALDI-Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FTICRMS) offers a direct detection of the distinct unambiguous composition of human milk oligosaccharides by high resolution measurements (Pfenninger and others 2002b).

Especially for the widely used prebiotic oligosaccharides the classical dietary fiber analyses have been insufficient since these molecules show good solubility compared to typical fibers the so called nonstarch polysaccharides. For the analyses of prebiotics like fructans (oligofructoses, inulin) and galactooligosaccharides, AOAC methods (Association of Official Analytical Chemists) have been recently published.

77.3.3 Future Developments

Although the understanding of the molecular mechanisms of dietary oligosaccharides is not complete there are some health benefits which can be directly attributed to these ingredients. This stimulates the future attempts to investigate the structural basis of these functions. In fact, there are some possibilities to produce a particular "designed" oligosaccharide molecules. Therefore, the development of test systems to investigate biological effects of oligosaccharides *in vitro* as well as *in vivo* has a high priority.

Because the possible health benefits of dietary oligosaccharides are species dependent animal studies have a limited importancein elucidating the beneficial effects of oligosaccharides to humans.

The intestinal microbiota plays a key role as a mediator of the physiological effects of dietary oligosaccharides. During the last decade, an enormous progress has been made in improving the techniques in analyzing of fecal microbiota. The intestinal microbiota in humans can usually be studied using fecal samples which does not adequatably reflect the intestinal microbial ecosystem. Therefore, noninvasive methods will be developed to investigate the metabolic activity of the intestinal microbiota using stable isotope techniques.

In summary, dietary oligosaccharides of different origins offer a variety of functional effects which might have significant benefits to the general health of humans. Because oligosaccharides are safe, quite stable and can easily be processed in dairy and food industry there is a great pontential in contributing as functional dietary ingredients in various functional products.

77.4 PROTEINS

Human milk contains a lot of different proteins needed as a well-balanced amino acid source for rapidly growing infants. Therefore, traditionally the quality of a dietary protein for infants is mainly evaluated on the basis of its amino acid composition

TABLE 77.4 Amino Acid Composition of Human Milk.

aa: Amino acids.

(Volz and others 1983; Picone and others 1989; Polberger and others 1990; Hanning and others 1992; Lönnerdahl 2003). Although human milk is considered as a "gold standard" for the composition of infant formulas, the milk composition is far away being a standard. In Table 77.4 literature data commonly used as reference are summarized. The variations found in the different studies are the reason that authorities like FDA or EFSA have not similar reference values leading to different quality evaluation of dietary proteins of identical composition.

From a metabolic point of view, the amino acid composition is only one factor of the nutritive quality of a dietary protein. Measurements of postprandial plasma amino acid profiles demonstrate that the postprandial metabolic response differs significantly between human milk protein and bovine milk protein feeding which cannot predict from the composition (Moro and others 1999). The glycosylation of some proteins have been identified as one factor influencing the digestibility but also technological processes such as heating can influence the postprandial amino acid pattern (Boehm and Räihä 1994).

Besides these nutritional proteins also functional proteins were found in human milk (Table 77.5). In the combination of "nutritive" and "functional" proteins, human milk provides an adequate nutrition and protect the infants against infections and facilitate an optimal development of important physiologic functions in newborns (Lönnerdahl 2003).

77.4.1 Human Milk Proteins in Comparison to Bovine Milk Proteins

The most infant milk formulas contain cow's milk proteins, intact or for hypoallergenic formulas in the form of peptides. These proteins show considerable differences to human milk proteins (Table 77.6). The total protein content is three times higher in bovine milk than in human milk and the casein/whey protein ratio is also completely different with approximately 40 : 60 in human milk and 80 : 20 in bovine milk (Prentice 1996). Also the individual proteins belonging to caseins or whey proteins are very different between human milk and bovine milk. The main casein of bovine milk is α-casein which is not found in human milk or only in small traces. The main difference in whey proteins is the high amount of β-lactoglobulin in bovine milk which is missing in human milk (Table 77.6).

Despite these big differences in both milk proteins, the casein whey protein ratio and the amino acid composition of infant milk formulas could be adapted very similar to human milk proteins, which is particularly important for starting formulas. These formulas have a casein/whey protein ratio of 40 : 60 or 50 : 50 and a total protein content of 1.3–1.6%. Follow-on formulas are higher in protein content (1.7–1.9%) and have sometimes the same casein/whey protein ratio as cow's milk.

77.4.1.1 Caseins. Caseins are the main protein fraction in bovine milk and can be separated from the whey proteins by acid precipitation at the isoelectric point (pH 4.6) or enzymatically by chymosine. All caseins are phosphorylated and especially the κ-casein is additionally glycosylated. Casein phosphopeptides which are released during the digestion can increase the calcium absorption which is important for growing infants. Furthermore, increased zinc absorption could be shown (Hansen and others 1996; Newburg 1997). The sugar structures of the κ-casein, especially the sialic acids seem to be effective in the prevention of the attachment of bacteria to the gastrointestinal mucosa (Lönnerdahl 2003).

TABLE 77.5 Human Milkborne Peptide Hormones and Hormonally Active Peptides (Peptides also Found in Bovine Milk Marked with #).

Hypothalamo-hypophysial hormones
Follicle stimulating hormone (FSH)
Gonadotropin releasing hormon (GnRH)
Growth hormone releasing factor (GRF)
Human growth hormone (GH)
Prolactin (PRL) #
HGH/PRLBP (binding peptide)
Thyrotropin releasing hormone (TRH) #
Thyroid stimulating hormone (TSH)
Calcitonin-like peptide
Parathyroid hormone-related peptide
Growth factors and cytokines
Acid growth factor (CAGF) = (EGF-like)
Basic growth factor (BAGF) = platelet differentiation GF-like)
Epidermal growth factor (EGF) #
Insulin
Insulin-like growth factor-I (IGF-I) #
Insulin-like growth factor-II (IGF-II) #
IGFBP-2, IGFB-3; not detected −1 and −4
Milk growth factor (MGF-S1, MGF-S2)
Milk derived growth factor 1
Neural growth factor (NGF)
Transforming growth factor (TGF α)
Transforming growth factor (TGF β) 1 and 2
Fibronectin stimulating activity (FnSA)
Granulocytes colony stimulating factor (GT-CSF)
Interleukins (IL 6, IL 8)

Somatostatin #
Vasoactive intestinal peptide (VIP)
Others
Atriopeptin (atrial factor; ANF)
Erythropoietin
Leptin
Melatonin
Relaxin #

77.4.1.2 Whey Proteins. For adaptation of the whey protein/casein ratio of infant milk formulas to human milk additional whey proteins are necessary. Such whey protein predominant formulas have had the disadvantage of causing hyperthreoninemia in infants (Moro and others 1989).

The threonine content in human milk proteins is similar to the threonine content of cow's milk proteins (Davis and others 1994). The reason for the hyperthreoninemias is

TABLE 77.6 Protein Composition of Human and Bovine Milk.

Proteins (g/100 mL)	Human Milk	Bovine Milk
Total protein	1.1	3.3
Casein	0.4	2.7
α-Casein	–	1.30
β-Casein	0.3	1.05
κ-Casein	0.1	0.35
Whey protein	0.7	0.6
α-Lactalbumin	0.3	0.13
β-Lactoglobulin	–	0.34
Serum albumin	0.05	0.04
IgA	0.1	0.003
IgG	0.001	0.08
Lactoferrin	0.2	0.01
Lysozyme	0.05	Trace

the glycomacropeptide (GMP) which is very rich in threonine and which increases the threonine content of whey predominant formulas for approximately 30% compared to human milk (Boehm and others 1998). GMP is released from casein during the enzymatic (chymosin) precipitation of κ-casein (Fig. 77.4). Because GMP does not precipitate it remains in the sweet whey fraction (Kawasaki and others 1994) (approximately 15 g/100 g whey protein) which is commonly used for the production of whey predominant infant milk formulas. Thus, the high threonine content of such formulas is a result of milk processing and not due to a high threonine content of bovine whey protein. The use of acid whey proteins which do not contain GMP can avoid the development of hyperthreoninemia in formula fed infants (Rigo and others 2001).

Infant formulas containing α-lactalbumin enriched whey proteins have the advantage of higher tryptophan contents similar to human milk. In the newborn, tryptophan and its metabolites like serotonin are essential for brain maturation and for the development of neurobehavioral regulations of food intake, satiation, and sleep–wake-rhythm. Today technological processes are available to adapt the amino acid composition of the formula according to the target composition.

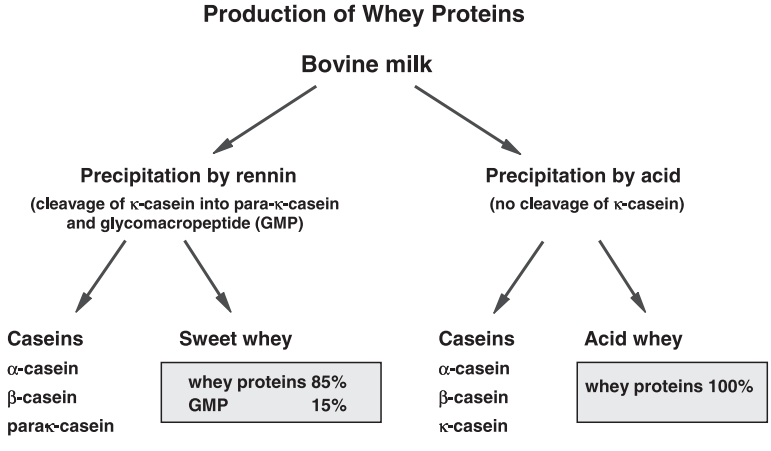

Figure 77.4 *Composition of sweet and acidic whey proteins with particular respect to the content of glycomacropeptide (GMP).*

77.4.1.3 Bovine Milk Protein Hydrolysates. For all infants with a cow's milk and/or soy protein allergy, products with hydrolyzed proteins are available. It can be distinguished between extensively hydrolyzed proteins or formulas based on free amino acids which are used for the treatment of allergies and partially hydrolyzed proteins used for allergy prevention in high risk infants (von Berg and others 2003).

The wide use of protein hydrolysate in infant formula led to the interesting question of the physiological role of peptides deriving during intestinal digestion of dietary proteins. In Tables 77.7 and 77.8 peptides are summarized which appear during digestion of either human milk proteins or bovine milk proteins. Although the tables are not complete they indicate very different functions which might be influenced by these peptides. In fact, in preterm infants an acceleration of the gastrointestinal transit of milk and stool and a more rapid establishment of full enteral feeding was observed with formulas based on hydrolyzed proteins (Mihatsch and others 2001, 2002) when compared to a formula based on the same protein source but without hydrolyzation. Such data indicate that these peptides can play a physiological role in the regulation of gastrointestinal functions as wells as its maturation.

77.4.2 Plant Proteins as Sources for Infant Formulas

77.4.2.1 Soy Proteins. Infant formulas based on soy proteins are widely used for infants suffering from cow's milk allergy particularly in the United States. However, up to 14% of the cow's milk allergic infants have also an allergy against soy proteins (Zeiger and others 1999). The biological quality of soy protein isolates ranges from 65% to 85% of that of casein (Muraro 2001). By addition of free amino acids like methionine, the quality can be made comparable to milk proteins.

Based on new technologies the phytate content of soy proteins could clearly be decreased resulting in a comparable, sometimes better absorption of calcium and zinc from infant soy formulas compared to cow's milk formulas (Boscher and others 1998).

Since several years isoflavones (phytooestrogens) in soy formulas are under discussion. The content of isoflavones is much higher in such formulas compared to cow's milk based formulas (Knight and others 1998). Not much is known about the oestrogenic effect of these phytooestrogens in infants. More clinical dates are necessary for a final evaluation of possible effects later in life caused by soy formulas.

77.4.2.2 Other Plant Proteins. More recently, other proteins deriving from plants are under discussion as protein sources for infant nutrition. Rice protein and potato protein are now adays technologically productible. However, relevant clinical data to evaluate the possible role of these new protein sources in infant nutrition are missing. Nevertheless, these new sources might be of interest in particular under the aspect of increasing allergy against nutritive proteins traditionally used in early life.

77.4.3 Analytical Techniques

77.4.3.1 Whey Proteins

α-Lactalbumin. α-Lactalbumin has been identified as a calcium metalloprotein, but can also bind other divalent cations (Hiraoka and others 1980). Several methods exist for the purification and quantification of α-lactalbumin. Chromatographic protocols use ion-pair

TABLE 77.7 Physiological Activities of Peptides Derived from Human Milk Digestion.

Bioacitve Peptide	Sequence	Effect
Opioid agonists		
β-Casomorphin-4	Tyr-Pro-Phe-Val [f51-4]	β-Casomorphins have only been found in the plasma of newborns. Reason may be the greater permeability of the newborn intestinal tract. Human β-casomorphins are less potent than bovine β-casomorphins
β-Casomorphin-4-amide (Valmuceptin)	[f51-4]	
β-Casomorphin-5	Tyr-Pro-Phe-Val-Glu [f51-5]	
β-Casomorphin-7	Tyr-Pro-Phe-Val-Glu-Pro-Ile [f51-7]	
β-Casomorphin-8	Tyr-Pro-Phe-Val-Glu-Pro-Ile-Pro [f51-8]	Antidiarrheal and sleep-inducing effects
β-Casomorphin-9	Tyr-Pro-Phe-Val-Glu-Pro-Ile-Pro-Tyr [f51-9]	
α-Lactorphin	Tyr-Gly-Leu-Phe [f50-3]	
β-Casomorphin	Tyr-Val-Pro-Phe-Pro [f158-62]	μ-Opioid receptor ligand with low potency
α_{S1}-Casomorphin amide	Tyr-Val-Pro-Phe-Pro-NH_2	Inhibition of the proliferation of T47D human breast cancer cells. No interaction with somatostatin receptors
		Inhibition of the proliferation of T47D human breast cancer cells. No interaction with somatostatin receptors
Opiod antagonists		
Casoxin C	Tyr-Pro-Tyr-Tyr [f31-4]	Opioid antagonist activity in the guinea pig ileum assay. Casoxin C has the same effect as naloxone
Lactoferroxin A	Tyr-Leu-Gly-Ser-Gly-Tyr	μ-Opioid receptor-selective antagonists with moderate potency
Lactoferroxin B	Arg-Tyr-Tyr-Gly-Tyr	μ-Opioid receptor-selective antagonists with moderate potency
Lactoferroxin C	Lys-Tyr-Leu-Gly-Pro-Gln-Tyr	μ-Opioid receptor-selective antagonists with moderate potency
Inhibition of ACE	Ser-Phe-Gln-Pro-Gln-Pro-Leu-Ile-Tyr-Pro [f43-52]	ACE inhibitory
Immunomodulatory effects		
β-Casein derived peptide	Val-Glu-Pro-Ile-Pro-Tyr [f54-9]	Stimulation of phagocytosis of sheep red blood cells by murine peritoneal macrophages
β-Casein derived peptide	Gly-Phe-Leu [f60-2]	Protective effect against bacterial (Klebsiella pneumoniae) infection in mice

(*Continued*)

TABLE 77.7 *Continued.*

Bioacitve Peptide	Sequence	Effect
α-Lactalbumin derived peptide	Gly-Leu-Phe [f51-3]	Protective effect against bacterial (Klebsiella pneumoniae) infection in mice
Calcitonin-gene-related peptide (CGRP)	Consist of 37 amino acids	Inhibitor of gastric acid secretion Involved in the protection of gastric mucosa from ulcerogenic agents. Present in human milk but not in infant formulas
Antimicrobial activity		
Lactoferricin	[f1-47]	Causes cell death by disruption of membrane integrity in Gram-negative bacteria
Antithrombotic activity		
Peptide derived from lactotransferrin	Lys-Arg-Asp-Ser	Inhibition of thrombin-induced serotonin release
κ-Caseinglycopeptide	[f39-42]	Inhibition of platelet-aggregation and fibrinogen-binding to ADP-activated platelets. Detected in plasma of newborns ingesting either formula or human milk
Sleep-inducing effects		
DSIP (delta-sleep-inducing peptide)		Circadian changes in concentration. High levels in colostrum. Part of the DSIP-LI in human milk seems to be present as free DSIP

TABLE 77.8 Physiological Activities of Peptides Derived from Bovine Milk Digestion.

Bioacitve Peptide	Sequence	Effect
Opioid agonists		
β-Casomorphin-4	Tyr-Pro-Phe-Pro [f60-3]	Most potent in inducing muscular rigidity
β-Casomorphin-4amide (Morphiceptin)	Tyr-Pro-Phe-Pro-NH_2 [f60-3]	Potent opioid activity both *in vivo* and *in vitro*. Most potent β-Casomorphin
β-Casomorphin-5	Tyr-Pro-Phe-Pro-Gly [f60-4]	Induces alterations of the amino acid transfer across the intestinal epithelium. Causes behavioral change (increases pain threshold) when injected systemically or ICV
β-Casomorphin-7	Tyr-Pro-Phe-Pro-Gly-Pro-Ile [f60-6]	Increases plasma prolactin release in rat
β-Casomorphin-11	[f60-70]	Proved to be an intestinal digestion product *in vivo*
α_{S1}-Casein-exorphin	Arg-Tyr-Leu-Gly-Tyr-Leu-Glu [f90-6]	Opioid agonist, efficient ligand for Cu^{II} ions
α-Lactorphin	Tyr-Gly-Leu-Phe [f50-3]	μ-Opioid receptor ligand with low potency
β-Lactorphin	Tyr-Leu-Leu-Phe [f102-5]	Induces contraction of guineapig ileum longitudinal muscle in the absence of electric stimulation and agonist. In addition antihypertensive activity
β-Lactotensin	His-Ile-Arg-Leu [f146-9]	Induces contraction of guineapig ileum longitudinal muscle in the absence of electric stimulation and agonist. Smooth muscle stimulating effect was not mediated by an opioid mechanism
κ-Casein glycomacropeptide	[f106-69]	Is supposed to induce the production of cholecystokinin
Opiod antagonists		
Casoxin-A	Tyr-Pro-Ser-Tyr-Gly-Leu-Asn [f35-41]	Opioid antagonist activity in the guinea pig ileum assay, Casoxin-A has the same effect as naloxone
Casoxin-B	Tyr-Pro-Tyr-Tyr [f58-61]	Opioid antagonist activity in the guinea pig ileum assay. Casoxin B has the same effect as naloxone
Casoxin-C	Tyr-Ile-Pro-Ile-Gln-Tyr-Val-Leu-Ser-Arg [f25-34]	Agonist for C3a receptors. Ileum-contracting peptide. Phagocyte-stimulating activity
Inhibition of ACE		
α_{S1}-Casokinin-12	Phe-Phe-Val-Ala-Pro-Phe-Pro-Glu-Val-Phe-Gly-Lys [f23-34]	Casein dodeca peptide ("casein DP") launched in Japan, approved as a "Food for Specific Health Use"

(*Continued*)

TABLE 77.8 *Continued.*

Bioacitve Peptide	Sequence	Effect
α_{S1}-Casokinin-5	Phe-Phe-Val-Ala-Pro [f23-7]	ACE inhibitory. $IC_{50} = 6\ \mu M$
α_{S1}-Casokinin-6	Thr-Thr-Met-Pro-Leu-Trp [f194-9]	ACE inhibitory. $IC_{50} = 16\ \mu M$
Peptides derived from β-casein	Lys-Val-Leu-Pro-Val-Pro-Gln [f169-75] Lys-Val-Leu-Pro-Val-Pro [f169-74]	Significant antihypertensive effect in SHR. Pancreatic digestion leads to a hexapeptide with stronger antihypertensive activity ($IC_{50} = 5\ \mu M$)
Peptides derived from β-casein	Val-Tyr-Pro-Phe-Pro-Gly [f59-64] Val-Tyr-Pro [f59-61] Thr-Pro-Val-Val-Val-Pro-Pro-Phe-Leu-Gln-Pro [f80-90] Phe-Pro [f62-3;157-8;205-6]	ACE inhibitory
β-Lactoglobulin derived peptide	Ile-Pro-Ala [f78-80]	ACE inhibitory
β-Lactoglobulin peptide	Ala-Leu-Pro-Met-His-Ile-Arg [f142-8]	ACE-inhibition index of 84.3%. Resistant to further digestion with pepsin
α-Lactalbumin derived peptides	Tyr-Gly Leu-Phe	ACE inhibitory
Albutensin A	Ala-Leu-Lys-Ala-Trp-Ser-Val-Ala-Arg [f208-216]	ACE inhibitory, ileum contracting and relaxing activcities
Peptides derived from α_{S1}- and β-caseins	Pro-Pro-Gln-Ser-Val-Leu-Ser-Leu-Ser-Gln-Ser-Lys-Val-Leu-Pro-Val-Pro-Glu Leu-Leu-Tyr-Gln-Gln-Pro-Val-Leu-Gly-Pro-Val-Arg-Gly-Pro-Phe-Pro-Ile-Ile-Val Asp-Glu-Leu-Gln-Asp-Lys-Ile-His-Pro-Phe-Ala-Gln-Thr-Gln-Ser-Leu-Val-Tyr-Pro-Phe-Pro-Gly-Pro-Ile-Pro-Asn-Ser	Effective ACE inhibitory activity in SHR rats
Calpis™ sour milk	Val-Pro-Pro Ile-Pro-Pro	Inhibition of ACE in the abdominal aorta of spontaneously hypertensive rats. Blood pressure of hypertensive human subjects was significantly reduced following daily ingestion of 95 mL sour milk for 2 months
Immunostimulatory effects		
α_{S1}-Casein derived peptide	Thr-Thr-Met-Pro-Leu-Trp [f194-9]	Stimulation of phagocytosis of sheep red blood cells by murine peritoneal macrophages. Protective effect against bacterial (*Klebsiella pneumoniae*) infection in mice

(*Continued*)

TABLE 77.8 *Continued.*

Bioacitve Peptide	Sequence	Effect
Isradicin	[f1-23]	Protected mice against *Staphylococcus aureus* and *Candida albicans* by stimulation of both phagocytosis and immune responses
β-Casein derived peptides	Pro-Gly-Pro-Ile-Pro-Asn [f63-8] Leu-Leu-Tyr [f191-3]	Stimulation of phagocytosis of sheep red blood cells by murine peritoneal macrophages. Protective effect against bacterial (*Klebsiella pneumoniae*) infection in mice
κ-Casein and α-lactalbumin derived peptides	Tyr-Gly [f38-9] Tyr-Gly [f18-9; f50-1] Tyr-Gly-Gly [f18-20]	Enhance the proliferation of human peripheral blood lymphocytes
Lactoferrin pepsin hydrolysate (LFH)		Enhancement of mucosal immunity
Tuftsin	Thr-Lys-Pro-Arg	Enhancement of neutrophil and macrophage chemotoxis, cytotoxic activity of macrophages and natural killer cells, antigen processing
Immunosuppressive effects		
Glycomacropeptide (CMP)	[f106-69]	*In vitro* inhibition of the mitogen-induced proliferation of mouse spleen B lymphocytes and rabbit Payer's patch cells. Suppression of IgG class antibody production
Antimicrobial activity		
Lactoferricin B	[f17-41] [f17-31]	Bacterial activity against gram negative bacteria (e.g., *E. coli, Kl. pneumonia, Sal. enteritidis, St. haemo-lyticus, Str. thermophilus, Corynebacterium ammoniagenes, B. subtilis, Bifidobacterium infantis*), some yeasts, Gram-positive bacteria, fungi, protozoa and tumors. No effect against *Bifidobacterium*
Casocidin-I	f165-203	Inhibits the growth of *E. coli* and *Staphylococcus carnosus*
κ-Casein glycomacropeptide	[f106-69]	Exerts antiviral effects by inhibiting haemagglutination of influenza virus or by blocking receptor to cholera toxin
Probiotic effects		
κ-Casein glycomacropeptide	[f106-69]	Enhances growth of Bifidobacteria, especially *Bifidobacterium infantis* S_{12}

(*Continued*)

TABLE 77.8 *Continued.*

Bioacitve Peptide	Sequence	Effect
Antithrombotic activity		
Casoplatelins	Undecapeptide: Met-Ala-Ile-Pro-Pro-Lys-Lys-Asn-Gln-Asp-Lys [f106-16] Pentapeptide: Lys-Asn-Gln-Asp-Lys [f112-6] Caseinglycopeptide: [f106-69]	Inhibitors of the aggregation of ADP-activated platelets as well as binding of human fibrinogen γ-chain to a specific receptor site on the platelet surface
Mineral binding porperties		
α_{S1}-Casein-exorphins	Arg-Tyr-Leu-Gly-Tyr-Leu-[Glu] [f90-5; 90-6]	Efficiant ligands for Cu^{II} ions
α_{S1}-Casein phosphopeptides	[f43-58] [f59-79] Ser-Ser-Ser-Glu-Glu-Ile-Val-Pro-Asn [f66-74]	Calcium-binding phosphopeptides can have an anticariogenic effect through recalcification of the dental enamel
α_{S2}-Casein peptides	[f46-70] [f1-21] [f2-21]	Formation of organophosphate salts, may function as carrier for different minerals, especially calcium
β-Casein phosphopeptides	[f1-25] [f1-28]; [f33-48]	Formation of organophosphate salts, may function as carrier for different minerals, especially calcium
Calmodulin-binding properties		
	Leu-Lys-Lys-Ile-Ser-Gln-Arg-Tyr-Gln-Lys-Phe-Ala-Leu-Pro-Gln-Tyr [f164-79] Val-Tyr-Gln-His-Gln-Lys-Ala-Met-Lys-Pro-Trp-Ile-Gln-Pro-Lys-Thr-Lys-Val-Ile-Pro-Tyr-Val-Arg-Tyr-[Leu] [f183-207] [f183-206]	Inhibition of calmodulin-dependent cyclic nucleotide phosphodiesterase activity

reversed phase HPLC (Neyestani and others 2003) or immobilized metal ion affinity chromatography (IMAC) (Blomkalns and Gomez 1997). α-Lactalbumin may also be quantified by an enzyme-linked immunosorbent assay (ELISA) technique.

β-Lactoglobulin. Quantification of β-lactoglobulin is conveniently carried out by ELISA technique for which commercially available test kits exist. Qualitative analysis of β-lactoglobulin during purification and isolation can be accomplished by gel electrophoresis but also liquid chromatographic techniques like ion exchange or reversed phase chromatography.

Lactoferrin. Various analytical techniques for the determination of lactoferrin are reported. High performance liquid chromatography (HPLC) or fast protein liquid

chromatography (FPLC) in combination with ion-exchange chromatography is applied to isolate lactoferrin (Eigel and others 1984; Ekstrand and Björck 1986), due to the high isoelectric (Ekstrand and Björck 1986). It can also be measured by ELISA.

77.4.3.2 Caseins. The casein components exist in strong association with each other as a micellar complex stabilized by van der Waals forces, hydrophobic interactions, hydrogen bonding, electrostatic, and steric stabilization. For the purification and isolation of individual caseins it is necessary to eliminate these protein–protein interactions. Various concentrations of urea, dimethylformamide, β-mercaptoethanol, or dithiothreitol are used in protocols to primarily cleave hydrogen bonds and reduce disulfide linkages (Bramanti and others 2002). Separation and determination of bovine caseins can be achieved by hydrophobic interaction chromatography. Alternatively the caseins can be isolated by FPLC (Hollar and others 1991) using a strong cation exchanger.

The glycomacropeptide (GMP) can be prepared by cation exchange processes taking advantage of the highly negative charge on GMP even at low pH (Kawasaki and others 1994) where the other whey proteins are positively charged. Alternatively, whey at pH less than 4 is contacted with an anion exchanger. GMP can also be purified by IMAC on copper containing affinity supports (Etzel 1999) or solely by an ultrafiltration process of sweet whey at a pH below 4 (Tanimoto and others 1991).

77.4.3.3 Milk Protein Hydrolysates. For the characterization of protein hydolysates the degree of hydrolysis (DH) is most often applied. The DH is defined as percentage of peptide bonds cleaved, thus $DH = (h/h_{total}) \times 100\%$, where h is hydrolysis equivalent defined as concentration in milliequivalents per g of protein of α-amino groups formed during hydrolysis and h_{total} is hydrolysis equivalent at complete hydrolysis to amino acids. h_{total} is calculated by summing up the contents of individual amino acids per g of protein. Traditionally, DH can be measured with the trinitro benzene sulfonic acid method as described by Adler-Nissen (1979). Along with the DH the molecular weight distribution of the hydrolysate is used for characterization which can be done by gel filtration. To describe a protein hydrolysate it is also important to know the amount of free amino acids. Free amino acids can be determined by reversed-phase HPLC with precolumn derivatization or ion exchange chromatography.

77.4.4 Future Trends

Based on the long experience with measurements of protein metabolism the nutritive quality of the dietary proteins is nearly simmilar than that of human milk proteins. However, there is an intensive discussion ongoing concerning the relationship of early growth veloicity and the incidence of metabolic disorders like obesity in later life (Metges 2001; Hoppe and others 2004). Because growth velocity depends mainly on protein intake the target protein concentration for infant formulas are under reevaluation. Although this discussion is still on a very early stage and the mechanisms behind are not identified first products are on the market that claim the beneficial effect of low protein concentration in infant formula.

Due to the increasing incidence of allergic diseases in the developed countries the hypoallergenic formulas play an important role for prevention of allergic diseases. Although products with this type of protein are since more than 25 years on the market only few valid data exists about their preventive effects. There is consensus that in

cases of infants with a risk for bovine milk allergy a hypoallergenic product should be used. However, in infants at risk for other forms of allergy or atopy the preventive effect is still under debate.

77.5 NEXT STEPS FOR DEVELOPMENT OF FUNCTIONAL COMPOUNDS FOR INFANT FORMULAS

The fact that diseases later in life can be influenced by nutrition during infancy has raised a completely new perspective regarding the judgement of infant formulas. Basically, the discussion is not new: Effects of LCPUFA on brain development or the consequences of pre- or probiotics on the development of the immune system are current examples, which have been extensively reviewed in this chapter. However, starting point of the development were the current requirements of the infant rather than the prevention of later diseases. Therefore, the composition of human milk served as an example. This development has not been finalized, yet.

Thus, the question still remains why there is such a huge structural variety of the oligosaccharide fraction of human milk. It may be assumed that a great variety of functions is associated with the large number of structures and largely exceeds the prebiotic concept. For instance, in experimental trials direct effects of oligosaccharides on the cells of the immune system have been found. Should this be confirmed, the existing concept of allergy prevention by avoidance and reduction of antigen load would have to be reassessed.

In future, the concept of prevention will play an ever increasing role. As a result, diseases that are important in adulthood will be the focus of attention. It has to be assumed that the prevention of civilization diseases was of minor importance during the evolutionary development of human milk. Thus, it could happen that on developing infant nutrition for the prevention of civilization diseases, the composition of human milk would no longer serve as an example.

ACKNOWLEDGMENT

The authors thank Ms A. Frings and D. Krämer for their editorial support and Mr M. Euler for his specific technical assistance.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

78.1 INTRODUCTION

Fresh milk (raw or pasteurized) of overall good flavor quality has a bland but characteristic flavor (Badings 1991). Various dairy products made from this basic raw material can be described as mild/weak (e.g., yogurt, mozzarella cheese) to intensely flavored (e.g., concentrated/evaporated milk, blue cheeses, Italian hard cheeses). The overall sensory experience is composed of three elements: (1) the mouthfeel from the constituents of the milk, especially milk fat and proteins which are essential for the viscosity and/or texture, (2) taste components, for example, a slight sweet/salty taste that is due to lactose, milk salts, and added salt (NaCl), and (3) aroma caused by proper balance of numerous volatile organic compounds.

In the past, the stability of milk and milk products was the primary consideration, but is no longer the principal objective due to the evolution of modern sanitary practices, as well as pasteurization. Today, the manufacture of dairy products of consistently good flavor and texture is crucial. In previous flavor research, researchers had identified hundreds of volatile compounds, with little or no attention paid to their sensory contribution to the overall flavor of the products. The availability of powerful chromatographic separation techniques like capillary gas chromatography in combination with mass spectrometry and olfactory detection techniques (sniffer ports), has revolutionized the work on characterization of flavor compounds. Advancements in instrumental/chemical analysis have paralleled the developments in sensory methods for the analysis of flavor compounds. Recently, published reviews by Parliment and McGorrin (2000), McGorrin (2001), and Singh and others (2003a) described various sensory-directed analytical flavor techniques used in the evaluation of key aroma compounds in milk and dairy products.

This chapter presents a discussion on the aroma/taste compounds of various dairy products and reactions involved with their production. Specific flavor notes, off-flavors, and their causative agents are also discussed.

78.2 REACTIONS INVOLVED IN THE PRODUCTION OF FLAVOR COMPOUNDS IN MILK AND MILK PRODUCTS

The volatile flavor and taste compounds in milk products originate from degradation of the major milk constituents, namely lactose, citrate, milk lipids, and milk proteins (collectively called caseins). The physicochemical parameters, that is, heat treatment, pH, water activity, salt concentration, and ripening temperature, necessary for the right balance of biochemical changes are set during manufacturing. In case of deviation of any of these parameters, cheeses or other dairy products could potentially develop texture and/or flavor inconsistencies. Degradation of milk constituents during manufacture of dairy products involves a concerted series of chemical and biochemical reactions. Reactions and/or pathways involved in the production of milk and milk products can be subdivided into three major categories:

1. Thermally-induced changes
2. Lipid oxidation
3. Fermentation by lactic acid bacteria.

78.2.1 Thermally-Induced Changes

Thermal treatment of fluid milk, such as pasteurization or production of various concentrated/dried milk products, leads to a whole series of desirable and undesirable chemical changes which have major consequences for the texture, taste, and flavor. Selected changes, which directly influence the flavor/off-flavor of milk and milk products, are outlined below:

- Thermal degradation of lipids (e.g., accelerated degradation of hydroperoxides resulting in formation of 2-alkanones). For details on thermal degradation of lipid see Nawar (1989) and Yoo and others (1989).
- Thermal reactions involving amino side chains (e.g., generation of H_2S and other S-compounds).
- Maillard reactions: reaction of lactose, a reducing sugar, with most ε-amino groups on the side chain of lysine residues in milk proteins (e.g., resulting in the formation of a wide variety of odorants, namely furfurals, 3-/4-furanones, Strecker aldehydes, pyrazines, pyrroles, thiazoles, maltol, furaneol, etc.) (see Fig. 78.1).

This is in no way the complete list of thermally induced reactions in milk and milk products. Many other reactions, such as hydrolysis of peptide bonds, dephosphorylation of proteins, and so on, occur but are not important from a flavor point of view.

78.2.2 Lipid Oxidation

Autoxidation of milk fat in milk and milk products usually starts with the phospholipids of the milk fat globule membrane. These lipids have highly unsaturated fatty acid residues.

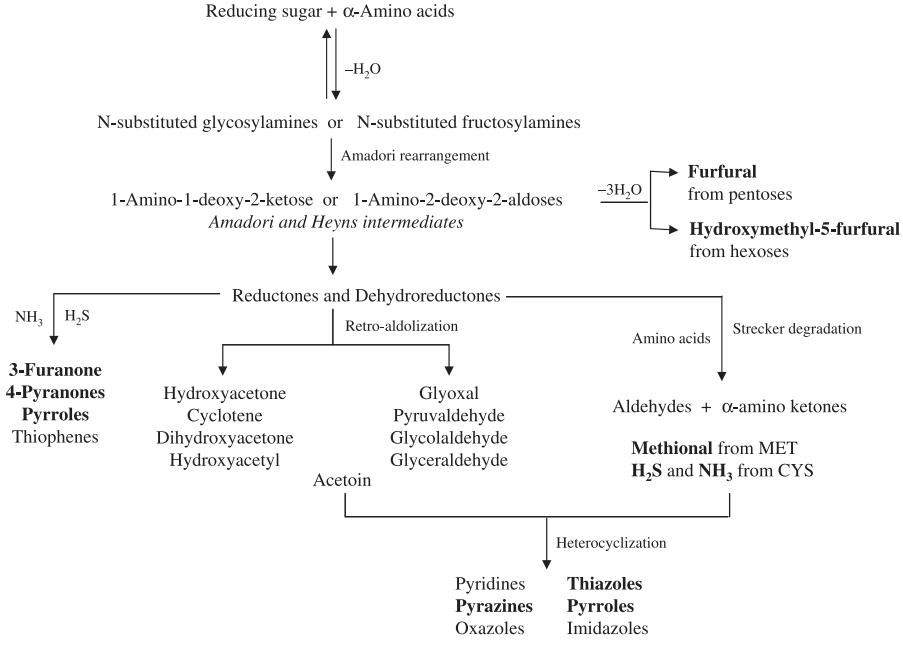

Figure 78.1 *Formation of aroma compounds via Maillard reaction/non-enzymatic browning.*

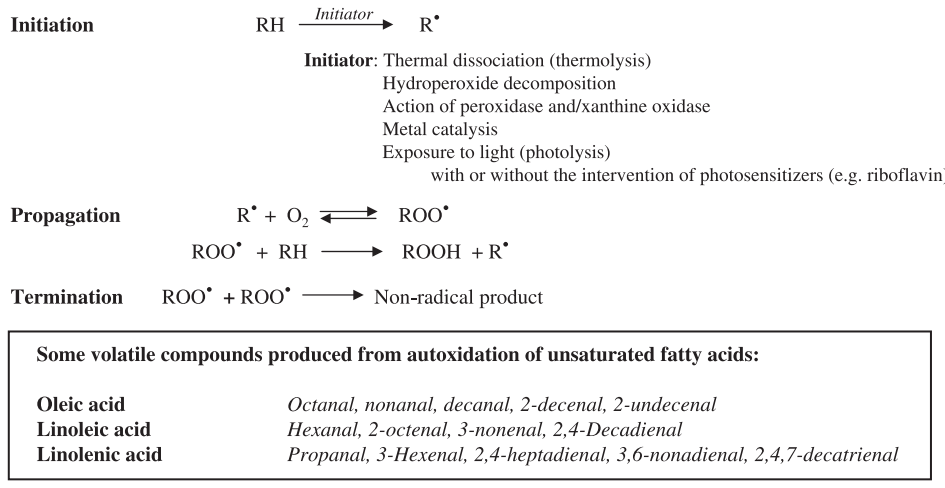

Figure 78.2 *General pathway way for the autoxidation of unsaturated lipid, with some examples of volatiles produced from individual unsaturated fatty acid. Information compiled from Frankel (1980), Ho and Chen (1994), and Lee and Morr (1994).*

A simplified scheme of lipid oxidation involving three distinct steps is put together with the oxidation products of fatty acids (see Fig. 78.2) (for further details see Frankel 1980; Walstra and others 1999). Some of these oxidation products can be perceived in exceptionally low concentrations and thereby cause off-flavors, described as fatty, fried, plastic, tallowy, fishy, metallic, and cardboard-like. Off-flavor development can cause problems in fluid milk, sour cream buttermilk, cream, butter, butter oil, milk powders, cheeses, and casein and whey protein products.

78.2.3 Fermentation by Lactic Acid Bacteria

Considerable knowledge on the principal changes and pathways involved in manufacture of fermented milk and cheese ripening has been accumulated over the last several decades. The three primary biochemical processes are:

- Glycolysis
- Lipolysis
- Proteolysis.

Their relative importance depends on the type of fermented dairy product. These primary changes are followed and overlapped by a host of secondary catabolic changes, including deamination, decarboxylation, and desulfurylation of amino acids; β-oxidation of fatty acids; and even some synthetic changes, for example, esterification. Most of these changes involve biochemical reactions, but some may be purely chemical. The abovementioned primary reactions are mainly responsible for the basic textural changes and are also largely responsible for the basic flavor of fermented dairy products. However, the secondary transformations are mainly responsible for the finer aspects of cheese flavor and modify cheese texture. In the next few sections, glycolysis, lipolysis, proteolysis, and other related reactions are discussed.

78.2.3.1 Glycolysis and Related Reactions. During fermented milk and cheese manufacture, starter lactic acid bacteria ferment lactose to (mainly L) lactic acid (Fig. 78.3). In the case of Cheddar-type cheeses, most of the lactic acid is produced in the vat before salting and molding. During manufacture or shortly thereafter, curd pH reaches ~5.0, but the rate is characteristic of cheese variety (6–24 h). Even after losing ~98% of the total milk lactose in the whey as lactose or lactate, the cheese curd still contains 0.8–1.5% lactose at the end of manufacture (Huffman and Kristoffersen 1984).

The pH at whey drainage largely determines the mineral content of a cheese. The loss of Ca^{2+} and phosphate from casein micelles determines the extent to which the micelles are disrupted and this largely determines the basic structure and texture of a cheese (Lawrence and others 1983). In general, curds with a low pH, for example, Cheshire, have a crumbly texture, while high pH curds, for example, Emmental, tend to be more elastic.

The racemization of L-lactate is probably not significant from a flavor viewpoint, but D-lactate may have undesirable nutritional consequences in infants. Calcium D-lactate is believed to be less soluble than calcium L-lactate and may crystallize in cheese, especially on cut surfaces (Dybing and others 1988). Consumers may mistake the crystals as spoilage, and crystal formation is generally considered negative.

Lactic acid is further metabolized by propionic acid bacteria, for example, in the production of Swiss-type cheeses, to propanoic acid and carbon dioxide (CO_2). The production of CO_2 is responsible for the eye formation which is a characteristic of Swiss-type cheeses (Fox and others 1995). Oxidation of lactate can also occur in cheese. During this process, lactate is converted to acetate and CO_2. Acetate is present at fairly high concentrations in Cheddar and is considered to contribute to cheese flavor, although high concentrations of acetate may cause off-flavors (Aston and Dulley 1982).

78.2.3.2 Citrate Metabolism. Bovine milk contains relatively low levels of citrate (~8 mM). Approximately 90% of the citrate in milk is soluble and most is lost in the whey; however, the concentration of citrate in the aqueous phase of cheese is ~3 times that in whey (Fryer and others 1970), presumably reflecting the concentration of colloidal citrate. Cheddar cheese contains 0.2–0.5% (w/w) citrate, which is not metabolized by *Lc. lactis* ssp. *lactis* or ssp. *cremoris*, but is metabolized by *Lc. lactis* biovar *diacetylactis* and *Leuconostoc* ssp., with the production of diacetyl and CO_2. Due to CO_2 production, citrate metabolism is responsible for the characteristic eyes in Dutch-type cheeses. Diacetyl and acetate produced from citrate contribute to the flavor of Dutch-type and cheddar cheeses (Aston and Dulley 1982). Several species of mesophilic lactobacilli metabolize citrate with the production of diacetyl and formate (Fryer 1970); the presence of lactose influences the amount of formate formed.

The principal flavor compounds produced from metabolism of citrate are acetate, diacetyl (2,3-butanedione), acetoin (3-hydroxy-2-butanone), and 2,3-butandiol (Cogan 1995) (see Fig. 78.4.) Diacetyl is usually produced in small amounts but acetoin is generally produced in much higher concentration (10–50-fold higher than diacetyl). Acetate is produced from citrate in equimolar concentrations.

78.2.3.3 Lipolysis and Related Reactions. Like all types of food with a high fat content, lipolytic (enzymatic hydrolysis by lipases and esterases) and oxidative (chemical) changes are likely to occur in dairy products. Lipases and esterases in cheese originate from milk, starter, and secondary starter and nonstarter bacteria. A number of

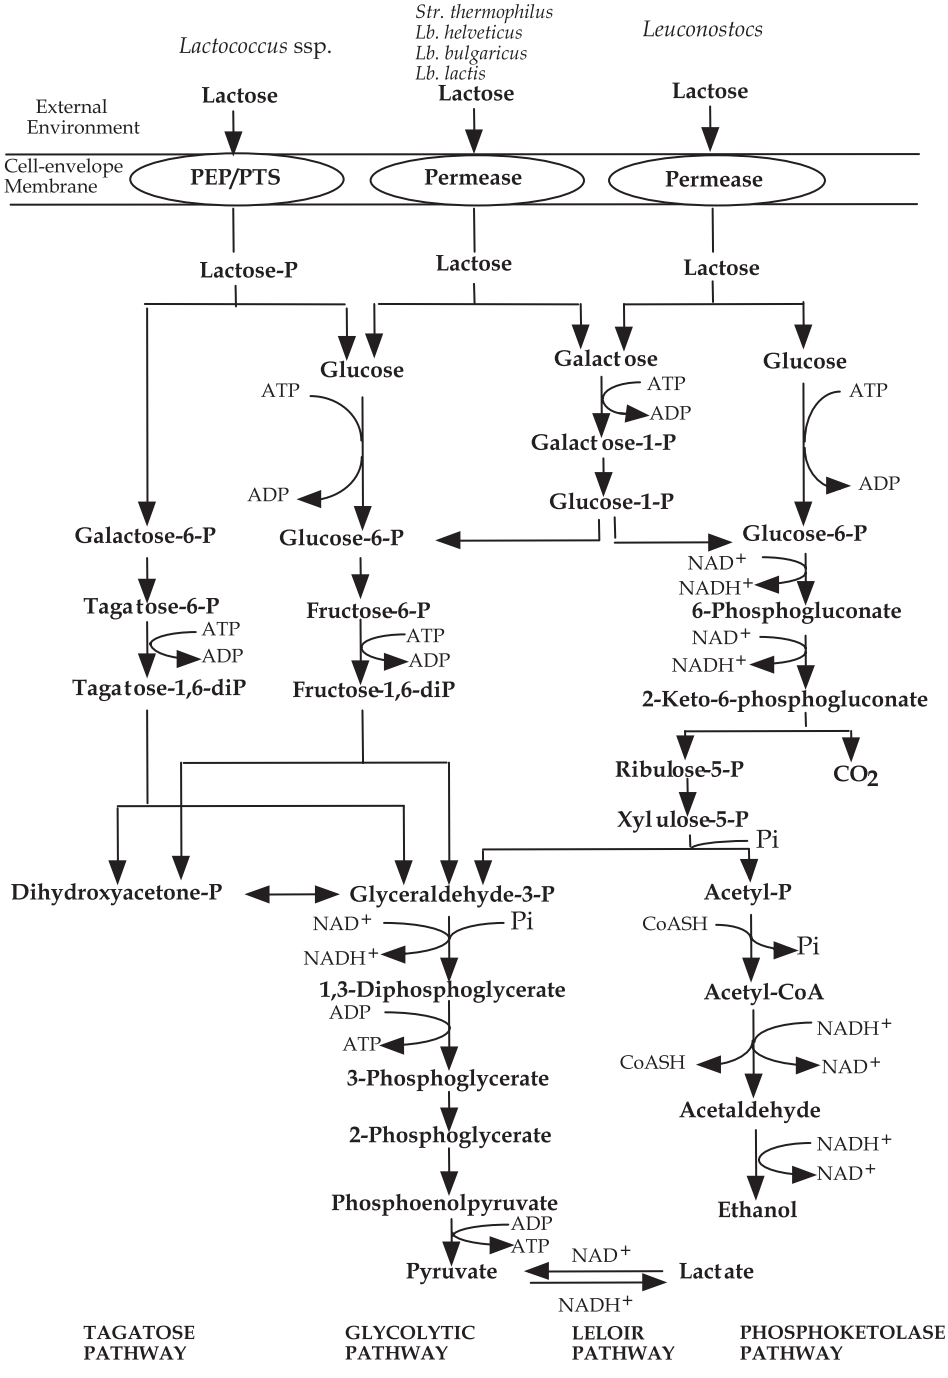

Figure 78.3 *Probable pathways for the metabolism of lactose by mesophilic and thermophilic lactic acid bacteria. (Adapted from Fox and others 1990.)*

psychrotrophic organisms, which can dominate the microflora of refrigerated milk, produce heat-stable lipases. The hydrolysis of triglycerides, which constitute more than 98% of milk fat, is the principal biochemical transformation of fat, which leads to the production of free fatty acids (FFA), di- and monoglycerides and possibly glycerol (Fig. 78.5). FFA contribute to the aroma of cheese. Individual FFA, particularly acids between $C_{4:0}$ and $C_{12:0}$, have specific flavors (rancid, sharp, goaty, soapy, coconut-like). The flavor intensity of FFA depends not only on the concentration but also on the distribution between aqueous and fat phases, the pH of the medium, the presence of certain

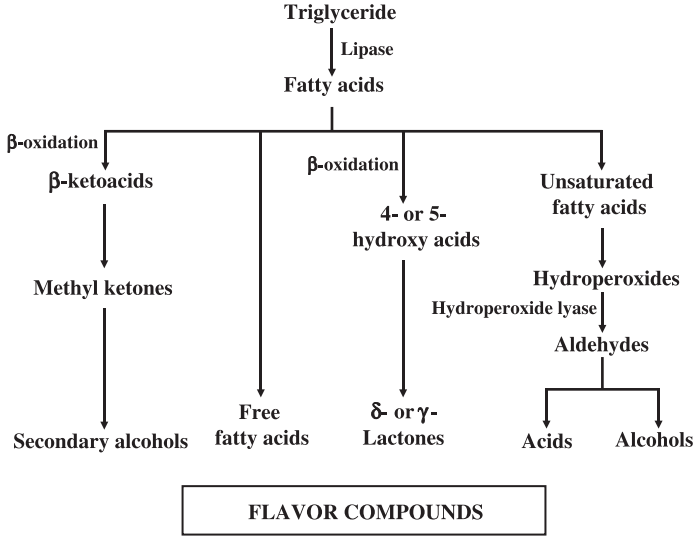

Figure 78.5 *General pathways for the metabolism of milk triglycerides and fatty acids.*

cations (e.g., Na^+, Ca^{2+}), and protein degradation products (Adda and others 1982). The pH has a major influence on the flavor impact of FFA. At the pH of Cheddar (pH ~5.2), a considerable portion of FFA are present as salts, which are nonvolatile, thus reducing their flavor impact. In most cheese varieties, relatively little lipolysis occurs during ripening and too much is considered undesirable. Most consumers would consider Cheddar, Dutch, and Swiss-type cheeses containing even moderate levels of free fatty acids to be rancid. Even lesser amounts of FFA would make fermented milk, such as yogurt, rancid. However, extensive lipolysis is desirable as part of overall flavor development in certain cheeses, such as hard Italian cheeses (Romano, Provolone), blue, and feta.

The fat fraction of the dairy product is also important for the development of typical flavor. Cheddar cheese made from nonfat milk does not develop full aroma, even after 12 months (Ohern and Tuckey 1969). Foda and others (1974) also suggested that the fatty acid composition and natural emulsion of milk fat are important for flavor development.

Metabolism of Fatty Acids. FFA are involved in several types of reactions which vary in importance with the type of dairy product involved (Fig. 78.5). Methyl ketones are produced from fatty acids by oxidative degradation. The production of methyl ketones involves oxidation of fatty acids to β-ketoacids, which are then decarboxylated to corresponding methyl ketones with one carbon atom less, mainly from $C_{6:0}$ to $C_{12:0}$ fatty acids (Hawke 1966). Methyl ketones are responsible for the characteristic aroma of blue-veined cheeses (Gripon and others 1991). However, they do play a limited role in Cheddar cheese flavor. Ultimately, methyl ketones can be reduced to secondary alcohols, which do not contribute to cheese aroma. Another reaction in which polyunsaturated and, perhaps, monounsaturated fatty acids can be involved is oxidation. The extent of oxidation in cheese is, however, rather limited, possibly due to a low redox potential. This, together with the presence of natural antioxidants, could prevent the initiation of oxidation mechanisms, or create conditions in which the primary oxidation products are reduced (Adda and others 1982).

Aliphatic and aromatic esters play an important part in the flavor and, sometimes, the off-flavor of cheese. This synthesis mainly concerns the above mentioned short- or medium-chain fatty acids and the alcohols involved may be aliphatic (ethanol), aromatic (phenylethanol), or thiols (methanethiol). Esters can be produced enzymatically, by lactic acid bacteria (Hosono and others 1974; Harper and others 1980) but can also easily result from a purely chemical reaction. Esters generally contribute a fruity flavor to dairy products which is desirable and characteristic in many cheeses (Parmesan, Parrano) but undesirable in others (cheddar).

γ- and δ-lactones have been identified in cheeses, particularly in cheddar, where they have been considered as important for flavor (Wong and others 1973; Drake and others 2001). Lactones are cyclic esters resulting from the intramolecular esterification of hydroxy acids through the loss of water to form a ring structure. Lactones possess a strong aroma, which although not specifically cheese-like, may be important in the overall cheese flavor impact.

78.2.3.4 Proteolysis and Related Reactions. Proteolysis is the most widely studied biochemical change. During the manufacture of fermented milks and cheeses and during ripening of cheeses, a gradual decomposition of caseins occurs due to the

combined action of various proteolytic enzymes. These generally include enzymes from the following sources:

- Coagulant
  a. Chymosin (genetically engineered)
  b. Chymosin/pepsin (from calf stomach)
- Indigenous milk enzymes
  a. Plasmin
  b. Cathepsin
- Starter and nonstarter bacterial enzymes
  a. Cell envelope-associated proteinases (CEP)
  b. Peptidases
     i. Endopeptidases
     ii. Aminopeptidases
     iii. Di- and tri-peptidases
     iv. Proline specific peptidases
- Secondary starter enzymes.

Enzymes from the first three sources are active in most ripened cheeses. The secondary starter (microorganisms added to cheese milk or curd for purposes other than acidification, for example, surface smear organisms, blue/white molds) exerts considerable influence on the maturation of cheese varieties in which they are used. Exogenous enzymes used to accelerate ripening could be added to the above list, and when present can be very influential.

The correct pattern of proteolysis is generally considered to be a prerequisite for the development of the correct flavor of cheese. Products of proteolysis per se (i.e., peptides and free amino acids) probably are significant in cheese taste, at least to "background" flavor, and some off-flavors, for example, bitterness, but are unlikely to contribute aroma. Compounds arising from the catabolism of free amino acids contribute directly to cheese taste and aroma.

In the cheese environment, with a high ionic strength and a low a_w, rennet-induced breakdown of α_{s1}-casein proceeds much faster than that of β-casein (α_{s2}-and κ-caseins are quite resistant to hydrolysis by the rennet) (Visser 1993). The residual chymosin rapidly hydrolyses α_{s1}-casein at the bond Phe^{23}–Phe^{24} during the initial stages of ripening (Creamer and Richardson 1974). Hydrolysis of this single bond of α_{s1}-casein causes a rapid change in the rubbery texture of young Cheddar curd into a smoother, more homogeneous product (Lawrence and others 1987). The peptide α_{s1}-CN f1-23, produced by chymosin action on the bond Phe^{23}–Phe^{24} of α_{s1}-casein, is further hydrolyzed in Cheddar cheese (Singh and others 1994) by CEP from starter *L. lactis* ssp. *cremoris* resulting in the production of whole range of small molecular weight peptides. The small peptides from α_{s1}-CN f1-23 representing N-terminal (α_{s1}-CN f1-7, 1-9, 1-13, and 1-14) and C-terminal (α_{s1}-CN f14-17, 17-21) sequences were found to be bitter in taste (Lee and others 1996; Richardson and Creamer 1973). Chymosin produced large peptide α_{s1}-CN f24-199 is further hydrolyzed by chymosin and CEP (for further details see McSweeney and others 1994; Singh and others 1995, 1997).

Chymosin has limited action on β-casein in Cheddar, although some activity is indicated by the presence of the peptide β-CN f1-192 (McSweeney and others 1994). Hydrolysis of the bond Leu^{192}–Tyr^{193} of β-casein by chymosin releases a small corresponding C-terminal fragment, β-CN f193-209, which is extremely bitter (Singh and others 2004b). Nearly half of the β-casein in Cheddar cheese is hydrolyzed during the ripening. Plasmin, an indigenous milk proteinase, is mainly responsible for the initial proteolysis of this protein. Plasmin hydrolysis of β-casein results in the formation of three γ-caseins [γ_1- (β-CN f29-209), γ_2- (β-CN f106-209), and γ_3- (β-CN f108-209) caseins], representing C-terminal region, and five proteose-peptones [β-CN f1-28, β-CN 1-105/107, and β-CN f29-105/107] representing the corresponding N-terminal region. The γ-caseins seem to accumulate in Cheddar over the ripening period. The proteose-peptones are extensively hydrolyzed by the starter bacterial CEP and peptidases to produce small peptides and free amino acids (Singh and others 1995, 1997).

Proteolysis in cheese seems to be a sequential process involving rennet, milk proteinase (particularly plasmin), the starter culture, secondary microorganisms, and NSLAB. The hydrolysis of casein to high molecular weight peptides is thought to be primarily the result of chymosin and plasmin (Singh and others 2003a). The subsequent hydrolysis of high molecular weight peptides is primarily the result of proteolytic enzymes from lactic acid bacteria. Proteolytic degradation of caseins into peptides in Cheddar (Singh and others 1994, 1995, 1997; Fernandez and others 1998), Emmentaler (Gagnaire and others 2001), and Parmigiano-Reggiano cheeses (Addeo and others 1992, 1994) were characterized in detail.

Metabolism of Amino Acids. In lactococci, the first step in the degradation of amino acids is transamination (see Fig. 78.6; Gao and others 1997), leading to formation of α-keto acids (α-KA). Aromatic aminotransferase enzymes have been previously characterized from *Lactococcus lactis* ssp. *cremoris* (Yvon and others 1997; Rijnen and others 1999a) and *Lactococcus lactis* ssp. *lactis* (Gao and Steele 1998). These enzymes initiate the degradation of Val, Leu, Ile, Phe, Tyr, Trp, and Met, all of which are known precursors of cheese flavor compounds. Inactivation of aminotransferase enzymes involved in the breakdown of amino acids by lactococci has been shown to reduce aroma formation during cheese ripening (Rijnen and others 1999b).

The volatile fraction of cheese has several sulfur-containing compounds, such as methanethiol, methional, dimethyl sulfide, dimethyldisulfide, dimethyltrisulfide, dimethyltetrasulfide, carbonyl sulfide, and hydrogen sulfide (Lindsay and Rippe 1986; Urbach 1995; Weimer and others 1999) and they contribute to the aroma of cheese (Milo and Reineccius 1997). These compounds are known to originate from Met. Methanethiol has been associated with desirable Cheddar-type sulfur notes in good quality Cheddar cheese (Manning and Price 1977; Manning and Moore 1979; Price and Manning 1983). However, alone or in excess, methanethiol does not produce typical Cheddar cheese flavor (Weimer and others 1999).

Methanethiol is readily oxidized to dimethyl disulfide and dimethyl trisulfide (Parliment and others 1982; Chin and Lindsay 1994). Occurrence of these compounds is a direct result of methanethiol content and is modulated by the low redox potential present in cheese. Methanethiol can potentially oxidize during analysis to form these compounds, and this may account for some reports of dimethyl disulfide and dimethyl trisulfide in cheese. Dimethyl sulfide (Milo and Reineccius 1997) and dimethyl trisulfide were

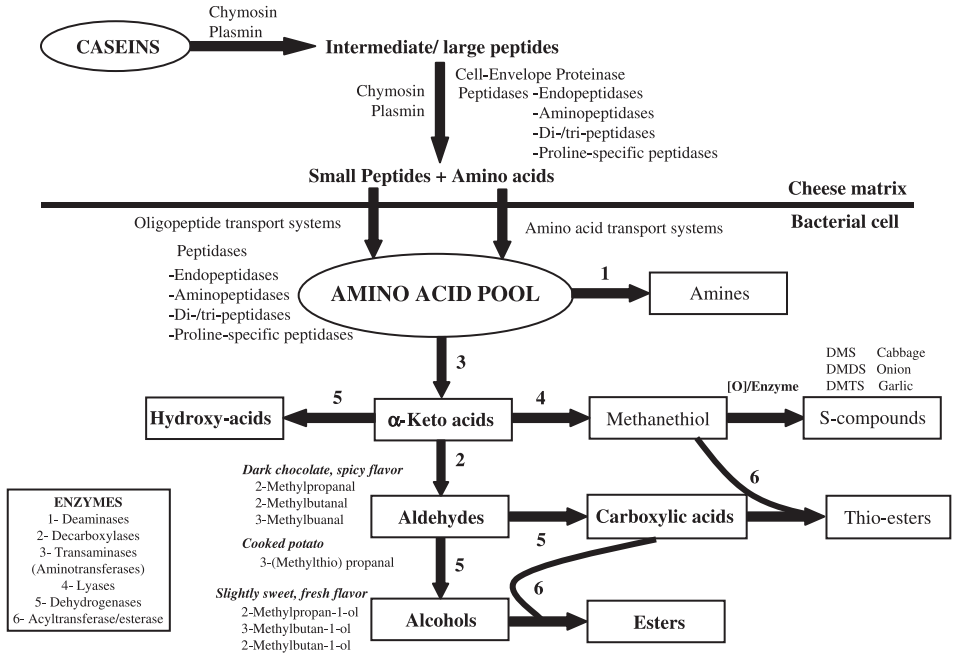

Figure 78.6 *Generation of flavor compounds from milk protein degradation. DMS, dimethyl sulfide; DMDS, dimethyl disulfide; DMTS dimethyl trisulfide. (Modified from Kranenburg and others 2002.)*

recently noted as important odorants in aged Cheddar cheese (Milo and Reineccius 1997; Suriyaphan and others 2001b; Zehentbauer and Reineccius 2002). Further work is needed to define the mechanism and cheese conditions needed for production.

Amino acid degradation plays a vital role in flavor development in cheese. A number of works in the past attempted to enhance free amino acid content in Cheddar cheese by direct addition of amino acids (Wallace and Fox 1997) and genetic modification of lactococci with increased aminopeptidase N activities (McGarry and Others 1994; Christensen and others 1995). But increased amino acid content in Cheddar did not affect the flavor development, which led Yvon and others (1998) to hypothesize that the rate-limiting factor in flavor biogenesis was not the release of amino acids but their subsequent conversion to aroma compounds. Yvon and others (1998) identified the transaminase acceptor α-ketoglutarate as the first limiting factor in the degradation of amino acids. Addition of α-ketoglutarate to Cheddar curd resulted in increased volatile components originating from branched chain and aromatic amino acids (Banks and others 2001). Results of a recent study showed that Cheddar cheese made using adjunct starter *Lactobacillus casei* (genetically modified to enhance expression of hydroxyl acid dehydrogenase, HADH) retarded the flavor development (Broadbent and others 2004). HADH catalyses conversion of α-keto acids to α-hydroxy acids, which has little or no importance from a flavor point of view. But it may still be possible to selectively suppress aromatic amino acid (Phe, Tyr, Trp)-derived off-flavor compounds by overexpression of an alternative HADH with more narrow specificity for aromatic amino acid-derived α-keto acids.

78.3 CHARACTERIZATION OF FLAVOR OF MILK AND MILK PRODUCTS

Flavor of milk and milk products is produced by a correct balance and concentration of a wide range of sapid and aromatic compounds ("Component balance theory" – Mulder 1952; Kosikowski and Mocquot 1958), see Tables 78.1 and 78.2 for a compilation of odorants found in milk and milk products. If a proper balance of components is not achieved, then undesirable or defective flavor occurs. The delicate but weak flavor of milk is caused by very low concentrations of numerous odorants (Badings 1991; Bendall 2001). Varying levels of heat treatment during processing of raw milk, for example, pasteurization, UHT-treatment or sterilization, has been shown to increase lipid oxidation products (see Table 78.1). When milk is severely heated, both flavor and color are affected. Volatile compounds that contribute particularly to sterilized milk are lipid oxidation products (mainly 2-alkanone : $C_{5,7,9,11}$) and several heterocyclic compounds, such as pyrazines, furans, pyrones, and other nonenzymatic browning/Maillard reaction products (e.g., maltol, furaneol, 2,5-dimethylpyrazine, and o-aminoacetophenone); see Badings (1991). Sweetened condensed milk also involves similar compounds in its volatile flavor profile (Shimoda and others 2001).

Flavor of fat enriched products like cream and butter are characterized, as one would expect, by lactones and lipid oxidation products (Table 78.1). Compounds like 2,3-butandione play an important role in the aroma of sour cream and sour cream butter. Aroma impact compounds of fresh and heat sweet cream butter were studied by Peterson and Reineccius (2003a,b).

Aroma of dried milk products, such as nonfat dry milk, with varying heat treatment, involves very similar compounds, as shown in Table 78.1. But the high heat-treated nonfat dried milk particularly has a strong aroma intensity caused by furaneol, butanoic acid, methional, o-aminoacetophenone, (*E*)-4,5-epoxy-(*E*)-2-decenal, sotolon, and vanillin. A stored sample of nonfat dried milk had particularly high odor intensities for methional and o-aminoacetophenone (see Table 78.1). Other dried products, such as rennet casein, an important food ingredient, particularly suffer from off-flavor. Results of aroma extract dilution analysis (AEDA) indicated o-aminoacetophenone to be a potent odorant; however, sensory descriptive sensory analysis of model aroma systems revealed that the typical odor of rennet casein was principally caused by hexanoic acid, indole, guaiacol, and p-cresol (Karagul-Yuceer and others 2003b). It is essential for rennet casein to be bland and free of any off-flavor for its use as a food ingredient. Diacetyl and acetaldehyde are important odorants in yogurt, and are produced by lactic acid bacteria as starter cultures. There are numerous other fermented milks produced around the world involving lactic acid bacteria and/or in some cases fairly complicated set of microflora in which a host of volatile compounds play a crucial role in flavor.

There has been extensive research on the flavor of cheeses, but despite this effort, only limited information is available on the chemistry of flavor of most cheese varieties and the flavor of none is characterized sufficiently to permit its reproduction by mixtures of pure compounds in a cheese model (Fox and others 1995; Parliment and McGorrin 2000; McGorrin 2001; Singh and others 2003a). Cheeses in many previous studies were simply analyzed for flavor by cheese graders. Such qualitative sensory data has limited use. More defined and analytical information using descriptive sensory and instrumental analysis is required. In the last couple of decades, a number of published works attempted to characterize the mechanism/enzymology of various reactions involved in generation of

TABLE 78.1 Aroma Compounds Identified in Milk and Milk Products (Compounds are Listed in the Order of Their Importance).

Milk (fresh)[a]	**Fresh butter**[c]	**Nonfat dry milk (low heat)**[e]	**Nonfat dry milk (high heat)**[e]	**Rennet casein**[g]
Ethyl hexanoate	δ-Decalactone	4-Hydroxy-2,5-dimethyl-(2H)-furan-3-one	4-Hydroxy-2,5-dimethyl-(2H)-furan-3-one	o-Aminoacetophenone
Ethyl butyrate	1-Hexen-3-one	Butanoic acid	Butanoic acid	2-Methoxyphenol
Dimethyl sulfone	δ-Dodecalactone	3-(Methylthio) propanal	3-(Methylthio) propanal	Hexanoic acid
Nonanal	1-Octen-3-one	o-Aminoacetophenone	o-Aminoacetophenone	Maltol
1-Octen-3-ol	Skatole	δ-Decalactone	(E)-4,5-Epoxy-(E)-2-decenal	4-Hydroxy-2,5-dimethyl-(2H)-furan-3-one
Indole	(Z)-6-Dodecen-γ-lactone	(E)-4,5-Epoxy-(E)-2-decenal	δ-Decalactone	4,5-Diemthyl-3-hydroxy-2(*5H*)-furanone
		Pentanoic acid	Pentanoic acid	Decanoic acid
Milk (pasteurized)[a]	**Heated butter**[c]	4,5-Diemthyl-3-hydroxy-2(*5H*)-furanone (Sotolon)	4,5-Diemthyl-3-hydroxy-2(5H)-furanone	(Z)-6-Dodecen-γ-lactone
Dimethyl sulfone	δ-Decalactone	3-Methoxy-4-hydroxybenzaldehyde (Vanillin)	3-Methoxy-4-hydroxybenzaldehyde phenyl acetic acid	Skatole
Hexanal	Skatole	2-Acetyl-1-pyrroline	Nonanal	Dodecanoic acid
Nonanal	3-(Methylthio) propanal	2-Acetyl-2-thiazoline	1-Octen-3-one	3-Methoxy-4-hydroxybenzaldehyde
1-Octen-3-ol	δ-Dodecalactone	Hexanoic acid	2-Acetyl-1-pyrroline	
Indole	4-Hydroxy-2,5-dimethyl-(2H)-furan-3-one (Furaneol)	Phenyl acetic acid	Hexanoic acid	**Liquid cheddar whey**[h]
Benzothiazole	1-Octen-3-one	Octanoic acid	Octanoic acid	2,3-Butanedione
δ-Decalactone	1-Hexen-3-one	Nonanal	(E)-2-Nonenal	Dimethyl sulfide
2-Tridecanone	(Z)-2-Nonenal	1-Octen-3-one		Hexanal
	(E)-2-Nonenal			
UHT milk[a]	(E,E)-2,4-Decadienal			
2-Heptanone	(E)-4,5-Epoxy-(E)-2-decenal			
2-Nonanone	γ-Octalactone			
2-Undecanone				
δ-Decalactone				
2-Tridecanone				
Dimethyl sulfone				
Benzothiazole				
Hexanal

volatiles in cheese. Only recent work in the last decade has attempted to study cheese flavor in detail.

In recent years, key odorants in a number of cheese varieties have been characterized by gas chromatography olfactometry/aroma extract dilution analysis (GCO/AEDA). Mozzarella cheese produced using buffalo and cow milk was found to have very different volatile compounds in their aroma profiles (Table 78.2). Odorants in surface mold ripened cheeses like Camembert were studied in detailed by Kubickova and Grosch (1997, 1998a,b). Aroma compounds were analyzed by GCO using both aroma extract dilution and aroma extract concentration analysis. Compounds like 1-octen-3-ol and the corresponding ketone were found to be responsible for the mushroom/musty aroma note of Camembert. Kubickova and Grosch (1998a) incorporated key odorants identified in Camembert in a model cheese, which was found to be close to the genuine Camembert. Origins and properties of compounds involved in the flavor of surface ripened cheeses were reviewed by Molimard and Spinnler (1996). Key odorants in Swiss Emmentaler aroma profile were methional, furaneol, ethyl furaneol, diacetyl, 3-methyl butanal, and esters (Preininger and Grosch 1994). Cheese models composed of methional, furaneol, ethyl furaneol, acetic acid, propanoic acid, lactic acid, succinic acid, glutamic acid, sodium, potassium, calcium, magnesium, ammonium, phosphate, and chloride were judged to match the flavor of Swiss Emmentaler cheese very well (Preininger and others 1996). The flavor of typical Swiss Gruyere cheese and a Gruyere sample exhibiting a potato like off-flavor were characterized by Rychlik and Bosset (2001a,b). Odorants like methional, 2-ethyl-3,5-dimethylpyrazine, and 2,3-diethyl-5-methylpyrazine were the probable source of potato-like off-flavor in Gruyere.

Muenster cheese made in the United States, using *Streptococcus thermophilus* as culture and no surface smear, was described by cooked/milky, whey, milk fat/lactone, sour, and salty notes using descriptive sensory analysis. The use of dynamic headspace dilution analysis (DHDA) methodology, previously described by Cadwallader and Baek (1998), showed that the most aromatic compounds in the headspace of Muenster were 2,3-butanedione, dimethyl sulfide, dimethyl disulfide, 2/3-methyl butanal, and 2-acetyl-2-thiazoline (Singh and others 2003b).

4-Methyl octanoic and 4-ethyl octanoic acids were found to impart waxy/crayon odors to fresh goat cheese (Carunchia-Whetstine and others 2003b). Numerous other odor active compounds were identified in goat cheese and assessed by sensory analysis of model cheeses for their specific role in the overall aroma.

Flavor of Cheddar cheese is by far the most widely studied. It is generally accepted that the flavor quality of Cheddar cheese in the marketplace today differs considerably from that manufactured before the wide use of pasteurization, microbial rennets, and other modern manufacturing practices (Dunn and Lindsay 1985). Much of the differences between traditional and contemporary Cheddar flavors probably should be attributed to current marketing of bland-flavored young cheeses. However, even longer aged cheeses are frequently criticized for a lack of adequate Cheddar-type flavor.

The significance of sulfur-compounds, such as H_2S, methanethiol, and dimethyl sulfide, in Cheddar cheese was shown by Manning and Robinson (1973). The compounds with low vapor pressure/high boiling points in the distillate, such as 2,3-butanedione, methyl ketones, and volatile fatty acids were also considered to play an important role in Cheddar flavor. Analysis of Cheddar headspace volatiles also reconfirmed the important role played by H_2S, methanethiol, and dimethyl sulfide in flavor (Manning and Price 1977; Manning and Moore 1979; Price and Manning 1983).

In order to evaluate important odorants, GCO/AEDA was first applied to Cheddar cheese by Christensen and Reineccius (1995). The components found to have the highest potency (dilution factor) in a 3-year-old Cheddar cheese were ethyl acetate, 2-methylbutanal, 3-methylbutanal, 2,3-butanedione, α-pinene, ethyl butyrate, ethyl caproate, 1-octen-3-one, acetic acid, methional, propionic acid, butyric acid, valeric acid, caproic acid, capric acid, and lauric acid. The authors pointed out that the technique did not allow the determination of the most volatile odor fraction, which included hydrogen sulfide, acetaldehyde, and methanethiol. Descriptive sensory analysis was not conducted on the cheese used in the study, which limited conclusions about the role of individual compounds on specific cheese flavors. Based on these results, a subsequent sensory study using a concept matching technique was conducted. Dacremont and Vickers (1994) found that a recognizable Cheddar aroma was produced by a mixture of 2,3-butanedione, methional, and butyric acid. However, the authors also indicated a possible contribution of other aroma compounds that were not commercially available at that time.

Milo and Reineccius (1997) applied both traditional high vacuum isolation/aroma extract dilution analysis (AEDA) and static headspace-olfactometry (GCO-H) to further study the aroma of a regular and a low-fat Cheddar cheese (see Table 78.2). After the quantification and calculation of respective odor activity values, based on sensory thresholds in oil and water, they suggested acetic acid, butyric acid, methional, 2,3-butanedione, and homofuraneol as the primary odorants responsible for the pleasant mild aroma of Cheddar cheese. In addition to the above mentioned compounds, the contribution of highly volatile sulfur compounds, such as methanethiol and dimethyl sulfide, to nasal perception of Cheddar cheese was quite obvious on the basis of GCO analysis of static headspace samples. The authors further hypothesized that the meaty-brothy odor characteristic of low-fat Cheddar was caused by high concentrations of methional, furaneol, and especially homofuraneol. The furaneol-type odorants are known to be produced by certain strains of lactobacilli (Preininger 1995; cited from Milo and Reineccius 1997). While the mixture of these volatile compounds in a model cheese matrix had Cheddar aroma, attribute profiling described it as lacking in sour, moldy, and sulfurous notes relative to the real cheese. Also the overall odor was described as weak. This discrepancy in sensory character between the aromatized model and real cheese was partially caused by aroma-matrix interactions, which resulted in quantitative errors (Wang and Reineccius 1998).

A comparison of the volatile compositions of full- and reduced-fat Cheddar showed that the level of methanethiol in the cheese is highly correlated with the flavor grade. This observation may indicate that the lack of aroma in reduced-fat Cheddar is due to lack of methanethiol. However, a combination of methanethiol and decanoic acid or butanoic acid in all cheeses gave a better correlation with Cheddar flavor than methanethiol alone (Dimos and others 1996). Addition of methanethiol to a bland slurry of reduced-fat Cheddar produced a strong Cheddar aroma (Urbach 1997).

The use of DHDA methodology has suggested additional volatiles as being important to Cheddar cheese aroma as compared to gas chromatography olfactometry-static headspace (GCO-H) and solvent extraction/AEDA (Zehentbauer and Reineccius 2002), (see Table 78.2) Results of DHDA showed that in addition to the odorants previously identified by AEDA and GCO-H, (Z)-4-heptenal, 2-acetyl-1-pyrroline, dimethyl trisulfide, 1-octen-3-one, (Z)-1,5-octadiene-3-one, and (E)/(Z)-2-nonenal, which have been underestimated or not even perceived during AEDA, may also contribute to the overall aroma of Cheddar cheese.

The volatile aroma components of two sharp Cheddar cheeses of British Farmhouse origin, made using raw milk and ripened for at least 1 year, were analyzed by AEDA (Suriyaphan and others 2001b; Table 78.2). Descriptive sensory analysis of these cheeses was also conducted. Key flavors in sharp Cheddar cheeses were "barnyard" and "earthy." Following instrumental analysis, model system addition was used to confirm compounds responsible for specific flavor notes. p-Cresol was mainly responsible for a "cowy-barny" note, whereas an intense "soil-like" note was due to 2-isopropyl-3-methoxypyrazine. At much lower odor intensity, 2-isobutyl-3-methoxypyrazine contributed a "bell pepper-like" note. Direct addition of p-cresol (>100 ppb) or 2-isopropyl-3-methoxypyrazine (>3 ppb) in a mild domestic Cheddar cheese resulted in increases in intensities of cowy/phenolic and earthy/bell pepper aroma notes. Additionally, within the same wedge of cheese, the concentrations of p-cresol and 2-isopropyl-3-methoxypyrazine were lower at the center than at the rind.

It is important to note that in each of the studies mentioned previously, different Cheddar cheeses of different ages, microflora, and biochemistry were studied. Cheddar cheese encompasses a wide category and there are numerous potential flavor profiles. Thus, to elucidate Cheddar cheese flavor is a large task and descriptive sensory analysis should be conducted in conjunction with any instrumental study to provide clarification.

78.3.1 Chemical Anchors for Specific Flavors or Off-Flavors in Milk and Milk Products

In addition to the characteristic desirable flavors, dairy products frequently suffer from specific flavor defects. While desirable flavor has been difficult to define in chemical and sensory terms since consumers vary in preference and definition of dairy products flavor, the specific cause(s) of many of these specific flavor or off-flavor notes have been established more or less definitively. This section presents an overview on chemicals responsible for the specific flavor/off-flavor notes in dairy products.

It is important to note that in the beginning of the development of flavor defects, or before the aroma detection threshold of certain off-flavors is reached, the fluid milk may show a poor/flat flavor that lacks freshness (Badings 1991). Off-flavors in milk could develop via several different mechanisms outlined below (see Table 78.3 for causative chemical/mechanism involved):

- Off-flavor transferred to milk during lactation
  - Feed off-flavors (e.g., from green forages, silage, etc.) consumed by animal a few hour before milking
  - Weed off-flavor (e.g., volatiles formed from certain weeds during digestion)
- Cowy flavors (related to ketosis and acetonemia in cattle resulting in increased concentration of acetone)
- Stable off-flavors (e.g., transferred via respiratory system from stable/feed to cow)
- Lipid oxidation – most widely implicated in the defects in milk
- Microbial action
- Contamination (e.g., compounds from sanitizers)
- Thermal abuse

TABLE 78.3 Specific Flavor and Off-Flavor Compounds in Cheeses.

Defect	Chemicals	Mechanism of Formation	Reference
Processed milk			
Oxidized	Heptanal, octanal, nonanal, 2-octenal, 2-nonenal	Lipid oxidation, light abuse, Cu oxidation	Forss and others (1955a,b)
Malty	2/3-methyl butanal	Microbial, enzymatic, Strecker degradation	Morgan (1970a,b)
Metallic	1-Octen-3-one	Lipid oxidation	Day and others (1963)
Fruity	Ethyl butanoate, ethyl hexanoate	Microbial, enzymatic	Wellnitz-Ruen and others (1982) Whitfield and others (2000)
Rancid	FFAs (C4-10)	Microbial, enzymatic, sanitizer	Azzara and Campbell (1992) Marsili (2000)
Oxidized	Hexanal, 1-octen-3-one	Lipid oxidation, light abuse, Cu oxidation	Cadwallader and Howard (1998) Marsili and Miller (1998)
Oxidized (general)	Aldehydes and ketones	Lipid oxidation	Badings (1991)
Oxidized (fatty/fried)	2-Alkenals (C7-C10), 2,4-alkadienals (C7, C10)	Lipid oxidation	Badings (1991)
Oxidized (green/cucumber)	(Z)-3-Hexenal, (E,Z)-2,6-nonadienal	Lipid oxidation	Badings (1991)
Oxidized (tallowy)	2-Alkenals (C7-C10), alkanals	Lipid oxidation	Badings (1991)
Oxidized (fishy)	2,4,7-Decatrienal	Lipid oxidation	
Cooked flavor	H2S, methanethiol, dimethylsulfide and other sulfide	Thermally induced	Boelrijk and de Jong (2003)
	Maltol, furans, pyrazines and other Maillard products	Thermally induced	Badings (1991)
Weed taints	Indole, skatole, mercaptans, sulfides, nitriles, thiocyanates	Metabolites of weed	Badings (1991)
	Skatole (fecal odor)	Metabolites of weed	Park and others (1969)
	Benzylthiol, benzyl methyl sulfide (burnt odor)	Metabolites of weed	Park and others (1969)
Feed flavors	Dimethyl sulfide, acetone, butanone, isopropanol, ethanol, propanol	Metabolites of feed and silage	Badings (1991)
Light induced	Dimethyl disulfide	Light induced degradation (singlet oxygen oxidation) of methionine	Jung and others (1998)
Heat abuse, cooked	2-Pentanone, 2-heptanone, 2-nonanone	Thermally induced, microbial	Marsili and Miller (2003)

Swiss Gruyere			
Potato-like aroma	Methional	Microbial, enzymatic	Rychlik and Bosset (2001a,b)
Gruyere de Comte			
Potato-like aroma	3-Methoxy-2-propylpyridine	Microbial	Dumont and others (1975)
Smear-coated cheese			
Potato-like aroma	2-Methoxy-3-isopropylpyrazine	Microbial	Dumont and others (1983)
Feta			
Kerosene-like	*trans*-1,3-Pentadiene	Microbial, enzymatic	Horwood and others (1981)
Goat cheese			
Waxy/crayon	4-methyl octanoic acid, 4-ethyl octanoic acid	Milk, enzymatic	Carunchia-Whetstine and others (2003b)
Cheddar cheese			
Unclean-off-flavor	2-Methyl propanoic acid, 3-methyl butanoic acid	Microbial, enzymatic	Nakae and Elliot, (1965a,b)

(*Continued*)

TABLE 78.3 *Continued.*

Defect	Chemicals	Mechanism of Formation	Reference
Catty flavor	2-mercapto-2-methylpentan-4-one	Reaction of mesityl oxide (contaminant) and sulfide	Badings (1967), Spencer (1969a,b) Drake and others (2001, 2002)
Fruitiness	Ethyl butanoate, ethyl hexanoate, ethyl octanoate	Microbial, enzymatic	Bills and others (1965), Morgan (1970b)
Floral/rose-like	Phenyl ethanol, Phenyl acetaldehyde	Microbial, enzymatic	Dunn and Lindsay (1985)
Unclean, utensil-like p-Cresol	(Off-flavor enhanced by FFAs)	Microbial, enzymatic	Dunn and Lindsay (1985)
Unclean (dull harsh)	2/3-Methyl butanal, 2-methyl propanal	Microbial, enzymatic, Strecker degradation	Dunn and Lindsay (1985)
Rosy/floral	Phenylacetaldehyde, phenylacetic acid	Microbial, enzymatic	Carunchia-Whetstine and others (2004)
Yeasty flavor	Ethanol, ethyl acetate, ethyl butanoate	Microbial, enzymatic	Horwood and others (1987)
Mayonnaise/bread-like	(E,E)/(E,Z)-2,4-Decadienal	Microbial, Lipid oxidation, enzymatic	Suriyaphan and others (1999, 2001a)
Cowy/barny-flavors	p-Cresol	Microbial, enzymatic	Suriyaphan and others (2001b)
Earthy/bell pepper	2-isopropyl-3-methoxypyrazine	Microbial, Maillard reaction	Suriyaphan and others (2001b)
Brothy flavor	3-(Methylthio)-propanal, 4-hydroxy-2,5-dimethyl-3(*2H*)-furanone, 2-ethyl-4-hydroxy-5-methyl-3(*2H*)-furanone, 2-Methyl-3-furanthiol (its dimerized form)	Microbial, enzymatic, Maillard reaction	Singh and others (2004a)
Nutty flavor	2-Methyl propanal, 2/3-Methyl butanal	Microbial, enzymatic, Strecker degradation	Avsar and others (2004)

Some of the mechanisms of off-flavor development, in particular lipid oxidation and microbial metabolites, have also been responsible for the development of a whole variety of off-flavors in milk and milk products (see Table 78.3). Specific flavors like nutty or brothy flavors were also characterized in Cheddar cheese (Table 78.3), which may or may not be considered as an off-flavor depending on the consumer preference.

78.3.2 Taste Compounds in Milk and Milk Products

Research on taste compounds in dairy products is fairly limited but there seems to be an increasing interest in this area in recent years. In food systems such as milk and milk products, study of taste sensation/compounds in isolation or devoid of contribution from volatile aroma compounds is difficult due to complex nature, in terms of both number of food constituents and their competing/synergistic effect on taste and/or aroma. Compounds which contribute to taste of milk and milk products can originate from three possible sources:

1. Naturally found in milk, for example, lactose,
2. Added/produced during the manufacturing process, for example, NaCl, lactic acid,
3. Produced by many biochemical reactions occurring during fermentation.

Table 78.4 lists a number of compounds and their taste contribution, present in dairy products. Important details available in the literature on taste compounds are summarized below:

- The main taste compounds in milk are lactose (approximately 0.3 times as sweet as sucrose) and the dissolved salts, which cause a sweet and salty taste, respectively. The sweet taste dominates, whereas salty taste is prevalent if the Ca/lactose ratio is high as in the case of mastitic milk. The casein reportedly somewhat masks the sweet taste of lactose in milk (Walstra and others 1999). Lactose hydrolyzed milk and whey have sweeter taste than regular pasteurized milk.
- A chalky taste is noticed in the high heat-treated or UHT treated milks. This may be the result of precipitation of colloidal calcium phosphate/change in mineral balance.
- Sodium chloride is an important contributor to the taste of cheeses. The apparent saltiness of cheese increases with maturity, increased NaCl concentration, and decreasing pH (McSweeney 1997).
- The principal acid in fermented milk and cheese is lactic acid. The concentration of lactic acid, and also the pH, varies considerably with:
  - The type of fermented dairy products
  - Initial production by the starter culture
  - Extent of loss in whey
  - Its metabolism by the non-starter microflora.
- Several other acids, for example, acetic, propanoic, and C_{4-10}, also contribute to sour/soapy taste but they predominantly contribute to the aroma. Some of the characteristic taste (sour, sweet, salty) compounds of Emmentaler (Swiss) cheese were acetic acid, propanoic acid, lactic acid, succinic acid glutamic acid, each in free form and/or as ammonium, sodium, potassium, magnesium, and calcium salts as well as corresponding chlorides and phosphates (Warmke and others 1996). Magnesium and calcium propionate mainly caused the sweetish note in the taste profile of Emmentaler cheese.
- Casein is hydrolyzed to varying degrees depending on the type of fermented milk and cheese, resulting in the production of peptides and free amino acids. The precise role of the intermediate to small molecular weight peptides is not clear; however it is generally accepted to play an important role in the background taste of cheese (Fox and others 1994). Several peptides were identified in different types of cheeses as bitter, see Table 78.4 for a list of bitter peptides. An interesting relationship was established by Ney (1981) between the average hydrophobicity (Q) of a peptide, as measured by the hydrophobicity of amino acid side chains determined by Tanford (1962), and bitterness. The peptides with Q-values >1400 cal/mol/residue and molecular weights up to 6000 Da (molecules >6000 Da are likely to be too large to interact with the taste receptors) taste bitter, and no bitterness occurs when Q is <1300 cal/mol/residue. Peptide β-CN f193–209, identified in both Cheddar and Gouda, determined to be bitter by detailed sensory analysis (Singh and others 2004b). This peptide with Q value 1839 cal/mol/residue and molecular weight 1882.51 Da was also classified

TABLE 78.4 Bitter Peptides Identified in Cheddar Cheese.

Peptide	Hydrophobicity	Sequence	Type of Cheese and Reference

TABLE 78.5 Taste Compounds in Milk and Milk Products.

Compounds	Taste/Other Complex Sensation	Products
Lactose	Sweet	Milk, concentrated/evaporated milks, dried milk powders
Sucrose	Sweet	Sweetened yogurt, ice creams, sweetened condensed/ evaporated milks
Lactic acid	Sour	Fermented milks/cream, cheeses
Acetic/propanoic acid	Sour	Fermented milks, cheeses
Ca/Mg salt of propanoic acid	Sweet	Cheeses
Peptides	Mostly bland, some can be bitter, sour or umami	Milk, Fermented milks, cheeses
Amino acids Gly, Ala, ser, Thr	Sweet	Cheeses
Glu, Asp, Gln, Asn	Sour, umami	Cheeses
His	Sour (?)	Cheeses
Pro, Lys	Sweet, bitter3	
Leu, Val, Ile, Arg, Phe, Tyr	Bitter	Cheeses
TrpNaCl	Salty	Cheeses
Ethanol	Slightly sweet, cooling/drying sensation	Fermented milks (e.g., kefir, koumiss)
CO_2	Sour, fresh, cooling sensation	Fermented milks (e.g., kefir, koumiss)

as potentially bitter in the Q value model proposed by Ney (1981). Amino acids are also known to elicit different taste, (see Table 78.5).

Recently, a number of workers studied taste active compounds in Camembert (Engel and others 2001a,b,c), Cheddar (Yang and Vickers 2004), Comte (Salles and others 1995), Goat (Engel and others 2000a,b, 2002; Salles and others 2002), and Emmentaler cheeses (Warmke and others 1996). The topic of cheese taste was also reviewed by McSweeney (1997).

78.4 CONCLUSIONS

A concerted series of chemical and biochemical reactions are involved in the formation of dairy flavor and off-flavor compounds. General chemical/biochemical pathways, that is, (1) heat-induced changes, (2) lipid oxidation, (3) glycolysis, (4) lipolysis, and (5) proteolysis, involved in the degradation of milk constituents are now fairly well characterized. Recent works on the enzymology and genetic manipulation of the starter and nonstarter lactic acid bacteria have helped in the better understanding of further catabolic modification of the products of primary degradation pathways. This has lead to immense progress in understanding of the fermented dairy products flavor chemistry. So far a large number of volatile compounds have been characterized from various types of cheeses but still it is not possible to duplicate cheese flavor by pure chemicals in model systems. But there is now good understanding on the causes of bitterness and specific flavors/off-flavors in dairy products.

Developments in sensory and instrumental methodologies in flavor analysis have been of immense help in the understanding of dairy products flavor chemistry. Further work on

the characterization of flavor compounds, volatile flavor compounds-matrix interaction mechanisms and flavor release mechanisms are needed to fully elucidate dairy products flavor. The better understanding of flavor chemistry will be useful in the development of new technology/mechanisms for the effective control and acceleration of the ripening process in cheese.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

79.1 INTRODUCTION

The poultry industry has had a remarkable growth all over the world during the last three decades. According to the National Chicken Council, per capita consumption of poultry in the United States has increased 120% since 1975 and it is expected to continue this way. Meanwhile, red meat and fish consumption had small variations during the same period (Fig. 79.1) due to changes in consumer life style and food preferences even with the recent fear of an avian influenza outbreak that has already infected millions of birds throughout Asia and parts of Europe. For instance, increases in broiler meat consumption from 2005 to 2006 were forecasted for Brazil (4%), China (3%), India (16%), Mexico (5%), Russia (7%), and the United States (3%) by the Foreign Agricultural Service (FAS/USDA 2005). In order to maintain this continuous growth in poultry consumption, producers and processors necessitate products that meet consumer demands for nutritious, safe, affordable, and convenient foods, which cook faster and require less preparation time. Nowadays, further processed poultry such as boneless and marinated items represent 50% of the total broiler market in the United States (Fig. 79.2); therefore the poultry industry and researchers should build up advanced processing technologies to produce consumer-oriented products, and to solve critical issues such as color, flavor, texture, and microbial safety related to the quality of poultry meat.

Marinating dates from the early 17th century, when meat was cured by immersion in brine (*aqua marina*) for preservation or mask off-flavors; a variety of liquids such as vinegar, lemon, wine, and oils, added with salt and spices have been used to marinate according to the cuisine and consumer preferences. Currently, this term involves an industrial process where meat, fish or poultry become tenderized and/or absorb flavor by the addition of water, flavors, and functional ingredients accomplished by immersion, injection, tumbling, or massaging. The marinating solution or marinade may be formulated with salt, phosphates, seasonings, carbohydrates, vegetable and dairy proteins, acids, antimicrobials, and antioxidants, among other ingredients (Brant 2003). However,

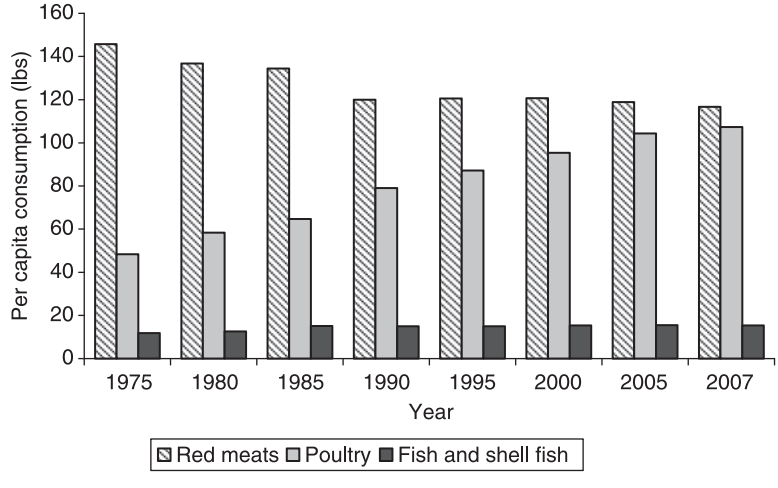

Figure 79.1 *Per capita consumption of poultry, livestock, fish and shellfish. (Red meats include beef, pork, veal, mutton, lamb, but exclude edible offals. Source: National Chicken Council.*

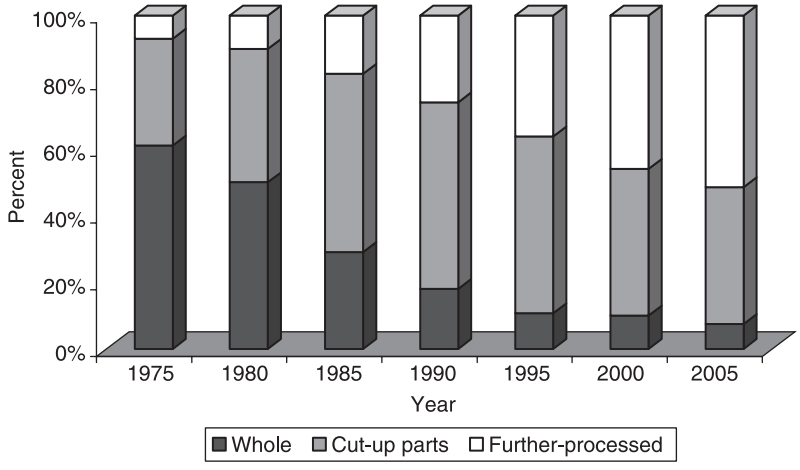

Figure 79.2 *Broiler presentation in market (data estimated for 2005). Source: National Chicken Council.*

it is necessary to understand how this process affects raw materials, as well as the functionality of ingredients, packaging materials, and also good manufacturing practices to create a high quality, safe, value added, tender, and flavorful marinated poultry.

79.2 RAW MATERIALS

Marinated poultry items include whole birds, cut-up parts, boneless or skin-less parts, and chopped or reformed meats. Meat must be inspected and achieve sanitary specifications, in the United States a representative of USDA's Food Safety Inspection Services (FSIS) ensures compliance of regulatory requirements. Meat must be free of off-odors (rancidity, sulfide, oily, etc.), and defects (discoloration, blood clots, excessive fat, soft like texture, etc.), with no evidence of mishandling, dehydration, or freezing and thawing, or apparent microbial growth, along with a characteristic color. Poultry may be fresh chilled or frozen, but chilled meat should not be above 40°F (4.4°C), and frozen meat should be below 0°F (−17.8°C) when received; the higher receiving temperature means a risk for pathogens and accelerates spoilage. In addition, temperature must not exceed 55°F (12.8°C) at any time during the preparation and processing according to the regulation of the U.S. Agricultural Marketing Service (AMS/USDA). Furthermore, the presence of foreign materials, chemical residues, insects, or other contaminants make raw materials inedible and inappropriate to be processed.

Poultry meat contains about 20% protein that according to their solubility and location are classified as myofibrillar, sarcoplasmic, and stroma. Miofibrillar proteins constitute 55% of total protein, are insoluble in water, and include more than 20 different proteins divided into three groups according to their function as: contractile (responsible for muscle contraction), regulatory (direct contraction), and citoskeletal proteins (give support and maintain muscle ultra structure). The contractile proteins, myosin and actin compose the actomyosin complex during muscle contraction and post mortem, also

they are the main proteins responsible for meat quality and functionality. On the other hand, sarcoplasmic proteins represent 30–35% of total muscle protein, they are water soluble and play a minor role in meat protein functionality; although myoglobin and other water-soluble compounds are responsible for meat color as the amount of myoglobin varies within species, age, and muscle fiber distribution. Dark muscles in turkey thigh are mainly comprised of red fibers and contain more myoglobin (0.6–2 mg/g) than light breast muscles (0.1–0.4 mg/g) as data reported by Froning and Mckee (2001). Lastly, stroma proteins are rather insoluble, comprise about 3–6% of total protein; collagen is the main component of this fraction in combination with small quantities of reticulin and elastin; but the amount of collagen and the age-associated collagen cross-linking influences meat texture (Miller 1994; Hettiarachchy and Gnanasambandam 2000).

Several factors influence poultry meat quality; for instance, post mortem condition at the time of removal from skeletal frame alters texture and meat quality. It is common that poultry carcasses are stored either under refrigeration or in ice for up to 8 h to ensure depletion of muscle ATP to prevent toughening (Lyon and Lyon, 2002; Sams 2001; Young and others 2004). After dead, individual cells remain alive and continue their metabolism; with the loss of blood and oxygen supply, cells gradually shift from aerobic to anaerobic glucolysis with production of lactic acid that accumulates in the muscle cells causing pH to decrease from neutrality to an acidic pH of about 5.7. The pH reduction alter the activity or some ATP producing enzymes until ATP depletion and the onset of rigor mortis. ATP is the primary energy supply that regulates the muscle contraction–relaxation cycle; when ATP concentration falls below 1 μM/g, muscle adopts a steady contraction state called rigor mortis as ATP is needed to break down the actomyosin complex between the overlapped thin and thick muscle filaments (Sams 2001; Ponce-Alquicira 2006a). The rate of pH decrease and the final pH value have a great influence on meat quality. A rapid drop in ATP and pH causes extensive drip loss because of muscle protein denaturation by combination low pH and high temperature exposition; this condition is known as PSE (pale, soft, and exudative) and it is associated to stress during slaughtering. In contrast, DFD-meat (dark, firm, and dry) has a high pH and a low level of lactic acid post mortem, this condition is caused by low levels of muscle glycogen when animals are exposed to a long-term preslaughter stress. Pale broiler breast fillets had similar marinade uptake but greater cooked losses than normal fillets (Cavitt and Owens 2001). Therefore, the myofibrillar protein and the physicochemical condition (PSE or DFD) mainly determine the functional properties and quality of raw materials.

Poultry marketing is moving towards cut-up parts and further processes commodities as shown in Figure 79.2. This change in the consumer preferences has shortened the time between slaughtering and cut-up or deboning. However, muscle cutting and deboning before rigor mortis will cause severe contraction or shortening, since the skeleton no longer restrains muscle length. Some processing plants use electrical stimulation to accelerate ATP depletion; this process involves application of an electric current either during bleeding or prior evisceration to accelerate ATP depletion, reducing the time for further processing and improves marinade absorption (Young and others 2004; Ponce-Alquicira 2006a). The main objective of marinating is to improve juiciness, flavor, and tenderness; these qualities are directly associated to protein hydration and water holding capacity. These functional properties are based into protein–water interactions that are affected by several intrinsic and extrinsic factors, therefore it is necessary to review those factors to ensure quality of marinated poultry products.

79.2.1 Water Holding Capacity

Water holding capacity (WHC) is the ability of meat to retain or absorb added water in the presence of an external force. Meat contains about 76% water; however, less than 5% is tightly bound to the hydrophilic sites while the additional 95% is hold by capillary forces between the thick and thin filaments, or physically entrapped within muscle structure. WHC is largely influenced by the contractile miofibrillar proteins organization, based in the distribution of hydrophobic and hydrophilic groups as well as in the charge and molecular flexibility of muscle proteins. All these characteristics may vary according to the post mortem state. WHC is elevated immediately after slaughter, but after the onset of rigor mortis, meat becomes rigid and WHC starts to decrease. After some time, endogenous muscle proteases cause morphological changes that disrupt the cytoskeleton organization. As a consequence, meat becomes soft and tender again with a slight rise in pH and WHC during post rigor. However, WHC is also affected by extrinsic factors such as pH and temperature, meat integrity, salt concentration, and addition of other nonmeat components (Lawrie 1998).

Myofibrillar proteins have the lowest water affinity at a pH set in the isoelectric point (pI) at pH $\sim$ 5.1, as they have a cero net charge and tend to aggregate; however, proteins become more negatively charged and repulsive forces between them increase at pH values close to neutrality, allowing more water to interact with the hydrophilic protein sites, thus increasing WHC. Changes that take place post mortem alter WHC as pH decreases and myofibrillar proteins are tightly bound forming the actomiosin complex. Addition of NaCl up to 0.6 M (2–3.5%) reduces electrostatic interactions between proteins, increases protein extractability, solubility and water binding in both breast and thigh muscle. Additionally, alkaline phosphates in combination with salt increases pH, myofibrillar protein solubilization and WHC (Zheng and others 2000; Li and others 2001; Aktas and others 2003). Furthermore, mechanical work during tumbling and massaging disrupts the muscle fibers facilitating water absorption and swelling; but an excess of mechanical work can lead to muscle fibers disintegration and protein denaturation due to an increase in temperature and excessive shearing; those denatured proteins as in PSE muscle form aggregates that have low water affinity (Lawrie 1998; Totosaus-Sanchez and Guerrero-Legarreta 2006).

79.2.2 Texture

Texture as well as color and flavor influences consumer's acceptance and poultry meat quality. This attribute is affected by the amount of collagen and the age-associated collagen crosslinking degree; therefore, meat from older animals is likely to be tougher than meat from young animals. In addition, meat from muscles involved in locomotion is higher in connective tissue than meat obtained from muscles used for structural support; for instance, Wattanachant and others (2004) reported that total collagen contents of broiler *pectoralis* and *biceps femoris* muscles were 3.86 mg/g and 8.70 mg/g, respectively.

On the other hand, the final pH and myofibril organization play an important role for meat texture; the biochemical and physical conditions during rigor affects the final contractile state and thus meat texture. The Z-line structure and the sarcomere length, that is, the distance between two adjacent Z-lines is primarily responsible of meat tenderness. As a result of rigor mortis, the sarcomere length decreases and muscle becomes tough;

later during post rigor, morphological changes affect the cytoskeleton in which Z-lines get disorganized, and meat becomes soft and tender again. The calcium activated sarcoplasmic factor (CASF) or calpains are proteases with an optimal activity at pH around 7, primarily responsible for degradation of desmin and conectin present in the Z-line, as well as M-line proteins, troponin T, and tropomyosin. Furthermore, the lysosomal proteases called cathepsins alter troponin T, myosin and actin in a synergistic action (Miller 1994; Pérez-Chabela and others 2005). To achieve optimum texture, poultry processing involves chilling and aging for 4–8 h after evisceration to allow rigor development and post-rigor tenderization (Miller 1994; Zheng and others 2000). It has been reported that marination at either high or low pH had positive effects in texture and WHC. Additionally, cooking losses were decreased as a result of the loss of M-line at low pH, and due to the loss of Z-line when marinating at high pH. The use of organic acids such as 0.1 M acetic or lactic acids, or red wine marinade induces a rapid degradation of myosin heavy chains, titin and nebulin, probably caused by activation of chatepsins as compared with nonmarinated meats (Oreskovich and others 1992; Hwang and others 2000; Lin and others 2000).

79.2.3 Color

Meat color of either raw or cooked varies according to species, muscle function, age, storage conditions, and further processing. Myoglobin is the mayor pigment in meat but its content varies according to the muscle physiological role. For example, high use leg muscles have a higher myoglobin content as they need it to store and deliver oxygen to support ATP production during long-lasting contractions. In addition, the myoglobin content increases with age, meat from older animals is darker than the one obtained from younger animals; also male birds have higher myoglobin than females (Claus an others 1994; Miller 1994; Wattanachant and others 2004; Pérez-Álvarez 2006). The mioglobin content is three times higher in turkey dark meat (0.37 mg/g) than in white meat (0.12 mg/g) obtained from 14 weeks aged male birds; but turkey white meat obtained from 24 weeks male birds has a mioglobin content of 0.37 mg/g. Hemoglobin is the mayor pigment in blood and also contributes to meat color; the hemoglobin content in meat varies according to conditions prior to and during exangination, which influence blood removal. Improper bleeding practices result in a great amount of haemoglobin within muscles. Other meat pigments such as cytochromes, catalase, and flavins have a minor influence in color (Miller 1994; Pérez-Álvarez 2006).

Deleterious changes during storage and further-processing have a less dramatic impact in poultry meat color than that for red meats. The bloody, undercooked appearance or "pinking" is one of the most common color problem in cooked poultry meat and it is associated to the presence of blood. However, several factors such as bird age, diet (intake of nitrites or moldy feed animals); preslaughter transport and handling, improper stunning; as well as meat aging, processing, and cooking method, among others are involved in meat "pinking." It has been suggested that the ferrous *heme* iron from metmyoglobin can weakly bind to other nitrogen-containing compounds such as denaturated proteins or nicotinamide causing "pinking"; but a decrease in the oxidation-reduction potential and CO-myoglobin formation are also associated this color phenomena (Claus and others 1994; Nam and others 2001; Smith and Northcutt 2004).

Other color defect is called bone darkening found in cooked chicken meat, where the tissue around the bone is discolored with a black appearance, this color defect is commonly observed when poultry is frozen prior to cooking, as a result of bone marrow

leaking trough the bone onto surrounding meat, which becomes dark during cooking; blast freezing and reheating increase darkness in raw and cooked bone-in broiler tights, but removal of femur prior to freezing decreased this problem. The less common color problem that affects poultry is the intense red, bloody discoloration of bone-in fully cooked products; it seems that the presence of blood derived from hemorrhages and bruises is more important than bone marrow for the dark and red discoloration of broiler meat. However, marinating with phosphates citric acid and EDTA may reduce the redness discoloration in both raw and cooked chicken breast meat (Smith and others 2001; Smith and Northcutt 2004).

79.2.4 Flavor

Poultry flavor is composed by meat-like water soluble reducing sugars, amino acids, and lipids. Free sugars, free amino acids, peptides, nucleotides, and other nitrogenous components such as thiamine, are among the main water-soluble flavor precursors, although frozen storage and cooking may change their concentration. Raw poultry (as other meats) has a light metallic bloody flavor, but during heating and storage, nonenzymatic browning reaction, Strecker degradation, lipid oxidation, thiamine degradation, and proteolysis among other chemical reactions, take place to create the characteristic poultry flavor (Farmer 1999; Ang 2000). Undesirable tastes may derive from low molecular weight compounds, lipid oxidation, or protein degradation that happen during long-term storage, or by cell disruption and releases of haemoglobin and lipids from the bone marrow (Miller 1994; Froning and Mckee 2001; Smith and Acton 2001; Ponce-Alquicira 2006b,c). It is well known that marinating improves flavor by incorporation of salt, phosphates, sugars, and several seasonings but care must be taken as formulation errors can yield to flavor deterioration and product rejection. Salt may promote lipid oxidation and off-flavor development; whereas, an excess in of phosphates will cause bitterness, therefore, correct formulation, high quality materials, and good manufacturing practices will ensure the flavor attributes expected by consumers.

79.3 FUNCTIONAL INGREDIENTS

Ingredient formulation is critical in new product development to maximize quality and yield, attending both producer and consumer requirements. Incorporation of the appropriate functional ingredients at effective levels is crucial for a successful marinating process. Salt, phosphates, water, seasonings, sweeteners, polysaccharides, vegetable or dairy proteins, acids, antimicrobials, and antioxidants, among other additives are common ingredients present in the marinade. These components add value to poultry meat as they increase WHC, improve yield, juiciness, flavor, tenderness, extend product storage-shelf, and control costs (Bacon 2001; Keeton 2001). However, processors have to keep in mind that food additives are minor constituents intentionally added to enhance food quality and strict regulations are imposed to control their use.

Marinade formulation needs to be created also according to the postprocessing handling; for instance, frozen cooked products that will be cooked twice (during processing and before eating) must retain even more moisture, therefore ingredient technology needs to contemplate this actions (Bacon 2001). Tables 79.1 and 79.2 present the typical formulation of marinade for chicken fajita strips.

TABLE 79.1 Marinating Solution Formulation for Chicken Fajita Strips.[a]

	Percent of Total
Water (maximum)	65.63
Spices/seasonings (maximum)	25.00
Binders[b]	6.25
Sodium phosphates (maximum)	3.12
Total	100.00

79.3.1 Salt

Sodium chloride or common salt is considered safe by the U.S. Food and Drug Administration (FDA) and receive the status of GRAS (generally recognized as safe). Salt enhances flavor and taste, increases ionic strength, protein solubility, and WHC, also reduces shrinkage and cooking loss, limits drip loss following freeze-thaw, and acts in combination with sodium nitrite to prevent outgrowth of *Clostridium botulinum*. Salt may be considered as antibacterial because, at high concentration (above 5%), it restricts bacterial growth by lowering the water activity or free water molecules in foods; therefore, it is used to improve flavor, texture, and as a basic curing agent for meat preservation. However, the recommended salt concentration in finished poultry products varies from 1.5% up to 2%. Salt levels in meat products are decreasing due to consumer healthy concerns; thus, some products may be low in sodium by partial substitution of sodium by potassium, calcium, or magnesium salts. However, marinate absorption is related to the salt type and the ionic strength needed to dissociate proteins and increase WHC. Samples marinated with calcium salts retain less water than those marinated with sodium chloride, thus low sodium marinades should be formulated in a way to achieve the appropriately muscle functionality and yield. Moreover, care should

be taken as salt may contain metal contaminants that accelerate lipid oxidation and rancidity diminishing flavor qualities (Aktas and others 2003; Brant 2003).

79.3.2 Phosphates

Marinade solutions containing phosphates in combination with salt enhance WHC, overall moisture, juiciness, and yield; while reducing cooking and purge loss. Phosphates also limit drip loss following freezing-thaw and increase tenderness. Muscle proteins show the lowest water binding capacity at a pH close to its pI (pH $\sim$ 5.4). After slaughtering, meat pH approaches to the isoelectric point and WHC decreases, but phosphate addition increases meat pH to an optimal range of 6–6.4. The USDA establishes a maximum phosphate content of 0.5% in the finished product, but levels close to the maximum limit may cause soapy and bitter taste, and may also produce a rubbery like texture; in consequence, most formulations include 0.3–0.4% phosphates in the final product (expressed as phosphate pentoxide, P_2O_5); in addition, only clear solutions may be injected into poultry (Li and others 2000, 2001).

There are several chemical forms of phosphates, but not all produce the same effect; thus, choices can be made according to the required functionality (see Table 79.3). Alkaline phosphates increase meat pH and ionic strength, also they break down crosslinks between myofibrillar proteins and increase the number of hydrophilic protein groups available for water binding, thus increasing WHC, juiciness, and product yield during thawing, reheating, and storage (Li and others 2000, 2001). Phosphates also help to maintain color, enhance meat flavor, and delay oxidative rancidity by chelating metal ions. Phosphates vary

in their solubility and pH, therefore, several types of phosphates alone or in a combination thereof are commonly used in meat processing (see Table 79.3). These include ortophosphates, diphosphates, or pyrophosphates (PP), tripolyphosphates (TPP), polyphosphates, and tripolyphosphates or "glass" phosphates, and metaphosphates (MP). Once incorporated into meat, some phosphates may be hydrolyzed nonenzymatically or enzymatically by muscle phosphatases to monophosphate increasing muscle pH at various rates according to their chemical structure. Diphosphates are the most effective chemical form for marinating but have relatively low solubility; thus, diphosphates are normally combined with more soluble, longer chain phosphates such as tripolyphosphates and hexametaphosphates in a 10/90 ratio. Whereas, orthophosphates have less impact on water binding for marinated poultry products. Therefore, the correct choice of phosphate blend may improve quality and reduce cost (Li and others 2000, 2001; Zheng and others 2000; Rocha 2003).

79.3.3 Species and Flavorings

In general poultry meat posses a delicate flavor and adapts very well to any flavoring combination according to the consumer taste preferences and flavor profile, either traditional or emerging tastes (Ponce-Alquicira 2006b). There is an innumerable source of flavorings that could be used for poultry marinating to impart or modify flavor, such as spices, chilli peppers, oils, vinegars (apple, rice, red wine, etc.), fruit juices or nectars, or synthetic flavors (see Table 79.4). Spices are marketed ungrounded or as coarsely or finely ground powders, but after grinding aroma is lost gradually during storage; in addition powders are commonly contaminated with microorganisms and may accelerate food spoilage. Therefore spice extracts, essential oils, oleoresins, or microencapsulated flavorings are commonly added in industrial scale food preparation, since they are free of microorganism, uniform, and easy to handle. The way in which these ingredients are added into the marinade will depend on the marinating process, in particular it is preferable to use flavor concentrates and/or oleoresins when marinating by injection to avoid needle blocking caused by the presence of small particles. In addition to spices, smoke flavor has been used for years to enhance and modify flavor for barbecue and grilled marinated products. Smoke components include phenols, acids, and carbonyl compounds derived from the pyrolysis of lignin and cellulose. Among them, syringol is a phenolic compound derived from lignin, and the main responsible for the smoke and hickory flavor; while carbonyl compounds have minor flavor impact (Rocha 2000; Brant 2003; Ponce-Alquicira 2006b,c).

The flavoring industry is aware of the potential that spices and seasonings have on product development to create healthy and enjoyable dishes, and to reinvent classic tastes, throughout the correct selection of spices and flavorings. Nowadays, species are seen as functional ingredients that not only improve flavor, but enhance salty perception, alleviate diabetes and high cholesterol, promote antioxidant, and antimicrobial activities, and also help to expand and reinvent conventional cuisines. As a result of globalization and immigration, consumers are more familiar to a wide range of cultures, and willing to taste other cuisines such as African, Asian, Brazilian, Indian, Italian, Mexican, Mediterranean, Cajun, Buffalo style, and so on. Thus, flavorings can also help to reshape or create foods such as the great variety of marinated poultry products. The Mexican cousin flavor can be obtained by marinating with chipotle, jalapeño or habanero chili-peppers; fresh coriander, paprika, as well as *mole* (sauce made of chocolate, ancho chili pepper, tomato, garlic, onion, nuts, and spices), *adobo*

TABLE 79.4 Spices Used in Meat Industry.

Group	Common Name	Latin Name	Flavor Characteristics
Leaves	Basil	*Ocimum basilicum*	Hay-like and minty, slightly bitter and musty
	Chervil	*Anthriscus cerefolium*	Sweet, aromatic
	Chives	*Allium schoenoprasum*	Delicate, peppery-onion
	Dill	*Anethum graveolens*	Sweet, green/grassy, tea-like
	Marjoram	*Origanium hortensis*	Minty, aromatic and slightly bitter
	Mint	*Mentha spicata L. (spearmint) Mentha piperita L. (peppermint)*	Aromatic, strong, sweet flavor with a cool aftertaste
	Oregano	*Origanum spp. or Lippia spp. (Mexican)*	Strongly, camphoraceous aroma, slightly bitter, pungent
	Parsley	*Petroselinum crispum*	Green and vegetative
	Rosemary	*Rosmarinus officinalis*	Pine-woody aroma with fresh, bittersweet
	Sage	*Salvia officinalis*	Medicinal, piney-woody
	Savory	*Satureja hortensis*	Aromatic, piquant and a fragrant aroma
	Tarragon	*Artemisia dracunculus*	Aromatic, licorice-like
	Thyme	*Thymus vulgaris*	Minty-green, hay-like, and musty notes.
Fruits	Allspice	*Pimenta dioica*	Pleasant blend of cinnamon and clove
	Anise	*Pimpinella anisum*	Pleasant, licorish-like, similar to fennel
	Caranway seed	*Carum carvi*	Pleasantly aromatic and biting
	Chilli pepper	*Capsicum annum*	Sweet to moderate heat, and biting notes
	Coriander	*Coriandum sativum*	Mildly sweet and spicy
	Pepper	*Capsicum frutescens*	Tobacco, hay-like, hot/pungent
Seeds	Cardamon	*Elettaria cardamomum*	Soapy with menthol notes
	Cumin	*Cuminum cyminum*	Distinctive, slightly bitter
	Mustard	*Brassica hirta Brassica juncea*	Fresh aroma and a pungent, slightly biting
	Nutmeg	*Myristica fragans*	Strongly aromatic, citrus, piney
	Sesame	*Sesamum indicum*	Nut-like
Rhizomes	Ginger	*Zingiber officinale*	Lemon/citrus, soapy and musty/earthy notes
Flowers	Cloves	*Syzygium aromaticum*	Strong, pungent, sweet and hot
Barks	Cinnamon	*Cinnamomun zeyland, Cinnamomun cassia*	Sweet and pungent
Color spices	Annatto seeds	*Bixa orellana*	Rich yellow/orange color, musky-flavour
	Curcuma	*Curcuma longa*	Yellow like color; aromatic and spicy fragrance
	Papika (sweet red pepper)	*Capsicum annum*,	Bright Red color; sweet in flavor with fragrant aroma
	Saffron	*Crocus sativus*	Rich yellow, strong perfume and bitter honey-like taste

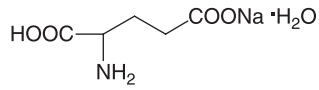
Figure 79.3 *Variety of fresh and frozen marinated poultry meat products (chicken and turkey parts with herbs, adobo, achiote, butter, oriental, arrachera, natural, smoke, mesquite, teriyaki, and California marinade flavors).*

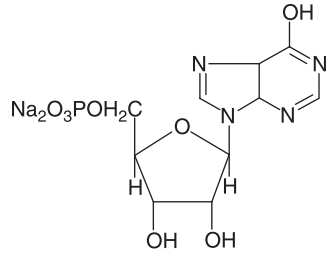
(spiced red chili sauce), or *achiote* (Yucatan-style sauce from ground annatto seeds, onion, garlic, and tomatoes), among others. Caribbean flavors include cinnamon, pineapple, coconut, orange, and lemon juices. The Asian marinade includes garlic, ginger, coconut, lemongrass (*Cymbopogon citratos)*, mushrooms, sesame seeds, soy sauce, and teriyaki sauce (sugar, soy sauce, and sake marinade); while the Hindu influenced marinade may include strong flavors from cardamom, ginger, curcuma, cumin, and hot chilli-peppers). These days, marketing for marinade products in the United States are reoriented to the "Nuevo Latino flavor trend" with flavor profiles such as citrus, chilli peppers, heat, and fresh herbs. Therefore, flavorings have gone to a more complex mixtures as consumers will look at the wide variety; upcoming products include a combination of Asian and Caribbean flavors prepared with ginger, honey, orange, garlic, and pineapple; in addition to, flavor blends such as fruity-sweet combined with heat, or cool and spicy flavor notes (Rocha 2000, 2001; Brandt 2003; Pszczola 2005; http://www.mccormick.com 2006). In general, poultry meat adapts very well to all sorts of flavor trends, and this is the cause for the large increase in consumption for further processed poultry items over other meats such as those presented in Figure 79.3.

79.3.4 Flavor Enhancers

There are several compounds that enhance the original taste or flavor; the most widely used flavor enhancers are monosodium glutamate (MSG), inosine-5′-monophosphate (IMP) and guanosine-5-monophospahte (Fig. 79.4), and hydrolyzed vegetable protein (HVP). They are currently accepted as GRAS food additives, but enhancing mechanisms are not well understood. It has been suggested that these compounds are responsible for the *umami* flavor perception, they act in a synergistic mode to increase salty, and sweet flavors, due to an increase in the time of residence of active flavorings with the gustative receptors. The amount of MSG added varies from 0.1% to 1%, whereas, levels for IMP



monosodium glutamate



disodium inosine-5´-monophosphate

and GMP range from 0.002% to 0.03% (Hettiarachchy and Kalapathy 2000; Marcus 2005; Ponce-Alquicira 2006c).

79.3.5 Sweeteners

Dextrose, sucrose, corn syrup solids, sorbitol, manitol, honey. Molasses and other sweeteners are commonly added to marinated poultry products in order to increase moisture retention, and enhance flavor by reducing salt harshness. These compounds differ in sweetness and taste intensity; although, temperature, pH, and the presence of other sweet compounds could modify also their taste perception. Sugars participate in Maillard and caramelization browning reactions generating color and flavor compounds (Ponce-Alquicira 2006c). Therefore, the use of sweeteners is somewhat self-limiting, because they can cause excessive browning and sweetness. Maltodextrins and corn syrup solids are tasteless and water soluble products, which offer reduced sweetness and browning, while providing solids and a slight increase in viscosity according to their molecular weight and on their dextrose equivalents (DE), thus helping to retain the marinade in the poultry product (Keeton 2001; Brant 2003). Furthermore, honey is high in fructose, not only contributes to retain water and flavor development; but honey also reduces lipid oxidation improving quality as reported by Hashim and others (1999); mainly because honey contains various phenolic compounds such as α-tocopherol,

ascorbic acid, β-carotene, catalase, and peroxide, which can function as antioxidants. Besides, it has been claimed that honey inhibits formation of heterociclic aromatic amines during cooking and grilling, thus resulting in a reduction of mutagenicity in cured poultry (Shin and Ustunol 2004).

79.3.6 Binders and Extenders

Water-binding agents such as starches, hydrocolloids, and nonmeat proteins are used alone or more often in combination to help minimize marinade purge. These ingredients enhance the yield and quality of marinated poultry products as they retain moisture, provide freeze-thaw stability, and reduce losses during cooking. Nonmeat proteins used in poultry meat products include soy flour, soy protein concentrate and isolate, nonfat dry milk, dry whey, whey protein concentrates and isolates, and plasma proteins. These proteins prevent shrinkage during cooking and retain juiciness, contribute to nutrition and flavor, and they have a significant effect on the pH of meat systems because of their buffering capacity. On the other hand, polysaccharides include starches and hydrocolloids. Native and food grade modified starches and cellulose derivates are widely used due to their low cost and availability; they bind four times their weight in moisture, and contribute to texture. Levels vary from 1 to 3.5 and up to 18% according to the application and regulatory restrictions. Hydrocolloids such as carrageenan, konjac, and alginate, among others are long-chain polymers which dissolve readily in water to give a thickening effect at levels below 2%. Label restrictions sometimes limit the amount of total binders included; once a limit has been established, the best combination of synergistic ingredients should be used to give the desired moisture and texture for the product; that can become a very complex matrix of ingredients to achieve the desired product effect (Keeton 2001; Brant 2003; Valdés Martínez 2006).

79.3.7 Acidulants

The most common acidulants are acetic, citric, fumaric, lactic, and phosphoric acids or their salts, as well as, glucono-delta-lactone (GDL), which produce acid during hydrolysis. Acetic acid is used in foods as vinegar; it is produced by *Acetomonas* and *Acetobacter* bacteria through fermentation from grapes, grains, cane sugar, apple or pineapple juice, and other substrates. Each type of vinegar has its own distinctive flavor profile such as acid, fruity, musty, and so on Vinegar addition reduces pH, controls the microbial growth, and enhances flavors. Lactic acid and sodium lactate are widely used in meat processing to reduce water activity and inhibit spoilage bacteria. Citric acid is widely distributed in nature in both vegetal and animals tissues. It is used for flavor enhancement because its ability to chelate potentially prooxidative metal ions, thus retarding oxidation and increasing effectiveness of antioxidants. In meats, citric acid is used at levels below 0.01% to prevent oxidative rancidity protecting flavor and color. GDL slowly hydrolyzes releasing acid; it is commonly used in cured poultry products to reduce the cure time, to inhibit undesirable microorganisms, to promote color development, and to reduce nitrate and nitrite levels (Dziezak 1990; Belitz and Grosh 1999).

Latin, Asian, and Caribbean cuisines incorporate acids and citrus flavors (lemon, lime, and orange), that are difficult to apply in meats because highly acidic marinates ($pH < 5$) may accelerate protein denaturation and proteolysis, causing meat to become too soft in detriment of texture. For instance, Hwang and others (2000) claimed that marinated

goose breast with 0.1 M lactic or acetic acids for 24 h at 5°C exhibit degradation of myosin heavy chain, titin, and nebulin myofibrillar proteins; thus the marinade formula must balance the acidic effect to obtain the appropriate texture (Brant 2003).

79.3.8 Antioxidants

Lipid oxidation is one of the main problems for poultry meat due to disruption of the integrity of muscle membranes during processing, and freeze-thawing. Further reactions involved in lipid oxidation leads to "warmed-over flavor" (WOF) development during cooking. The term WOF refers to the rapid development of off-flavor in cooked meat during refrigerated storage, and it has become a serious problem for precooked and reheated poultry, as well as in fresh ground and restructured meat; along with cooked, refrigerated, or irradiated poultry products. Lipid oxidation may be initiated by catalysis of heme iron present in haemoglobin and myoglobin, and also by enzymic lipid peroxidation, in conjunction with higher polyunsaturated fatty acids of membrane phospholipids (Ahn and others 1993; Hettiarachchy and Gnanasambandam 2000; Armitage and others 2002; Lee and Ahn 2003; Sucan 2004; Rababah and others 2005; Ponce-Alquicira 2006b,c).

Several substances have been examined to prevent lipid oxidation in meat products, antioxidants such as butyl hydroxytoluene (BHT) and butyl hydroxyanisole (BHA), tertiary-butylhidroquinone (TBHQ), proppyl gallate, and α-tocopherols are free radical scavengers that react with peroxyl or alcoxyl radicals and terminate the chain reaction of peroxidation (Fig. 79.5). All this antioxidants in addition to metal chelating agents (EDTA, citric acid, and phosphates) are commonly used to reduce lipid oxidation in both raw and cooked poultry meat (Anh and others 1993; Hettiarachchy and Gnanasambandam 2000). However, since BHA has been identified as a carcinogen in laboratory animals, there is an increasing interest to study other natural antioxidants. Plant extracts

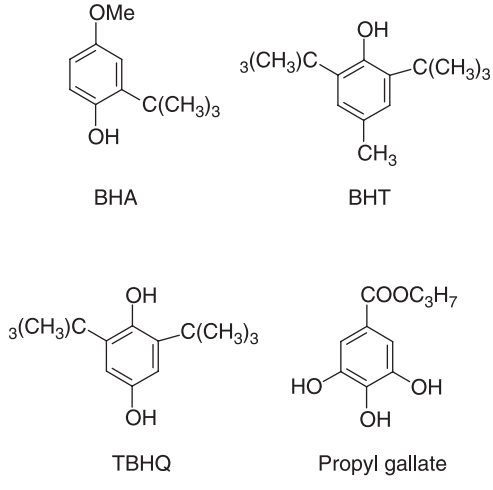

Figure 79.5 *Chemical structure of butyl hydroxyanisol (BHA), butyl hydroxytoluene (BHT), teritiary-butyl hydroquinone (TBHQ), and propyl gallate (PG). (Adapted from Belitz and Grosch 1999; Hettiarachchy and Kalapathy 2000.)*

such as green tea, grapefruit seed, cocoa leaves, oregano, and rosemary extracts; as well as, tea catechins, vitamin E, and honey could retard lipid oxidation (Tang and others 2001; Armitage and others 2002; McKibben and Engesth 2002; Basmacioglu and others 2004; Hassan and Fan 2005; Rababah and others 2005; Hernández-Hernández and others 2006; Peña-Ramos and others 2006). However, results in terms of oxidative prevention are unequal and usually modest with large variations, according to storage conditions, aerobic or anaerobic packaging, amount of free polyunsaturated fatty acids, and integrity of raw tissues (Lee and Ahn 2003; Lee and others 2003; Mielnik and others 2003; Soares and others 2004).

79.3.9 Antimicrobials

The use of antimicrobials is intended to reduce the number of microorganisms and subsequent spoilage. The three most common preservatives are sorbates, propionates, and benzoates. In general, sorbates are the more effective preservatives against a wider spectrum of food spoilage microorganisms than benzoates or propionates for mildly acidic foods (pH

TABLE 79.5 Antimicrobials in RTE Meat and Poultry Products.

Name	Amount	Reference	Labeling Requirements
Aqueous octanoic acid (0.1–1.0%) and glycerin or polysorbate (0.5–5%), pH 1.5–4	Applied as pray 0.12 mL/ in^2 of product surface	Acceptability determination	Not under the accepted conditions of use
Acidified sodium chloride	500–1200 ppm in combination with any GRAS acid to achive a pH 2.3–2.9	21 CFR 173.325	Not under the accepted conditions of use
Cetylpyridinium chloride	Applied as fine mist spray (1% aqueous solution)	21 CFR 173.325	Not under the accepted conditions of use
Egg white lysozyme	2.5 mg per pound finished product	GRAS notice No. 000064	Listed by common name
Blend of citric acid, hydrochloric acid, and phosphoric acid	Sufficient for purpose	Acceptability determination	Listed by common name
Hops beta acids	2 mg per pound on cooked meat and poultry	GRAS notice No. 000063	Listed by common name
Lauramide arinine ethyl ester (LAE)	Applied to the surface not exceed 200 ppm	GRAS notice No. 000164	Listed by common name
Nisin	2.5 mg per pound on cooked poultry	GRAS notice No. 000065	Listed by common name
Sodium citrate buffered with citric acid pH 5.6	$<$1.3% product formulation	Acceptability determination	Listed by common name
Sodium metasilicate	$<$2% by weight of marinade	Acceptability determination	Listed by common name

Source: Safe and Suitable Ingredients Used in the Production of Meat and Poultry Products FSIS Directive 7120.17120.1 Amend 6. Available at http://www.fsis.usda.gov/OPPDE/rdad/FSISDirectives/7120.1 Amend 6.pdf (03/2006).

5.5–6.0) as most poultry products. Other common antimicrobials include acidified sodium chloride, organic acids, peptides, trisodium phosphate, bacteriocins, natamycin, cetylpyridinium, lactoferrin, lysozyme, lactoperoxidase, and so on. However, their use in poultry processing requires approval and need to complaint with regulatory limits, according with the type of products. Recent applications include combination of antimicrobials for synergistic effect with packaging and antimicrobial components such as grape seed, rosemary, and garlic natural extracts, as well as honey, among others (Arrit and others 2002; Pszczola 2002; Ricke 2003; Joerger 2003; Oyarzabal 2005). Antimicrobials are listed in the table of safe and suitable ingredients for use in the production of meat and poultry products under FSIS Directive 7120.1 regulations that are presented in Table 79.5.

79.4 MARINATING SYSTEMS

Soaking is the simplest method for marinating, where poultry is placed into a container with the marinade and kept for about 24 h under refrigeration below 40°F (4.4°C). This process is low in cost and offers good adhesion of skin-on products; however, inconsistent marinade uptake, extra labor, and cooler space requirements are some disadvantages associated to this marinating process. Therefore, most poultry products are typically injected with marinade and the subjected to mechanical forces to enhance the action of salt and phosphates. Injection traps the marinade within the meat fibers and promotes even distribution throughout the entire poultry item to impart the desired effect. The marinade is pumped in and injected using single-needle injectors for smaller pilot-plants, or using large multineedle injectors, according to the type and cut being treated. Injectors can be adjusted for specific fluid pickup, as well as pressure and rate. Once meat is released from the injector, it may be cooked, tumbled, or packaged, depending on the desired finished product. Tumblers or tumbler-massagers are equipped with baffles or paddles to maximize physical contact and provide mechanical agitation between meat and the marinade solution. The meat and the marinade solution or dry mix are placed into a revolving container and allowed to tumble, ideally at 33–35°F (0.5–2°C); vacuum, rotation speed, total time, and temperature conditions are set according to the product allowing a rapid marinade uptake. Mechanical action helps to break the sarcolema and endomysium, allowing better brine penetration and greater swelling of the myofibrils. Tumbler design varies by type of mechanical action, from gentle motion to a more violent, cement-mixer type. The length of mechanical agitation depends on the type of cut, and tumbler speed. Chicken breasts may tumble for 15–30 min with good marinade uptake (Li and others 2000, 2001; Smith and Acton 2001; Brant 2003).

Large pieces or whole poultry carcass may be subjected to tumbling or massaging after injection to retain more marinade, with less drip losses during cooking, but required less force to shear than noninjected poultry meat items. However, injected chicken had a glossier and moister appearance; more intense flavors and more tender texture than immersed meats (Hashim and others 1999).

Marinade pickup is restricted to an 8% in boneless poultry and 3% in bone-in poultry. Processing parameters that affect marinating pickup and retention include marinade temperature, solubility of marinade ingredients, adequate pressure, and residence time for needle injectors; or appropriate mechanical action, vacuum and time in the case of tumblers or massagers (Toledo 2001). The amount of marinade injection generally depends on the pumping pressure, but injection is inadequate for marinades containing

large solid particles due to needle obstruction. Poultry cuts that have weak connective tissues are normally injected instead of tumbled because they will break apart in a tumbler. Moreover, blending is recommended for small pieces or ground meat while tumbling is preferred for a large variety of products such as skinless, skin-on, bone-in, whole muscles, and chopped pieces, but may not be appropriated for some fragile products or those with skin loosely attached (Smith and Acton 2001).

79.5 PACKAGING AND LABELING

Poultry marinated products are packaged in order to unitize the product according to the required marketing specifications. Packaging materials act as a barrier between the product and the environment, and must offer protection against microbial contamination, prevent moisture loss, physical and chemical deterioration. Plastic polymers are commonly used for primary poultry packaging due to their versatility, cost, and convenience. These polymers include polyethylene (PE), polypropylene (PP), ionomers, polyvinyl chloride (PVC), polyvinylidene chloride (PVdC), ethylene vinyl alcohol (EVOH), ethylene vinyl acetate (EVA), polystyrene (PS), polyamides (nylons), polyesters, polycarbonates (PC), and so on. Current practices for retail fresh poultry packaging include the use of high oxygen permeable polystyrene foam trays with a high oxygen permeable PVC or polymer-based stretch film over-wrap. Also poultry parts are placed in corrugated containers with plastic liners; the liner is gas-flushed with a modified atmosphere and sealed within the corrugated container. In addition EVA/PVdC/EVA or nylon/EVOH/inomer coextruded materials are commonly used for its oxygen barrier, toughness, heat resistance, and forming properties in modified atmosphere or vacuum systems. The leakage of food packages may cause microbial risk and increase chemical and autolytic spoilage (Randell and others 1995). Leakage is often caused by improper sealing or by mechanical damage during handling and transport. Emerging packaging technologies include edible coatings from polysaccharides, proteins and lipids; in addition to active packaging containing antimicrobials, antioxidants, moisture absorbers, oxygen scavengers, among others that increase hurdles to prevent deterioration (Gennadios 1997; Dawson 2001).

The Food Safety and Inspection Service (FSIS) of the U.S. Department of Agriculture (USDA) shares responsibility with FDA for the safety of food additives used in meat, poultry, and egg products. The statutes and regulations require in all cases that ingredients must be listed on the product label, in the ingredients statement in order by weight, from the greatest amount to the least. Substances such as spices and spice extracts may be declared as "natural flavors," "flavors," or "natural flavoring" on meat and poultry labels without naming each one. This is because they are used primarily for their flavor contribution and not because of their nutritional contribution. On the other hand, substances such as dried meat, poultry stock, meat extracts, or hydrolyzed protein must be listed on the label by their common or usual name because their primary purpose is not flavor; they may be used as flavor enhancers, binders, or emulsifiers. They must be labeled using the species of origin, for example, dried beef, chicken stock, pork extract, or hydrolyzed wheat protein. Color additives must be declared by their common or usual names on labels and not collectively as colorings. In addition, date of packing is required in Title 9 of the Code of Federal Regulations (9 CFR), Section 381.126(a) and (b).

79.6 MICROBIAL CONSIDERATIONS

Poultry provides an excellent medium for the growth of spoilage and pathogen microorganisms; although *Salmonella* and *Campylobacter* spp. are the predominant foodborne pathogens associated to poultry and frequently implicated in human illness; even though, other pathogens are also present such as *Clostridium perfringens*, *Escherichia coli* 0157, *Listeria monocytogenes*, *Arcobacter*, and *Helicobacter* spp. Spoilage microorganisms include *Pseudomonas* spp., *Staphylococcus*, *Micrococcus*, *Acinetobacter*, and *Moraxella*. Microbial contamination of poultry takes place during the slaughtering and further processing procedures, by contact of the carcass with feathers, feet or intestinal contents that contain a high microbial load; also because of the use of contaminated equipment, and physical manipulation during deboning and further processing. Prevention of microbial contamination involves careful regulation and monitoring of the slaughtering and processing plants, proper handling, and storage at low temperature. Poultry as other meats is very perishable if stored under ambient conditions, but storage under low temperature such as refrigeration and freezing extends storage life. Several marinade ingredients have an antimicrobial activity such as salt, nitrates, phosphates, spices, sugars, and acids; in particular GDL, sodium, or potassium lactate, as well as sodium acetate, and diacetate can be added to poultry products to extend shelf-life, control pathogen growth, and improve flavor and moisture retention.

However, implementation of Hazard Analysis Critical Control (HACCP) and Quantitative Risk Assessment (QRA) systems in processing plants are essential to control contamination with spoilage microorganisms. The systems brings obvious benefits by optimizing plan hygiene, ensuring compliance with legislation, and providing evidence of processor outstanding conscientiousness, as microbiological safety and quality of poultry meat products are equally important to producers, retailers and consumers (Mead 2004).

79.7 CONCLUSION AND FUTURE TRENDS

Poultry marketing is moving towards cut-up parts and further processes commodities, therefore the poultry industry and researchers should build up advanced processing technologies to produce quality consumer-oriented products. Marinating is becoming widespread in the poultry industry in the United States, Latin America, and Europe, essentially because it improves not only sensorial qualities but also increases shelf-life and product yield during processing, defrosting and cooking. Marinating offers a great prospect to enhance poultry consumption and processing in terms of flavor adaptation to new and traditional flavor trends. Furthermore, marinated poultry can easily adapt to the emerging packaging technologies such as the active and edible coatings made from polysaccharides, proteins, and lipids; in conjunction with alternative food processing technologies like microwave radio frequency, ohmic and inductive heating, high pressure processing, or pulsed electric field, and other technologies under research.

80.1 INTRODUCTION

World poultry meat consumption is of significant economic importance in more than 50 countries worldwide. After pork, poultry is the second most consumed meat globally in the world meat market. There are three classifications for the factors driving the future demand for poultry: demographic, economic, and nutritional. First, the increase in demographic population, specifically in urban areas, requires an increase in animal protein production, in which poultry industry can satisfy. Second, the cost of feed grains, oil seeds, and other primary feed ingredients make poultry a relatively low animal-origin food compared to competing foods, such as pork and beef. Third, there is an increased poultry preference related to nutrition and health concerns. In addition to these factors, poultry product development, using bird parts not generally consumed can meets the market chain requirements and end-consumer desires (Roenigk 1999).

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

The increase in poultry consumption provides considerable quantities of leftover parts including the back, neck, and frame meat available for mechanically deboning. The remaining adhering meat is recovered using mechanical separators, enabling an efficient use of whole chickens carcasses, which cannot be economically deboned by hand (Smith and Brekke 1985; Perlo and others 2003; Pettersen and others 2004). An alternative to employ this important animal protein source is the manufacture of sausages from mechanically deboned poultry meat.

80.2 MECHANICALLY DEBONED POULTRY MEAT

The process of mechanical deboning was created to make all of the meat left on the carcass, neck, and back of the chicken commercially viable, providing a new raw material for processed meat products, called mechanically deboned poultry meat (MDPM). The raw material obtained has a fine consistency and relatively low cost, with good nutritional value and functional properties suitable for the formulation of comminuted meat products (Yuste and others 1999; Sousa and others 2003; Pettersen and others 2004; Serdaroğlu and others 2005).

This process alters the original raw material composition, resulting in a material with higher fat and mineral content, by incorporation of lipids and heme pigments from marrowbone and the subcutaneous fat layer, besides calcium and phosphorus from bone particles (Sousa and others 2003). The main disadvantages of MDPM is the potential microbial load, which make it a highly perishable raw material (Yuste and others 1999). Also, the high heme pigments result in a darker colored product, susceptible to lipid oxidation (Lee and others 1997; Smyth and O'Neil 1997). In consequence, addition of MDPM affects physical, microbiological and sensorial properties of the product (Guerra-Daros and others 2005). These properties give MDPM particular characteristics as an ingredient in manufactured sausage.

80.2.1 Nutritional Properties

The nutritional quality of MDPM is comparable to normal poultry meat when evaluated by protein efficient ratio (PER) in rats. This suggests that MDPM may be beneficial in increasing the nutritional content of some processed poultry products because of MDPM's higher contents of calcium, phosphorus, iron, and other minerals (Babji and Yusof 1995). Reports have shown a high correlation between calcium and fluoride content in foods made with MDPM (Fein and Cerklewski 2001). As a result of inclusion of bone marrow in MDPM, there is a greater variation in the fatty acid content and higher percentage of cholesterol and phospholipids. Mechanical deboning increased monounsaturated fatty acids (MUFA), but had no effect on the percentage of polyunsaturated fatty acids (PUFA) (Serdaroğlu and others 2005). A major problem with products manufactured with MDPM is the rapid onset of oxidative rancidity, which results in off-flavor and odors, deteriorating sensory characteristics of sausages, even at frozen storage (Lee and others 1997; Pettersen and others 2004). On the other hand, sausages manufacture incorporating MDPM mixed with bovine plasma and red globules result in higher levels of isoleucine, which is considered a nonlimiting amino acid, with no detrimental effect on product acceptability (Benítez and others 2002). Table 80.1 compares the composition of deboned poultry meats (mechanically, manually and washed).

TABLE 80.1 Composition of Different Deboned Poultry Meats: Mechanically (MDPM), Manually Deboned (mDPM), and Washed Mechanically Deboned Poultry Meat (w-MDPM).

***Polyunsaturated fatty acids (PUFA).

80.2.2 Microbiological Properties

Poultry meat and its derivates are among the food products that cause the most concern to Public Health authorities, owing to the associated risk of bacterial food poisoning (Beli and others 2001). *Salmonella*, *Listeria*, and *Staphylococcus* are the microorganisms most frequently associated with this kind of meat (Greenwood and Swaminathan 1981; Bijker and others 1987; Marinsek and Grebenc 2002). Contamination is the result of the lack of hygienic measures observed during boning of carcasses, collection, storage, and transport of bones or poultry parts. In this view, MDPM has to be employed in fully-cooked cured meat products, in order to reduce the chance of microbial contamination. Deterioration of sensory characteristics of MDPM sausages after 8 days of storage at 4°C were attributed to the increased psychotropic growth (Lee and others 1997).

80.2.3 Functional Properties

Muscle proteins are the principal functional and structural components of processed meats, determining product texture and appearance (Smith 1988). For MDPM, the functional properties of most interest are water retention and ability to emulsify fat (Guerra-Daros and others 2005). MDPM had a higher emulsion capacity than manually deboned poultry meat, although it presented no difference in water-holding capacity (Abdullah and Al-Najdawi 2005). In the same way, muscle protein solubility is markedly affected by the cations present in the meat system. Calcium chloride tends to enhance muscle protein solubility as compared to sodium chloride (Morrissey and others 1987), improving myosin extractability and solubility (Nayak and others 1996). Based on the relatively high calcium content and great emulsifying properties, MDPM is a better raw source of low-cost muscle proteins for sausage manufacture, as compared to other kind of poultry meat. Also a partial proteolysis of MDPM improves protein functionality (Smith and Brekke 1985).

80.3 POULTRY SAUSAGE MANUFACTURE

Sausage manufacturing includes a consecutive series of steps, including extract and solubilized muscle proteins, to emulsify fat and form a protein gel matrix. The final gel lattice is responsible of water and fat retention, texture, and juiciness in the final product. MDPM presents some advantages for these types of products. Finely comminuted meat products, such as frankfurters, hot dogs, and bolognas, are made from meat that is entirely or partly disrupted under the presence of water, salt and other processing ingredients. Meat had to be ground and comminuted in order to extract muscle proteins. The higher the degree of comminuting, the larger the amount of extracted protein (Hoogenkamp 1995). The use of MDPM saves this step in sausage manufacture due to its finely ground texture.

The mechanical agitation of the mixer or cutter of the grounded or chopped lean meat with salt and water enhances salt activation of the proteins, initiating the formation of a lean meat lattice (Terrel 1980). Solubilization of protein in salt solutions is an important physicochemical process for manufacturing of processed muscle foods (Xiong 1994). MDPM has a fine consistency and is practically ground; protein solubility is easily achieved during this step. Since MDPM is handled frozen and less energy is required to disrupt the tissue, a lower temperature during mechanical agitation can be achieved.

After proteins were solubilized, fat is added in the mixer or cutter, in combination with the seasonings and more water. Mechanical agitation entraps the fat into the lean lattice, and final fine-cut batter is packed in a casing, which physically restrains the lattice until proteins form a gel in a casing-shaped semisolid gel (Terrel 1980). Solubilized protein surrounds the fat and during thermal processing forms a network which prevents the coalescence of fat. This network also arranges the fixation or structural enforcement of all supporting compositional ingredients, such as meat and nonmeat proteins (Hoogenkamp 1995).

The percent of MDPM that can be included in formulation affects the final product characteristics (Lee and others 1997; Benítez and others 2002; Sousa and others 2003; Guerra-Daros and others 2005). In some cases MDPM's dark color can alter the sausage color (Smyth and O' Neil 1997; Yuste and others 1999; Perlo and others 2003; Serdaroğlu and others 2005) without the use of colorants in formulation. A surimi process in MDPM, however, can increase myofibrillar protein concentration and removal of color of the washed meat with an important dark red color diminution and an increase in lightness (Yang and Froning 1992; Smyth and O'Neil 1997; Perlo and others 2003). Alternative processes such as high pressure cooking enhances MDPM sausage texture, color and yielding (Yuste and others 1999). Although the inclusion of

TABLE 80.2 Mean Composition for MDPM Sausages (at Least with 80% of MDPM in Formulation).

Parameter	Range	Reference
Humidity (%)	66.3–69.1	Lee and others 1997; Babji and others 1998
Protein (%)	11.2–12.0	Babji and others 1998; Guerra-Daros and others 2005
Cholesterol (mg/100 g)	78.71	Babji and others 1998
Ashes (%)	1.16–2.3	Babji and others 1998
Iron (mg/100 g)	1.5–3.1	Sousa and others 2003
Calcium (mg/100 g)	75–141	Sousa and others 2003
Fluoride (mg/100 g)	0.15–0.22	Guerra-Daros and others 2005

MDPM in sausages resulted in a decrease in protein content, myosin, reducing tensile, and compression strength due to the lower myofibrillar content of meat (Guerra-Daros and others 2005), this detrimental effect of MDPM in sausage structural integrity can be compensated with the addition of other nonmeat proteins. Table 80.2 presents the main characteristics of MDPM sausages.

80.3.1 Effect of Gelling Polysaccharides on MDPM Sausages Texture

Low cost and functional properties of MDPM represent a great advantage over other raw meat protein sources. The interaction of MDPM proteins and gelling polysaccharides can be employed as an alternative to reduce fat in poultry sausages. For example, low-fat (5% w/w) poultry sausages were manufactured employing MDPM (Comercializadora Avemex, SA de CV, México) and ground poultry meat (leg and thigh). Three different polysaccharides were employed: sodium alginate (ALG) and κ-carrageenan (KCG) and gellan gum (GLN) with 2% of NaCl, adjusting the formulation with ice. A textural profile analysis (TPA) was performed to 20 mm height samples (20 mm Ø) at a constant speed of 1 mm/s in a TA-HDi texture analyzer (Texture Technologies, Scarsdale, New York/Stable Micro Systems, Surrey, United Kingdom), equipped with a 25 kg load cell and a 25 mm diameter acrylic probe. TPA parameters, that is, hardness, cohesiveness, springiness, and resilience, were calculated in a double compression force-deformation curves (Bourne 1978; Texture Technologies 2005).

Poultry sausages manufactured with MDPM were less hard than the ones made with poultry meat. Similarly, both sausages containing KCG resulted in a harder product

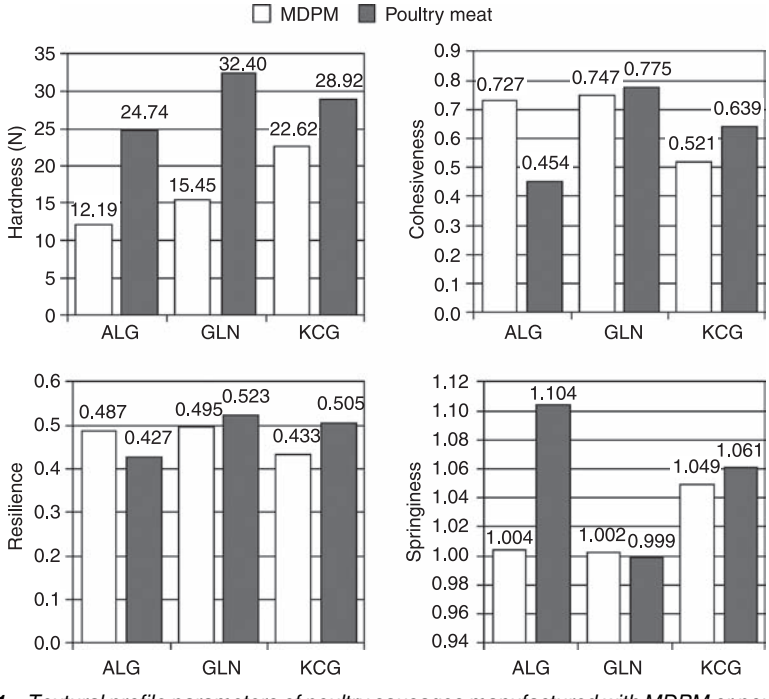

Figure 80.1 *Textural profile parameters of poultry sausages manufactured with MDPM or poultry meat and mixed with sodium alginate (ALG), gellan gum (GLN), or κ-carrageenan (KCG).*

than GLN or ALG sausages. Sausages made with MDPM and ALG resulted in a more cohesive product than the sausages made with poultry meat, with no significant difference between both MDPM or poultry meat mixed with GLN or KCG. No difference was detected in samples resilience. Poultry meat sausages with ALG had higher springiness values than MDPM sausages, but no difference was observed between the types of poultry meat with the same gum (Fig. 80.1). The main difference in texture can be explained by the effect of different cations on the gelling properties of the polysaccharides or gums employed, such as sodium alginate (Clare 1993), κ-carrageenan (Therklensen 1993) or Gellan (Sworn 2000). The presence of calcium in MDPM is supposed to be high however, the availability to interact with these gums may be limited. Only samples of MDPM with sodium alginate (ALG) presented a more compact and dense structure. The cohesiveness and resilience of these samples were higher than poultry meat-ALG sausages, with the interrelated lower springiness. With lower fat sausage formulation, the relatively higher fat content of MDPM could explain no differences in texture. This maybe due to the effect of the calcium present in this kind of meat over the gelling polysaccharides employed, making MDPM a good alternative from both nutritional and functional points of view for sausage manufacturing.

81.1 INTRODUCTION

Poultry is derived from the skeletal muscles of various species of birds that have been domesticated to reproduce and grow in captivity, accompanied by a high animal feed to meat conversion ratio and an ability to survive under extreme temperatures. Chickens and turkeys are the most common types of poultry; other commercially available species are ducks, geese, pigeons, quails, pheasants, ostriches, and emus (Parkhurs and Mountney 1988). Poultry consumption has risen considerably in the last two decades, with an annual growth rate close to 10% (Table 81.1), and estimates indicate that production will continue to rise at the expenses of red meat, mainly because of health and food-safety concerns, such as the recent international problems with BSE, foot and mouth disease, dioxin-tainted products, and cholesterol and related cardiac problems.

In general, poultry meat is a good source of protein, fat, vitamins, and minerals in the diet (Table 81.2 shows the composition of various poultry cuts). Moreover, poultry is considered healthier than other, red meats, as it is lower in fat and cholesterol, higher in protein, and white, with good flavor qualities; it is also accepted by most cultures, and lower in cost when compared to red meats and fish. Flavor quality is affected by several factors, including antemortem determinants occurring over the bird's life, such as breed, physiology, nutrition, or diseases, which affect the composition of raw meat and therefore availability of flavor precursors. In addition, harvesting, slaughtering, and postmortem handling also have a great influence on poultry meat quality and flavor stability. The aim of this chapter is to review production and processing factors that influence flavor quality of fresh and frozen poultry.

81.2 POULTRY PROCESSING

The first stage of poultry meat production involves conversion of a live animal into meat; it is critical to avoid microbial contamination all the way from slaughtering until chilling or freezing, in order to maximize food quality for marketing and further processing. When

birds reach "harvest" time, they are generally taken off feed and water to empty their digestive tract and reduce the potential for contamination during processing. Birds are placed into plastic or wooden transport cages and then transported to the slaughterhouse. In the next step, birds are removed from the cages and transferred to continuously moving shackles where they are suspended by both legs. Birds are usually stunned by running their heads through a water bath that conducts an electric current to produce unconsciousness, and killed either by hand or by a mechanical rotary knife, which cuts the jugular veins and the carotid arteries at the neck, after which they are left to bleed. Following bleeding, birds go through scalding tanks of hot water (50–60°C), which softens the skin, so that the feathers can be removed efficiently. Carcasses then go through feather-picking machines equipped with rubber "fingers" designed to beat off the feathers, then pass through a flame that burns off any remaining feathers. Finally, heads, legs, and viscera are removed. Carcasses are generally inspected during the evisceration process. The inspection procedures in the poultry industry vary around the world and may be performed by government inspectors, veterinarians, or plant personnel, depending on the country's laws. After carcasses have been washed, they are chilled to a temperature below 4°C. Usually, carcasses are cut up into pieces and the frame, back, neck, drumsticks, and wings are often mechanically separated. Carcasses and cut-up pieces must be chilled immediately after slaughter, reaching 4°C within 4 h of death for chickens and 8 h for turkeys. The two common methods for chilling include immersion in an iced water bath, or air chilling in chambers with circulating cold (−7 to 2°C) air for 1 to 3 h (Sams 2001).

Boneless cuts and poultry pieces can be iced in combos or boxes and held in a cooler at −2.2°C up to 24–36 h prior to being processed. On the other hand, poultry pieces or mechanically deboned poultry (MDP) are usually boxed in plastic-lined or waxed cardboard containers (to exclude air and protect the surface from excessive drying) and frozen immediately. Water chilling is used throughout North America and involves a prechilling step in which a countercurrent flow of cold water is used to lower the temperature of carcasses and to minimize bacterial contamination by diluting microorganisms into the water tank. At the entrance of the prechiller, the carcass temperature is about 38°C, and

lipids are still fluid. Water penetrates into the skin and other subcutaneous tissues, leading to an increase in poultry weight. The amount of water gained is carefully regulated, in the United States the legal limits for water pickup are 8% for birds going directly to market and 12% for birds to be further processed. After prechilling, carcasses enter the main chilling tank, which rapidly reduces the temperature to 4°C, and temperature declines, lipids solidify, which stops the water being absorbed. The air-chilling method is the standard in Europe; carcasses are hung by shackles and moved through coolers with rapidly moving air. The process is less energy-efficient than water chilling, and the birds may lose weight due to dehydration. Air chilling prevents cross-contamination between birds. However, if a single bird contains a high number of pathogens, this pathogen count will remain on the bird. The final temperature of the carcasses before shipment is usually about −2 to −1°C, just above the freezing point for poultry. In some cases a slight crusting on the surface occurs during the final chilling. For water-chilled carcasses this final chilling takes place after packaging, when the carcasses are placed in an air chiller (Sams 2001).

81.3 FRESH AND FROZEN POULTRY

Raw materials include fresh chilled or frozen skeletal muscles such as boneless breasts, legs, thighs, desinewed drumsticks, and mechanically deboned poultry meat (MDP), with or without skin. Whole or individual parts of birds may be packaged raw for direct sale. Poultry provides an excellent medium for the growth of spoilage and pathogen microorganisms such as Pseudomonas, Staphylococcus, Micrococcus, Acinetobacter, Moraxella, and Salmonella. Contamination of poultry takes place during the slaughtering and processing procedures, by contact of the carcass with feathers, feet, or intestinal contents, which have a high microbial load, and also because of the use of contaminated equipment and physical manipulation during deboning and grinding. Prevention of microbial contamination involves careful regulation and monitoring of slaughtering and processing plants, proper handling, and storage at low temperature. Poultry, similar to other meats, is very perishable if stored under ambient conditions, and storage under low temperature such as refrigeration and freezing extends storage life.

A large portion of poultry is used as a basic raw material to manufacture ready meals; where it can be supplied as boneless or mechanically deboned frozen meat blocks and is used in the meat industry. Freezing is widely used in the poultry meat industry as the safest and most economical preservation method, as it prevents microbial spoilage and minimizes the rate of biochemical reactions in muscle for several months. Freezing is also used in the household as a common storage practice for raw poultry between purchasing and cooking, as well as for precooked and ready-to-eat frozen chicken products. However, undesirable quality changes do occur during frozen storage such as texture toughening, color darkening, and off-flavor development, which all reduce its acceptability and shelf-life. Therefore, poultry packages must include instructions about safe handling.

Most raw turkey is sold frozen, but most chicken is sold fresh. Poultry carcasses are generally cut into a number of pieces, which are placed on plastic foam trays and covered with a plastic film. A "diaper" (absorbent paper) is often used to catch any liquid that may be released from the meat. Fresh poultry should be used within 14–21 days after slaughter and generally should not be kept in the home refrigerator for more than three days. In the United States, poultry that has been frozen to a temperature of −5° to −4°C is allowed to be thawed and sold as "fresh." Frozen poultry is usually vacuum-packed in plastic bags and then frozen in high-velocity freezers. Before freezing,

the poultry carcass may be injected with various salts, flavorings, and oils in order to increase the juiciness of the meat. Injections are usually done with a multineedle automatic injector, and information about the added ingredients is indicated on the package label. Frozen storage time for poultry products (including poultry bought fresh and frozen in a home freezer) depends on the temperature of the freezer, the quality of the packaging, and the cycling of the freezer; frozen products should be used within three months.

Chilling, and frozen storage with subsequent thawing, may decrease the levels of some poultry components such as proteins and minerals due to drip loss. Decreases in thiamin, riboflavin, and niacin have also been reported for dark meat; in particular, thiamin is very sensitive to freezing and can be destroyed during extended frozen storage (Hettiarachchy and Gnanasambandam 2000). For storage up to 6–10 months, frozen materials must be held at between $-17^{\circ}C$ and $-28.9^{\circ}C$, avoiding temperature changes, as this causes large ice crystals to grow in the muscle cells and excessive drip water to appear during thawing. Fresh cuts should not be stored above $4.4^{\circ}C$ when received, and frozen materials should be kept below $-17.8^{\circ}C$. Higher temperatures or temperature abuse in transit or processing means a potential decrease in shelf-life or a potential pathogen risk and off-flavor formation. Therefore, it is imperative to monitor temperature during all stages of processing, including transit and storage. Raw materials that show browning or graying may indicate prolonged storage, temperature abuse, or early microbial spoilage; greening, slime formation, putrefaction, souring, or other off-flavor are signs of apparent spoilage and therefore must be avoided (Mandava and Hoogenkamp 1999). Storage under low temperature slows most chemical and biochemical reactions with an increase in shelf-life. However, even under freezing conditions, solutes present in the unfrozen phase are in close proximity and some rate reactions such as lipid oxidation may increase. Therefore, lipid autoxidation is one of the most important chemical reactions to reduce shelf-life during frozen storage (Ang 2000; Shahidi 2000; Ponce-Alquicira 2004).

81.4 BASIS OF POULTRY MEAT FLAVOR

Flavor is one of the most important attributes to influence poultry meat acceptability; it is the result of taste odor and textural sensations perceived in the oral and nasal cavities. Compounds responsible for taste are nonvolatile at room temperature; they interact with the taste receptors located in the taste buds of the tongue. Taste is usually described with five basic tastes (salty, acid, sour, sweet, bitter and umami). While, aroma comprises a large amount of volatile compounds that are transported through the throat to the olfactory receptors located in the nose where they are sensed as acid, brothy, chickeny, fruity, and so on (Farmer 1999; Ang 2000; Ponce 2004).

Raw poultry, like other meats, has a metallic bloody flavor. However, during heating and storage, various chemical reactions take place between precursors, resulting in the production of numerous volatile compounds responsible for the poultry meat aroma. The main poultry flavor precursors are water-soluble compounds and lipids. The major reactions involved in the generation of poultry flavor include nonenzymatic browning (or the Maillard reaction), Strecker degradation, lipid oxidation, thiamin degradation, and proteolysis, among others (Farmer 1999; Ang 2000).

Free sugars, sugar phosphates, nucleotide-bound sugars, free amino acids, peptides, nucleotides, and other nitrogenous components such as thiamin are among the main water-soluble flavor precursors. All are present in the raw meat, but frozen storage and cooking may change their concentration because many of these substances are also precursors for

the aroma compounds. Interaction of nonvolatile compounds and/or their breakdown products generated during cooking and storage produce a large number of intermediates and volatiles that contribute to flavor. For example, ribose is one of the main sugars present in ribonucleotides such as adenosin triphosphate (ATP), which is essential for muscle function; during postslaughter, it is converted to inosine monophosphate (IMP) (Mottram 1998). Also, carnosine, an imidazole dipetide (α-alanine-L-histidine) occurs naturally in meat. Its concentration varies with species, from 50 to 276 mg/100 g in chicken leg and swine shoulder meat, respectively. This dipeptide has a buffer capacity and a strong antioxidant activity that reduces lipid oxidation. However, it is also the nitrogen source for pyrazine and thiazole generation, giving the roasty and nutty poultry flavor notes during cooking (Chen and Ho 2002). Carnosine executes its antioxidant activity by acting as a hydrogen donor and metal-chelating agent; however, the antioxidant activity varies according to concentration. At high levels (1.5%) it is a better hydrogen donor than α-tocopherol and BHT (Cuppet 2001).

Deteriorations in flavor, such as the appearance of rancidity, bitterness, or undesirable taste, are due to the formation of low-molecular-weight compounds from lipid oxidation or protein degradation and can take place during storage. Compounds derived mainly from lipids such as aliphatic hydrocarbons, aldehydes, ketones, alcohols, carboxylic acids, esters, lactones, and alkylfuranes may lead to rancid off-flavors in both cooked and raw meat during long-term storage. Poultry and pork meats have a large proportion of unsaturated fatty acids, when compared with beef, and generate more unsaturated volatile aldehydes (as shown in Table 81.3). Unsaturated fatty acids undergo autoxidation much more readily than those that are saturated; therefore, triglycerides and structural phospholipids present in lean tissue are an important source of flavor compounds. Phospholipids are essential structural components of all cells and contain a higher proportion of unsaturated fatty acids than triglycerides, such as arachidonic acid ($C_{20}H_{32}O_2$) present in phosphatidylethanolamine, phosphatidylcholine and phosphatidylinositides. This makes them more susceptible to oxidation and they have been associated with "warmer-over" flavor in reheated cooked meats (Mottram 1998). Grinding disrupts muscle tissue and allows the contact of cell contents with oxygen and the access of pro-oxidants to the more unsaturated fatty acids in the membrane phospholipids. During storage, reducing agents such as ascorbate and the superoxide anion can release the iron from myoglobin and ferritine, which is very active as a pro-oxidant against unsaturated fatty acids (Cuppett 2001).

81.4.1 Maillard Reaction

Another chemical reaction that causes major food flavor formation is nonenzymatic browning, also known as the Maillard reaction. This reaction takes place between reducing

TABLE 81.3 Lipid Composition of Meat (Value per 100 g of Edible Portion).

	Total Fat (g)	Total Fatty Acids			Cholesterol (mg)
		Saturated	Monounsaturated	Polyunsaturated	
Lean beef	5	2.25	2.151	0.257	62
Lamb	17.17	6.63	8.46	1.06	156
Pork	12.59	3.57	6.289	1.092	88
Chicken light meat	1.65	0.44	0.39	0.37	58
Turkey light meat	1.57	0.5	0.28	0.42	60

sugars and a free amino group on amino acids or proteins present in foods. Products of the Maillard reaction lead to a darkening of color, reduction in protein solubility, development of bitter flavors, and loss of essential amino acids such as lysine. Flavor compounds generated include heterocyclic compounds, carbonyls, pyrazines, and furans, among others. The rate of this reaction is influenced, by water activity, temperature, and pH (Jousse and others 2002).

81.4.2 Lipid Oxidation

The fat content of poultry differs from that found in red meat (Table 81.3). Poultry has a higher proportion of unsaturated fatty acids; both turkey and chicken contain about 30% saturated, 43% monounsaturated, and 22% polyunsaturated fatty acids (Hettiarachchy and Gnanasambandam 2000). The high levels of unsaturated fatty acids make poultry more susceptible to rancidity through the oxidation of the double bonds in the unsaturated fatty acids, as saturated fatty acids are more resistant to oxidation. However, this fatty acid ratio has led to the suggestion that poultry may be a more healthful alternative to red meat. In birds, fat is primarily deposited under the skin or in the abdominal cavity; therefore, a significant amount of the fat can be removed by removing the skin before eating (Shahidi 2000).

The unsaturated fatty acids present in poultry meat are susceptible to autoxidation when exposed to oxygen. Unsaturated fatty autooxidation is autocatalytic and proceeds by a free-radical chain reaction. Free radicals contain an unpaired electron, and are capable of reacting energetically and indiscriminately with various compounds and initiate nonspecific hydrogen absorption and chemical addition; therefore, free radicals are highly reactive chemical molecules. The basic mechanisms in a free-radical chain reaction involve initiation, propagation, and termination steps. The initiation reaction comprises a free-radical molecule ($X^{\bullet}$) present in the food that removes a hydrogen (H) atom from a lipid molecule, producing a lipid radical ($L^{\bullet}$). This lipid radical reacts with molecular oxygen (O_2) to form a peroxy radical ($LOO^{\bullet}$). The peroxy radical removes a hydrogen atom from another lipid molecule and the reaction starts over again in the propagation stage. During the propagation steps, hydroperoxide molecules (LOOH) are formed that may break down into alkoxy ($LO^{\bullet}$) and peroxy radicals plus water (H_2O). The lipid, alkoxy, and peroxy radicals may combine to form stable, nonpropagating products (termination). Peroxides are unstable and will decompose to acids, alcohols, aldehydes carbonyls, and ketones, which results in the development of rancid off-flavors. In addition to promoting rancidity, the free radicals and peroxides produced in these reactions may have other negative effects, in color and destruction of vitamins A, C, and E. Lipid oxidation is catalyzed by ultraviolet light, heat, high pressure, metals, and oxygen (Belitz and Grosch 1999; Schmidt 2000). In addition, the low water activity found in frozen poultry meat also promotes lipid oxidation. Storage time and temperature have a significant influence on the formation of secondary lipid oxidation products, such as hexanal, octanal, and nonanal. At low refrigeration and freezing temperatures, lipid oxidation develops slowly, but can alter the flavor profile (Duncan 2000; Wiggers and others 2004).

81.4.3 Cholesterol Oxidation

Cholesterol is found in the cell membrane and is associated with polyunsaturated fatty acids of the membrane associated phospholipids. Oxidation of cholesterol occurs easily

in foods and is promoted by prolonged storage, application of heat, exposure to air, light, or irradiation; it is affected by the same factors involved in lipid oxidation and is closely related to the neighboring fatty acids, generating a series of oxidation products (COPs) such as 7-ketocholesterol (7-k). There is a great interest in cholesterol because it is associated with cardiovascular diseases, and also because its oxidation products have adverse effects such as atherogenesis, cytotoxicity, mutagenesis, carcinogenesis, and Alzheimer's disease. Cholesterol oxidation proceeds via a free radical mechanism, similar to polyunsaturated fatty acid oxidation, thus the use of antioxidants may prevent or retard cholesterol oxidation; however, results are diverse and sometimes contradictory. BHT and TBHQ are more effective inhibitors than BHA, while PG is unable to inhibit the synthesis of COPs. In addition to synthetic antioxidants, it has been claimed that tocopherols exhibit different antioxidant effect, where g-Tocopherol acts as the strongest antioxidant, followed by a-tocopherol. d-Tocopherol and b-tocopherol. Also, rosemary extract obtained from the leaves of *Rosmarinus officinalis. L*, that contains four antioxidants (carnosol, rosmanol, isorosmanol, and rosemarydiphenol) show some antioxidant cholesterol activity. (Lercker and Rodríguez-Estrada 2000; Lee and others 2001; Valenzuela and others 2003; Ponte and others 2004).

81.5 PROCESSING FACTORS RELATED TO POULTRY FLAVOR

Flavor quality is affected by several factors, including antemortem determinants that take place over the bird's life, such as breed, physiology, nutrition, or diseases. In addition, slaughter, postmortem handling, and storage conditions could affect the composition of raw meat and therefore availability of flavor precursors. Some factors related to fresh and frozen poultry processing are discussed below.

81.5.1 Genotype and Age

There are contradictions in the literature on the effect of genotype; however, reports regarding flavor differences between genotypes having different grow rates claim that those differences were mainly due to differences in age and body weight. In general, breast meat from older birds received higher scores in flavor than those from chickens slaughtered at younger ages. Chickens undergo physiological changes as they grow older and reach maturity, which may affect flavor precursors, as precursors may be present in higher concentrations in older chickens. There is a high genetic correlation between abdominal fat production and deposition that influences flavor (Farmer 1999; Zerehdaran and others 2004).

81.5.2 Feeding

The phospholipid profile is closely influenced by the fat composition of feed. Thus, the way in which a bird is fed can influence meat quality. The type of fatty acid composition in poultry and its stability are correlated to the fatty acid composition of ingested fats. Meat composition can be modified by diet; feeding of fish oils or highly unsaturated vegetable oils is known to produce fishy flavors in the meat (Farmer 1999). Birds fed on diets rich in unsaturated fats have an increase in the polyunsaturated fatty acid content of their lipid fraction. This modification is nutritionally desirable, but increases susceptibility of meat to oxidation. However, dietary supplementation with antioxidants such as

tocopherols, carotenoids, and ascorbic acids supplements is recommended to avoid discoloration and improve oxidative stability of cooked and raw poultry meat during frozen storage (James 2000; Grau and others 2001). Bou and others (2004) supplied diets with 2.5% fish oil and produced chicken meat with eicosapentaenoic and docosahexaenoic acid contents double those of diets supplied with 1.25% fish oil. Also, consumer acceptability revealed no variation after 5 months of storage at $-20^{\circ}C$ in comparison with fresh commercial chicken meat used as blind control. Cortinas and others reported similar data (2004). Inclusion of dietary polyunsaturated fatty acids (PUFA) also increased the level of fatty acid in meat; however, increasing the PUFA content decreased total fatty acids in thigh and had no effect in breast meat. In addition, Du and others (2001) fed chicken with conjugated linoleic acid (CLA), which is easily incorporated into tissue and egg, increasing storage stability with respect to oxidative changes in the meat, due to an increase in saturated fatty acids and CLA. The dietary carbohydrate source also appears to affect meat flavor and general acceptance of broiler meat. Some reports indicate that broilers on rations containing dairy products produced meat with more flavor, and corn-fed poultry was more flavorful than poultry fed barley, oats, milo, and wheat (Lyon and others 2004).

81.5.3 Antioxidants

Antioxidants can react with peroxyl or alcoxyl radicals and terminate the chain reaction or peroxidation by scavenging chain-propagating radicals and prevent lipid oxidation. The use of antioxidants such as gallate, sesamol, tocopherols, and carotenoids, added directly to meat or via dietary supplementation, increases the oxidative stability of muscle foods (Lee and Ahn 2003). The activity of endogenous antioxidant enzymes (catalase, superoxide dismutase, and glutation reductasa) seems to be directly related to the dietary polyunsaturated fats; however, contradictory data have been reported regarding the activity of these antioxidant enzymes.

Vitamin E compounds (tocopherols and tocotrienols) are well recognized for their effective inhibition of lipid oxidation in food and biological systems. There are many data that have proved the effect of tocopherol and carotenoid diet supplementation is increasing the oxidative stability of poultry meat. Dietary natural antioxidants may be better alternatives to direct addition after slaughtering, as it ensures an even distribution of antioxidants in the meat. In addition, those natural antioxidants bring health benefits in disease conditions such as cancer, coronary heart disease, and those related to immune functions (Kang and others 2001).

When tocopherol is added via the diet in the range 25–2000 IU/kg, it is incorporated into the subcellular membrane and intercepts free radicals as they are formed in both dark and white broiler meat. Also, supplementation of vitamin E from 200 up to 600 IU/kg and β-carotene alone may increase oxidation in meat, even though this practice is very common as it gives a golden tone desirable by consumers. Some level of tocopherols needs to be added to carotenoids to act as antioxidants in raw and cooked meat; the tocopherols act as a hydrogen donor and canthaxantine stops the peroxy free-radical chain propagation by trapping the radical in its conjugated polyene systems. Reports indicate that vitamin E and carotenes have a higher effect on poultry flavor than dietary fat (Ruiz and others 2001).

Low concentrations (200–300 ng/kg of meat) of ascorbic acid in meat lead to a prooxidant effect by reducing free transition metals such as Fe(III) or Cu(II) to Fe(II) and Cu(I), at which catalysis of lipid hydroperoxide decomposition to free radicals is more active. In

contrast, at higher concentrations, ascorbic acid acts as an antioxidant because of its ability to scavenge oxygen and lipid free radicals. Amounts of ascorbic acid produced by self-synthesis in chicken meat vary from 40 to 65 mg/kg. Supplementation effectively increases the levels of ascorbic acid in meat; however, levels decrease rapidly after removal of dietary supplementation. Additionally, ascorbic acid is readily oxidized by heat in the presence of metal ions at very low levels of oxygen (Grau and others 2001).

81.5.4 Slaughtering and Postmortem Factors

In general, meat flavor improves during postmortem ageing of meat. When animals die, muscle cells remain active, continuing their metabolism by using energy stored in them. With the loss of blood and oxygen supply, muscle cells gradually shift from aerobic metabolism to anaerobic. Accumulation of lactic acid derived from the anaerobic metabolism causes the pH to decrease from near neutrality to a pH value close to 5.7. This pH reduction reduces the activity of some ATP-producing enzymes; therefore, ATP muscle concentration falls to levels below 1 μM/g, inducing the severe muscle contraction known as rigor mortis. The breakdown products of lipids, proteins, and nucleic acids, which are formed by the action of indigenous meat enzymes during the ageing process, are likely to be related to the flavor precursors. Lysosomal enzyme acid phosphatase activity decreases rapidly during postmortem ageing, but cathepsin B and D activities continue, leading to formation of small peptides and free amino acids that act as flavor enhancers (Farmer 1999; Liu and others 2004).

81.5.5 Frozen Storage

The shelf-life of poultry is increased to a large extent by frozen storage at -18°C to -20°C. Flesh can be directly frozen in one single step or cooled and then frozen using an air blast freezer (with an air stream at -40°C, 3–10 m/s). Freezing involves removal of heat accompanied by a phase change, converting water to ice; however, in the remanding unfrozen water, the concentration of dissolved compounds increases and water activity decreases. Although the physicochemical reactions slow down at low temperatures, they will continue during frozen storage. Therefore, the shelf-life of frozen chicken is affected by storage temperature, and deterioration is mainly due to oxidative changes in the lipids. Poultry is more susceptible than pork, beef, or mutton (Belizt and Grosch 1999; Zaritzky 2000). Lipid oxidation is one of the main issues limiting the quality and acceptability of poultry and poultry products. This process affects lipids, pigments, proteins, carbohydrates, and vitamins, causing discoloration, drip losses, off-flavor development, and loss of nutrient value. The susceptibility to lipid oxidation depends on several factors such as the level of polyunsaturated fatty acids present in meat, preslaughter events such as stress, postslaughter handling, storage temperature, pH, and disruption of muscle membranes and cooking. Catalysis of lipid oxidation can occur by the action of low-molecular-weight metals and iron-containing heme proteins. Disruption of lipid membranes, as in mechanically separated poultry meat, facilitates the interactions of pro-oxidants such as oxygen with unsaturated fatty acid, resulting in the generation of free radicals and the propagation of oxidative reactions (Petterson and others 2004). Secondary lipid oxidation products such as α- and β-unsaturated aldehydes are more polar than their parent compounds and can diffuse from membranes into the surrounding sarcoplasm, interacting with sarcoplasmic proteins including myoglobin, which also act as

a prooxidant (Fausman and others 1999). Poultry meat contains more polyunsaturated fatty acids than red meat and can be more susceptible to oxidative changes (Kilic and Richards 2003).

81.5.6 Packaging

Packaging materials protect and preserve products during storage and distribution. Polymers used for food packaging include polyolefins such polyethylene (PE) and polypropylene (PP) because of their good heat sealability and excellent moisture resistance; however, those materials can absorb low-molecular-weight compounds and flavors. Poultry meat may undergo loss of quality due to failure of the package and because of product–package interactions, as packaging is used in direct contact with meat and adsorption of flavor compounds may alter the aroma and taste. Van Willige and others (2002) demonstrated that the rate of flavor absorption of polyolefins (PE, PP) is 3–2400 times higher than polyesters (polycarbonate, polyethylene terepthalate, and polyethylene naphathalate) and that absorption increases with temperature from 4 to 40°C. Therefore, fresh poultry is more susceptible to the changes generated by product–package interactions.

It is unavoidable that certain water evaporation from the meat surface takes place during frozen storage, resulting in quality and weight losses. Surface of meat improperly packaged will dehydrate, developing the commonly called freezer burn, which has a brown appearance and quickly leeds to rancidity, thus altering the quality and flavor. Only if the product is tightly packaged in a water vapor impermeable film, can evaporation be completely avoided, but if there are small spaces between the product and the package material, ice is deposited there (Dawson 2001).

81.6 CONCLUSIONS

Poultry is a very popular source for protein; however, flavor quality can be affected by several factors, including both ante-mortem and post-mortem conditions that influence raw meat composition and therefore availability of flavor precursors. Understanding of mechanisms involved in poultry flavor formation and improvement of storage conditions for fresh and frozen poultry will guarantee the acceptability and the continuous consumption increment.

82.1 INTRODUCTION

Due to their chemical composition, poultry meat and other muscle foods are extremely susceptible to suffer deterioration during storage. These modifications include changes in food texture, as well as loss of flavor, color, or nutritional value (Wu and others 2002). Additionally, poultry meat can be contaminated with pathogenic and spoilage microorganisms that accelerate deteriorative changes and are associated to food intoxication. Therefore, several methods of preservation such as freezing, curing, salting, heating, and others have been used to improve safety and maintain food quality. In response to the increasing demand for high quality ready-to-eat foods, food technologists have focused their attention on the development of mildly preserved foods that maintain their natural and fresh appearance as far as possible (Guilbert and others 1996).

Poultry meat shelf-life is reduced by contamination with chemicals and microorganisms present in the environment or by contact with contaminated surfaces during slaughtering, processing, and distribution. The use of packaging is the result of ancestral humankind's instinct to cover food and protect it from the environment, either by using fresh or dehydrated leaves, guts, cloth, baskets, and paper, among other materials (Miller and Krochta 1997). In 1950 heat shrinkable polyvinyl chloride (PVC) was introduced, and integrated into packaging films; nowadays, more than 90% of the poultry meat produced in the United States is marked under vacuum or modified atmospheric packaging (Cutter and Sumner 2002). However, food packaging is dominated by petroleum derivates polymers such as polyethylene and polystyrene (Cha and Chinnan 2004). These materials are nonbiodegradable and adversely impact the environment. Recently, the development of edible packaging in the form of films and coatings has received increasing interest in response to the tendency for reducing the amount of food packaging materials and/or substitute synthetic materials for biodegradable based packaging materials (Petersen and others 1999; Wu and others 2002). Additionally, edible films can be consumed along with the wrapped food providing additional nutrients, enhancing organoleptic properties, and offering protection even when the package has been opened (Guilbert and others 1996; Cutter and Sumner 2002).

However, edible films and coatings will never replace the nonedible packaging made from synthetic materials, even though edible packaging is made from natural biodegradable and renewable biopolymers. The utility of edible films depends on their capacity to:

- Improve overall foods quality;
- Extend shelf-life;
- Improve economic efficiency of packaging materials.

One obvious advantage is that edible films will reduce synthetic waste materials used in food packaging (Kester and Fennema 1986; Krochta and De Mulder-Johnston 1997).

Natural biopolymers for edible packaging include lipids, polysaccharides, and proteins. These materials can act as a barrier by limiting moisture, aroma, and lipid migration between food components, and their efficiency will depend on their chemical characteristics (Kester and Fennema 1986; Guilbert and others 1996; Gennadios and others 1997; Wu and others 2002). In addition to the barrier properties, edible films and coatings can be incorporated with functional additives such as antioxidants, nutrients, and antimicrobial agents (Wu and others 2002). This type of edible packaging is part of the classification of a new generation called "active packaging," which has been defined as "the packaging that changes its condition to extend shelf-life, improve safety and sensory properties while maintaining the quality"; making the antimicrobial food packaging the most promising form of active packaging (Quintavalla and Vicini 2002). This type of packaging has a great potential to be used for ready-to-eat and cured poultry products in response to the U.S. Department of Agriculture (USDA) policy of "zero tolerance" for *Listeria monocytogenes* (Zhu and others 2005), which may contaminate the products.

The aim of this chapter is to explore the importance of edible packaging, the materials and functionality, and their application in poultry meat preservation. In addition, special attention is drawn to analyze the advances in antimicrobial edible packaging to ensure meat safety.

82.2 DEFINITION AND HISTORY ASPECTS OF EDIBLE PACKAGING

Edible packaging can be applied on foods in the form of films or coatings. An edible film or coating can be defined as a thin layer of material that can be eaten by the consumer, providing barrier protection against microbial contamination and moisture losses, and extending shelf-life (Guilbert and others 1996; Wu and others 2002).

The use of edible packaging to extend the shelf-life of foods is not a new concept. In China, during the 12th and 13th centuries, coating of fresh oranges and lemons with wax was used to prevent desiccation (Kester and Fennema 1986). Later on, the application of lipid coatings was first documented in the 16th century (Cutter and Sumner 2002). However, patents on edible films to extend the food shelf-life date back to the 1950s, comprising films for frozen meat, sea foods, and poultry using alginates, fats, gums, and starches (Guilbert and others 1996). Currently, there are several reports where edible films are used to improve the sensorial and microbiologic quality of meats and poultry products (Herald and others 1996; Natrajan and Sheldon 2000a,b; Dawson and others 2002; Janes and others 2002; Lungu and Johnson 2005a,b; Theivendran and others 2006).

82.3 IMPORTANCE OF THE APPLICATION OF EDIBLE FILMS AND COATINGS IN MEAT AND POULTRY

According to Gennadios and others (1997), the potential benefits of using edible coatings in muscle foods such as poultry are:

1. Reduction in moisture loss during storage of fresh or frozen meats that leads to texture, flavor, and color changes while reducing weight.

2. Prevention of drip losses of fresh meats, and eliminating the need to use absorbent pads.
3. Reduction of the lipids and myoglobin oxidation rate, by using edible coatings with low oxygen permeability.
4. Reduction of the load of pathogenic and spoilage flora, and partial inactivation of proteolytic enzymes on the meat surface.
5. Restricting loss of volatile flavors and foreign odor pick-up.
6. Serving as carriers of antioxidants and antimicrobials in active packaging.
7. Reduction of oil uptake during frying.

Therefore, edible packaging applied as coatings on foods may also maintain the quality of foods after the package is opened, thus protecting against moisture change, oxygen uptake, and aroma loss (Krochta and De Mulder-Johnston 1997).

82.4 TYPES OF EDIBLE FILMS: CHARACTERISTICS AND SOME APPLICATIONS

Edible films and coatings can be made from lipids, polysaccharides, proteins, and composites (Kester and Fennema 1986; Gennadios and others 1997; Wu and others 2002). Each film type presents its own functional properties; some film characteristics are presented below in addition to examples of their application.

82.4.1 Lipid Based Films

Several film forming solutions prepared from waxes (carnauba, beeswax, and paraffin wax), oils (vegetal, animal, and mineral) and surfactants can be used as protective coatings (Kester and Fennema 1986; Gennadios and others 1997; Cutter and Sumner 2002). Coatings made from lipids can block moisture transport due to their relatively low polarity. In this context, wax coatings have shown to be substantially more resistant to moisture transport than other lipid or nonlipid edible coatings (Kester and Fennema 1986; Gennadios and others 1997). Hence, lipids are mainly used for their efficiency as a water–vapor barrier in edible films. Lipid characteristics such as structure, degree of saturation, chain length, physical state, and crystallization shape influence their film functional properties (Cutter and Sumner 2002). Nevertheless, lipid based films have rather poor mechanical properties (Yang and Paulson 2000).

The application of lipid coatings was first documented in the 16th century, when animal fats were used to coat meat cuts in order to prevent shrinkage; this process was called larding (Cutter and Sumner 2002). In 1955, McNally dipped whole dressed chickens into molten wax, mineral oil, corn oil, or lard prior to freezing (Gennadios and others 1997). Today animal fats are still used to coat a variety of foods, including frozen poultry. Frozen poultry did not undergo substantial dehydration when coated in oil–water emulsions prepared at 60–80°C by blending an animal fat or vegetable oil with emulsifiers, water, seasonings, and preservative agents (Gennadios and others 1997). Lipid materials have also been used in edible films to impart hydrophobicity, cohesiveness, and flexibility. However, lipid coatings can produce anaerobic conditions at higher storage temperatures (Cutter and Sumner 2002). If the film is formed from lipid,

it can be applied in molten form followed by solidification, or applied as solution in inorganic solvent and then freed of the solvent, or also applied as oil-in-water emulsion with subsequent drying (Kester and Fennema 1986).

82.4.1.1 Waxes. These substances are non polar lipids; they are insoluble in bulk water, have a high hydrophobicity and are soluble in organic solvents (Cha and Chinnan 2004). Coating frozen meats with waxes eliminated fresh meat low-grading caused by discoloration and reduced packaging labor (Cutter and Sumner 2002).

82.4.1.2 Glycerides. Monoglycerides are mainly used in edible films as emulsifiers; they stabilize the emulsion film and increase adhesion between the film components with different hydrophobicity (Cha and Chinnan 2004).

82.4.2 Polysaccharide Based Films

Originally, polysaccharides have been used in the food industry to provide hardness, crispness, thickening, adhesiveness, and compactness because of their gel forming ability (Cutter and Sumner 2002). However, several polysaccharides and their derivates (including alginate, pectin, carragenan, starch, hydrolyzed starch, cellulose derivatives, various plant microbial gums, and chitosan) can also be used to produce films and coatings (Kester and Fennema 1986; Gennadios and others 1997). Phan and others (2005) suggest that functionality varies within the polysaccharide material, as agar and cassava derived starch have better functional properties than normal and waxy rice starch films.

Polysaccharide films generally exhibit limited water vapor barrier ability due to their hydrophilic nature; but they can prevent water condensation and reduce microbial growth on the surfaces of poultry (Gennadios and others 1997; Cha and Chinnan 2004). Polysaccharide films are selectively permeable to CO_2 and O_2, they can increase shelf-life of foods, by preventing dehydration, oxidation, rancidity, and surface browning. For all these reasons polysaccharide films are used in Japan for packing processed meats, including ham and poultry (Cutter and Sumner 2002; Cha and Chinnan 2004).

82.4.2.1 Alginates. Alginates are salts of alginic acid extracted from brown seaweeds *Macrocystis pyrifera*. They are linear copolymers of D-manopyranosyluronic acid and L-guluropyranosyluronic acid units (Cha and Chinnan 2004). Alginate films are formed by crosslinking with a calcium salt or other di- or trivalent metal ions, or by exposition to pH 3 or less (Kester and Fennema 1986; Krochta and De Mulder-Johnston 1997; Cutter and Sumner 2002). Calcium is more effective in gelling alginates than magnesium, manganese, aluminum, ferrous, and ferric ions. However, calcium chloride used at concentrations greater than 5 M imparts bitter flavor to foods (Cutter and Sumner 2002).

Thus, alginate films are impervious to oils and fats, but they are poor moisture barriers and have high oxygen permeability coefficient (Krochta and De Mulder-Johnston 1997; Buonocore and others 2005). However, gelatinous alginate coatings have been applied to various meats such as beef and pork cuts, and poultry parts to reduce dehydration acting by sacrifice, as they lose water before food (Kester and Fennema 1986; Krochta and De Mulder-Johnston 1997). Moreover, alginates are good oxygen barriers and can provide protection against oxidation of food ingredients (Kester and Fennema 1986; Krochta and De Mulder-Johnston 1997). In addition, alginates can improve flavor, texture, and batter adhesion (Krochta and De Mulder-Johnston 1997). In this context,

Earle received a patent for the calcium alginate gel edible coating that can be used to prevent dehydration and color changes in raw fish, meat, and poultry during refrigerated storage (Cha and Chinnan 2004).

82.4.2.2 Carrageenan. Carrageenan is a water-soluble galactose polymer extracted from the Irish moss called *Chondrus crispus* and other species of red seaweeds. It is composed of a mixture from at least five polymers designated as ι-, κ-, λ-, μ-, and υ-carrageenan; but ι-, κ-, and λ-carrageenan have food applications. Gelation of ι- and κ-carrageenan occurs with both monovalent and divalent cations; whereas, λ-carrageenan is a nongelling and thickening agent (Gennadios and others 1997; Cha and Chinnan 2004). Carrageenan has been applied on poultry meat by Meyer and co-workers. They dipped chicken parts into 40 g/L aqueous solution of carrageenan at 64°C, which slightly increased poultry shelf-life at 2°C (Gennadios and others 1997). They also observed that the inclusion of an antibiotic was more effective to retard spoilage of poultry; however, antibiotics are no longer approved for use on poultry meat as a preservative (Gennadios and others 1997).

82.4.2.3 Agar. Agar is a gum derived from a variety of red seaweeds of *Rhodophyceae* class; this biopolymer is mainly composed of galactose polymers separable into two distinctive fractions known as agaran and agaropectin, which contain 5–10% sulfate esters. Agar forms strong reversible gels characterized by their melting point at about 85ºC, far above the initial gelation temperature (Gennadios and others 1997). Agar coatings added with antibiotics, such as soluble salts of chlortetracycline, neomycin, oxytetracycline, and polymyxin have been used to extend shelf-life of poultry parts stored at 2°C (Gennadios and others 1997; Cha and Chinnan 2004).

82.4.2.4 Starch. Starch, which is composed by amylose and amylopectin, is a material derived from cereal grains, potatoes, tapioca, banana, mango, and so on. Films obtained from this polysaccharide are odorless, tasteless, colorless, nontoxic, biologically absorbable, semipermeable to carbon dioxide, and resistant to the passage of oxygen. Films may be prepared by thermal gelation or by cold gelatinization with NaOH; although thermal gelation produces films with better barrier and mechanical properties (Romero-Bastida and others 2005). Starch presents physical characteristics very similar to plastic films and exhibit thermoplastic behavior, but films tend to recrystallize during long-term storage to the detriment of their functionality (Cutter and Sumner 2002; Cha and Chinnan 2004; Romero-Bastida and others 2005). Amylose is responsible for the film-forming capacity of starches and amylopectine is brittle and noncontinuous (Cha and Chinnan 2004). In 1960, hydroxypropylated amylose films were extruded and then they were used to wrap frozen meat, poultry, and fish, protecting them during frozen storage but dissolving during thawing and cooking (Cutter and Sumner 2002). Recently, Fama and others (2005), as well as, Veiga-Santos and others (2005) demonstrate that the mechanical properties and microstructure and color of starch films may be affected by pH modifications and inclusion of sorbate, xanthan gum, and other additives such as sucrose, soybean oil, sodium phosphate, and propylene glycol.

82.4.2.5 Chitosan. Chitosan is the mayor organic skeletal substance of invertebrates and the cell wall of fungi and green algae (Cutter and Sumner 2002). It is produced commercially by deacetilating chitin obtained from shellfish waste (Krochta and De Mulder-Johnston 1997). Chitosan films are clear, tough, and flexible, with good oxygen barrier

properties; it is produced by treating chitin with alkali and inhibits fungi and pathogens (Krochta and De Mulder-Johnston 1997; Cutter and Sumner 2002).

82.4.2.6 Cellulose and Cellulose Derivates. Cellulose is the most abundant natural polymer on earth, and it is essentially a lineal natural polymer of anhydroglucose. Due to its chemical structure, it is highly fibrous, and insoluble (Cha and Chinnan 2004). Cellulose derivates such as methylcellulose (MC), hydroxipropyl cellulose (HPC), hydroxipropyl methylcellulose (HPMC), and carboxymethylcellulose (CMC) are water-soluble ethers with good film forming properties (Gennadios and others 1997). They produce films resistant to fats and oils, tough, and flexible (Cutter and Sumner 2002). They may be combined with oil as a plasticizer to coat both fresh and frozen meats (Cutter and Sumner 2002). Edible films made from MC and HPMC have been useful to reduce the quantity of fat and to reduce moisture loss of meat balls prepared from ground chicken breast (Gennadios and others 1997; Holownia and others 2000). Holownia and others (2000) also observed that chicken strips coated with MC and HPMC hindered the migration of moisture and acetic acid into the frying oil and this activity was responsible for reduced free fatty acid generation in those oils used to fry the coated products.

82.4.3 Protein Based Films

Proteins commanded great attention as degradable, renewable polymer films (Petersen and others 1999). They can be manufactured from animal and vegetable resources such as collagen, gelatin, milk proteins, wheat gluten, soy proteins, rice, corn zein, peanut, egg albumen, and so on (Gennadios and others 1997; Cutter and Sumner 2002). Protein film formation results from polymerization of denatured protein chains, where disulfide, hydrogen, and hydrophobic interactions form a continuous film network; thus proteins containing high SH-aminoacid residues as cysteine have better film properties (Were and others 1999). Protein based-films have better mechanical and barrier properties than polysaccharides (Khwaldia and others 2004). These films adhere well to hydrophilic surfaces and provide good barriers for oxygen and carbon dioxide, but do not resist water diffusion (Cutter and Sumner 2002). Their limited resistance to water vapor transmission is attributed to the hydrophilic protein nature, as well as to the presence of hydrophilic plasticizers, such as glycerin and sorbitol, incorporated to impart flexibility (Gennadios and others 1997). Protein-based packaging presents some disadvantages, for example, they may be degraded by the endogenous enzymes present in raw meats; additionally, they may induce health problems, especially in people with food allergies to milk, egg, peanut, soybean, or gluten proteins (Gennadios and others 1997; Cutter and Sumner 2002).

82.4.3.1 Gelatin. Gelatin derivates from the partial hydrolysis of collagen. Gelatin coatings have been used as carriers directly into processed poultry meat surfaces to prevent microbial growth, grease bleeding, handling abuse, water transfer, moisture loss, and oil adsorption during frying. The preservation of meat and other foods with gelatin coatings was proposed in 1869 (Gennadios and others 1997; Cutter and Sumner 2002).

82.4.3.2 Corn Zein. Corn zein is the prolamine fraction or corn protein (Cha and Chinnan 2004), which give rise to strong water insoluble films, resistant to microbial attack (Weller and others 1998; Fu and others 1999; Padua and Wang 2002). Corn zein films have been commercially used in coating formulations for shelled nuts, candy, and

pharmaceutical tablets. They provide a good barrier to oxygen, and its water vapor permeability is about 800 times higher than that of a typical shrink-wrap film (Cha and Chinnan 2002).

The use of corn zein was suggested for poultry preservation by Herald and others (1996). They wrapped turkey breast with corn zein film added with antioxidant (butylated hidroxyanisole) and emulsifier (acetylated monoglyceride) and observed lower hexanal content in these samples in comparison with samples packaged in PVDC. Janes and others (2002) demonstrated that zein coating films added with nisin can prevent the growth of *Listeria monocytogenes* on ready-to-eat chicken. Also, Lungu and Johnson (2005a,b) incorporated nisin, sodium diacetate, and sodium lactate to inhibit *Listeria monocytogenes* on turkey frankfurters.

82.4.3.3 Soy Protein Isolates. Soy bean proteins are composed by two major componets, 11S (glycinin) and 7S (β-conglycinin); the 11S fraction has better film forming properties than the 7S (Yildirim and Hettiarachchy 1997). However, the film forming ability of soy protein has traditionally been utilized in the Far East for the production of soy protein-lipid called *yuba* films. Soy based films with added lauric acid and nisin have been used successfully to reduce the growth of *Listeria monocytogenes* on turkey Bologna (Dawson and others 2002).

82.4.3.4 Whey Protein Isolate. The use of milk proteins to produce films and coatings and their characteristics has been analyzed by Khwaldia and others (2004). Whey protein isolate produces transparent, flexible, edible films with excellent oxygen, and aroma barrier properties at relatively low humidity. These films are water insoluble, however, due their hydrophilic nature they are less effective moisture barriers. Whey protein coatings have been used to improve food integrity and reduce loss due damage in freeze-dried chicken (Pérez-Gago and Krochta 1999, 2002).

82.4.4 Composite Films

Edible packaging made from proteins, lipids, and polysaccharides or by their mixture presents distinct functional characteristics (Wu and others 2002). Each film material has its own particular functionality and application according to its molecular structure. Pure lipid films have extremely low water vapor permeability because their hydrophobic nature, but they are opaque and relatively inflexible; while protein and polysaccharide films exhibit low gas permeability and poor water barrier properties with suitable mechanical and optical properties (Kester and Fennema 1986; Guilbert and others 1996; Wu and others 2002). However, when lipids are incorporated into protein and/or polysaccharide films, the water permeability is reduced by either laminating a hydrophilic lipid layer or making a composite film where both the hydrophobic and hydrophilic components and dispersed (Ko and others 2001). For instance Chung and Lai (2005) reported that starch-beeswax composite films had better water-barrier properties than those simple starch films by using magnetic resonance. In addition it seems that protein-lipid composite films have better moisture barrier properties than those made of polysaccharides, as reported by Ryu and others (2005) for zein and high amylose corn starch composite films mixed with polyethylene glycol, glycerol, and oleic acid.

82.5 MECHANISMS TO MANUFACTURE EDIBLE FILMS AND COATINGS

Selection of edible materials for films and coatings for poultry meat and meat products, the nature of the materials, the manufacturing process and the application method on foods, as well as moisture barrier ability, water and lipid solubility, color, appearance, mechanical, rheological characteristics, manufacturing method, and toxicity need to be considered before selecting an edible packaging material (Cutter and Sumner 2002). These properties depend on the type of material used, its formation and application. Plasticizers, crosslinking agents, antimicrobials, antioxidants, texture agents, and so on, can be added to enhance functional properties of films (Guilbert and others 1996).

The mechanisms for film and coating formation have been analyzed by several authors (Kester and Fennema 1986; Guilbert and others 1996; Khwaldia and others 2004). According to Guilbert and others (1996) edible films and coatings can be formed by simple coacervation, complex coacervation and gelation or thermal coagulation.

- Simple coacervation: where a hydrocolloid dispersed in water is separated from the solvent phase due to its compatibility. This process takes place after solvent evaporation, previous addition of a hydrosoluble nonelectrolyte, in which hydrocolloid is not soluble, of after pH adjustment.
- Complex coacervation: where two hydrocolloid solutions with opposite electron charges are mixed, causing electrostatic interactions and precipitation of the polymer complex (Khwaldia and others 2004).
- Gelation or thermal coagulation: where heating of the hydrocolloid, which leads to its denaturalization followed by gelation or precipitation; also cooling polymer dispersion may cause gelation. However, hot casted films show lower gas diffusion than cool-casting films (Lukasik and Ludescher 2006). In particular, globular protein films are produced by thermal gelation followed by dehydration.

82.6 SUBSTANCES USED TO IMPROVE MECHANICAL PROPERTIES OF FILMS

In order to improve functional characteristics from films, addition of other substances such as plasticizers, crosslinking agents, and lipids are incorporated into film forming solutions (Cutter and Sumner 2002). Plasticizers are compounds of low volatility which may be added to impart flexibility to a polymer film (examples of these are glycerol, propylene glycol, sorbitol, manitol, sucrose, polyethylene glycol, etc.) by weakening intermolecular forces between adjacent polymer chains, thus decreasing tensile strength while the film flexibility increases (Kester and Fennema 1986; Krochta 2002). Unfortunately, plasticizers also decrease the barrier properties against moisture, oxygen, aroma, and oils (Krochta 2002). The heat applied during protein thermal gelation induces aggregation and conversion of the regular secondary structures into antiparallel beta-sheets, while dehydration induces further aggregation. The presence of the plasticizer allows specific conformational rearrangements into extended beta-sheets and ordering of the polypeptide chains improving film functionality (Lefevre and others 2005). Tang and others (2005) have suggested that moisture barrier properties are highly correlated with the surface hydrophobicity film network. The incorporation of microbial transglutaminase in combination with various

plasticizers for film soy protein isolates can slow down the moisture loss rate during the drying process due to the increase of surface hydrophobicity. This increase generates a more homogeneous or compact films structure compared to the controls. Transglutaminase enhances globular protein crosslinking by introducing ε-(γ-Glu)-Lys intra and intermolecular covalent bonds that improve film water resistance (Yildirim and Hettiarachchy 1997). Other crosslinking agents include formaldehyde, glutaraldehyde, and glyoxal that impart greater mechanical strength to gliadin films (Hernandez-Muñoz and others 2005). Moreover, incorporation of waxes and/or fatty acids (such as beeswax, estearic and palmitic acids, among others) improves moisture barrier properties; however, the barrier efficiency will depend on the polarity of components and on the homogenous dispersion of hydrophobic substances (Pérez-Gago and Krochta 1999; Yang and Paulson 2000).

82.7 METHODS FOR APPLICATION OF EDIBLE FILMS AND COATINGS

Edible coatings are applied and/or formed directly on the food product surface; whereas edible films are structures that are applied after being previously formed (Guilbert and others 1996). Edible films can be applied on foods by wrapping, dipping, brushing, spraying, casting, and foaming (Cutter and Sumner 2002; Wu and others 2002). Selection of the method will depend on the food type and cost. Additionally, shelf-supporting films can be obtained by techniques such as extrusion, molding, or rolling mill procedures (Guilbert and others 1996).

82.8 SAFETY AND HEALTH CONSIDERATIONS OF EDIBLE FILMS

One of the most important topics in the production of edible films is the selection of ingredients because all of them have to be safe. According to Krochta and De Mulder-Johnston (1997), there are several safe aspects that have to be studied before film formulation:

1. Edible film polymers have to be generally recognized as safe (GRAS), this joined to good manufacturing practices.
2. If the edible ingredient is not currently GRAS but the manufacture can demonstrate safety, the manufacturer can apply for a GRAS petition to the Food Drug Administration (FDA) or proceed to mark the material without FDA concurrence (shelf-determination).
3. Manufacturer may not need to establish that use of the edible polymer in edible films is GRAS if the material received pre-1958FDA clearance and thus has "prior sanction."
4. If the material cannot be demonstrated to be GRAS or "prior to sanction," the manufacturer must submit a food additive petition of FDA.

There are edible polymers used for packaging manufacture (films or coatings) that have received special attention. They are: cellulose ethers, starch, hydroxypropilated starch, corn zein, wheat gluten, soy protein, and milk proteins because some people have wheat gluten intolerance, milk protein allergies, or lactose intolerance (Krochta and De Mulder-Johnston 1997). Hence, it is necessary to declare when these materials have been used in the manufacture of edible packaging (Krochta and De Mulder-Johnston 1997).

82.9 ACTIVE AND EDIBLE PACKAGING

Nowadays, there are big efforts for innovation of food packaging technology. These efforts are result of the increasing demand for minimally processed foods and the change in retail and distribution practices associated with the globalization such as new consumer products logistics, new distribution tendencies, and automatic handling system and distribution centers. These factors have contributed to the development of a new concept of packaging known as active packaging (Suppakul and others 2003; Yam and others 2005). An active packaging is a mode of packaging in which the package, the product, and the environment interact to prolong shelf-life or enhance safety or sensory properties while maintaining the quality of the product (Suppakul and others 2003). In general, active food packaging can provide several functions that do not exist in conventional packaging systems (Quintavalla and Vicini 2002). These functions include: oxygen scavenging systems, moisture-absorbing control systems; carbon dioxide generating systems, ethanol generating systems, antioxidant systems, and antimicrobial migrating/not migrating systems (Suppakul and others 2003).

Oxygen scavenger systems remove the residual oxygen after packaging. This technology is based on oxidation of iron power, ascorbic acid, photo sensitive dyes, enzymes (glucose oxidase), unsaturated fatty acids (such as oleic, linoleic, and linolenic acids), rice extract or immobilized yeast on a solid subtract (Suppakul and others 2003). This kind of packaging can be used to prevent the growth of aerobic bacteria and molds (Han 2000a,b). They are also useful for products that are sensitive to oxygen and light (Suppakul and others 2003). While systems of water absorption used to control liquid water in foods consist in a super absorbent polymer (such as polyacrilate salt or starch graft copolymers) located between two layers of a micro-porous polymer (Suppakul and others 2003).

82.9.1 Carbon Dioxide Generating Systems

Carbon dioxide generating systems are useful in certain applications such as fresh meat, poultry, fish, and cheese packaging (Suppakul and others 2003).

82.9.2 Ethanol Generating Systems

Ethanol prevents microbial spoilage of intermediate moisture foods such as cheeses and bakery products. In addition, it can reduce the rate of staling and oxidative changes (Suppakul and others 2003).

82.9.3 Antioxidants

One of the main problems for raw and cooked poultry meat quality is to prevent lipid oxidation. Traditionally, antioxidants of synthetic origin such as butyl hydroxyanisol (BHA) or butyl hydroxytoluene (BHT) and terbutyl hydroquinine (TBHQ) have been used delay the onset of oxidative rancidity in meat products by sequestering free radicals. However, in recent years there has been increasing interest in the use of natural antioxidants due to consumer concerns about the potential toxicity of some synthetic antioxidants. Natural antioxidants such as α-tocopherol, rosemary (*Rosmarinus officinalis* L.), or sage (*Buddleia perfoliata* Kunth), basil, and garlic extracts, among other

spices and herbal extract may be used to delay rancidity (Gruen 2005). Armitage and others (2002) incorporate fenugreek seeds, rosemary and vitamin E as antioxidants in egg albumen films to reduce lipid oxidation in cooked and uncooked poultry; but no differences were detected in poultry samples coated with egg albumen containing antioxidants, data suggested that the use of egg albumen coating was responsible for lipid oxidation delay.

82.10 ANTIMICROBIAL FOOD PACKAGING

Antimicrobial packaging is a promising area in active packaging for meat poultry products (Quintavalla and Vicini 2002). The interest in this packaging has increased in recent years due to a concern over the risk of food borne illness, and advances in the film production technology (Dawson and others 2002). One example of antimicrobial food packaging is the antimicrobial absorbent foods pads used in trays for packed retail meats and poultry to soak up meat juice. This pad has the capacity to inhibit food borne pathogens due the presence of anionic surfactants such as alkyl sulfonate salts, alkyl sulfate salts, as well as citric and malic acids (Cha and Chinan 2004; Brody 2005).

Antimicrobial food packaging allows extending the lag period and thus reducing the growth of microorganisms, improving shelf-life and food safety (Han 2000a; Suppakul and others 2003). Active packaging can be classified in two groups: (1) those were the antimicrobial agent migrates to the surface of the food, and (2) those that are effective against surface growth microorganisms without migration (Suppakul and others 2003; Cha and Chinnan 2004). Although, antimicrobial films may also incorporate radiation-emitting materials (Cha and Chinnan 2004; Brody 2005).

Several compounds are used as antimicrobials; these include: organic acids, enzymes, lisozyme, EDTA, essential oils, chitosan, lactoperoxidase system, lactoferrine, and bacteriocins (Ouattara and others 2000; Cha and Chinan 2004; Min and Krochta 2005; Min and others 2005; Quintero-Salazar and others 2005).

Most works related to antimicrobial packaging have focused their attention on the application of bacteriocins, described peptides with antibacterial inhibitory action produced by some lactic acid bacteria; as antimicrobial agents into edible and nonedible films (see Fig. 82.1 as well as Tables 82.1 and 82.2). One of the first reports was made by Cutter and Siragusa (1996, 1997) for films made of alginates added with nisin to inhibit

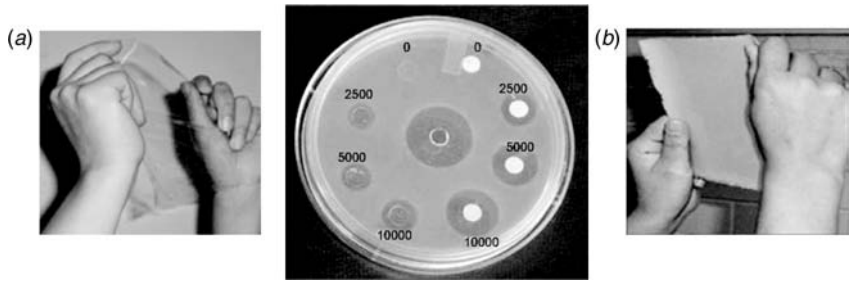

Figure 82.1 *Inhibition halos generated by (a) transparent whey protein isolate films, and (b) opaque corn zein films (added with several levels of the bacteriocin pediocin from 0 up to 10000 IU/mL of film forming solution) placed on an agar plate inoculated with Listeria innocua ATCC 33090 incubated at 37°C for 18 h.*

HMPC	Nisin	*Listeria monocytogenes* *Staphylococcus aureus*	Sebti and others 2002

Brochotrix thermosphacta. These authors suggested that nisin was more effective when it was immobilized into alginate gels that when it was added directly to muscle substrates. Also, Ming and others (1997) incorporated the bateriocins, nisin, and pediocin into cellulose films, to completely inhibit *Listeria monocytogenes* growth on ham, chicken, and beef

meat, during 12 weeks. In 1998, Padgett and others demonstrated that the inhibitory inhibition spectrum of corn zein and soy protein edible films added with nisin could be increased against Gram-negative bacteria when nisin was added in combination with lisozyme and EDTA. In 1999 Sigarusa and others, as well as, Cutter and others (2001)

observed that nisin antimicrobial activity was maintained in a synthetic polymer of nylon and it was useful in to inhibit the growth of *Lactobacillus helveticus* and *Brochotrix thermosphacta* when applied on beef carcasses. Scannell and others (2000) incorporated nisin and lacticin 3147 into a polyethylene/polyamide polymer and cellulose to inhibit *Listeria innocua* and *Staphylococcus aureus* in cheese and ham. Natrajan and Sheldon (2000a) incorporated nisin, EDTA, citric acid, and tween 80 into synthetic polymers and into absorbent pads to inhibit the growth of *Salmonella thypphymurium* on chicken skin. The same authors also used protein and polysaccharide-based films added with nisin to inhibit *Salmonella* on poultry skin (Natrajan and Sheldon 2000b). Ouattara and others (2000) prepared antimicrobial films by incorporating acetic or propionic acid into chitosan matrix, with or without lauric acid or cinnamaldehyde to be applied onto bologna, regular cooked ham. Hoffman and others (2001) incorporated EDTA, lauric acid and nisin into corn zein which against *Listeria monocytogenes* and *Salmonella enteritis*. Dawson and others (2002) used soy protein films added with nisin and lauric acid to inhibit *Listeria monocytogenes* in Bologna turkey. While, Cha and others (2003), made films of sodium aginate and carragenan added with EDTA, lisozyme, nisin, and grape extract against *Micrococcus luteus. Listeria innocua*, *Salmonella enteritis*, *Escherichia coli*, and *Staphylococcus aureus*. Eswaranandam and others (2004) incorporated organic acids and nisin into soy films to inhibit *Listeria monocytogenes* and *E. coli* O157:H7. Lungu and Johnson (2005a,b) established that treatments using nisin alone or in combination with zein, etanol-glycerol, or propylene glycol was appropriated to be applied on ready-to-eat foods, promising for use the use of antimicrobial films as barriers against L. *monocytogenes* recontamination on turkey frankfurters.

Most work using antimicrobial edible films have been done on model poultry meat products; however, there is a need to explore industrial applications to ensure safety as part of the hurdle technology for poultry preservation.

82.11 CONCLUSIONS

Edible packaging has been applied over several years on a number of foods including fresh, frozen, and processed poultry products, as a means of preservation to improve quality and safety. There are many opportunities for research in this area in order to improve mechanical and barrier properties, or develop new packaging concepts according to the consumer demands and processors' needs in order to renew the packaging technology, using natural and biodegradable under-valued materials from animal and vegetable resources; as well as by the inclusion of additives to improve mechanical, barrier and other functional characteristics to ensure poultry quality.

83.1 INTRODUCTION

This book is not the proper forum to discuss the manufacture of every frozen seafood product available in the market. However, regulatory agencies such the National Marine Fisheries Service (NMFS) have issued some minimal criteria for several frozen seafood and seafood products: what they are, what types and styles are available, and so on. The information in this chapter describes each available frozen seafood product and has been modified from the product grades issued by the NMFS. A product grade is established to achieve two objectives: to assure product safety and to minimize economic fraud.

83.2 FROZEN HEADLESS DRESSED WHITING

83.2.1 Product Description

The product described in this part consists of clean, wholesome whiting (silver hake) *Merluccius bilineraris*, *Merluccius albidus* completely and cleanly headed and adequately eviscerated. The fish are packaged and frozen in accordance with good commercial practice and are maintained at temperatures necessary for the preservation of the product.

83.2.2 Grades of Frozen Headless Dressed Whiting

U.S. Grade A is the quality of frozen headless dressed whiting that possess a good flavor and odor.

U.S. Grade B is the quality of frozen headless dressed whiting that possess at least reasonably good flavor and odor.

Substandard or Utility is the quality of frozen headless dressed whiting that otherwise fail to meet the requirements of U.S. Grade B.

83.2.3 Determination of the Grade

Good flavor and odor (essential requirements for a U.S. Grade A product) means that the cooked product has the typical flavor and odor of the species and is free from rancidity, bitterness, staleness, and off-flavors and off-odors of any kind.

Reasonably good flavor and odor (minimum requirements of a U.S. Grade B product) means that the cooked product is lacking in good flavor and odor but is free from objectionable off-flavors and off-odors of any kind.

Arrangement of product refers to the packing of the product in a symmetrical manner, bellies or backs all facing in the same direction, fish neatly dovetailed.

Condition of the packaging material refers to the condition of the cardboard or other packaging material of the primary container.

If the fish is allowed to stand after packing and prior to freezing, moisture from the fish will soak into the packaging material and cause deterioration of that material.

Dehydration refers to the presence of dehydrated (water-removed) tissue on the exposed surfaces of the whiting. Slight dehydration is surface dehydration that is not color-masking. Deep dehydration is color-masking and cannot be removed by scraping with a fingernail.

Minimum size refers to the size of the individual fish in the sample. Fish that are two ounces or over are considered acceptable. Smaller fish cannot be cooked uniformly with acceptable size fish.

Heading refers to the condition of the fish after they have been headed. The fish should be cleanly headed behind the gills and pectoral fins. No gills, gill bones, or pectoral fins should remain after the fish have been headed.

Evisceration refers to the cleaning of the belly cavities of the fish. All spawn, viscera, and belly strings should be removed.

Scaling refers to the satisfactory removal of scales from the fish.

Color of the cut surfaces refers to the color of the cut surfaces of the fish after heading and other processing.

Bruises and broken or split skin refers to bruises over one-half square inch in area and splits or breaks in the skin more than one-half inch in length that are not part of the processing.

Texture defects refers to the absence of normal textural properties of the cooked fish flesh, which are tenderness, firmness, and moistness without excess water. Texture defects are dryness, softness, toughness, and rubberyness.

83.3 FROZEN HALIBUT STEAKS

83.3.1 Product Description

Frozen halibut steaks should be clean, wholesome units of frozen raw fish flesh with normally associated skin and bone and should be two ounces or more in weight. Each steak should have two parallel surfaces and be derived from whole or subdivided halibut slices of uniform thickness that result from sawing or cutting perpendicular to the axial length, or backbone, of a whole halibut. The steaks, prepared from either frozen or unfrozen halibut (*Hippoglossus* spp.), should be processed and frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

83.3.2 Styles of Frozen Halibut Steaks

Style I: Random weight pack. The individual steaks are of random weight and neither the weight nor the range of weights are specified.

Style II: Uniform weight or portion pack. All steaks in the package or in the lot are of a specified weight or range of weights.

83.3.3 Recommended Dimensions

1. The recommended dimensions of frozen halibut steaks are not incorporated in the grades of the finished product since dimensions, as such, are not factors of quality for the purpose of these grades. However, the degree of uniformity of thickness among units of the finished product is rated since it is a factor affecting the quality and utility of the product.
2. It is recommended that the thickness (smallest dimension) of individually frozen halibut steaks be not less than $\frac{1}{2}$ inch and not greater than $1\frac{1}{4}$ inches.

Percentage glaze on halibut steak means the percent by weight of frozen coating adhering to the steak surfaces and includes the frost within the package.

Uniformity of thickness means that the thickness is substantially the same for one or more steaks within a package or sample unit.

83.3.4 Color Defects

1. Discoloration of drip liquor means that the free liquid that drains from the thawed steaks is discolored with blood residue usually from the dorsal aorta of the halibut.
2. Discoloration of light meat means that the normal flesh color of the main part of the halibut steak has darkened due to deteriorative influences.
3. Discoloration of the dark meat means that the normal color of the surface fat shows increasing degrees of yellowing due to oxidation.
4. Non-uniformity of color refers to noticeable differences in color on a single steak or between adjacent steaks in the same package.
5. Dehydration refers to the appearance of a whitish area on the surface of a steak due to the removal of water or drying of the affected area.
6. Honeycombing refers to the visible appearance of numerous discrete holes or openings of varying size on the steak surface.
7. Workmanship defects refers to appearance defects that were not eliminated during processing and are considered either objectionable or poor commercial practice.
8. Texture defect refers to an undesirable increase in toughness and/or dryness, fibrousness, and watery nature of halibut examined in the cooked state.

83.4 FROZEN SALMON STEAKS

83.4.1 Product Description

Frozen salmon steaks should be clean, wholesome units of frozen raw fish flesh with normally associated skin and bone and should be $2\frac{1}{2}$ ounces or more in weight. Each steak should have two parallel surfaces and be derived from whole or subdivided salmon slices of uniform thickness that result from sawing or cutting dressed salmon perpendicularly to the axial length, or backbone. The steaks, prepared from either frozen or unfrozen salmon (*Oncorhynchus* spp.), should be processed and frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product. The steaks in an individual package should be prepared from only one species of salmon.

83.4.2 Species

Frozen salmon steaks covered by this standard are prepared from salmon of any of the following species:

Silver or Coho (*O. kisutch*).

Chum or Keta (*O. keta*).

King, Chinook, or Spring (*O. tshawytscha*).

Red, Sockeye (*O. nerka*).
Pink (*O. gorbuscha*).

83.4.3 Styles

Style I: Random weight pack. The individual steaks are of random weight and neither the individual steak weight nor the range of weights is specified. The steaks in the lot represent the random distribution cut from the head to tail of a whole dressed salmon.

Style II: Random weight combination pack. The individual steaks are of random weight and neither the individual steak weight nor range of weights is specified. The steaks in the lot represent a combination of cuts from selected parts of the whole dressed salmon.

Style III: Uniform weight or portion pack. All steaks in the package or in the lot are of a specified weight or range of weights.

83.4.4 Recommended Dimensions

It is recommended that the thickness (smallest dimension) of individually frozen salmon steaks be not less than $\frac{1}{2}$ inch and not greater than $1\frac{1}{2}$ inches.

General appearance defects refer to poor arrangement of steaks, distortion of steaks, wide variation in shape between steaks, greater than normal number of head and/or tail pieces, imbedding of packaging material into fish flesh, inside condition of packaging, frost deposit, excessive or non-uniform skin glaze, and undesirable level of natural color.

Dehydration refers to the appearance of a whitish area on the surface of a steak due to the evaporation of water or drying of the affected area.

Uniformity of thickness means that the steak thickness is within the allowed manufacturing tolerance between the thickest and thinnest parts of the steaks within a package or sample unit.

Workmanship defects refers to appearance defects that were not eliminated during processing and are considered objectionable or poor commercial practice. They include the following: Blood spots, bruises, cleaning (i.e., inadequate cleaning of the visceral cavity of blood, viscera and loose or attached appendages), cutting (i.e., irregular, inadequate, unnecessary, or improper cuts and/or trimmings), fins, foreign material (i.e., any loose parts, of fish or other than fish origin), collar bone, girdle (i.e., bony structure adjacent to fin), loose skin, pugh marks, sawdust and scales.

83.4.5 Color Defects

Discoloration of fat portion means that the normal color of the fat shows increasing degrees of yellowing due to oxidation.

Discoloration of lean portion means that the normal surface flesh color has faded or changed due to deteriorative influences.

Nonuniformity of color refers to noticeable differences in surface flesh color on a single steak or between adjacent steaks in the same package or sample unit. It also includes color variation of the visceral cavity and skin watermarking.

Honeycombing refers to the visible appearance on the steak surface of numerous discrete holes or openings of varying size.

Texture defect refers to an undesirable increase in toughness and/or dryness, fibrousness, and watery nature of salmon examined in the cooked state.

83.5 FROZEN FISH FILLET BLOCKS

83.5.1 Product Description

Frozen fish blocks should be rectangularly-shaped masses made from a single species of fish flesh, and made from fillets or fillet pieces that are either skin-on and scaled or skinless. Blocks processed from skin-on fish flesh should be labeled as such. The blocks should not contain minced or comminuted fish flesh. The blocks should not be made by restructuring (reworking) pieces of fish blocks into the shape of a fish block.

83.5.2 Definitions of Defects

83.5.2.1 Dehydration. This defect refers to loss of moisture from the surface of a fish block during frozen storage. Affected areas have a whitish appearance.

Moderate dehydration masks the surface color of the product and affects more than 5% up to and including 15% of the surface area. If more then 15% of the surface area is affected, each additional 15% of surface area affected is another instance. Moderate dehydration can be readily removed by scraping with a blunt instrument.

Excessive dehydration masks the normal flesh color and penetrates the product. It affects more than 5% up to and including 10% of the surface area. If more than 10% of the surface area is affected, each additional 10% of surface area affected is another instance. Excessive dehydration requires a knife or other sharp instrument to remove.

83.5.2.2 Uniformity of Block Size. This defect refers to the degree of conformity to the declared size. It includes deviations from the standard length, width or thickness. Only one deviation for each dimension should be counted.

Moderate. A deviation of length and width of $\frac{1}{8}$ inch (0.32 cm) or more up to and including $\frac{1}{4}$ inch (0.64 cm). A deviation of thickness of $\frac{1}{16}$ inch (0.16 cm) or more up to and including $\frac{1}{8}$ inch (0.32 cm).

Excessive. If over $\frac{1}{4}$ inch (0.64 cm), each additional $\frac{1}{8}$ inch (0.32 cm) of length and width is another instance. If over $\frac{1}{8}$ inch (0.32 cm), each additional $\frac{1}{16}$ inch (0.16 cm) of thickness is another instance.

83.5.2.3 Underweight. Underweight refers to underweight deviations from the stated weight.

Slight. From 0.1 ounce (2.84 g) up to and including 1 ounce (28.35 g).

Moderate. Over 1 ounce (28.35 g) up to and including 4 ounces (113.4 g).

Excessive. If over 4 ounces (113.4 g), each additional 1 ounce (28.35 g) is another instance.

83.5.2.4 Angles. An acceptable edge angle is an angle formed by two adjoining surfaces whose apex (deviation from 90 degrees) is within 0.95 cm off a carpenter's

square placed along its surfaces. An acceptable corner angle is an angle formed by three adjoining surfaces whose apex is within 0.95 cm of a carpenter's square.

83.5.2.5 Improper Fill. This defect refers to voids, air pockets, ice pockets, ragged edges, bumps, depressions, damage, and embedded packaging material, each of which being greater than $\frac{1}{8}$ inch (0.32 cm) in depth, and that would result in product loss after cutting. It is estimated by determining the minimum number of 1 ounce (28.35 g) model units that could be affected adversely. For the purpose of estimating product loss, the 1 ounce (28.35 g) model unit should have the dimensions $4 \times 1 \times \frac{5}{8}$ inch ($10.16 \times 2.54 \times 1.59$ cm). The total number of model units that would be affected adversely is the number of instances.

83.5.2.6 Belly Flaps (Napes). May be either loose or attached to a fillet or part of a fillet. The maximum amount of belly flaps should not exceed 15% by declared weight of the block if this amount does exceed 15%, each additional 5% by declared weight is another instance.

83.5.2.7 Blood Spots. Each lump or mass of clotted blood greater than $\frac{3}{16}$ inch (0.48 cm) up to and including $\frac{3}{8}$ inch (0.95 cm) in any dimension is an instance. If a blood spot is larger than $\frac{3}{8}$ inch (0.95 cm), each additional $\frac{3}{16}$ (0.48 cm) is another instance.

83.5.2.8 Bruises. Includes distinct, unnatural, dark, reddish, grayish, or brownish off-colors due to diffused blood. Each instance is each bruise larger than $\frac{1}{2}$ square inch (3.32 cm^2) and less than $1\frac{1}{2}$ square inch (9.68 cm^2). For each bruise $1\frac{1}{2}$ square inch (9.68 cm^2) or larger, each additional complete 1 square inch (6.45 cm^2) is another instance.

83.5.2.9 Discoloration. Refers to deviations from reasonably uniform color characteristics of the species used, such as melanin deposits, yellowing, rusting or other kinds of discoloration of the fish flesh.

Moderate. A noticeable but moderate degree that is greater than $\frac{1}{2}$ square inch (3.23 cm^2) up to and including $1\frac{1}{2}$ square inch (9.68 cm^2) is one instance. If the discoloration is greater than $1\frac{1}{2}$ square inch (9.68 cm^2), each additional complete 1 square inch (6.45 cm^2) is another instance.

Excessive. An excessive degree of discoloration that is greater than $\frac{1}{2}$ square inch (3.23 cm^2) up to and including $1\frac{1}{2}$ square inch (9.68 cm^2) is one instance. If the discoloration is greater than $1\frac{1}{2}$ square inch (9.68 cm^2), each additional complete 1 square inch (6.45 cm^2) is another instance.

83.5.2.10 Viscera, Roe, and Lace. Viscera and roe refer to any portion of the internal organs. Each occurrence of viscera and roe is an instance. Lace (frill) is a piece of tissue adhering to the edge of a flatfish (*Pleuronectifonnes*) fillet. For each lace, each $\frac{1}{2}$ inch (1.27 cm) is an instance.

83.5.2.11 Skin. In skinless fish blocks, each piece of skin larger than $\frac{1}{2}$ square inch (3.23 cm^2) up to and including 1 square inch (6.45 cm^2) is an instance. For each piece of skin that is larger than 1 square inch (6.45 cm^2), each additional complete $\frac{1}{2}$ square

inch (3.23 cm^2) in area is another instance. For pieces of skin smaller than $\frac{1}{2}$ square inch (3.23 cm^2), the number of $\frac{1}{2}$ square inch (3.23 cm^2) squares fully or partially occupied after collecting these pieces on a grid is the number of instances.

83.5.2.12 Membrane (Black Belly Lining). Each piece of membrane (black belly lining) larger than $\frac{1}{2}$ square inch (3.23 cm^2) up to and including $1\frac{1}{2}$ square inch (9.68 cm^2) is an instance. For pieces of membrane (black belly lining) that are larger than $1\frac{1}{2}$ square inch (9.68 cm^2), each additional complete $\frac{1}{2}$ square inch (3.23 cm^2) in area is another instance.

83.5.2.13 Scales. For skin-on fillets that have been scaled, an instance is an area of scales over $\frac{1}{2}$ square inch (3.23 cm^2) up to and including $1\frac{1}{2}$ square inch (9.68 cm^2). If the area is greater than $1\frac{1}{2}$ square inch (9.68 cm^2), each additional complete 1 square inch (6.45 cm^2) is another instance. Loose scales are counted and instances are deducted in the same manner as for skinless fillets.

For skinless fillets, the first 5–10 loose scales is an instance. If there are more than 10 loose scales, each additional complete count of five loose scales is another instance.

83.5.2.14 Foreign Material. Any harmless material not derived from fish, such as packaging material. Each occurrence is an instance.

83.5.2.15 Bones. Includes pin bone and fin bone.

1. Each bone defect to a bone or part of a bone whose maximum profile is $\frac{3}{16}$ inch (0.48 cm) or more in length, or at least $\frac{1}{32}$ inch (0.08 cm) in shaft diameter or width, or, for bone chips, a longest dimension of at least $\frac{3}{16}$ inch (0.48 cm).
2. An excessive degree of bone defect is each bone whose maximum profile cannot be fitted into a rectangle, drawn on a flat, solid surface, that has a length of $1\frac{3}{16}$ inch (3.02 cm) and a width of $\frac{3}{8}$ inch (0.95 cm).

83.5.2.16 Fins or Part Fins. This defect refers to two or more bones connected by membrane, including internal or external bones, or both, in a cluster.

Moderate. Connected by membrane in a cluster, no internal bone.

Excessive. Connected by membrane in a cluster with internal bone.

83.5.2.17 Parasites

Metazoan parasites. Each such parasite or fragment of such a parasite that is detected is an instance.

Parasitic copepods. Each such parasite or a fragment of such a parasite that is detected is an instance.

83.5.2.18 Texture. The cooked product should have the textural characteristics of the indicated species of fish. Not included are any abnormal textural characteristics such as mushy, soft, gelatinous, tough, dry or rubbery.

Moderate. Moderately abnormal textural characteristics.

Excessive. Excessively abnormal textural characteristics.

83.6 FROZEN MINCED FISH BLOCKS

83.6.1 Product Description

Frozen minced fish blocks should be uniformly-shaped masses of cohering minced fish flesh, and may contain flesh from a single species or a mixture of species with or without food additives. The minced flesh should consist entirely of mechanically separated fish flesh processed and maintained in accordance with good commercial practice. This minced flesh should be made entirely from species that are known to be safe and suitable for human consumption.

83.6.2 Product Forms

83.6.2.1 Types

Unmodified: No food additives used.

1. Single species.
2. Mixed species.

Modified: Contains food additives

1. Single species.
2. Mixed species.

83.6.2.2 Color Classifications

1. White.
2. Light.
3. Dark.

83.6.2.3 Texture

Coarse. Flesh has a fibrous consistency.

Fine. Flesh has a partially fibrous consistency because it is a mixture of small fibers and paste.

Paste/Puree. Flesh has no fibrous consistency.

83.6.3 Definitions of Defects

83.6.3.1 Deteriorative Color. Discoloration from the normal characteristics of the material used. Deterioration can be due to yellowing of fatty material, browning of blood pigments, or other changes.

Slight deteriorative discoloration. A color defect that is slightly noticeable but does not seriously affect the appearance, desirability, or eating quality of the product.

Moderate deteriorative discoloration. A color defect that is conspicuously noticeable but does not seriously affect the appearance, desirability, or eating quality of the product.

Excessive deteriorative discoloration. A defect that is conspicuously noticeable and that seriously affects the appearance, desirability, or eating quality of the product.

83.6.3.2 Dehydration. A loss of moisture from the surfaces of the product during frozen storage.

Slight dehydration. Surface color masking, affecting more than 5% of the area, which can be readily removed by scraping with a blunt instrument.

Moderate dehydration. Deep color masking penetrating the flesh, affecting less than 5% of the area, and requiring a knife or other sharp instrument to remove.

Excessive dehydration. Deep color masking penetrating the flesh, affecting more than 5% of the area, and requiring a knife or other sharp instrument to remove.

83.6.3.3 Uniformity of Size. The degree of conformity to the declared contracted dimensions of the blocks. A deviation is considered to be any deviation from the contracted length, width, or thickness; or from the average dimensions of the blocks, physically determined, if no dimensions are contracted. Only one deviation from each dimension may be assessed. Two readings for length, three readings for width, and four readings for thickness will be measured.

Slight. Two or more deviations from declared or average length, width, and thickness up to $\pm\frac{1}{8}$ inch.

Moderate. Two or more deviations from declared or average length, width, and thickness from $\pm\frac{1}{8}$ inch to $\pm xx$ inch (variable, depending on products).

Excessive. Two or more deviations from declared or average length, width, and thickness over $\pm\frac{3}{8}$ inch.

83.6.3.4 Uniformity of Weight. The degree of conformity to the declared weight. Only underweight deviations are assessed.

Slight. Any minus deviation of not more than two ounces.

Excessive. Any minus deviation over two ounces.

83.6.3.5 Angles. An acceptable edge angle is an angle formed by two adjoining surfaces of the fish block whose apex is within $\frac{3}{8}$ inch (0.95 cm) of a carpenter's square placed along the surfaces of the block. For each edge angle, three readings will be made and at least two readings must be acceptable for the whole edge angle to be acceptable. An acceptable corner angle is an angle formed by three adjoining surfaces whose apex is within $\frac{3}{8}$ inch (0.95 cm) of the apex of a carpenter's square placed on the edge surfaces. Any edge or corner angle that fails to meet these measurements is unacceptable.

Slight. Two unacceptable angles.

Moderate. Three unacceptable angles.

Excessive. Four or more unacceptable angles.

83.6.3.6 Improper Fill. Surface and internal air or ice voids, ragged edges, or damage. Improper fill is measured as the minimum number of 1-ounce units that would be adversely affected when the block is cut. For this purpose, the dimensions of a 1-ounce unit are $4 \times 1 \times \frac{5}{8}$ inch.

Slight. One to three units adversely affected.

Excessive. More than three units adversely affected.

83.6.3.7 Blemishes. Pieces of skin, scales, blood spots, nape (belly) membranes (regardless of color), or other harmless extraneous material. One instance means that the area occupied by a blemish or blemishes is equal to a $\frac{1}{4}$ inch square. Instances are prorated on a per pound basis.

Slight. Five to 15 instances per pound.

Moderate. More than 15 but less than 30 instances per pound.

Excessive. 30 or more instances per pound.

83.6.3.8 Bones. Any objectionable bone or piece of bone that is $\frac{1}{4}$ inch or longer and is sharp and rigid. Perceptible bones should also be checked by their grittiness during the normal evaluation of the texture of the cooked product. Bones are prorated on a five pound sample unit basis.

Slight. One to two bones per five pound sample unit.

Moderate. Three to four bones per five pound sample unit.

Excessive. More than four bones; but not exceeding 10 bones; per five pound sample unit.

83.6.3.9 Flavor and Odor. Evaluated organoleptically by smelling and tasting the product after it has been cooked.

Good flavor and odor (essential requirements for a Grade A product) means that the cooked product has the flavor and odor characteristics of the indicated species of fish and is free from staleness, bitterness, rancidity, and off-flavors and off-odors of any kind.

Reasonably good flavor and odor (minimum requirements of Grade B product) means that the cooked product is moderately absent of flavor and odor characteristics of the indicated species of fish and is free from staleness, bitterness, rancidity, and off-flavors and off-odors of any kind.

Minimal acceptable flavor and odor (minimum requirements of a Grade C product) means that the cooked product has moderate storage induced flavor and odor, but is free from any objectionable off-flavors and off-odors that may be indicative of spoilage or decomposition.

83.6.3.10 Texture Defects. Judged on a sample of the cooked fish.

Slight. Flesh is fairly firm, only slightly spongy or rubbery. It is not mushy. There is no grittiness due to bone fragments.

Moderate. Flesh is mildly spongy or rubbery. Slight grittiness may be present due to bone fragments.

Excessive. Flesh is definitely spongy, rubbery, very dry, or very mushy. Moderate grittiness may be present due to bone fragments.

83.6.4 Additives

Minced fish blocks may be modified with food additives as necessary to stabilize product quality in accordance with federal requirements.

83.6.5 Hygiene

Fish material should be processed and maintained in accordance with federal requirements.

83.7 FROZEN RAW FISH PORTIONS

83.7.1 Product Description

The product described in this part should be clean, wholesome, shaped masses of cohering pieces (not ground) of fish flesh. The fish portions should be cut from frozen fish blocks, packaged in accordance with good manufacturing practice, and maintained at temperatures necessary for the preservation of the product. All fish portions in an individual package should be prepared from the flesh of one species of fish.

83.7.2 Styles

Style I: Skinless portions. Portions prepared from fish blocks that have been made with skinless fillets.

Style II: Skin-on portions. Portions prepared from fish blocks that have been made from demonstrably acceptable skin-on fillets.

83.7.3 Types

Type I: Uniform shaped. All portions in the sample are uniformly shaped.

Type II: Specialty cut. All portions not covered in Type I.

83.7.4 Definitions of Defects

83.7.4.1 Dehydration. The presence of dehydrated (water-removed) tissue in the portions. Slight dehydration is surface dehydration that is not color masking. Deep dehydration is color masking and cannot be removed by scraping with a blunt instrument.

83.7.4.2 Uniformity of Size. The degree of uniformity in length and width of the frozen portions. Deviations are measured from the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest in the sample.

83.7.4.3 Uniformity of Weight. The degree of uniformity of the weights of portions. Uniformity is measured by the combined weight of the two heaviest portions divided by the combined weight of the two lightest portions in the sample. No deductions are made for weight ratios less than 1.2 for Type I.

83.7.4.4 Blemishes. Skin (except for Style II), blood spots or bruises, objectionable dark fatty flesh, or extraneous material. Instances of blemishes refer to each occurrence measured by placing a plastic grid composed of $\frac{1}{4}$-inch squares (i.e., squares with an

area of $\frac{1}{16}$ square inch) over the defect area. Each square is counted as one whether it is full or fractional.

83.7.4.5 Bones. The presence of potentially harmful bones in a portion. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.

83.7.4.6 Texture Defects. Fish flesh and texture of skin in Style II refers to the absence of the normal textural properties of the cooked fish flesh and to the absence of tenderness of the cooked skin in Style II.

Normal textural properties of cooked fish flesh are tenderness, firmness, and moistness without excess water. Texture defects of the cooked flesh are dryness, mushiness, toughness, and rubberiness. Texture defects of the cooked skin in Style II are mushiness, rubberiness, toughness, and stringiness.

83.7.5 General Definitions

Small (overall assessment) refers to a condition that is noticeable but is only slightly objectionable.

Large (overall assessment) refers to a condition that is not only noticeable but is seriously objectionable.

Minor (individual assessment) refers to a defect that slightly affects the appearance and/or utility of the product.

Major (individual assessment) refers to a defect that seriously affects the appearance and/or utility of the product.

Net weight of the portions, if glazed, should be determined by the following method:

1. Weigh the portions with the glaze intact, which gives the gross weight.
2. Thaw the glaze from the surfaces of the product with flowing tap water.
3. Gently wipe off the excess water from the surfaces with a single water saturated paper towel.
4. Weigh the deglazed portions, which gives the net weight.

83.8 FROZEN RAW BREADED FISH STICKS

83.8.1 Product Description

Frozen raw breaded sticks should be clean, wholesome, rectangular-shaped, unglazed masses of cohering pieces (not ground) of fish flesh coated with breading. The sticks should be cut from frozen fish blocks, coated with a suitably wholesome batter and breading, packaged, frozen in accordance with good commercial practice, and maintained at temperatures necessary for the preservation of the product. Frozen raw breaded fish sticks should weigh up to and including $1\frac{1}{2}$ ounces, be at least $\frac{3}{8}$ inch thick, and their largest dimension be at least three times the next largest dimension. All sticks in an individual package should be prepared from the flesh of one species of fish.

83.8.2 Composition of the Product

Frozen raw breaded fish sticks should contain 72% by weight of fish flesh determined by the official end-product method. Fish flesh content may be determined by the on-line method provided that the results are consistent with the fish flesh content requirement of 72% by weight when verified by the official end-product method. Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any of the factors that may affect the relative fish flesh content.

83.8.3 Definitions

Selection of the sample unit. The sample unit should consist of 10 frozen raw breaded fish sticks taken at random from one or more packages as required. The fish sticks should be spread out on a flat pan or sheet and examined.

83.8.3.1 Examination of Sample, Frozen State

Condition of package. The presence in the package of loose breading and/or loose frost.

Ease of separation. The difficulty of separating sticks from each other or from the packaging material that have frozen together during the freezing.

Broken stick. A stick with a break or cut equal to or greater than one-half of the width of the stick.

Damaged stick. A stick that has been mashed, physically or mechanically injured, misshaped, or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of $\frac{1}{4}$ inch squares (i.e., squares with an area of $\frac{1}{16}$ square inch each) to measure the area of the stick affected. No deductions are made for damage of less than $\frac{1}{16}$ square inch.

Uniformity of size. The degree of uniformity in length and width of the frozen sticks. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest. Deductions are not made for overall deviations in length or width up to $\frac{1}{4}$ inch.

Uniformity of weight. The degree of uniformity of the weights of the sticks. Uniformity is measured by the combined weight of the two heaviest sticks divided by the combined weight of the two lightest sticks in the sample. No deductions are made for weight ratios of less than 1.15.

Cooked state. Is the state of the product after being cooked in accordance with the instructions accompanying the product. However, if specific instructions are lacking, the product for inspection is cooked as follows: the product is transferred while still in a frozen state into a wire-mesh frying basket that is large enough to hold the fish sticks in a single layer. The fish sticks are then cooked by immersing them for 2–3 min in a liquid or hydrogenated cooking oil at a temperature of 375°F (190°C). After cooking, allow the fish sticks to drain for 15 s and place the fish sticks on a paper napkin or towel to absorb excess oil.

83.8.3.2 Examination of Sample, Cooked State

Distortion. Is the degree of bending of the long axis of the stick. Distortion is measured as the greatest deviation from the long axis. Deductions are not made for deviations of less than $\frac{1}{4}$ inch.

Coating defects. Includes breaks, lumps, ridges, depressions, blisters or swells, and curds in the coating of the cooked product.

Breaks in the coating are objectionable bare spots through which the fish flesh is plainly visible.

Lumps are objectionable outcroppings of breading on the stick surface.

Ridges are projections of excess breading at the edges of the fish flesh.

Depressions are objectionable visible voids or shadow areas that are lightly covered by breading.

Blisters are measured by the swelling or exposed area in the coating resulting from the bursting or breaking of the coating.

Curd refers to crater-like holes in the breading filled with coagulated albumin.

Instances of these defects are measured by a plastic grid composed of $\frac{1}{4}$-inch squares ($\frac{1}{16}$ square inch in area). Each square is counted as one whether it is full or fractional.

Blemishes. Skin, blood spots or bruises, objectionable dark fatty flesh, or extraneous material. Instances of blemishes refer to each occurrence measured by placing a plastic grid composed of $\frac{1}{4}$-inch squares ($\frac{1}{16}$ square inch in area) over the defect area. Each square is counted as one whether it is full or fractional.

Bones. The presence of potentially harmful bones in a stick. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.

Texture defects of the coating. Absence of the normal textural properties of the coating, which are crispness and tenderness. Coating texture defects are dryness, sogginess, mushiness, doughiness, toughness, pastiness as sensed by starchiness or other sticky properties felt by mouth tissues and/or mealiness.

Texture defects of the fish. Absence of the normal textural properties of the cooked fish flesh, which are tenderness, firmness, and moistness without excess water. Texture defects of the flesh are dryness, mushiness, toughness, and rubberiness.

83.9 FROZEN RAW BREADED FISH PORTIONS

83.9.1 Product Description

Frozen raw breaded portions should be clean, wholesome, uniformly-shaped, unglazed masses of cohering pieces (not ground) of fish flesh coated with breading. The portions should be cut from frozen fish blocks, coated with a suitably wholesome batter and breading, packaged, frozen in accordance with good commercial practice, and maintained at temperatures necessary for the preservation of the product. Frozen raw breaded fish portions should weigh more than $1\frac{1}{2}$ ounces and be at least $\frac{3}{8}$-inch thick. Frozen raw breaded fish portions should contain not less than 75%, by weight, of fish flesh. All portions in an individual package should be prepared from the flesh of one species of fish.

83.9.2 Styles

Style I: Skinless portions. Portions prepared from fish blocks that have been made with skinless fillets.

Style II: Skin-on-portions. Portions prepared from fish blocks that have been made with demonstrably acceptable skin-on fillets.

83.9.3 Composition of the Product

Frozen raw breaded fish portions should contain 75% by weight of fish flesh. Fish flesh content may be determined by the on-line method provided that the results are consistent with the fish flesh content requirement of 75% by weight when verified by the official end-product method. Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any factors that may affect the relative fish flesh content.

83.9.4 Examination of Sample, Frozen State

Condition of package. The presence in the package of loose breading and/or loose frost.

Ease of separation. The difficulty of separating the portions from each other or from the packaging material.

Broken portion. A portion with a break or cut equal to or greater than one-half the width or length of the portion.

Damaged portion. A portion that has been mashed, physically or mechanically injured, misshaped, or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of $\frac{1}{4}$-inch squares (i.e., squares with an area of $\frac{1}{16}$ square inch each) to measure the area of the portion affected. No deductions are made for damage of less than $\frac{1}{16}$ square inch.

Uniformity of size. The degree of uniformity in length and width of the frozen portions. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest portions in the sample. Deductions are not made for overall deviations in length or width up to $\frac{1}{4}$ inch.

Uniformity of weight. The degree of uniformity of the weights of the portions. Uniformity is measured by the combined weight of the two heaviest portions divided by the combined weight of the two lightest portions in the sample. No deductions are made for weight ratios of less than 1.2.

Cooked state. Is the state of the product after being cooked in accordance with the instructions accompanying the product.

83.9.5 Examination of Sample, Cooked State

Distortion. Is the degree of bending of the long axis of the portion. Distortion is measured as the greatest deviation from the long axis. Deductions are not made for deviations of less than $\frac{1}{4}$ inch.

Coating defects. Includes breaks, lumps, ridges, depressions, blisters or swells, and curds in the coating of the cooked product.

Breaks in the coating are objectionable bare spots through which the fish flesh is plainly visible.

Lumps are objectionable outcroppings of breading on the portion surface.

Ridges are projections of excess breading at the edges of the portions.

Depressions are objectionable visible voids or shadow areas that are lightly covered by breading.

Blisters are measured by the swelling or exposed area in the coating resulting from the bursting or breaking of the coating.

Curd refers to crater-like holes in the breading filled with coagulated white or creamy albumin.

Instances of these defects are measured by a plastic grid composed of $\frac{1}{4}$-inch squares ($\frac{1}{16}$ square inch in area). Each square is counted as one whether it is full or fractional.

Blemishes. Skin (except for Style II), blood spots or bruises, objectionable dark fatty flesh, or extraneous material. Instances of blemishes refer to each occurrence measured by placing a plastic grid composed of $\frac{1}{4}$-inch squares ($\frac{1}{16}$ square inch in area) over the defect area. Each square is counted as one whether it is full or fractional.

Bones. The presence of potentially harmful bones in a portion. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.

Texture defects of the coating. Absence of the normal textural properties of the coating, which are crispness and tenderness. Defects in coating texture are dryness, sogginess, mushiness, doughiness, toughness, pastiness as sensed by starchiness or other sticky properties felt by mouth tissues and/or mealiness.

Texture defects of the fish flesh and texture of skin in Style II. Absence of the normal textural properties of the cooked fish flesh and to the absence of tenderness of the cooked skin in Style II. Normal textural properties of cooked fish flesh are tenderness, firmness, and moistness without excess water. Texture defects of the cooked flesh are dryness, mushiness, toughness, and rubberiness. Texture defects of the cooked skin in Style II are mushiness, rubberiness, toughness, and stringiness.

Minimum fish flesh content–End-product determination. The minimum percent, by weight, of the average fish flesh content of three frozen raw breaded portions (sample unit for fish flesh determination).

83.10 FROZEN FRIED FISH STICKS

83.10.1 Product Description

Frozen fried fish sticks should be clean, wholesome, rectangular-shaped, unglazed masses of cohering pieces (not ground) of fish flesh coated with breading, and partially cooked. The sticks should be cut from frozen fish blocks, coated with a suitably wholesome batter and breading, fried, packaged, frozen in accordance with good manufacturing practices, and maintained at temperatures necessary for the preservation of the product.

Frozen fried fish sticks should weigh up to and including $1\frac{1}{2}$ ounces, be at least $\frac{3}{8}$ inch thick, and their largest dimension be at least three times the next largest dimension. All sticks in an individual package should prepared from the flesh of one species of fish.

83.10.2 Composition of the Product

Frozen fried fish sticks should contain 60% by weight of fish flesh. Fish flesh content may be determined by the on-line method provided that the results are consistent with the fish flesh content requirement of 60 percent by weight when verified by the official end-product method. Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any factors that may affect the relative fish flesh content.

83.10.3 Definitions of Factors for Point Deductions

83.10.3.1 Examination of Sample, Frozen State

Condition of package. The presence in the package of free excess oil and/or loose breading and/or loose frost.

Ease of separation. The difficulty of separating sticks from each other or from the packaging material that have frozen together after the frying operation and during the freezing.

Broken stick. A stick with a break or cut equal to or greater than one-half of the width of the stick.

Damaged stick. A stick that has been mashed, physically or mechanically injured, misshaped, or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of $\frac{1}{4}$-inch squares (i.e., squares with an area of $\frac{1}{16}$ square inch each) to measure the area of the stick affected. No deductions are made for damage of less than $\frac{1}{16}$ square inch.

Uniformity of size. The degree of uniformity in length and width of the frozen sticks. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest. Deductions are not made for overall deviations in length or width up to $\frac{1}{4}$ inch.

Uniformity of weight. The degree of uniformity of the weights of the sticks. Uniformity is measured by the combined weight of the two heaviest sticks divided by the combined weight of the two lightest sticks. No deductions are made for weight ratios of less than 1.15.

Cooked state. Is the state of the product after cooking in accordance with the instructions accompanying the product.

83.10.3.2 Examination of Sample, Cooked State

Distortion. Is the degree of bending of the long axis of the stick. Distortion is measured as the greatest deviation from the long axis. Deductions are not made for deviations of less than $\frac{1}{4}$ inch.

Coating defects. Includes breaks, lumps, ridges, depressions, blisters or swells, and curds in the coating of the cooked product.

Breaks in the coating are objectionable bare spots through which the fish flesh is plainly visible.

Lumps are objectionable outcroppings of breading on the stick surface.

Ridges are projections of excess breading at the edges of the fish flesh.

Depressions are objectionable visible voids or shadow areas that are lightly covered by breading.

Blisters are measured by the swelling or exposed area in the coating resulting from the bursting or breaking of the coating.

Curd refers to crater-like holes in the breading filled with coagulated albumin.

Instances of these defects are measured by a plastic grid composed of $\frac{1}{4}$-inch squares ($\frac{1}{16}$ square inch in area). Each square is counted as one whether it is full or fractional.

Blemishes. Skin, blood spots, or bruises, objectionable dark fatty flesh, carbon specks or extraneous material. Instances of blemishes refer to each occurrence measured by placing a plastic grid composed of $\frac{1}{4}$-inch squares ($\frac{1}{16}$ square inch in area) over the defect area. Each square is counted as one whether it is full or fractional.

Bones. The presence of potentially harmful bones in a stick. A potentially harmful bone is one that after being cooked is capable of piercing or hurting the palate.

Texture defects of the coating. Absence of the normal textural properties of the coating, which are crispness and tenderness. Coating texture defects are dryness, sogginess, mushiness, doughiness, toughness, pastiness as sensed by starchiness or other sticky properties felt by mouth tissues, oiliness to the degree of impairment of texture, and/or mealiness.

Texture defects of the fish flesh. Absence of normal textural properties of the cooked fish flesh, which are tenderness, firmness, and moistness without excess water. Texture defects of the flesh are dryness, softness, toughness, and rubberiness.

83.11 FROZEN FRIED FISH PORTIONS

83.11.1 Product Description

Frozen fried fish portions should be clean, wholesome, uniformly-shaped, unglazed masses of cohering pieces (not ground) of fish flesh coated with breading and partially cooked. The portions should be cut from frozen fish blocks, coated with a suitably wholesome batter and breading, fried, packaged, frozen in accordance with good manufacturing practices, and maintained at temperatures necessary for the preservation of the product. Frozen fried fish portions should weigh more than $1\frac{1}{2}$ ounces and be at least $\frac{3}{8}$ inch thick. All portions in an individual package should be prepared from the flesh of one species of fish.

83.11.2 Composition of the Product

Frozen fried fish portions should contain 65% by weight of fish flesh. Fish flesh content may be determined by the on-line method provided that the results are consistent with

the fish flesh content requirement of 65% by weight when verified by the official end-product method. Production methods employed in official establishments should be kept relatively constant for each production lot so as to minimize variation in any factors that may affect the relative fish flesh content.

83.11.3 Examination of Sample, Frozen State

Condition of package. The presence in the package of free excess oil and/or loose breading and/or loose frost.

Ease of separation. The difficulty of separating portions from each other or from the packaging material that are frozen together after the frying operation and during the freezing.

Broken portion. A portion with a break or cut equal to or greater than one-half of the width or length of the portion.

Damaged portion. A portion that has been mashed, physically or mechanically injured, misshaped, or mutilated to the extent that its appearance is materially affected. The amount of damage is measured by using a grid composed of $\frac{1}{4}$-inch squares (i.e., squares with an area of $\frac{1}{16}$ square inch each) to measure the area of the portion affected. No deductions are made for damage of less than $\frac{1}{16}$ square inch.

Uniformity of size. The degree of uniformity in length and width of the frozen portions. Deviations are measured from the combined lengths of the two longest minus the combined lengths of the two shortest and/or the combined widths of the two widest minus the combined widths of the two narrowest. Deductions are not made for overall deviations in length or width up to $\frac{1}{4}$ inch.

Uniformity of weight. The degree of uniformity of the weights of the portions. Uniformity is measured by the combined weight of the two heaviest portions divided by the combined weight of the two lightest portions. No deductions are made for weight ratios of less than 1.20.

Cooked state. Is the state of the product after cooking in accordance with the instructions accompanying the product.

83.12 FRESH AND FROZEN SHRIMP

83.12.1 Product Description

The products should be clean wholesome shrimp that are fresh or frozen, raw or cooked.

83.12.2 Types

1. Chilled, fresh (not previously frozen).
2. Unfrozen, thawed (previously frozen).
3. Frozen individually (IQF), glazed or unglazed.
4. Frozen solid pack, glazed or unglazed.

83.12.3 Styles

1. Raw (uncoagulated protein).

2. Blanched (parboiled). Heated for a period of time so that the surface of the product reaches a temperature adequate to coagulate the protein.
3. Cooked. Heated for a period of time so that the thermal center of the product reaches a temperature adequate to coagulate the protein.

83.12.4 Market Forms

1. Heads on (head, shell, tail fins on).
2. Headless (only head removed: shell, tail fins on).
3. Peeled, undeveined, round, tail on (all shell removed except last shell segment and tail fins, with segments unslit).
4. Peeled, undeveined, round, tail off (all shell and tail fins removed, with segments unslit).
5. Peeled and deveined, round, tail on (all shell removed except last shell segment and tail fins, with segments shallowly slit to last segment).
6. Peeled and deveined, round, tail off (all shell and tail fins removed, with segments shallowly slit to last segment).
7. Peeled and deveined, fantail or butterfly, tail on (all shell removed except last shell segment and tail fins, with segments deeply slit to last segment).
8. Peeled and deveined, fantail or butterfly, tail off (all shell and tail fin removed, with segments deeply slit to last segment).
9. Peeled and deveined, western (all shell removed except last shell segment and tail fins, with segments split to fifth segment and vein removed to end of cut).
10. Other forms of shrimp as specified and so designated on the label.

83.12.5 Examination of Sample, Frozen State

Dehydration refers to a general drying of the shrimp flesh that is noticeable after any glaze and shell are removed. It includes any detectable change from the normal characteristics of the bright appearance of freshly caught, properly iced or properly processed shrimp.

Slight dehydration. Scarcely noticeable drying of the shrimp flesh that will not affect the sensory quality of the sample.

Moderate dehydration. Conspicuous drying of the shrimp flesh that will not seriously affect the sensory quality of the sample.

Excessive dehydration. Conspicuous drying that will seriously affect the sensory quality of the sample.

83.12.6 Examination, Sample, Fresh or Thawed State

Uniformity of size. The degree of uniformity of the shrimp in the container to determine their conformity to the declared count.

Black spots, improperly headed (throats), and improperly cleaned ends. The presence of any objectionable black or darkened area that affects the desirability or sensory quality of the shrimp, whether the market form is shell-on or peeled. Objectionable black spot refers to more than three instances of penetrating black spot that is visible but difficult to measure because of its small size (approximately the size of a pencil point); any areas larger than a pencil point that penetrates the flesh;

and aggregate areas of non-penetrating surface black spot on the shell or membrane that is equal to or greater than $\frac{1}{3}$ the area of the smallest segment. Assessments are made on individual shrimp. Throats are those portions of flesh and/or extraneous material from the head (cephalothorax) that remain attached to the first segment after heading.

Pieces of shrimp, broken or damaged shrimp

Shrimp pieces. Piece means, for a count of 70 or less unglazed shrimp per pound (0.45 kg), any shrimp that has fewer than five segments (with or without tail fins attached). Also, for a count of more than 70 unglazed shrimp per pound (0.45 kg), any shrimp that has fewer than four segments. Finally, any whole shrimp with a break in the flesh greater than $\frac{2}{3}$ of the thickness of the shrimp where the break occurs.

Broken shrimp. A shrimp having a break in the flesh greater than $\frac{1}{3}$ of the thickness of the shrimp.

Damaged shrimp. A shrimp that is crushed or mutilated so as to materially affect its appearance or usability.

Unusable material

Legs. Walking legs only, whether attached or not attached to the body (heads-on market form excepted).

Loose shell and antennae. Any pieces of shell or antennae that are completely detached from the shrimp.

Flipper. Any detached tail fin with or without the last shell segment attached, with or without flesh inside.

Extraneous material. Any harmless material in a sample unit that is not shrimp material.

Unacceptable shrimp and heads

Unacceptable shrimp. Abnormal or diseased shrimp.

Head. The cephalothorax, except for heads-on shrimp.

Inadvertently peeled and improperly peeled shrimp. The presence or absence of head, shell segment, swimmeret, or tail fin, which should or should not have been removed for certain market forms. (Shell-on shrimp with tail fins and/or telson missing is inadvertently peeled, but if the last segment of flesh is missing, the shrimp is damaged.)

Improperly deveined shrimp. The presence of the dark vein (alimentary canal) containing sand or sediment; or roe that should have been removed from peeled and deveined market forms. For shrimp of 70 count per pound (0.45 kg) or less, aggregate areas of dark vein or roe that are longer than one segment is a defect. For shrimp of 71 to 500 count per pound (0.45 kg), aggregate areas of dark vein or roe that are longer than two segments are a defect. (*Note*: This does not pertain to the last segment. For shrimp of over 500 count per pound (0.45 kg), dark vein or roe of any length is not a defect.)

83.12.7 Examination of Sample, Cooked State

Texture. The texture of cooked shrimp should be firm, slightly resilient but not tough, moist but not mushy. Texture as a defect refers to an undesirable toughness, dryness

or mushiness that deviates from the normal characteristics of the species when freshly caught, properly processed, and cooked.

Slight. Slightly tough, dry, but not mushy.

Moderate. Moderately tough, dry or mushy.

Excessive. Excessively tough, very dry or very mushy.

83.13 FROZEN RAW BREADED SHRIMP

The FDA has provided the following standards for frozen raw breaded shrimp.

83.13.1 Product Description

Frozen raw breaded shrimp should be whole, clean, wholesome, headless, peeled shrimp that have been deveined where applicable for the regular commercial species, coated with a suitably wholesome batter and/or breading. Whole shrimp should consist of five or more segments of unmutilated shrimp flesh. They should be prepared and frozen in accordance with good manufacturing practice and maintained at temperatures necessary for the preservation of the product.

Frozen raw breaded shrimp is the food prepared by coating one of the optional forms of shrimp with safe and suitable batter and breading ingredients. The food is frozen.

Not less than 50% of the breaded product is to be shrimp material as determined by the end product method.

The term shrimp means the tail portion of properly prepared commercial species of shrimp. Except for composite units, each shrimp unit is individually coated. The optional forms of shrimp are as follows.

Fantail or butterfly. Prepared by splitting the shrimp; the shrimp are peeled, except that tail fins remain attached and the shell segment immediately adjacent to the tail fins may be left attached.

Butterfly, tail off. Prepared by splitting the shrimp; tail fins and all shell segments are removed.

Round. Round shrimp, not split; the shrimp are peeled, except that tail fins remain attached and the shell segment immediately adjacent to the tail fins may be left attached.

Round, tail off. Round shrimp, not split; tail fins and all shell segments are removed.

Pieces. Each unit consists of a piece or a part of a shrimp; tail fins and all shell segments are removed.

The above information is categorized as follows.

83.13.2 Styles

Style I: Regular breaded shrimp. Frozen raw breaded shrimp containing a minimum of 50% of shrimp material.

Style II: Lightly breaded shrimp. Frozen raw breaded shrimp containing a minimum of 65% of shrimp material.

83.13.3 Types

Type I: Breaded fantail shrimp.

Subtype A: Split (butterfly) shrimp with the tail fin and the shell segment immediately adjacent to the tail fin.

Subtype B: Split (butterfly) shrimp with the tail fin but free of all shell segments.

Subtype C: Split (butterfly) shrimp without attached tail fin or shell segments.

Type II: Breaded round shrimp.

Subtype A: Round shrimp with the tail fin and the shell segment immediately adjacent to the tail fin.

Subtype B: Round shrimp with the tail fin but free of all shell segments.

Subtype C: Round shrimp without attached tail fin or shell segments.

Type III: Breaded split shrimp.

83.13.4 Definitions and Methods of Analysis

83.13.4.1 Fantail Shrimp. This type is prepared by splitting and peeling the shrimp except that for Subtype A, the tail fin remains attached and the shell segment immediately adjacent to the tail fin remains attached. Subtype B, the tail fin remains, but the shrimp are free of all shell segments. Subtype C, the shrimp are free of tail fins and all shell segments.

83.13.4.2 Round Shrimp. This type is the round shrimp, not split. The shrimp are peeled except that for Subtype A, the tail fin remains attached and the shell segment immediately adjacent to the tail fin remains attached. Subtype B, the tail fin remains, but the shrimp are free of all shell segments. Subtype C, the shrimp are free of all shell segments and tail fins.

83.13.4.3 Composite Units. Each unit consists of two or more whole shrimp or pieces of shrimp, or both, formed and pressed into composite units prior to coating; tail fins and all shell segments are removed; large composite units, prior to coating, may be cut into smaller units.

The batter and breading ingredients referred to are the fluid constituents and the solid constituents of the coating around the shrimp. These ingredients consist of suitable substances that are not food additives as defined by regulations. If they are food additives, as so defined, they are used in conformity with established regulations of the U.S. Food and Drug Administration. Batter and breading ingredients that perform a useful function are regarded as suitable, except that artificial flavorings, artificial sweeteners, artificial colors, and chemical preservatives, other than those specifically permitted, are not suitable ingredients for frozen raw breaded shrimp. Chemical preservatives that are suitable are:

1. Ascorbic acid, which may be used in a quantity sufficient to retard development of dark spots on the shrimp.
2. The antioxidant preservatives that may be used to retard the development of rancidity of the fat content of the food, in amounts within the limits prescribed by U.S. regulations.

The label should name the food, as prepared from each of the optional forms of shrimp specified, and following the numbered sequence of the following data.

1. "Breaded fantail shrimp." The word "butterfly" may be used in lieu of "fantail" in the name.
2. "Breaded butterfly shrimp, tail off."
3. "Breaded round shrimp."
4. "Breaded round shrimp, tail off."
5. "Breaded shrimp pieces."
6. Composite units.

If the composite units are in a shape similar to that of breaded fish sticks the name is "Breaded shrimp sticks"; if they are in the shape of meat cutlets, the name is "Breaded shrimp cutlets."

If prepared in a shape other than that of sticks or cutlets, the name is "Breaded shrimp _____," the blank to be filled in with the word or phrase that accurately describes the shape, but which is not misleading.

The word "prawns" may be added in parentheses immediately after the word "shrimp" in the name of the food if the shrimp are of a large size (e.g., "Fantail breaded shrimp (prawns)"). If the shrimp are from a single geographical area, the adjectival designation of that area may appear as part of the name (e.g., "Breaded Alaskan shrimp sticks").

The names of the optional ingredients used should be listed on the principal display panel or panels of the label with such prominence and conspicuousness as to render them likely to be read and understood by the ordinary individual under customary conditions of purchase. If a spice that also imparts color is used, it should be designated as "spice and coloring," unless the spice is designated by its specific name. If ascorbic acid is used to retard development of dark spots on the shrimp, it should be designated as "Ascorbic acid added as a preservative" or "Ascorbic acid added to retard discoloration of shrimp."

If any other antioxidant preservative is used, such preservative should be designated by its common name followed by the statement "Added as a preservative."

Frozen raw lightly breaded shrimp complies with the provisions of frozen raw breaded shrimp except that it contains not less than 65% of shrimp material and that in the name prescribed the word "lightly" immediately precedes the words "breaded shrimp."

83.13.5 Factors Evaluated on Unbreaded or Thawed Debreaded Product

Factors affecting qualities that are measured on the product in the unbreaded or thawed debreaded state are degree of deterioration, dehydration, sand veins, black spot, extra shell, extraneous material, and swimmerets.

1. *Dehydration*. The occurrence of whitish areas on the exposed ends of the shrimp (due to the drying of the affected area) and to a generally desiccated appearance of the meat after the breading is removed.

2. *Deterioration*. Any detectable change from the normal good quality of freshly caught shrimp. It is evaluated by noting in the thawed product deviations from the normal odor and appearance of freshly caught shrimp.
3. *Extraneous material*. Consists of nonedible material such as sticks, seaweed, shrimp thorax, or other objects that may be accidentally present in the package.
4. *Slight*. A condition that is scarcely noticeable but does affect the appearance, desirability, and/or eating quality of breaded shrimp.
5. *Moderate*. A condition that is conspicuously noticeable but that does not seriously affect the appearance, desirability, and/or eating quality of the breaded shrimp.
6. *Marked*. A condition that is conspicuously noticeable and that does seriously affect the appearance, desirability, and/or eating quality of the breaded shrimp.
7. *Excessive*. A condition that is very noticeable and is seriously objectionable.
8. *Halo*. An easily recognized fringe of excess batter and breading extending beyond the shrimp flesh and adhering around the perimeter or flat edges of a split (butterfly) breaded shrimp.
9. *Balling up*. The adherence of lumps of the breading material to the surface of the breaded coating, causing the coating to appear rough, uneven, and lumpy.
10. *Holidays*. Voids in the breaded coating as evidenced by bare or naked spots.
11. *Damaged frozen raw breaded shrimp*. Frozen raw breaded shrimp that have been separated into two or more parts or that have been crushed or otherwise mutilated to the extent that their appearance is materially affected.
12. *Black spot*. Any blackened area that is markedly apparent on the flesh of the shrimp.
13. *Sand vein*. Any black or dark sand vein that has not been removed, except for that portion under the shell segment adjacent to the tail fin when present.
14. *Extra shell*. Any shell segment(s) or portion thereof, contained in the breaded shrimp except the first segment adjacent to the tail fin for Type I, Subtype A, and Type II, Subtype A.

83.14 FROZEN RAW SCALLOPS

83.14.1 Product Description

Frozen raw scallops should be clean, wholesome, adequately drained, whole or cut adductor muscles of the scallop of the regular commercial species. The portion of the scallop used should be only the adductor muscle eye, which controls the shell movement. Scallops should be washed, drained, packed, and frozen in accordance with good manufacturing practice and maintained at temperatures necessary for the preservation of the product. Only scallops of a single species should be used within a lot.

83.14.2 Styles

Style I: Solid pack scallops. Scallops that are frozen together into a solid mass and are either glazed or not.

Style II: Individually quick frozen (IQF) pack. These scallops are individually quick frozen enabling individual scallops to be separated without thawing and are either glazed or not.

83.14.3 Types

Type 1: Adductor muscle.

Type 2: Adductor muscle with catch (gristle or sweet meat) portion removed.

83.14.4 Definitions

Dehydration. The loss of moisture from the scallops surface during frozen storage. A small degree of dehydration is color-masking but can be easily scraped off. A large degree of dehydration is deep, color-masking, and requires a knife or other instrument to scrape it off.

Extraneous materials. Pieces or fragments of undesirable material that are naturally present in or on the scallops, which should be removed during processing.

Minor. An instance of minor extraneous material includes, but is not limited to, each occurrence of intestines, seaweed, and so on, and each aggregate of sand and grit up to $\frac{1}{2}$-inch square and located on the scallop surface. Deduction points should be assessed for additional instances of intestines, seaweed, and so on, and aggregates of sand and grit up to $\frac{1}{2}$-inch square.

Major. An instance of major extraneous material includes, but is not limited to, each instance of shell or aggregate of embedded sand or other extraneous embedded material that affects the appearance or eating quality of the product.

Texture. The firmness, tenderness, and moistness of the cooked scallop meat, which is characteristic of the species.

Net weight. The total weight of the scallop meats within the package after removal of all packaging materials, ice glaze, or other protective materials.

83.15 FROZEN RAW BREADED SCALLOPS AND FROZEN FRIED SCALLOPS

83.15.1 Product Description

83.15.1.1 Frozen Raw Breaded Scallops. Frozen raw breaded scallops should be:

1. Prepared from wholesome, clean, adequately drained, whole or cut adductor muscles of the scallop of the regular commercial species, or scallop units cut from a block of frozen scallops that are coated with wholesome batter and breading.
2. Packaged and frozen according to good commercial practice and maintained at temperatures necessary for preservation.
3. Composed of a minimum of 50% by weight of scallop meat.

83.15.1.2 Frozen Fried Scallops. Frozen fried scallops should be:

1. Prepared from wholesome, clean, adequately drained, whole or cut adductor muscles of the scallop of the regular commercial species, or scallop units cut from a block of frozen scallops that are coated with wholesome batter and breading.

2. Precooked in oil or fat.
3. Packaged and frozen according to good commercial practice and maintained at temperatures necessary for preservation.
4. Composed of a minimum of 50% by weight of scallop meat.

83.15.2 Styles

The styles of frozen raw breaded scallops and frozen fried scallops include:

Style I: Random pack. Scallops in a package are reasonably uniform in weight and/or shape. The weight or shape of individual scallops is not specified.

Style II: Uniform pack. Scallops in a package consist of uniformly shaped pieces that are of a specified weight or range of weights.

83.15.3 Types

Type 1: Adductor muscle.

Type 2: Adductor muscle with catch (gristle or sweet meat) portion removed.

83.15.4 Definitions

Appearance. The condition of the package and ease of separation in the frozen state and continuity and color in the cooked state.

Condition of the package. Freedom from packaging defects and the presence in the package of oil, and/or loose breading, and/or frost. Deduction points are based on the degree of the improper condition as small or large.

Ease of separation. The difficulty of separating scallops that are frozen together after the frying operation and during freezing.

Continuity. The completeness of the coating of the product in the cooked state. A lack of continuity is exemplified by breaks, ridges, and/or lumps of breading. Each $\frac{1}{16}$ square inch area of any break, ridge, or lump of breading is considered an instance of lack of continuity. Individual breaks, ridges, or lumps of breading measuring less than $\frac{1}{16}$ square inch are not considered objectionable. Deduction points are based on the percentage of the scallops within the package that contain small and/or large instances of a lack of continuity.

83.15.5 Workmanship Defects

Workmanship defects refer to the degree of freedom from doubled and misshaped scallops and extraneous material. The defects of doubled and misshaped scallops are determined by examining the frozen product, while the defects of extraneous materials are determined by examining the product in the cooked state. Deduction points are based on the percentage by count of the scallops affected within the package.

Doubled scallops. Two or more scallops that are joined together during the breading and/or frying operations.

Misshaped scallops. Elongated, flattened, mashed, or damaged scallop meats.

Extraneous material. Pieces or fragments of undesirable material that are naturally present in or on the scallops, which should be removed during processing.

Minor. Includes intestines, seaweed, and each aggregate of sand and grit within an area of $\frac{1}{2}$-inch square.

Major. Includes shell, aggregate of embedded sand or other extraneous embedded material that affects the appearance or eating quality of the product.

83.15.6 Texture in the Cooked State

83.15.6.1 Texture of the Coating

Firm or crisp, but not tough, pasty, mushy, or oily.

Moderately tough, pasty, mushy, or oily.

Excessively tough, pasty, mushy, or oily.

83.15.6.2 Texture of the Scallop Meat

Firm, but tender and moist.

Moderately tough, dry, and/or fibrous or mushy.

Excessively tough, dry, and/or fibrous or mushy.

83.15.7 Character

Character refers to the texture of the scallop meat and of the coating and the presence of gristle in the cooked state.

Gristle. Gristle (type 2 only) is the tough elastic tissue usually attached to the scallop meat. Each instance of gristle is an occurrence.

Texture. The firmness, tenderness, and moistness of the cooked scallop meat and the crispness and tenderness of the coating of the cooked product. The texture of the scallop meat may be classified as a degree of mushiness, toughness, and fibrousness. The texture of the coating may be classified as a degree of pastiness, toughness, dryness, mushiness, or oiliness.

83.16 NORTH AMERICAN FRESHWATER CATFISH AND CATFISH PRODUCTS

83.16.1 Scope and Product Description

The descriptions apply to products derived from farm-raised, or from rivers and lakes, North American freshwater catfish of the following common commercial species and hybrids thereof:

1. Channel catfish (*Ictalurus punctatus*).
2. White catfish (*Ictalurus catus*).
3. Blue catfish (*Ictalurus furcatus*).
4. Flathead catfish (*Pylodictis olivaris*).

Fresh products should be packaged in accordance with good commercial practices and maintained at temperatures necessary for the preservation of the product. Frozen products should be frozen to 0°F (−18°C) at their center (thermal core) in accordance with good commercial practice and maintained at a temperature of 0°F (−18°C) or less.

The product may contain bones when the principle display panel clearly shows that the product contains bones.

83.16.2 Product Presentation

Catfish products may be presented and labeled as follows:

83.16.2.1 Types

1. Fresh.
2. Frozen.

83.16.2.2 Styles

1. Skin on.
2. Skinless.

83.16.2.3 Market Forms. These include, but are not limited to, the following:

1. Headed and gutted.
2. Headed and dressed are headed and gutted usually with the fins removed. This form may be presented with or without the dorsal spine and with or without the collar bone.
3. Whole fillets are practically boneless pieces of fish cut parallel to the entire length of the backbone with the belly flaps and with or without the black membrane.
4. Trimmed fillets are whole fillets without belly flaps.
5. Fillet strips are strips of fillets weighing not less than $\frac{3}{4}$ ounce.
6. Steaks are units of fish not less than $1\frac{1}{2}$ ounces in weight that are sawn or cut approximately perpendicular (30 degrees to 90 degrees) to the axial length or backbone. They should have two reasonably parallel surfaces. The number of tail sections that may be included in the package must not exceed the number of fish cut per package.
7. Nuggets are pieces of belly flaps with or without black membrane and weighing not less than $\frac{3}{4}$ ounce.

83.16.2.4 Bone Classifications

1. Practically boneless fillet.
2. Bone-in (fillet cut, with bones).

83.16.3 Definitions

Dehydration applies to all frozen market forms. It refers to the loss of moisture from the surface resulting in a whitish, dry, or porous condition.

Slight. Surface dehydration that is not color masking (readily removed by scraping) and affecting 3–10% of the surface area.

Moderate. Deep dehydration that is color masking, cannot be scraped off easily with a sharp instrument, and affects more than one percent but not more than 10% of the surface area.

Excessive. Deep dehydration that is color masking, and cannot be easily scraped off with a sharp instrument and affects more than 10% of the surface area.

Condition of the product applies to all market forms. It refers to freedom from packaging defects, cracks in the surface of a frozen product, and excess moisture (drip) or blood inside the package. Deduction points are based on the degree of these defects.

Slight. A condition that is scarcely noticeable but does not affect the appearance, desirability or eating quality of the product.

Moderate. A condition that is conspicuously noticeable but does not seriously affect the appearance, desirability, or eating quality of the product.

Excessive. A condition that is conspicuously noticeable and does seriously affect the appearance, desirability or eating quality of the product.

Discoloration applies to all market forms. It refers to colors that are not normal to the species. This may be due to mishandling or the presence of blood, bile, or other substances.

Slight. From $\frac{1}{16}$ square inch up to and including one square inch in aggregate area.

Moderate. Greater than one square inch up to and including two square inches in aggregate area.

Excessive. Over two square inches in aggregate area. Also, each additional complete one square inch is again assessed for points under this category.

Uniformity will be assigned in accordance with weight tolerances as follows (weight of portion: 0.75 to 4.16 ounces):

Moderate. Over $\frac{1}{8}$ ounce but not over $\frac{1}{4}$ ounce above or below declared weight of portion.

Excessive. In excess of $\frac{1}{4}$ ounce above or below declared weight of portion 4.17 to 11.20 ounces.

Moderate. Over $\frac{1}{8}$ ounce but not over $\frac{1}{2}$ ounce above or below declared weight of portion.

Excessive. In excess of $\frac{1}{2}$ ounce above or below declared weight of portion 11.21 to 17.30 ounces.

Moderate. Over $\frac{1}{8}$ ounce but not over $\frac{1}{8}$ ounce above or below declared weight of portion.

Excessive. In excess of $\frac{1}{8}$ ounce above or below declared weight of portion.

Skinning cuts apply to skinless market forms. It refers to improper cuts made during the skinning operation as evidenced by torn or ragged surfaces or edges, or gouges in the flesh that detract from a good appearance of the product.

Slight. From $\frac{1}{16}$ square inch up to and including one square inch in aggregate area.

Moderate. Over one square inch up to and including two square inches in aggregate area.

Excessive. Over two square inches in aggregate area. Also, each additional complete one square inch is again assessed for points under this category.

Heading applies to the presence of ragged cuts or pieces of gills, gill cover, pectoral fins or collar bone after heading. Deduction points will also be assigned when the product is presented with the collar bone and it has been completely or partially removed.

Slight. From $\frac{1}{16}$ square inch up to and including one square inch in aggregate area.

Moderate. Over one square inch up to and including two square inches in aggregate area.

Excessive. Over two square inches in aggregate area. Also, each additional complete one square inch is again assessed for points under this category.

Evisceration applies to all market forms. It refers to the proper removal of viscera, kidney, spawn, blood, reproductive organs, and abnormal fat (leaf). The evisceration cut should be smooth and clean. Deduction points are based on the degree of defect.

Slight. $\frac{1}{16}$ square inch up to and including one square inch in aggregate area.

Moderate. Over one square inch up to and including two square inches in aggregate area.

Excessive. Over two square inches in aggregate area. Also, each additional complete one square inch is again assessed for points under this category.

Fins refer to the presence of fins, pieces of fins or dorsal spines. It applies to all market forms except headed and gutted or headed and dressed catfish or catfish steaks. Deduction points will also be assigned when the product is intended to have the dorsal spine but it has been completely or partially removed.

Slight. Aggregate area up to and including one square inch.

Moderate. Over one square inch area up to and including two square inches.

Excessive. Over two square inches in aggregate area. Also, each additional complete one square inch is again assessed for points under this category.

Bones (including pin bone) apply to all fillet and nugget market forms. Each bone defect is a bone or part of a bone that is $\frac{3}{16}$ inch or more at its maximum length or $\frac{1}{32}$ inch or more at its maximum shaft width, or for bone chips, a length of at least $\frac{1}{16}$ inch. An excessive bone defect is any bone that cannot be fitted into a rectangle, which has a length of $1\frac{9}{16}$ inch and a width of $\frac{1}{8}$ inch. In market forms intended to contain bones, the presence of bones will not be considered a physical defect.

Skin refers to the presence of skin on skinless market forms. For semi-skinned forms, a skin defect is the presence of the darkly pigmented outside layers. Points will be assessed for each aggregate area greater than $\frac{1}{2}$ square inch up to and including one square inch.

Bloodspots refer to the presence of coagulated blood.

Bruises refer to softening and discoloration of the flesh. Both bloodspots and bruises apply to all market forms. Points will be assessed for each aggregate area of bloodspots or bruises greater than $\frac{1}{2}$ square inch up to and including one square inch.

Foreign material refers to extraneous material, including packaging material, not derived from the fish that is found on or in the sample. Each occurrence will be assessed.

Texture applies to all market forms and refers to the presence of normal texture properties of the cooked fish flesh, that is, tender, firm, and moist without excess water. Texture defects are described as dry, tough, mushy, rubbery, watery, and stringy.

Moderate. Noticeably dry, tough, mushy, rubbery, watery, stringy.

Excessive. Markedly dry, tough, mushy, rubbery, watery, stringy.

84.1 INTRODUCTION

Fish and shellfish are perishable and easily spoil after harvesting due to postmortem chemical, physical, bacteriological, and histological changes. These degradation processes are usually accompanied by the gradual loss or development of different compounds that affect fish quality. The quality changes are highly affected by many factors, the most important of which is temperature. If fresh fish is not properly stored, exposure to ambient temperature can cause serious deterioration in fish quality. Commercially, icing or chilling continues to play a major role in slowing down bacterial and enzymatic

degradation of fish muscle. However, this process is not designed to eliminate totally the changes in quality, since it only offers protection for 2–3 weeks, depending on the species.

Freezing of food is an excellent method of preservation with wide applications. Freezing inhibits the growth of food spoilage and pathogenic organisms, and the low storage temperature greatly slows down the enzymatic and biochemical reactions that normally occur in unfrozen foods. It accomplishes these objectives in two ways: (1) by lowering the temperature of food, and (2) the removal of water by converting it into ice. Lowering the temperature to below freezing point inhibits the growth and activity of many but not all microorganisms and endogenous enzymes. Converting most of the water into ice with the concomitant increase in concentration of dissolved substances reduces the water activity of food to the point where no microorganisms can grow. Although biochemical reactions slow down at lower temperature, they still, unlike microbiological activities, progress even at low storage temperatures in some commercial freezer. In addition, conversion of water into ice initiates complex physical and physicochemical changes that can cause general deteriorative quality changes not ordinarily occurring in fresh foods. Pretreatments such as blanching, cooling, and so on, freezing, and storage conditions should therefore be carefully and individually selected for each product to minimize the effect of these deteriorative reactions.

In most commercial frozen foods, water, major component, in the tissue dissolves soluble cell components, while a small part is bound up in hydrates and in macromolecular colloidal complexes. In addition, most of the aqueous solution is part of the gel like or fiber like structures in the cell. The most obvious change that occurs on freezing is the solidification of water, which means that water is removed from its normal position within the tissues. It appears that removal of water from its normal position is only partly reversible upon thawing, leading to drip (exudate from thawed tissue) and other changes. It is very difficult to practically distinguish from superficial moisture or glaze and sometimes enhances susceptibility of microorganism invasion through the moist surfaces during thawing. Conversion of water into ice increases: the concentration of soluble cell components (in some cases to the point where they become saturated and precipitate), changes the pH of the aqueous solution, and consequently affects the amount of water that is involved in the colloidal complexes and in the gel-like and fiber-like structures. The concentrated cell components lead to a high concentration of electrolytes, some of which interpose themselves in the polypeptide chains of proteins, leading to protein denaturation. In living cells, this often leads to death (e.g., freezing and frozen storage causes a slight reduction in numbers of most microorganisms), but in foods, which usually consist of dead tissue prior to freezing, it can lead, during storage, to irreversible changes in texture (e.g., toughness in fish) and to undesirable biochemical reactions (enzymatically produced off-flavors). An understanding of freezing, therefore, involves physical, physicochemical, and biochemical aspects.

As mentioned above, freezing is an excellent process for keeping the original quality of foods, such as long term stored fish (commercially, up to 12 months or more). Freezing and subsequent frozen storage are particularly useful in making seasonal species of fish, like herring and mackerel, available all year round. In addition, freezing preservation is also applied in a number of different products made from various fish species. For example, tuna is frozen on board in the large commercial fishing vessels, brought to land, and then thawed for canning. In the production of various value-added fish products, freezing is applied to breaded and battered fish sticks, fillets, steaks, or nuggets. Likewise, high-quality fish are usually filleted, frozen, and eventually sold to consumers.

Ideally, there should be no distinguishable differences between fresh fish and frozen fish after thawing. If kept under appropriate conditions, fish in the frozen state can be

stored for several months or longer without appreciable changes in quality. However, it is now well recognized that deteriorative changes take place in fish and seafood during freezing, frozen storage, and thawing, which influence the quality of final products. Considerably more knowledge of the basic structure of fish muscle and its chemical composition are essential to the understanding of these changes occurred during processing.

84.2 NATURE OF FISH MUSCLE

Fish muscle has a unique arrangement of muscle fibers. It is divided into a number of segments called myotomes, which are separated from one another by a thin sheath of connective tissue called the myocomma or myoseptum. The number of myotomes in fish is dependent on the size of fish, while their diameters vary from head to tail (Love 1958). There are two major types of fish skeletal muscles, white and red. The red or dark muscle lies along the side of the body next to the skin, particularly along the lateral lines, and may comprise up to 30% of fish muscle, depending on the species (Green-Walker and Pull 1975).

Cells in red or dark muscle contain more lipids than that in white muscle (Buttkus and Tomlinson 1966; George 1962). They are basically employed for sustained swimming activities, functioning aerobically using lipids for fuel. In addition, red muscle has more mitochondria but less sarcoplasmic reticulum than white muscle (Patterson and Goldspink 1973). It has a large supply of oxygen and a high content of myoglobin, the colored compound that gives its red color. These characteristics, coupled with the presence of the large amount of lipid, particularly among the fatty species, present a serious problem of preservation because of increased susceptibility of this muscle to lipid oxidation. The red muscle of some species has also been reported to contain enzymes that are responsible for chemical reactions such as lipid oxidation and the conversion of trimethylamine oxide (TMAO) to dimethylamine (DMA) and formaldehyde (FA) (Castells and others 1973a,b; Dyer and Hiltz 1974). The shape of red muscle area in different species varies considerably. Lean fish such as flounder, hake, sole, cod, pollock, and whiting have a very small amount of red muscle, which lies along the fish skin, whereas the fatty and semifatty fish species have larger areas of red muscle.

White muscle, on the other hand, constitutes the majority of fish muscle. Unlike red muscle, it has minimal myoglobin and a restricted blood supply. It is often referred to as the fast tissue (Shewfelt 1980).

Intermediate between these two types of muscle is intermixed red and white muscle, commonly referred to as "mosaic" muscle (Boddeke and others 1959). In some fish, this is a thin layer of muscle that separates the red from white muscle. However, in other fish, such as salmon, carp, and trout, this muscle is scattered throughout the body of the fish.

The chemical composition of fish varies depending on several factors, such as age, species, gender, maturity, method of catch, fishing grounds, and other seasonal and biological factors. Even within the same species, chemical composition may vary significantly. Generally, fish contain a considerable amount of protein, lipid, and water and small amounts of vitamins and minerals. Other components such as nonprotein nitrogenous compounds are also present in the muscle. These include urea, taurine, peptides, free amino acids, and nucleotides such as inosine and hypoxanthine (Konosu and others 1974).

These compounds, together with the macronutrients found in fish muscle, may be particularly important to fish processors, since they are frequently used as spoilage indices.

84.3 PREPARATION OF SEAFOOD BEFORE FREEZING

Most foods and food products are susceptible to attack by microorganisms and they are always contaminated by a variety of such organisms present in the food production chain. Foodstuffs are subjected to further contamination during preparation for freezing as a result of contact with the hands of factory staff during preparation, packaging and transport, and with air or water.

In view of the hazards to health and the effect of microbial contamination on quality, every effort must be made to reduce such contamination to a reasonable level during the preparation of foodstuffs for freezing. Throughout the world, frozen foods have very seldom been the cause of food poisoning incidents.

As pathogenic bacteria like *Salmonella* spp. and *Staphylococcus* spp. frequently derive from human sources, it is of vital importance that factory employees are aware of the basic concepts of good personal hygiene – the need for frequent washing and the wearing of clean clothes, overalls, hair covering, and so on. The use of rubber gloves and a protective mask for the mouth may be desirable in some instances. When gloves are worn they must be thoroughly cleaned and inspected before use. Medical supervision is advisable and in some cases should be made compulsory. Notices in lavatories should draw attention to personal hygiene, especially, the need for hand washing. Soaps, hand creams or dips containing antiseptic agents should be readily available.

Design of the building should ensure that both the buildings and drains are vermin proof. Interior walls, floor and ceilings should be finished with a nonflaking surface capable of withstanding detergents and sanitizers. All corners should be rounded to facilitate cleaning. The building should be large enough to house production equipment so that all sides of the equipment are accessible for cleaning. Entrance to the process area should be supplied with adequate washing facilities with foot-operated taps. Wood, almost impossible to sanitize, should not be used in contact with food. All windows should be both bird and fly proof.

Equipment usually becomes soiled with organic residues, which act as carriers of microorganisms. It should be designed and constructed to prevent hygienic hazard and permit easy and thorough cleaning. All surfaces should have a smooth, hard, waterproof finish. Cutting boards should be of a hard material; plastic is preferable to wood. Cleaning and disinfection of the food handling area, including equipment and utensils, should be carried out at frequent and regular intervals.

Waste materials should be frequently removed, in covered containers, from the working area during factory operation. Processes should be so separated – either in space or time – as to avoid recontamination of products in which the bacterial load has already been reduced. For cleaning purposes, an ample supply of potable water should be available. Chlorinated water is effective both for in-plant use (when concentrations of around 5–10 ppm are appropriate) and for sanitation of equipment and surfaces (when concentrations of around 100–200 ppm are used) but this should be followed by a rinse. Organic residues inactivate chlorine which, therefore, should only be used to sterilize already clean surfaces. Chlorine can be responsible for flavour loss or taint (due to the formation of chloramines or chlorophenols). Removal of the chlorine (by thiosulfate

addition, often combined with treatment in activated carbon towers) is practiced, especially in ice cream producing plants.

During the preparation of food for freezing, all efforts should be taken to avoid a build-up of an undesirable microbial population. For some foods, handling should take place at subambient temperature in temperature-regulated rooms, and where a heat treatment is a part of the processing this should be so severe that most of the microorganisms are killed. After heat treatment, the food should be promptly cooled to avoid multiplication of the surviving bacteria in the critical zone between 50° and 10°C. Cooling water, if used, should be chlorinated.

Proper organization of the various processes from the hygienic point of view is essential and a constant watch should be kept for lapses in hygiene. This should include a bacteriological control of the various stages in the processing line. Bacteriological methods are now available that give a good estimate of the bacterial load of the raw material and of food contact surfaces. Methods that give a rapid result are especially useful, as they supply plant management with information on the bacteriological state of products actually under preparation. The results of the examinations should be shown to the factory staff in order to make them comprehend the vital importance of hygiene in food production. Preferably, courses in food hygiene should be held at regular intervals for employees. The aim should be to give those engaged, in food production a thorough understanding of the hazard involved. The above considerations concerning personal hygiene, equipment, and preparation of foods also applies to handling of frozen foods in catering establishments. Thawing of frozen foods in these establishments should be completed as quickly as possible, and any storage of the food after thawing should be in a refrigerator.

84.4 FREEZING

Freezing is simply the crystallization of ice in muscle tissue and includes the consecutive processes of nucleation and growth. These processes are central to the effects of different freezing rates and subsequent effects on meat quality. Meat does not freeze immediately when its temperature drops below the freezing point and the latent heat (i.e., heat required during the phase change during crystal formation) has been removed. In other words there is a degree of supercooling. The greater the supercooling, the greater the number of nuclei formed. The number of nuclei is greatest in the extracellular space, and they are only formed within the cell when the rate of heat removal is higher. As soon as the nuclei form, they begin to grow by the accumulation of molecules at the solid/liquid interface. However, the way they grow depends on the microgeometry and the temperature distribution ahead of the freezing front, in a complex way, as a consequence of dendrite formation with supercooling in front of the dendrite growth. An important concept is characteristic freezing time, which is a measure of the local freezing rate and is defined as the time during which the point under consideration decreases from -1°C (freezing commences) to -7°C (when 80% of the water is frozen). The growth of extracellular ice crystals also takes place at the expense of intracellular water. This leads to partial dehydration of the muscle fibers and subsequent distortion. At high characteristic times (slow freezing), the ice crystals are larger and the tissue distortion is greater. The freezing process can rapidly minimize physical, biochemical, and microbiological changes in the food. This preservative effect is maintained by subsequent storage of the frozen food at a sufficiently cold temperature.

84.4.1 Freezing Process

The freezing process can be divided into three stages:

Stage 1: Cooling down from the initial temperature of the product to the temperature at which freezing begins. It must be borne in mind that the act of placing a product in a freezing apparatus does not render it "safe." Time will elapse before warm food passes out of the microbiologically hazardous temperature zone; this is particularly the case if freezing is carried out in slowly-moving air as in the freezing in bulk of products such as berries for subsequent jam manufacture.

Stage 2: This step covers the formation of ice in the products and extends from the initial freezing point to a temperature about $-5^{\circ}C$ colder at the center of the product. The major part of the freezable water will be converted to ice and this quite small reduction in temperature is accompanied by a massive enthalpy change.

Stage 3: Cooling down to the ultimate temperature for storage. When leaving the freezer, the frozen product will have a nonuniform temperature distribution; warmer in the center and coldest at the surfaces. Its average temperature will correspond to the value reached when the temperature of the product is allowed to equalize. In general, it is recommended to cool the product in the freezer to an equilibrium temperature of $-18^{\circ}C$ or colder. Product leaving the freezer with a warmer temperature will be stored for some time in relatively unfavorable conditions. Cooling down to storage temperature may take days or weeks.

84.4.2 Freezing Time

The effective freezing time is determined by (1) the initial and final temperature of the product and its change in enthalpy, and (2) the temperature of the heat transfer medium. The dimensions (especially the thickness) and shape of the product unit affect the overall heat transfer, which includes the surface heat transfer coefficient α and the heat conductivity λ characteristic of the product. When freezing by air blast α depends on the air velocity and the shape of the product. In an air blast freezer, the rate of freezing increases with increasing air velocity to an optimum value. The refrigeration load necessary to remove the heat produced by the fans increases with the cube of the air velocity; this factor should be taken into consideration when designing air blast freezers. It is important to direct the air circulation in such a way that the all product is equally exposed to the air current. In packaged food, the packaging material presents a resistance to the heat transfer, depending on its thickness and conductivity. This resistance is increased considerably if air is trapped between the package and the product.

Kato (1984) demosntrated the freezing time as a function of the thickness of fish fillets in packages frozen in a plate freezer ($\alpha = 200\ \mathrm{kcal/m^2 \cdot ^{\circ}C}$ including the packaging) and in a blast freezer with medium air velocity, $\alpha = 20\ \mathrm{kcal/m^2 \cdot ^{\circ}C}$) with heat removed from both sides of the package. A temperature of $-30^{\circ}C$ is assumed for the cooling medium (air, cold plates) and the process is considered to be complete when a temperature at the thermal center of $-15^{\circ}C$ is reached. The total freezing time is divided into two parts, one due to the influence of the internal conduction resistance ("λ-infl."), the other to the surface heat resistance, including package ("α-infl."). During plate freezing the heat conductivity of the product is the main factor determining freezing time. During air freezing the heat resistance of the surface (including packaging material) plays a dominant role for the product thickness encountered in practice.

Kato (1984) also showed that the freezing time in minutes for a 32 mm thick 450 g package of fish fillets in contact freezing is a function of the surface heat transfer coefficient. The total time is divided according to the influence of conduction resistance ("λ-infl.") and surface resistance, including package ("α-infl."). The type of packaging alone may increase the freezing time in a plate freezer by 2.5 times, and the surface heat transfer resistance by some four times. The freezing of packaged foods takes longer in an air blast freezer than in a plate freezer under comparable conditions. In the freezing of packaged food, where the λ-value is influenced by the air inside the package, the difference in freezing rate between plate and blast freezing diminishes as does the influence of packaging material.

84.4.3 Freezing Rate

Freezing must always be fast enough to minimize the development of microbiological and enzymatic changes in the product. A freezing process occupies a matter of days and will, in most cases, lead to deterioration in the frozen foodstuffs. In the past, the beneficial effect of very rapid freezing on the quality of frozen foods has been overestimated: within certain limits the rate of freezing does not materially affect the quality of most foods. This should not be interpreted to mean that the rate of freezing has no effect on the quality of frozen foods; most foods suffer from being frozen very slowly; a few foods demand ultra-rapid freezing. Fish and poultry seem to be more vulnerable to very slow freezing than most of other foods, and meat (beef, pork, and lamb) rather less. Strawberries and beans have a better texture and water holding ability if frozen ultra-rapidly while fruits and vegetables with a higher starch content such as peas are not as sensitive to freezing speed.

84.4.4 Formation of Ice

From a physical point of view, fish, land animal, and vegetable tissues can be roughly considered as dilute aqueous solutions. When they are chilled below 0°C, ice crystals form at a temperature characteristic of the product and the initial freezing point (FT), which is also the temperature at which the last ice crystals melt on thawing. The freezing point directly depends on the molar concentration of dissolved substances presented, but not on the water content. Fruits, for example, have high water content and a freezing point of −2 to −3°C, while fish contain less water, yet have a freezing point of about −1 to −2°C. The difference is due to the high sugar and acid content in fruits as compared with the low solute content of fish meat.

Supercooling is the phenomenon of reducing the temperature of a solution or material below its freezing point without crystallization occurring. Ice formation occurs during freezing only after a certain degree of supercooling has been achieved, and the formation of ice is accompanied by heating up of the supercooled product close to the freezing point. In commercial practice, the amount of supercooling is usually insignificant.

As the products are progressively cooled below their initial freezing point, more and more water will be turned into ice and the residual solutions will become more and more concentrated. If, at any time, the products are heated, some of the ice will be turned to water that will then dilute the residual solutions. The ratio of ice to residual solution in frozen foods is a function of temperature and initial concentration of solutes. At a temperature lower than −40°C, there is little or no measurable change in the amount of ice

presented in most frozen foods. The percentage ratio of freezing (RF) of frozen foods is usually estimated as follows:

$$\mathrm{RF}(\%) = 100 - [(\mathrm{FT}/\text{tem. frozen food}) \times 100]$$

where RF represents the percentage ratio of freezing and FT represents the freezing point of the frozen food.

84.4.5 Dimensional Changes

The volume change accompanying the conversion of pure water into ice is about 9%. The volume change of foods as a result of ice formation is less, about 6%, because only part of the water present is frozen and because some foods contain spaces. This volume change has to be taken into account in equipment design. In very fast freezing (e.g., immersion of large items in liquid nitrogen), it can lead to the build up of excessive pressure inside the product, causing breaking and shattering.

84.4.6 Desiccation

It is inevitable that a proportion of water of a product without packaging will evaporate during freezing. The faster the freezing, the smaller the amount of evaporated water. If the product is enclosed in a water-vapor proof package before freezing, no moisture will escapes from the packet. But, when there is an air gap (of the order of millimeters) between the surface of the product and the internal surface of the package frost may be deposited inside the package to the same extent as moisture evaporates from the product.

For products frozen unpackaged, moisture loss varies from 0.5 to 1.5% or more, depending on the temperature, rate and method of freezing, as well as the type of product. The colder the air temperature, the less moisture the air can absorb before it is saturated. Faster freezing methods lower the surface temperature of the product quickly to a value where the rate of moisture evaporation or sublimation is small. Where the surface of a product consists of a moisture-resistant layer (skin of the fish or fat on beef, for example), moisture losses are reduced in comparison with products with cut surfaces (fish fillets, hamburger patties, for example). Proper freezer design for a given product is, therefore, an important factor in minimizing moisture loss during freezing.

In commercial practice, mean freezing rates vary between 0.2 and 100 cm/h:

- 0.2 cm/h (slow freezing) for bulk freezing in blast rooms;
- 0.5 to 3 cm/h (quick freezing) for retail packages in air blast or plate freezers;
- 5 to 10 cm/h (rapid freezing) for individual quick freezing of small sized products, for example, in a fluidized bed;
- 10 to 100 cm/h (ultra rapid freezing) by spraying with or immersion in liquid gases.

For freezing of retail packages freezing rates faster than 0.5 cm/h and for individual quick freezing (IQF) products rates faster than 5 cm/h are considered satisfactory in most cases. Only very susceptible foods (such as tomatoes) may be improved by increasing the freezing to above 10 cm/h. Freezing rates should be taken with care to avoid cracking. When freezing larger units, such as beef quarters, with a mean freezing rate

of 0.1 cm/h a freezing time of 3–5 days is unavoidable and times up to 5 days are quite commonly used.

The rate at which freezing takes place can be considered both at micro and macro levels. At the micro level, freezing rate is described in terms of the speed with which the freezing front moves through the freezing object. At the macro level, the rate at which any given part of the object is cooled determines the temperature profile for that part, and thus has an important bearing on the biochemistry and microbiology of that part.

The undesirable changes in meat during freezing are associated with formation of large ice crystals in extracellular locations, mechanical damage by the ice crystals to cellular structures through distortion and volume changes, and chemical damage arising from changes in concentrations of solutes. The fastest freezing rates are associated with the least damage (Gruji and others 1993). Differences in freezing rate modify meat properties. Calvello (1981) discussed ice crystallization and its growth in meat tissues.

Freezing commences when the surface temperature of the meat reaches its freezing temperature. A continuous freezing front forms and proceeds from the exterior to the interior. Extracellular water freezes more readily than intracellular water because of its lower ionic and solute concentration. Slower freezing favors the formation of pure ice crystals and increases the concentration of solutes in unfrozen solutions. Intracellular solutions are often deficient in the nucleation sites necessary to form small ice crystals. Such conditions favor the gradual movement of water out of the muscle cells, resulting in a collection of large extracellular ice crystals and a concentration of intracellular solutes. Freezing damage arises from massive distortion and damage to cell membranes. Such effects have implications during thawing as the large extracellular ice crystals produce drip during thawing. The structural changes that occur also obliterate the recognizable muscle structure.

Fast freezing results in small ice crystal formation in both intracellular and extracellular compartments of the muscle and very little translocation of water. Drip loss during thawing is thus considerably reduced, and the surface reflects more light than that of slowly frozen meat. Consequently, the cut surface appearance is more acceptable.

84.4.7 Freezing Methods and Equipment

Freezing equipment may be divided into the following main groups with regard to the medium of heat transfer. These groups are metal: plate freezers; air (gaseous medium): blast freezers; liquid: immersion freezers; and evaporating liquid: liquid nitrogen and liquid fluorocarbon equipment. While blast freezers are used for all kinds of products packed or unpacked, blocks or IQF products, the plate freezer and immersion freezer accept only packaged product and evaporating liquid freezers are used only for IQF products.

84.4.7.1 Plate Freezers. In a plate freezer, the product is pressed by a hydraulic ram between metal plates. These plates have channels for the refrigerant. This arrangement gives very good heat transfer of metal contact. This high thermal efficiency is reflected in short freezing times, provided the product itself is a good heat conductor, as is the case with fish fillets or chopped spinach. It is important that the packets are well filled and the metal trays that are used to carry the packets are not distorted. The advantage of good heat transfer at the surface is gradually reduced with increasing thickness of the product. For this reason the thickness is often limited to a maximum of 50 mm. The

pressure from the plates maintained throughout the freezing process practically eliminates the "bulging" that may occur in air blast tunnels; the frozen packets will maintain their rectangular shape within close tolerances. There are two main types of plate freezers, horizontal plate freezers and vertical plate freezers:

- *Horizontal plate freezer.* Usually this type has 15–20 plates. The product is placed on metal trays, which are pushed in between the plates manually. This calls for a high labor content in the loading and unloading operation. In order to obtain automatic operation of a horizontal plate freezer, the whole battery of plates is movable up and down in an elevator system. At the level of a loading conveyor the plates are separated. Packages which have been accumulated on the conveyor are pushed in between these plates simultaneously discharging a row of frozen packages at the opposite end of the plates. This cycle is repeated until all frozen packages have been replaced. Then the space between the plates is closed and all plates are indexed up.
- *Vertical plate freezer.* The vertical plate freezer has been developed mainly for freezing fish at sea. It consists of a number of vertical freezing plates forming partitions in a container with an open top. The product is simply fed from the top. The frozen block is discharged either to the side, upwards or down through the bottom. Usually this operation is mechanized; the discharge of product often being assisted by a short hot gas defrost period at the end of the freezing cycle and the use of compressed air to force the product out.

84.4.7.2 Air Blast Freezers. Some foods, mainly bulk products such as beef quarters and fruits, for further processing are frozen in rooms with or without forced air circulation. Unless the room has been designed for freezing and equipped with suitable coolers and fans the freezing rate is very slow, resulting in an inferior quality for practically all products. If the room is also used for storage of frozen products the temperature of these products may rise considerably and the evaporators may frost up so quickly that the total refrigeration capacity is reduced below what is required to maintain the temperature of the store. Good commercial practices for air blast freezing uses include tunnel freezers, belt freezers and fluidized bed freezers.

- *Tunnel freezers.* In tunnel freezers the product is placed on trays, which stand in or pass through the tunnel in racks or trolleys one behind the other or singly. An air space is left between the trays. The racks or trolleys are moved in and out of the freezer by manual power or by a forklift truck (stationary tunnels), pushed through the tunnel with a pushing mechanism (push-through tunnel) or are carried through by driving equipment, chain drive, and so on (carrier freezer) or slid through (sliding tray freezer). Tunnels are also used for freezing hanging meat carcasses mostly carried on a suspension conveyor. Tunnel freezers are equipped with refrigeration coils and fans which circulate the air over the product in a controlled way. Guide devices, properly locating the trays of food, lead to uniform. Tunnel freezers are very flexible freezers. Products of every size and shape, Packaged or unpacked, can be frozen in stationary and push-through tunnels. Primarily they are used for freezing packaged products. Unpacked products tend to stick to the trays, which may cause weight losses and time-consuming handling in releasing, cleaning

and transport of the trays. To obtain free flow products, improved handling and an increase in the freezing rate, IQF is preferred.

- *Belt freezers*. Belt freezers are provided with a single belt. To increase throughputs and to reduce floor space, the belts may be positioned above each other which may run in the same or in opposite directions (multibelt-freezers), or as a spiral belt wound round a rotation drum stacking up to 30 tiers of the belt above each other (spiral-belt freezers). The belt, generally made of wire mesh, remains inside the freezer so that ancillary equipment for in and out feeding is necessary. Alternatively, the belt is carried to the outside as in some spiral-belt freezers. This arrangement has the advantage that the products can be placed on the belt in the processing room, where the operation can be supervised, before entering the freezer, and the product will remain undisturbed until removed at the outlet. System of baffles allows adjustment of the airflow. The belt is supported by rails and driven by passing round the rotating drum. Modern belt freezers have vertical airflow so that the air is forced through the product layer. In freezing, small products such as beans or cherries, good contact with all product particles is thus achieved. In single belt freezers with high air velocities, the products may be agitated. In all belt freezers, care should be taken to spread the product uniformly across the total belt width to avoid channeling, where the air stream bypasses the product. Belt freezers are used mainly for freezing unpackaged products, for example, IQF products. They are suitable for foods that need careful handling.
- *Fluidized bed freezer*. Fluidization occurs when particles of fairly uniform shape and size are subjected to an upward air stream. At an air velocity depending on the characteristics of the product, the particles will float in the air stream, each one separated from the other, but surrounded by air and free to move. In this state, the mass of particles behaves like a fluid. If the product is contained in an inclined trough fed at the higher end, the fluidized mass moves towards the lower end, as long as more products are added. The product is thus frozen and simultaneously conveyed by air without the aid of a mechanical conveyor.

The use of the fluidization principle has the following advantages when compared with a belt freezer:

- The product is always truly individually frozen (IQF). This applies even to products with a tendency to stick together, for example, shrimp, French style (sliced) green beans, sliced carrots, and sliced cucumber.
- Independence of fluctuations in load. If partly loaded the air distribution will be the same as for full load, that is, no hazard of channeling. If overloaded no product flows on to the floor.
- Reliability is improved when freezing wet products, because the deep fluidized bed can accept products with more surplus water.

An important factor in the overall operation economy of a blast freezer is the weight losses during freezing. Improperly designed equipment will have losses of 5% or more whilst a well-designed freezer normally operates with only 0.5–1.5% loss for unpackaged products. Parts of the weight losses are dehydration losses, which require particular

consideration. Low air temperatures and good heat transfer, that is, high air velocities, can minimize weight loss.

A freezing tunnel that is intended for packaged products should not, without due consideration, be used for thin unpackaged products, for example, fillets of fish. The result may be that the relation of coil surface to product surface is put out of balance so that air temperature in the tunnel rises resulting high weight losses. The coil may not be able to accommodate sufficient quantities of frost which results in reduced heat transfer or reduced airflow, both contributing to high weight losses.

It is important to note that in a vapor tight package containing a product that is not homogeneous, for example, beans or broccoli, the heat transfer inside the package is carried out by air. The heat transfer is very poor, because there is no air circulation. The result is evaporation of moisture, which actually may be greater than it would have been without the package. This moisture remains as frost on the inside surfaces of the package, so that it is not usually recorded as a weight loss. The influence on product quality is, of course, the same whether the dehydration is recorded or not.

Higher velocities of air give better heat transfer. However, it is not sufficient to just increase the fan power. The most important factor is to direct the air circulation in such a way that every product particle is efficiently and equally exposed to the air current. It is also important to study the conditions of the individual particles, because a close study may reveal surprising uneven airflow.

84.4.7.3 Immersion Freezers. For irregularly shaped products, for example, chicken, the best heat transfer is achieved in an immersion freezer. The immersion freezer consists of a tank with a cooled freezing medium, for example, a salt or propylene glycol solution. The product is immersed in this brine or sprayed while being conveyed through the tank. Immersion freezers are most commonly used for surface freezing of poultry to obtain a good color. The final freezing is affected in a separate blast tunnel or cold store. The latter alternative, however, involves quality hazards because of slow freezing of the core. However, the product must be protected by an absolutely tight, high quality packaging material. The brine on the package is washed off with water at the exit of the freezer.

84.4.7.4 Evaporating Liquid Freezers. Mainly two liquids or freezants are used, liquid nitrogen (LN2) and liquid fluorocarbon freezant (LFF).

- *LN2 freezer*. Liquid nitrogen at -196°C is sprayed onto a single belt freezer. The nitrogen evaporates and is allowed to escape to the atmosphere after the vapors have been used for precooling of the products. The very high freezing rate results in improved textures, particularly in certain fruits and vegetables while with other products there seems to be little quality advantage compared with other freezing methods. LN2-freezing may result in cracking of the product surface if sufficient precautions are not taken. Like immersion freezers LN2 freezers are often used only for surface freezing. If final freezing is to be carried out the LN2 consumption is of the order of 1.0–1.5 kg per kg of product which makes the operation rather expensive. In spite of this, the low investment and simple operation make this method economical for certain productions especially in-line processes.

- *LFF system*. The freezant is a specially purified dichlorodifluoromethane (fluorocarbon) which has a boiling point of $-30^{\circ}C$ at atmospheric pressure. The equipment consists of a container with openings at the top. The product is introduced into the container and dropped into a flowing stream of freezant. Owing to the extremely good heat transfer the surface is frozen instantaneously so the product may be stacked on the horizontal freezing belt, where it is sprayed with freezant until finally frozen.

A discharge conveyor brings the product up and out of the freezer. It is claimed that fluorocarbon leaves only small residues in most products. Experiments in this area are continuing. On contact with product the freezant evaporates. The vapors are recovered (with only a slight loss) by condensation on the surfaces of the refrigerator, the latter remaining in the container with only small losses to the atmosphere. There is no measurable product weight loss due to dehydration using this method.

84.5 PACKAGING

84.5.1 General Requirements

Not only must packaging used for frozen foods meet all the requirements of normal packaging but it must also meet requirements of packaging suitable for food such as:

- Chemical inertness and stability;
- Freedom from taint and odor;
- Freedom from toxic materials which may migrate into the food;
- Impermeability, or nearly so, to water vapor and other volatile constituents as well as to any odors from the surroundings;
- Suitability for use in automatic packaging systems;
- Suitable size and shape for display in retail cabinets;
- Protection from bacterial contamination and filth;
- Ease of opening;
- An attractive appearance.

In addition to these general requirements for food packages, frozen food packages should also:

- Be of such shape as to allow rapid freezing except for IQF;
- Permit volume expansion in the freezing process;
- Be impermeable to liquids and have good wet strength and resistance to water and weak acid;
- Be able to withstand low temperatures, not becoming excessively fragile at cold temperatures encountered during the freezing process;
- Not adhere to the contents in the frozen condition;
- Have a high reflectivity to reduce heat gain by radiation during display in retail cabinets;
- Be impervious to light as far as practicable;
- Surround the product closely, leaving the minimum of air entrapped, thus limiting sublimation during storage.

84.5.2 Packaging Materials

A wide variety of materials have been used in devising packaging systems for various frozen foods, for example, tinplate, paper, paper-board with a wax or plastic coating, aluminum foil, plastic film, thermoformed plastics and laminated combinations of these materials. Low permeability to water vapor is an important characteristic of packaging materials for frozen foods. Paper-board package for foods is generally in the form of folded cartons, either directly printed or provided with printed wrappers on the outside and in some cases with plastic coated liners. The coating or laminating materials including Wax blends (paraffin and microcrystalline compositions), plastics, for example, polyethylene or polypropylene (on one or both sides) and aluminum foil are commonly used.

84.5.2.1 Wrappers and Bags. Materials most commonly used are: waxed paper; hot melt or plastic coated paper; aluminum foil; coated cellulose films such as MSAT (moisture-proof, scalable, anchored and transparent) and plastic films, such as polyethylene (PE), polypropylene (PP), and polyvinylidene chloride (PVDC) films. Also of importance are the laminated materials built up from two or more of the abovementioned materials or other films. Common combinations are cellulose and PE films, sometimes with a PVDC coating. These materials are used as over wraps, liners and as single or double wall bags. The bags are either of the prefabricated type or are formed from roll stock on a filling machine. Particularly important are shrink-wrap materials because of their ability to adhere close to the product, leaving few if any air pockets. Shrink-wrap bags require evacuation of entrapped air before shrinking. Some of these bags can withstand boiling water and, therefore, the package can be used for end-cooking of the product before serving.

84.5.2.2 Wooden Boxes. Often used for fish, they require an inner liner or glaze on the product to guard against desiccation.

84.5.2.3 Rigid Aluminum Foil Packaging. These packages, in the form of trays, dishes and cups, are generally covered with a crimped-on aluminum sheet or a sheet of aluminum foil laminated to paper-board. Normally used for prepared foods and pastries, and so on, they allow rapid heating of the product in the package before serving.

84.5.2.4 Semirigid Plastic Packages. These are mostly manufactured from high density PE or PP in the form of trays and plates, covered by a lid; as with aluminum foil these can also be used for prepared foods requiring heating before serving, providing only gentle heat, such as steaming, is employed.

84.5.2.5 Tin and Composite Containers. These are used mainly for frozen juices that often have a mobile liquid phase even at cold store temperatures. A more recent development is to use coated paperboard in the body and aluminum for the ends, coupled with an easy opening device.

84.5.2.6 Shipping Containers. These are normally manufactured from different materials such as solid, corrugated fiberboard or vulcanized fiberboard paper, and plastics. They are often good heat insulators. Frozen-at-sea whole fish is frozen in blocks or individually. In both cases, the fish, if not packaged, should be glazed prior to storage to

minimize desiccation. Some fish is slabbed as skin-on fillets or made into blocks of skinned and boned fish for later cutting; both packs should be cartoned or bagged to minimize desiccation.

84.6 STORAGE

If the quality of frozen food is to be maintained during its storage life, the correct temperature must be selected for the expected period of storage. During the storage period, the following hazards to quality must be avoided:

- A low relative humidity in the cold store;
- Retention beyond the expected storage life;
- Fluctuations in temperature (both during storage and in the process of loading, unloading and dispatching vehicles);
- Physical damage to the product or packaging during the course of storage or handling;
- Contamination of the product by foreign bodies or vermin.

These hazards can be avoided by ensuring:

- That the design of the cold store is appropriate to the duty it will be required to perform, and is such that these hazards are as far as possible eliminated at the design stage;
- That operation methods, designed to avoid such dangers, are laid down and strictly adhered to.

Small fluctuations in temperature are normal and unavoidable. They should, however, be kept at a minimum both in amplitude and duration in order to minimize the amount of weight loss by drying and in-package desiccation.

84.6.1 Cold Store Design

The general design of a cold store is determined by the requirements for effective and safe handling of the merchandise, and a suitable storage climate for the products. The normal arrangement is that rooms are built side by side between road and railway loading banks, thus all rooms can communicate directly with the loading banks and traffic yards. Today, cold stores are frequently built with prefabricated concrete or steel structures. The insulation can be placed on the outside or the inside of the structure. Internal structure means that the insulation will form an unbroken envelope around the building. The insulation is well protected by the structure, internal installations are easy to fix, there is no hung insulated ceiling that can cause problems and extensions are very simple to carry out.

It is essential that considerable thought should go into the definition of the duties the cold store has to perform. A clear statement has to be prepared of the maximum and average daily activity expected to take place in the cold store:

- Quantity of each product to be received;
- Temperature at which each product will be received;

- Maximum number of operatives and trucks working in the cold store at any one time;
- Number of anticipated door openings;
- Maximum quantity to be out-loaded at any one time.

These considerations must be taken into account when calculating the maximum expected heat load. The temperature difference between the surface area of the cooling coils and the required room temperature should be as small as possible and not more than about 6°C.

84.6.2 Frost Heave

Frost heave under cold stores is prevented by a special under floor heating system or a ventilated space under the floor. The heating system may consist of an electrical mat or a pipe grid cast into the subfloor; glycol or oil is circulated in the pipes. The liquid is often heated by surplus heat from the refrigeration plant.

84.6.3 Insulation

The insulation represents a large percentage of the total cost for a normal cold store. It is, therefore, very important that it is designed from an economical point of view. However, one must also consider that the insulation value has an influence on the storage climate in that the transmission losses mean dry heat is entering the cold room. The choice of insulation system must be carried out carefully. The vapor barrier on the warm side must be completely water vapor tight, the insulation should contain no heat bridges and the internal cladding must be hard, hygienic and give a pleasant appearance. Today, most cold store insulations are carried out with prefabricated panels, slabs of polyurethane foam, expanded polystyrene, mineral fiber, or cork. Where special attention must be given to the risk of fire, the insulation is combined with a special firewall or the insulation is carried out with fiberglass between special insulation studs. The vapor barriers may consist of thin gauge aluminum, galvanized steel sheets, or heavy gauge polyethylene sheets. The joints are sealed with special sealing compounds. The internal cladding may be either profiled plastic, laminated galvanized steel sheet, or aluminum sheet. Good concrete kerbing and in some cases dunnage battens protect the internal finish and ensure that the merchandise is not stacked directly against the wall.

84.6.4 Refrigeration System

The refrigeration system must be designed with regard to the requirements of the climatic conditions for the stored merchandise. It must be adequate to allow for sufficient safety on peak days and summer conditions. The air coolers must be designed and located so that an even temperature can be maintained throughout the cold store even under severe conditions and without generating high air velocities in the cold store. Large evaporator surfaces and air distribution through air ducts or false ceilings will normally ensure this. Air ducts may be omitted if the cooling surface is divided on several cooler units distributed in the room so that the air velocity from the cooler fans is kept at a moderate level.

The most common refrigeration system for large cold stores is a two-stage compressor system with pump circulation of the cold refrigerant to the air coolers. The most common refrigerant is ammonia but halogenated hydrocarbons have also been used in some cases. For small cold stores a direct expansion one-stage compressor system using halogenated hydrocarbons is widely used. In order to improve safety and make control easier and cheaper most modern refrigeration plants are automated. The degree of automation may vary but normally the room temperature, compressor capacity, lubrication, cooling water, defrosting, pumps, fans, current and voltage of the main supplies, and so on, are controlled and supervised by a central control panel in the engine room.

84.6.5 Lighting

A cold store is a working place for fork lift drivers and others concerned with the handling of the products. Thus the lighting in the cold store must be good but at the same time it must be remembered that the lighting is adding to the heat load in a cold store. Lamps with a very high power/lighting ratio should be used. Mercury lamps are superior from this point of view and they are often used even if they can cause a slight discoloring of meat products during long storage. A normal cold store should have an average lighting of 100 lux at floor level and in break-up areas 200 lux.

84.6.6 Layout

The layout of the storage space should be such as to reduce to the maximum extent possible the ingress of warm air and the exposure of product to atmospheric temperatures. Where possible, product should be conveyed from factory areas into cold store by means of conveyors in insulated tunnels. There should be no facility for any accumulation of product in ambient temperature. If the operation is a palletized one, then palletization of the product should take place in the cold store in an area set aside for this purpose. Port doors should be provided so that the maximum amount of traffic in and out is handled in this fashion and the product is completely protected from temperature changes during loading/unloading operations. For safety reason, no glass should be allowed inside the cold store in any unprotected position. Translucent plastic visors should be placed around lamps or any other essential glass.

84.6.7 Jacketed Stores

The common jacketed stores has two two-speed fans. The classic operation for this type of jacketed stores is to have one fan circulating the air at lower speed and the other fan runs at the higher speed. This allows the air to enter the store through a system of movable vents that open via the effect of the increased air pressure. Thus, one can complete the cooling of foodstuffs that may have been subjected to warming up prior to being introduced into the cold store. Jacketed stores allow storage at near 100% relative humidity and at uniform and constant temperatures. These conditions, which greatly reduce weight losses of unpackaged foods and frost formation inside packaged frozen foods, are obtained by circulating the refrigerated air in a jacket around the load space to absorb the heat conducted through the insulation before it can enter the load space. This technique also increases the life and reduces the maintenance of the structure by preventing condensation and frost formation in the insulation.

84.6.8 Equipment

In equipping the store, care should be taken to choose equipment that is suitable to the product being handled and which minimizes the possibility of damage or contamination. Thus, timber pallets are suitable for properly packed products but lightly packed semiprocessed stock may need a pallet constructed in metal or some similar washable and less easily damaged material. It is likely, for economy reasons, that the store will be designed to maximize the use of height, and to this end some means of support for the product must be provided; for example, racks, pallet posts or pallet cages. The layout of pallets in the cold store should be such that damage to the products is minimized. Whilst accepting the need for maximum utilization of space, gangways and turnings should be wide enough for product to be moved without damage, whilst space should be allowed between lanes of pallets to permit the withdrawal or placing of a pallet when the adjacent lanes are full.

84.6.9 Operating Methods

It is important that everyone working in a cold store always bears in mind the prime objective of minimizing the exposure of products to ambient temperatures. Methods of handling and routes should be laid down which do not permit the product being placed in ambient temperature. If it is not possible to load a vehicle by means of a port door or some similar method that gives complete protection, the only alternative is to traverse a loading bank. Then the complete vehicle load should be assembled inside the cold store and conveyed direct to the vehicle without being placed on the loading bank. A similar procedure should apply in reverse for unloading. Doors should never be left open other than when personnel or goods are passing through them, and these should be as short a duration as practicable.

84.7 THAWING

Most frozen food processors find it necessary to thaw stock of frozen material in some of their operations, and if thawing is not carried out carefully, quality and yield can suffer. This section sets out the broad principles involved in the thawing techniques available, and indicates some of the problem areas. Irrespective of the procedure involved, heat energy must be supplied, most of it being required to melt the ice in the food. About 300 kJ are required to thaw 1 kg of white fish from a starting temperature of $-30^{\circ}C$. The figure for fatty herrings is smaller, about 250 kJ, because of the lower water content of herrings. Thawed materials spoil in the same way as their unfrozen equivalents and must be kept chilled until required; this can often be achieved conveniently by removing the product from the defroster just before thawing is complete so that the product has its own small reserve of cold.

There are two principal groups of thawing methods: those in which heat is conducted into the product from the surface; and those in which heat is generated within the product. In the first group, heat is applied to the surface of the product by exposing it to sources such as hot radiating surfaces, warm air, warm water, heated metal plates, or steam under vacuum. In the second group, heat is generated within the product by such means as electrical resistance, dielectric or microwave heating. Surface heating methods are much more commonly used than are internal heating methods.

84.7.1 Surface-Heating Methods

When using surface-heating methods, thawing time for a product decreases with:

- Decrease in physical size of the product;
- Increase in thermal conductivity (or, more precisely thermal diffusivity) of the thawed product;
- Increase in temperature difference between the surface of the product and its surroundings;
- Increase in the movement of the surrounding medium relative to the product surface;
- Increase in humidity of the surroundings.

Since the thermal diffusivity of thawed product is less than that of frozen, surface thawing methods suffer from the inherent disadvantage that resistance to heat transfer increases progressively once thawing has started. All surface-heating methods can take advantage of a programmed temperature difference between the surface and the surroundings. The temperature of the surroundings is arranged to start high, and to decrease as the surface warms up to a predetermined level, usually below the temperature where bacterial activity or surface damage could be a hazard to the quality of the food. Thawing times are greatly increased if the product is encased in packaging material. Thus packaging material should be removed where possible.

84.7.2 Still-Air Thawing

If thawing is conducted in still air, the air temperatures should not exceed 20°C and facilities for supplying heat to the room in which the product is laid out to thaw may be required. Air temperatures greatly in excess of the above should be avoided since the outer layer will warm up and spoil before the center is completely thawed. A typical block of sea frozen whole cod, 9 cm thick, will take up to 20 h to thaw under these conditions. This time can be reduced by immediately separating the fish without damage. Single fish, 10 cm thick, will take about 8–10 h to thaw.

84.7.3 Air Blast Thawing

A relative humidity of greater than 90% is advantageous both in reducing weight loss or shrinkage and also in obtaining a high level of heat transfer. Air velocities of 12–18 m/min at a temperature of 6–8°C for 3–5 days or 100 m/min for 2–2.5 days are needed for packages of boneless meat, whereas pork sides are normally thawed at 4–5°C for 2–4 days. Air speeds of the order of about 300 m/min at temperatures not exceeding 20°C with the air fully saturated with moisture will thaw sea frozen fish blocks 10 cm thick in 4 h. Higher air velocities at cool temperatures lead to surface desiccation while any higher temperature will lead to microbial growth on the heated surface.

84.7.4 Water Thawing

This method is not normally applicable to meat and with fish there is a risk that fillets or cut surfaces will become waterlogged and lose flavor but water thawing can be used

satisfactorily for frozen whole fish, even though there may be a slight loss of pigments. Usually there is a slight gain in weight, which is lost again when the fish is filleted. The temperature of the water being circulated around the frozen fish or sprayed on to the fish should be no warmer than 20°C and the water itself should flow at not less than 30 cm/min so as to obtain rapid thawing. The thawing time for a block of whole cod 10 cm thick in water at 20°C moving at about 120 cm/min is similar to that in an air blast defroster using humid air at the same temperature, that is, about 4 h. When frozen fish blocks are thawed in still water, water temperatures may, in the initial stages, marginally exceed 20°C, but the thawing should be arranged so that the fish surface temperature does not exceed 20°C.

84.7.5 Vacuum Thawing

In this method the product lies on racks inside a container from which the air has been evacuated. Water, usually at about 18°C is allowed to evaporate freely from heated vessels inside the container. In the absence of air, transfer of water vapor from a heated vessel to the product occurs readily, the water vapor giving up its latent heat on condensation. The advocates of this method claim faster thawing than other surface heating methods for products less than about 10 cm thick.

84.7.6 Double Contact Thawing

Plate frozen raw material lends itself particularly to plate thawing in an arrangement similar to that of a multiplate freezer, a liquid circulating through the plates (at a temperature not exceeding 20°C) providing the necessary heat. A 10 cm block of whole cod when thawed between plates at 20°C for 5 h is ready for filleting 3.5 h later, making a total of 8.5 h for complete thawing. Care must be taken not to allow distortion of the blocks to occur during cold storage since this will lead to poor contact with the plates during thawing. Thawing fluid or semifluid food in a vertical plate apparatus may be carried out using temperatures as high as 40–50°C as long as the melted material is allowed to run away from the plates continuously.

84.7.7 Internal Heating Methods

Internal heating methods rely on the use of applied electric fields which cause movement of the electric charges inherent in all products. The molecules of the product take up this energy of movement and the food warms up. The amount of heat generated in this way is strongly dependent on the electrical characteristics of the product. Since food is not usually homogeneous, there can be marked variations in the rate of heating of different parts of the food. Furthermore, for any particular component in the food, the rate of heating usually increases as the product thaws, making runaway heating a hazard. If these factors can be accommodated, the great advantage to be gained is extremely rapid, uniform thawing.

84.7.8 Electrical Resistance Thawing

In this method, the product is sandwiched between electrodes and an electric current is passed through the product. Some preliminary warming is usually necessary to achieve

good electrical contact and a satisfactorily high starting current. In practice this method has so far been used for thawing blocks of fish fillets up to 5 cm thick and weighing about 3 kg but it has not been found suitable for thicker blocks of fillets, blocks of whole fish (except herring) or single whole fish.

84.7.9 High Frequency Thawing

In the dielectric method, a high frequency electric field is applied to electrodes astraddling the product, but not physically in contact with it. The commonly used frequencies are either in the range 27–100 MHz (dielectric or high frequency heating) or 915–2450 MHz (microwave heating; where the energy is directed at the product enclosed in a chamber). The product must be reasonably homogeneous and regular in shape to achieve uniform heating. If the block is not homogeneous, or is irregular in shape, some parts may become overheated before the remainder is thawed. It has been found that if irregular blocks of fish are first immersed in water, thawing becomes uniform. The time taken for a 10 cm block of whole cod is typically just less than 1 h. Partial thawing by microwave is also used, thereby increasing the capacity of the thawing equipment. By going to the higher frequencies, the field strength can be substantially increased and thawing time reduced to a matter of minutes. Penetration into the food mass decreases so that the thickest block of meat which can be completely thawed at 2450 MHz is 3–4 cm.

84.8 PHYSICOCHEMICAL CHANGES OF FROZEN FISH

Freezing converts a large proportion of the water present in foods into ice and hence makes the remaining solution more concentrated in dissolved, colloidal and suspended substances. This increased concentration causes a change in acid-base equilibrium (pH) important in the stability of many colloids and suspensions. Shifts in pH (usually towards the acid side) of up to 1 pH unit have been observed under these conditions. A second result of this increased concentration is the precipitation of salts and other compounds that are only slightly soluble, such as phosphate. This can result in drastic pH changes (up to 2 pH units) and changes the salt composition of the aqueous solution in foods. These changes often affect the physicochemical systems in food irreversibly. It has been shown, for example, that lactic dehydrogenase, a muscle enzyme, and lipoproteins, an important egg yolk constituent, are irreversibly damaged by a pH decrease from 7 to 5 and by increased phosphate concentration during freezing.

Textural properties and the initiation and acceleration of several biochemical reactions depend on the physical chemistry of food constituents and hence are affected by the physicochemical changes brought about by freezing. Loss of water binding properties, resulting in drip, is an example of textural changes, while removal of enzymes from cell particles, allowing them free access to substrates in other parts of the cell, is an example of biochemical reactions initiated and accelerated by freezing. Other physicochemical changes in frozen foods are actomyosin changes in muscle, leading to toughening (fish) or dryness (poultry), loss of turgor in fresh fruits and vegetables, and gelation of egg yolk. Many physicochemical changes increase with increased salt concentration in the unfrozen phase, but will decrease with decreasing temperature as a result of the lower mobility of the salt in the unfrozen phase and the general effect of temperature on chemical

reactions. Consequently, physicochemical changes are most damaging in the range between the freezing point of a food and about $-10^{\circ}C$. It is important therefore to expose frozen foods for as short a time as possible to this temperature range, both during freezing and during thawing.

84.9 BIOCHEMICAL CHANGES IN FROZEN SEAFOODS

84.9.1 Postmortem Changes in Nucleosides

Fish muscle obtains energy by hydrolyzing adenosine triphosphate (ATP). At any one moment, its concentration is relatively small. During life it is quickly resynthesized using the energy produced when glycogen is oxidized to carbon dioxide and water. On death of the fish metabolism in the muscle continues for some time. Postmortem glycolysis, however, is a relatively inefficient process and it cannot maintain ATP at its level. Once ATP has fallen to a critical concentration, it can no longer prevent the major proportion of the muscle actin and myosin from crosslinking. This causes the loss of elasticity known as rigor mortis and usually a slow irreversible contraction. The continuing production of lactate and H^+ ions causes the pH of the muscle to fall from its *in vivo* value of about 7.2 to the so-called ultimate pH, which is usually about 5.5. A pH of 5.5 is near the isoelectric point of the muscle proteins, at which they have minimum water holding capacity and a consequent relatively high tendency to drip on thawing. A higher ultimate pH, therefore, means a greater water holding capacity than a lower pH. The quantity of glycogen present in the muscle at the moment of slaughtering will clearly determine how far the pH will fall during post mortem glycolysis. Like most chemical reactions, post mortem glycolysis is temperature dependent. It is generally found that the lower the temperature at which this process occurs, the slower is its rate. Thus if the carcass is maintained at body temperature after death, the rate of pH fall, of ATP depletion, and of rigor mortis onset is fast. If, however, the muscle is chilled quickly, these changes are slowed down and the water holding capacity of the muscle remains relatively high.

There is no practical cold shortening problem with fish properly chilled after catching. Fish muscle shows the least shrinkage if held at about $0^{\circ}C$. At warmer temperatures the shrinkage and weight loss are greater and they may be quite substantial for a fillet removed from the skeleton prerigor and kept at room temperature. One qualitative difference between fish and meat is the generally lower glycogen content in fish than in meat animals rested before death. Consequently, the post mortem fall of pH in fish is smaller and the resistance against surface bacterial growth less than in meat. In many fish species, therefore, bacterial spoilage is an overwhelming factor.

84.9.2 Postmortem Changes in Nucleosides and Lipid

The fat composition of fish differs markedly from that of meat, fish fat containing a higher proportion of polyunsaturated fatty acids. Although this factor may vary with species and is also influenced by dietary fat intake, it nevertheless implies that fish, in particular fatty fish, are very prone to development of rancidity by auto-oxidation. Such rancidity may even develop in fatty fish held before freezing, but it is particularly during storage of frozen fish that great care in packaging and the use of low temperatures are necessary to preserve quality.

84.9.3 Protein Denaturation of Frozen Fish

The proteins of fish muscle differ from those of meat especially in their higher susceptibility to cold store damage. Frozen storage of fish causes increase in drip loss upon thawing, toughness, coarseness and dryness on cooking, and loss of the desired glossy pellicle on smoking. These changes are highly associated with the so-called protein denaturation caused by freezing and subsequent storage. They are temperature dependent, the maximum rate of development being in the range -1 to $-5^{\circ}C$, which can be considerably slowed down by colder storage temperatures. The changes are mostly in the myofibrillar protein of fish muscle. In general, the sarcoplasmic proteins seem to be more stable on freezing and subsequent storage. This kind of protein denaturation is associated with the reaction of certain free fatty acids or their oxidized products on the myofibrillar proteins. Recently it has been found that the ultimate pH attained by fish can considerably affect texture. Thus, low pH in cod is associated with more pronounced toughness and larger drip loss on thawing.

Numerous studies indicated that denaturation of muscle proteins plays a dominant role in the quality changes (both physicochemical and sensory) of frozen stored fish muscle. The amount of extractable actomyosin decreased with the duration of storage, while no significant change in sarcoplasmic proteins was observed during frozen storage of cod and other fish (Dyer 1951; Dyer and Morton 1956; Dyer and others 1956).

Previous studies suggested that the aggregation of muscle proteins occurred during frozen storage. These study results include electron microscopic analyses (Ohnishi and others 1978), decreases in actomyosin peak (20s–30s), areas on ultracentrifugal analysis (Noguchi and Matsumoto 1970; Oguni and others 1975) and viscosity of soluble actomyosin with duration of storage (Oguni and others 1975; Ueda and others 1962a,b). In addition to aggregation, dissociation of F-actomyosin into f-actin and myosin also occurred. It appeared that the dissociated f-actin, as thin filaments, became entangled and aggregated and that the dissociated myosin monomers folded into globular form. At advanced stages of freeze denaturation, large masses with diffuse outlines were frequently found indicating the formation of aggregation complex of actin and myosin (Matsumoto 1980).

ATPase activity of actomyosin and myosin, another property of myosin related to its contractile function, also decreased with the increase of frozen storage (Chen and others 1989; Jiang and others 1988a,b, 1989; Noguchi and Matsumoto 1970; Oguni and others 1975; Ueda and others 1962a,b).

During the initial frozen storage, it appears that both myosin and actin undergo denaturation, while denaturation of tropomyosin and troponin was observed during prolonged frozen storage (Irisa and others 1978).

The involvement of SH group in the denaturation of muscle proteins during frozen storage has been emphasized by Buttkus (1970, 1971), Chen and others (1989), and Jiang and others (1988a,b, 1989). Therefore, the changes appear to be the result of rearrangements of disulfide bonds from intramolecular to intermolecular through a sulfhydryl-disulfide interchange reaction.

Myofibrils, a systematically organized complex of myofibrillar proteins, undergo some structural changes during frozen storage of fish. The most noticeable change is the fusion of the myofibrils as illustrated by cell fragility method (Love and Mackay 1962; Love and others 1965) and fragmentation into short pieces at the Z-bands (Jarenbäck and Liljemark 1975a,b; Jiang and others 1990, 1992; Tokiwa and Matsumiya 1969). More recently, studies have been done on the denaturation of enzymes during frozen storage

(Gould 1965; Tappel 1966). Inactivation of enzymes with globular molecule was considered to be due to the unfolding of intramolecular structure (Hanafusa 1973).

One of the most prevalent chemical reactions to occur in fish muscle during freezing and frozen storage is the complex phenomenon of protein denaturation. It has been postulated that the rupturing of different bonds in the native conformation of proteins in frozen fish is followed by side-by-side aggregation of myofibrillar proteins, specifically myosin, brought about by the formation of intermolecular cross-linkages (Connell 1960; Sikorski 1978). It is also believed that the significant decrease observed in the center-to-center distance between the thick filaments of the A-band of the sarcomere after prolonged frozen storage favors the formation of crosslinkages between molecules and stiffens the fibers (Jarenbäck and Liljemark 1975a,b). Such intermolecular crosslinkages result in aggregation (Matsumoto 1979), which leads to the formation of high molecular weight polymers (Childs 1973; Lewin 1974) and subsequent denaturation of myosin during frozen storage.

84.9.4 Effects of Freezing, Frozen Storage, and Thawing on Intrinsic Chemical Reactions

When frozen fish are subjected to excessively prolonged cold storage at temperatures above $-30^{\circ}C$, a series of intrinsic chemical reactions occurs in fish tissues. These reactions include protein denaturation, breakdown of TMAO and lipid oxidation.

Quite obviously, protein denaturation during frozen storage produces extensive textural changes and deterioration in fish. These changes are more pronounced in some species of fish, specifically the gadoids, and are related to another intrinsic chemical reaction, the breakdown of TMAO. After death, TMAO is readily degraded to DMA and FA through a series of reactions. This conversion of TMAO to DMA and FA is typically observed in frozen gadoid species such as cod, hake, haddock, whiting, red hake, and pollock (Castells and others 1973a,b).

The presence of air (oxygen) affects DMA and FA formation. It has been suggested that oxygen may actually inhibit the reaction by interacting with metal ions, which otherwise would accelerate the TMAO degradation (National Marine Fisheries Services 1986). Lundstrom and others (1981) observed that red hake (*Urophysis chuss*) minces stored in the absence of oxygen showed more rapid DMA and FA formation than red hake fillets stored in air. Likewise, the presence of air (oxygen) in packaged white hake (*Urophysis tenuis*) significantly prolonged the shelf-life of the frozen samples (Santos and Regenstein 1990).

TMAO degradation to DMA and FA was enhanced by the presence of an endogenous enzyme (TMAOase) in the fish tissues, as observed in cod muscles by Amano and Yamada (1965a,b). However, evidence also exists which demonstrates that breakdown of TMAO to DMA and FA is nonenzymic in nature (Spinelli and Koury 1979; Tarr 1958). The breakdown of TMAO, whether enzymatically or nonenzymatically induced, is believed to produce destabilization and aggregation of proteins. It has been suggested that TMAOs breakdown product, FA, may produce crosslinking of muscle proteins (Matsumoto 1979) due its high reactivity. Clearly, the presence of FA is not the only factor involved in textural changes during frozen storage. However, with certain species of fish, it appears to be of primary importance.

Another chemical reaction generally associated with quality changes during freezing, frozen storage, and thawing is lipid oxidation (oxidative fat rancidity), one of the major causes of frozen shelf-life reduction. The extent of oxidation in fish lipids varies with

the quantity and the type of lipids in the fish muscle, that is, fatty species are more prone to oxidation than lean species, and species with more highly unsaturated fatty acids are less stable than the other species. When oxidative rancidity progresses sufficiently, it leads to the development of obvious off-tastes and odors, resulting in reduced shelf life. Changes in fish lipids may be related to changes in protein during frozen storage. Several reports indicate that the unstable free radical intermediates formed during autoxidation attack the protein molecules, leading to the formation of protein free radicals (Castells and others 1973a,b; Karel and others 1975). Another possible mechanism for reaction between oxidized lipids and proteins occurs through stable oxidation products (Konosu and others 1974; Shenouda 1980) increasing the hydrophobicity of proteins, making them less water soluble. Free fatty acids (FFA) formed during autoxidation produce indirect effects on textural degradation by promoting protein denaturation (Colmonero and Borderias 1983). FFA are believed to bind myofibrillar proteins, specifically actomyosin, rendering it unextractable (Shenouda 1980; Sikorski and others 1975).

84.10 MICROBIOLOGICAL ASPECTS DURING FREEZING

Freezing and subsequent storage will kill some of the microorganisms present in the unfrozen material, but this is a slow and variable process depending, in part, upon the nature of the food. Thus freezing cannot be relied upon to substantially reduce bacterial contamination present in the foodstuff. The hygienic state of the product before freezing is consequently all-important. Storage at temperatures colder than $-12^{\circ}C$ inhibits microbial growth and therefore is one effective method of preserving food against microbial spoilage. Three aspects of bacteria in frozen seafoods including resistance to freezing and frozen storage, multiplication in frozen and thawed foods will be considered.

Some pathogens are more resistant to freezing than are ordinary spoilage organisms. Most of the common pathogenic bacteria are Gram-negative. This group is more sensitive to freezing, frozen storage and thawing than are the Gram-positive spoilage organisms. Even when microbial growth is completely inhibited, the frozen product can still deteriorate due to the activity of the released microbial enzymes that can still catalyze undesirable biochemical reactions in the food. When the handling of fish before freezing is improper, there is the danger that microorganisms may have released sufficient enzymes and toxin to affect the quality of the frozen product. For example, if lipases are produced before freezing, they can cause marked hydrolysis of fats in fatty fish even when stored at $-30^{\circ}C$. If fish has been held at relatively high temperatures before freezing, any pathogens present could multiply and some may produce toxins. The latter will survive freezing and constitute a health hazard. A product destined for freezing should receive the same degree of hygienic handling as that which is to be stored at chill temperature.

Several psychrotrophic microorganisms can multiply at freezing temperatures. In practice, bacterial growth does not occur below temperatures of $-10^{\circ}C$. This is probably due to the increasing concentration of soluble salts and organic compounds in the unfrozen water that will decrease the water activity of this fraction.

Upon thawing, frozen foods will spoil almost at the same rate as would be expected from unfrozen products with the same microbial population maintained at similar temperatures. Condensation of moisture on the surface of the product should be avoided as during thawing it may cause acceleration of microbial growth.

Pathogenic bacteria may grow and produce toxin in food without rendering the food unpalatable. They will be occasionally observed in any food even hygienically prepared. Contamination even with small numbers of pathogenic bacteria during preparation of foods for freezing should therefore be avoided as far as practicable. Competition between different types of bacteria is important if food that will be further prepared after thawing is stored in the thawed state before such preparation. A food lacking a normal flora of spoilage organisms, but contaminated with a few pathogens is more likely to present a health hazard than the same food contaminated to the same degree with normal spoilage flora. In the case of frozen foods allowed to thaw slowly, the psychrotrophic flora is likely to dominate and may so alter the substrate as subsequently to inhibit or slow down the multiplication of any pathogens present when thawing is complete. Packaging exerts little effect on the spoilage pattern, even vacuum packing causes a negligible increase in the growth rate of anaerobes like *Clostridium botulinum* during storage after thawing.

84.11 EFFECTS OF FREEZING CONDITIONS ON THE QUALITY

It is readily apparent that spoilage changes in fresh fish occur most commonly as a result of bacterial activity. The species of bacteria vary according to storage temperature. In fish stored in ice, *Alteromonas*, *Achromobacter*, and *Flavobacter* spp. predominate. At temperatures between 35 and 55°C, *Micrococcus* and *Bacillus* spp. constitute the main microflora. Some of these microorganisms produce very active proteolytic enzymes, which produce odor, flavor, and textural problems. When fish and seafood are frozen, the microorganisms present in their tissues are generally inactivated. Thus, during frozen storage, microbiological changes in fish tissue are usually minimal. Microorganisms not destroyed by the freezing process generally do not grow and in some cases die off slowly. Although some microorganisms survive storage at very low temperatures, their activities are suppressed, and bacterial numbers may be considerably reduced if recommended temperatures are maintained (Hultin 1985). The temperature below which microbial growth is considered minimal ranges from -10 to -12°C (Dellino 1986). Microorganisms, however, that survive and remain inactivated during frozen storage resume growth when the fish is thawed and may then lead to microbial spoilage of the thawed product. Frozen fish are far from sterile and cannot therefore be considered a microbiologically safe product. The microbial activities in fish after thawing depend on the degree of freshness of the raw material, the natural microflora in the fish tissues, and the thawing technique utilized.

The effects of various freezing conditions on quality and shelf stability of frozen fish and seafood have received considerable attention recently. Studies have dealt with either the stability of the frozen product as related to storage temperature and fluctuation in storage temperature or the effectiveness of food additives in providing shelf stability to frozen products.

84.11.1 Effects of Freezing, Frozen Storage, and Thawing

One problem encountered during handling, freezing, and storage of fish is the difficulty in retaining the color and appearance of the meat. Changes in color and appearance of fish occur even immediately after catch. Blood pigments become noticeably discolored to

various degrees after some period of time. The natural pigments in the fish meat contributes to its color. They also play an important role in the color changes and vary from one species to another. These pigments are subjected to considerable oxidation when the fish is frozen and stored. This then results in meat color darkening to either dark brown or, in some cases, black. This discoloration occurs especially when the fish is stored for an extended period of time.

Some fish, like tuna, develop discoloration during frozen storage, reportedly due to oxidation of myoglobin to met-myoglobin in fish blood (Bito 1964). Other species, such as salmon, swordfish, and shark, also exhibit color changes during storage. Salmon has a pink meat, but when subjected to oxidation its color slowly fades and, in extreme cases, may completely disappear after prolonged storage. Swordfish, on the other hand, develops green discoloration beneath its skin during frozen storage, which according to Tauchiya and Tatsukawa (1954) is due to the development of sulf-hemoglobin, a product of oxidation. Shark flesh also discolors and occasionally develops off-odors during storage, most probably as a result of the presence of high amounts of trimethylamine oxide. Interestingly, these marked differences in the color and appearance of frozen fish are quite noticeable in fish sold either as steaks or as fillets. This is especially true when cross-sectional cuts of the fish are made, which permits a comparison of the color of the exposed fish surface with that of the inner portion.

In shrimp, the rapid formation of black pigments, widely known as melanosis, occurs within a few hours after death and is enhanced by exposing the shrimp to air (oxygen). It can occur within just 2–12 h of exposure. The oxidation reaction leading to the formation of these black pigments can occur at 0°C, but at −18°C, no visible spots were detected at up to 3 months of storage (Reilly and others 1984). Below this temperature, it is believed that melanosis can still positively occur. It should be noted, however, that although black spots do not necessarily make shrimp unfit for human consumption, such discoloration is usually associated with spoilage, resulting in a decrease in market value. In other shellfish, such as crab and lobster, the development of blue or black discoloration, otherwise known as blueing, is one of the most troublesome problems. Blueing may occur after freezing or during frozen storage, or it may appear after thawing and subsequent air exposure or even shortly after cooking. Needless to say, these changes in color and appearance of fish and shellfish significantly affect consumer acceptance. When consumers select frozen fish, if these products can be seen through the packaging material used, the color and appearance of the frozen product provide an indication as to its degree of quality.

Thawing also influences the color and appearance of frozen fish and, inevitably, its consumer acceptability. Depending on the thawing technique used, discoloration may occur in fish and other seafood. For instance, when shrimp are thawed at temperatures higher than 0°C, black discoloration or melanosis may occur. This is due to the unnecessary exposure of the shrimp to air, leading to oxidation. A phenomenon known as "shimi" occurs in frozen-thawed fish meat. "Shimi" are the undesirable blood spots observed in the belly portion of carp upon thawing and are also the distinguishable spots tainting frozen-thawed tuna meat (Bito 1984). The latter condition is probably due to the blood vessels that remain in unbled tuna meat prior to freezing. When thawed, these blood vessels produce unsightly spots in the meat.

It is possible to determine if the product has been properly thawed and then refrozen. This is particularly noticeable in packaged frozen fish, where spaces on the sides of the package may be filled with a frozen cloudy liquid, known as thaw drip. Such muscle drip was originally attributed to the rupturing of cell walls caused by ice crystal formation

during freezing, resulting in excess drip during thawing. However, it has been postulated that drip or exudate formation is directly related to the capacity of the fish protein to hold moisture (Ciarlo and others 1985). This unsightly exudate from fish muscle indicates, among other things, inappropriate handling, prolonged ice storage prior to freezing, frozen storage at inappropriate cold-storage temperatures, or improper thawing. If not properly controlled, freezing, frozen storage, and thawing generally result in quality changes in fish and seafood that in most cases render the product unacceptable to consumers.

Changes in the texture, odor and flavor of fish and seafood affect their palatability. Fresh fish have a distinct succulence and a delicate odor and flavor, which are characteristic of the species. These attributes change noticeably when fish is frozen and stored for prolonged periods of time. Interestingly, the changes that influence the palatability of frozen fish and seafood can all be measured organoleptically, and to some extent chemically.

84.11.2 Change in Texture

Frozen fish gradually loses its juiciness and succulence after freezing and subsequent frozen storage. Such textural changes, reportedly caused by protein denaturation (Shenouda 1980; Sikorski and others 1975; Sikorski 1978, 1980), are more pronounced in some species of fish, specifically the gadoids. In these species, the chemical breakdown of TMAO to DMA and FA and the subsequent crosslinking of FA to muscle protein (Matsumoto 1979) produce the textural breakdown in the gadoids and result in a cottony or spongy texture. Fish muscle that has undergone such changes tends to hold its free water loosely like a sponge. When eaten, the fish muscle loses all its moisture during the first bite, and subsequent chewing results in a very dry and cottony texture.

In some species devoid of TMAO-degradation products, muscle fibers also tend to toughen and to become dry during freezing and storage. This is particularly true for most of the nongadoid species and for crab, shrimp, and lobster when stored for prolonged periods. In contrast, the effect of the thawing method on the texture of fish muscle basically depends on the product form. For instance, whole fish, when thawed, exhibits less textural change than filleted fish, basically as a result of the presence of the backbone, which serves as structural support for the flesh. In terms of the effect of the thawing method, it has been reported that microwave thawing results in higher gel strength of minced samples, when compared to samples thawed under running water (20°C) and samples thawed at room temperature (Jiang and others 1985). Consequently, the extent of textural changes depends upon the species of fish and upon the condition of handling, freezing, duration of frozen storage, and the thawing method used.

84.11.3 Changes in Odor and Flavor

Other important changes that affect the palatability of frozen fish include changes in the flavor and odor of fish and seafood. Fish are often described as having a "fishy" odor and flavor. Although the term sounds unpleasant, it can also be used to describe the pleasing taste and odor characteristics of freshly caught fish. Such pleasant, palatable characteristics may be retained as long as the fish are promptly and properly frozen, stored, and thawed. However, the transformation of these attributes to unpleasant and

unacceptable traits occurs very rapidly in some fish species, particularly the fatty fish species.

Changes in the delicate flavor of fish and seafood generally occur in three distinct phases during frozen storage:

- The gradual loss of flavor due to loss or decrease in concentration of some flavor compounds (Dyer 1951; Licciardello and others 1980);
- The detection of neutral, bland, or flat flavor;
- The development of off-flavors due to the presence of compounds such as the acids and carbonyl compounds that are products of lipid oxidation.

These phases, however, only apply to those species with originally delicate, sweet, and meaty flavors. Other species, such as hakes, have an originally bland flavor (Licciardello and others 1980), but develop off-flavors during prolonged frozen storage.

Changes in odor occur in two phases: the loss of characteristic odor and the development of off-odors, which render the frozen product unacceptable. Generally, fish and seafood initially have a fresh, seaweed odor, which can be retained even after freezing and frozen storage. However, gradually such odor is lost, and eventually an unpleasant odor is given off, particularly when abused with inappropriate storage temperature. The development of unpleasant odor is due either to lipid oxidation, a reaction more apparent among the fatty fish species that results in the production of a strong oily, blow oily, or rancid odor, or to the degradation of TMAO, which leads to the production of an unpleasant ammonia odor. Other species such as white hake (*Urophysus tenuis*) initially give off weak odors of sweet, boiled milk, but when frozen storage is extended, hake assumes weak off-odors (often described as milk jug odor) followed by a sour milk odor.

84.11.4 Effects of Storage Temperature

The apparent effects of storage temperature on shelf-life stability of frozen fish are related to protein denaturation and lipid oxidation. The effects of temperature on protein denaturation have been comprehensively studied (Dyer and Morton 1956; Hanson and Olley 1965). Maximum denaturation is reported to occur at $-4^{\circ}C$ in cod muscle (Dyer 1951), while changes in extractable proteins in haddock have been found to be greatest at -2 to $-6^{\circ}C$ (Reay 1983).

The rate of lipid oxidation and the accumulation of FFA were observed to increase with temperature (Connell 1975). In a study using various species of fish, it was observed that maximum production of FFA due to enzymic activities of lipases occurred at -12 to $-14^{\circ}C$ (Olley and others 1962), while the maximum rate of lipid hydrolysis was detected at temperatures just below freezing (Lovern and Olley 1962). Storage at much lower temperatures can, therefore, prolong the shelf life of frozen fish. For example, cod stored at $-160^{\circ}C$ showed no detectable deterioration after 6 months of storage (Connell 1975). Even at -65 and $-50^{\circ}C$, frozen samples exhibited very few changes after 9 months of storage. Such observations also suggest that low storage temperature limits the problems associated with protein denaturation and lipid oxidation during frozen storage.

Several studies have been conducted in an attempt to determine the shelf life of frozen fish at different temperatures and to establish storage temperatures that can minimize

quality deterioration in specific groups of fish. Poulter (1978) reported that *Rastrelliger brachysoma* (club mackerel) stored at −10°C remained acceptable until the ninth month of storage, whereas samples kept at −30°C were rejected after 12 months of storage. *Scomber scombrus* (Atlantic mackerel) stored unwrapped at −18°C were rejected after 3 months of storage, while samples at −26°C remained acceptable until the sixth month of storage (Ke and others 1976). Early rejection of fatty species at relatively low temperatures is reportedly due to the development of rancid flavor and odor. Several studies have also reported the same dependence of shelf-life for different fish species on temperature (King and Poulter 1985; Santos and Regenstein 1990; Screenivasan and others 1976). Clearly, fish composition has an appreciable effect on shelf-life stability of frozen fish. For instance, in a comprehensive study using different fish species, it was found that fatty fish such as mackerel, salmon, herring, sprat, and trout had a shelf life of 2–3 months at −18°C, whereas lean fish such as cod, flounder, haddock, ocean perch, and pollock exhibited storage stability of up to 4 months at the same storage temperature (Bramnaes 1969). Based on several studies, it is recommended that those species most susceptible to oxidative rancidity be stored at very low temperatures (at least −29°C) while species less susceptible to rancidity should be stored at temperatures between −18 and −23°C (Wheaton and Lawson 1985). For species with textural problems due to the TMAO breakdown, the storage temperature must be below −30°C.

84.11.5 Effects of Fluctuation in Storage Temperature

Fluctuations in storage temperatures affect the shelf-life stability of frozen products due to an increase in the size of the ice crystals formed in fish tissues (Shenouda 1980). With slight increases in temperature, small ice crystals melt faster than larger ones, so that when the temperature drops again, the melted ice refreezes around the large ice crystals, forming larger crystals. These large crystals accelerate freezing damage, leading to shorter storage stability.

84.11.6 Effect of Use of Additives

The effectiveness of different food-grade additives has also received considerable attention recently. The most commonly used types of additives for fish and seafoods function either as antimicrobial agents or as antioxidants. The selection of an antimicrobial agent or any combination of agents is rather complicated, especially when dealing with fish. The effectiveness of an antimicrobial agent depends on several factors, such as the moisture content of the product and the presence of other microbial inhibitors like smoke and salt. Several antimicrobial agents have been tested for fishery products. For instance, the sorbic acid salt, potassium sorbate (KS), has been found useful in extending the shelf-life of fresh fish. Studies have demonstrated that KS, when applied as part of the ice, increased ice storage stability of red hake and salmon up to 28 and 24 days, respectively (Fey 1980; Fey and Regenstein 1982). KS, in combination with modified atmosphere packaging (MAP), was also determined to be an effective method for prolonging the shelf-life of fresh whole and filleted haddock on ice (Regenstein 1982). The shelf life of fresh fish may also be extended under refrigerated conditions with the use of Fish Plus, which exhibits its preservative effect due to the combined action of components such as citric acid, polyphosphates, and potassium sorbate. Citric acid lowers the muscle pH, which consequently creates an optimum environment for potassium sorbate

to exhibit its antimicrobial effects. Dipping in Fish Plus has been found to extend the shelf life of lingcod on ice to as much as a week (Nawar 1996). Fish Plus may also be used on frozen fish.

An antioxidant is a substance capable of delaying or retarding the development of rancidity or other flavor deterioration due to oxidation. It is normally used in conjunction with freezing to reduce the rate of autoxidation during frozen storage. Antioxidants delay the development of rancidity either by interfering with the initiation step of the free radical reaction or by interrupting the propagation of the free radical chain reaction (Uri 1960). The kinetic of antioxidative action was considered to be that antioxidants act as hydrogen donors or free radical acceptors (AH) and react primarily with ROO· and not with R· radicals: $ROO\cdot + AH \rightarrow ROOH + A\cdot$.

A low concentration of this chain-breaking antioxidant (AH) can interfere with either chain or initiation, producing nonradical products:

$$\left.\begin{array}{l} A\cdot + ROO\cdot \longrightarrow \\ \\ A\cdot + A\cdot \longrightarrow \end{array}\right\} \text{nonradical products}$$

Various authors have suggested different versions of the antioxidant mechanism (Uri 1960; Hultin 1985). Other antioxidants may function as metal complexing agents, which partly deactivate the trace metals, often present as salts of fatty acid (Hultin 1985), which would otherwise promote the oxidative reaction. Citric, phosphoric, ascorbic, and erythorbic (isoascorbic) acids are typical metal-chelating agents. Among these antioxidants, erythorbic acid was used in studies by Licciardello and others (1980) and Kelleher and others (1981) of shelf-life stability of frozen fish. This antioxidant was emphasized due to encouraging results with the use of its salt, sodium erythorbate, in retarding oxidation in whiting, chub mackerel and white bass fillets (Greig 1967a,b; Licciardello and others 1980). Licciardello and others (1980) demonstrated the effectiveness of erythorbic acid in the retardation of oxidative rancidity in fillet blocks of Argentine hake stored at $-18^{\circ}C$. However, the use of erythorbic acid is limited to fish species in which rancidity is the main problem. Kelleher and others (1981) demonstrated the effect of this compound on the frozen storage of red hake (*Urophysis chuss*), a gadoid species, in which lipid oxidation is not the limiting factor for shelf-life extension. They found that the rate of DMA formation at $-18^{\circ}C$ in samples dipped in erythorbate solution was significantly greatly than the rate in untreated samples. Such effect of erythorbic acid on DMA formation may be explained by the fact that this acid acts as an alternative and preferred scavenger of oxygen. This leaves metal ions that would otherwise bind to oxygen and be inactivated, available to catalyze the degradation of TMAO to DMA and FA (Pedrosa-Menabrito and Regenstein 1988).

84.11.7 Effects of Packaging

Product preparation and packaging significantly affect the quality and shelf-life of frozen fish. If not properly controlled, these processes result in some deleterious effects after prolonged storage.

An efficient packaging system is essential to offset the detrimental quality changes that occur during frozen storage. Packaging materials and methods are obviously designed not

only to protect the product from microbial and chemical contamination, dehydration, and physical damage, but also to protect the environment from the packaged product. Fish and seafood can leak gases or unsightly fluids, which may have unpleasant odors. Therefore, the choice of appropriate packaging materials and methods for frozen fish is a critical factor in terms of shelf-life extension.

Studies have shown that packaging systems affect the quality and shelf stability of frozen fish. For instance, vacuum packaging is well established as a method to provide an oxygen-free environment to minimize the problems associated with lipid oxidation and dehydration during frozen storage. Several studies have shown the effectiveness of this method for frozen storage of some species of fish. For example, it has been reported that frozen blocks of fillets vacuum packed in moisture-proof films showed high degrees of acceptance and desirable frozen characteristics (Crawford and others 1979). Likewise, Santos and Regenstein (1990) reported the effectiveness of vacuum packaging for inhibiting lipid oxidation in frozen mackerel fillets. Ahvenainen and Malkki (1985) examined the influence of packaging on frozen herring fillets stored at different temperatures. They found that vacuum-packed product covered with metallized cardboard had a longer shelf-life than a product vacuum packed and stored without cardboard.

Vacuum packaging, on the other hand, need not be used if lipid oxidation is not the limiting factor affecting the shelf-life of a product. Although the effect or absence of oxygen in packages on some fish species must be considered, other packaging methods such as glazing and the use of heat-sealable packaging films should also be considered. Pacific hake minced blocks stored in moisture-proof, vapor-proof packaging films exhibited superior quality over glazed samples (Crawford and others 1979). Likewise, Colokoglu and Kundacki (1983) observed frozen mullet packed in plastic films with low permeability to oxygen and moisture to have a longer shelf life than when unpacked in the glazed form. However, it should be noted that glazing is still considered to be the cheapest means of protecting frozen fish during storage and transport. Glazing provides a continuous film or coating that adheres to the frozen product, which retards moisture loss and the rate of oxidation.

Many different glazes are available, including: (1) those with inorganic salt solutions of disodium acid phosphate, sodium carbonate, and calcium lactate; (2) alginate solution, otherwise known as the "Protan" glaze; (3) antioxidants such as ascorbic and citric acids, glutamic acid, and monosodium glutamate; and (4) other edible coatings such as corn syrup solids (Wheaton and Lawson 1985). Ice glaze is particularly important in handling frozen fish in developing countries. For products intended for short-term storage, glazing can be practically utilized as a viable alternative to storage without a protective covering. For instance, Jadhav and Magar (1970) concluded that glazing was a cheaper alternative to expensive packaging systems for glazed Indian mackerel (*Rastrelliger kanagurta*) stored at -20°C. Glazed samples had a shelf life of 6 months, while samples without a protective covering lasted only 3–4 months.

84.12 CONCLUSION

In summary, freezing, frozen storage, and thawing affect the quality and shelf stability of fish and seafood. If kept under appropriate conditions, fish and seafood can be stored in the frozen state for several months without appreciable changes in quality. During frozen

storage, microbiological changes in fish and seafood are very minimal. On the other hand, a series of changes such as protein denaturation, lipid oxidation, texture deterioration, loss of fresh odor and flavor, various enzymatically induced reactions, loss of volatile constituents, nutritional losses, and changes in moisture take place in fish and seafood when subjected to excessively prolonged frozen storage. Likewise, such changes may also occur in freeze-thawed fish and seafood. Quantitative evaluation of the influence of freezing, frozen storage, and thawing on fish and seafood is rather complex. The different variables that influence quality are related to one another. Therefore, it becomes almost impossible to describe some quality changes without actually discussing the other related changes that occur in fish tissues.

85.1 INTRODUCTION

Freezing is the most adopted method of preserving shellfish. Since chilling is not sufficient for maintaining the shellfish quality for longer storage periods, freezing has developed to be an excellent storage method. Good freezing and cold storage enables the shellfish to be kept for very long periods. Spoilage of shellfish occurs due to putrefactive bacteria that produce degrading enzymes leading to autodigestion. The growth of spoilage bacteria and the enzyme activity can be reduced by lowering the storage temperature.

The method of freezing is the most influencing factor affecting the quality of the frozen product. The choice of a particular freezing system largely depends on the type of product to be frozen, the freezing time required by a particular product, the product conditions and the amount of raw material. A number of freezers or freezing methods are in practice in the industry and careful selection of freezing equipment is necessary for best quality products. The popular methods of freezing are: blast freezing, cryogenic freezing, liquid nitrogen freezing, carbon dioxide freezing, spray or immersion freezing, and pressure shift freezing. Each method has its own advantages or drawbacks over other methods.

During freezing and cold storage, products undergo a complex sequence of chemical, physical, bacteriological and histological changes. These changes become more apparent when the product is thawed. Color, flavor, and texture of the products are the most vulnerable characteristics, which are affected by freezing. In shrimps, crabs, and lobsters, formation of black or blue pigments is observed. Protein denaturation causes loss of juiciness and results in a poor texture of the product. Similarly, the pleasant taste of shellfish is lost during storage due to lipid oxidation. These problems can be overcome by providing the most appropriate freezing and subsequent thawing conditions.

Freezing alone is not sufficient for preservation and is merely a method for preparing the shellfish for storage at a suitably low temperature. Different types of pretreatments such as cooking, boiling, blanching, and precooling are performed before subjecting the shellfish to freezing method. The methods or steps for preparation are solely dependent on type of shellfish and its anatomy. For example, shrimps are generally blanched in salt solution prior to freezing and lobsters need to be cooked in brine solution. Similarly butchered crabs are cooked before freezing and oysters are frozen with or without shell. A brief description of each method and its suitability is discussed in the subsequent section of this chapter. To ensure understanding of different types of shellfish and their handling prior to freezing, the following section includes description about shellfish in general.

85.2 SHELLFISH VARIETIES AND HARVESTING METHODS

85.2.1 Shrimps

There are almost 300 species of saltwater and aquaculture shrimps that are marketed worldwide. Saltwater shrimps are categorized as warm and cold water species. Warm water shrimps are classified by shell color such as white, pink, and brown and harvested in the South Atlantic and the Gulf of Mexico. These are *Penaeus setiferus*, *P. aztecus*, and *P. brasileinsis* (http://www.ncfisheries.net/kids/3shrimp.htm). Cold water shrimps that possess firmer meat and sweeter flavor are caught in North Atlantic and Northern Pacific regions. These are *Pandalus borealis*, *P. dispar*, *P. goniurus*, *P. platyceros*, and *Cragon franciscorum augustimana*. The sea shrimps are captured by a trawl net from the stern of the trawler. The trawl is a large funnel shaped bag held open by otter boards for entrapping the shrimps. Since the trawl catches other animals too, considerable time is needed to separate the shrimps from other sea fishes (http://www.seafoodhandbook.com/harvest.html).

Aquaculture shrimps, especially black tiger shrimps (*Penaeous monodon*), are commonly raised in Asia. In 1996, the world shrimp production was around 3 million tons. According to FAO, Thailand is the top farmed shrimp producer while China and India produce 80,000 and 70,000 tons, respectively (http://www.fao.org/waicent/ois/press_ne/presseng/1997/pren9735.html). Another species indigenous to Indo-pacific region is the blue-legged or giant–long-shrimp (*Macrobrachium rosenbergii*). This shrimp species can be sorted into eight categories based on physical parameters into large, medium, small short-claw males, long-claw males, females without eggs and females with eggs, soft shell or newly moulted males, and terminal growth males (Lin and Boonyaratpalin 1988). The common gears used for harvesting these varieties are cast net, haul net, large dip net (George 1969), and sometimes electric catching gear (Liao and Chao 1982). Two harvesting techniques that are applied are referred as cull (continuous) and drain (batch) harvesting. In cull harvesting, the shrimp are captured by a single seine operation where five to six labors at different locations in the pond beat the water surface and walk in the same direction as the seine is being pulled. The advantage of this practice is that the small-sized shrimps are returned to the pond. In batch technique, the water is drained through a water gate behind which a bag net is fixed. Shrimps swept along the stream of water are collected in this net. Drain operation is usually applied when the shrimps attain market size or when the cessation of farming activities is forced by lack of water or fall of temperature (New 1988). Those live shrimps are immobilized and killed by dipping in iced water or ice brine (3% salt) slurry and then packed single-layered on ice. This layering prevents the shrimps from damaging one another and retards tissue degradation (New and Singkolka 1982).

Shrimps are low in fat and calories but are higher in cholesterol than most seafood (Gordon and Martin 1982) (Table 85.1). Fresh shrimps have a clean smell, with no trace of ammonia and indole. If caught many miles from shore, the shrimps are usually beheaded before the vessel reaches the dockside so that considerable space is saved.

After unloading from the vessel, ice is removed and the shrimps are conveyed to a rotary drum that removes the surplus water and debris. After this operation, the shrimps are weighed and graded according to size. For peeled and deveined products, the shrimps with shells on are peeled and deveined by hand or by a mechanized process. After peeling, the tail meat is washed and inspected. They may be blanched in salt solution

[4]Wheaton and Lawson (1985a).

for about 10 min and dried to remove excess water prior to freezing. Four common forms of shrimps are prepared for the frozen markets. They are frozen headless, frozen peeled and deveined, uncooked frozen and breaded, and headed and unshelled (http://www.seafoodhandbook.com/harvest/shrimpforms.html).

A temperature of -32 to $-40^{\circ}C$ is recommended for freezing shrimps as at low temperatures, the development of rancid flavor is minimized (Dassow 1968). Such lower temperatures could be achievable by using blast or multiple freezers.

85.2.2 Lobsters

Lobster, the king of crustaceans, provides a sweet and succulent meat. Live lobsters have hard and intact shell and when the lobster is lifted, its tail curls (http://www.seafoodhandbook.com/safety/quality.html). Two species of lobster that are common in the market are the American lobster and rock lobster. American lobster or true lobster and Northern lobster (*Homerus americanus*) are caught from the main coast while rock lobster or spiny lobster (*Jasus lalandii*) are found off Florida West Coast, Southern California, and the Pacific, usually from Australia and New Zealand. The difference between those species is that the rock lobsters lack large claws but have long spiny antennae or feelers. Three rock lobster species that are marketed worldwide are *Panulirus*

argus, *P. interruptus*, and *P. Cyanus*. The lobsters are caught by either baited trap or trawlers. The trap that consists of an oblong box made of laths or wood slats spaced to allow the undersized animals to escape, is used to gather the inshore lobster. The latter gear is suitable for deep-sea lobsters inhabiting in water up to 200 fathoms deep.

Prior to freezing, different methods are used, for example, it needs to be cooked in 3% brine for 10–20 min. However, the heat requirement of deep sea lobster is only to cook the meat next to shell only. This is done to avoid sticking of the meat to the shell or it might give an electric shock. For spiny lobster, the preparation steps include breaking the tail from the body for removing the intestine.

Lobster meat is packed in cans for freezing with a normal packaging size between 14–16 oz. When lobster meat is stored frozen at a temperature of $-23^{\circ}C$ or lower, its quality is good and has an intended shelf life of 3 months.

85.2.3 Crabs

Crabs are found in the Atlantic and the Pacific and are divided basically into two categories such as the swimming crabs and the walking crabs. The dominant varieties in the market are blue crab (*Callinectes sapidus*), stone crab (*Menippe mercenaria*), dungeness crab (*Cancer magister*), Alaska king crab (*Paralithodes camschatica*) and tanner crab (*Chionectes* spp.). The crabs are mostly captured by single pots. This harvesting method is very selective and the products are of good quality. The pots are baited with fresh fish and dropped to the bottom of the ocean with a heavy line and marker buoy. The legal size male crabs are daily collected by hauling the pot up from the water. Trotline and dredges are other gears which are used for harvesting the blue crabs. The trotline, in which the baits or lures are dragged behind a vessel as it moves through water, is used to catch the crabs when the animals are actively feeding. The crabs in a dip-net are collected while the baits are raised to the water surface. The dredge, which has teeth along the bottom bar of metal frame to dislodge the animals from the bottom, is principally applied during winter. Two dredges are dragged from a boat and hauled alternatively (http://www.seafoodhandbook.com/harvest.html). The crabs are usually butchered by stationary iron blade and carapaces removed, after unloading. The animals are split into halves and cleaned. Both whole crabs and butchered crabs have to be cooked prior to freezing. The cooking is performed by subjecting the crabs in boiling water or 3% brine at temperature of $100^{\circ}C$ for 20–25 min, depending on species and form of preparation (Dassow 1968). In case of blue crabs, cooking retort may be applied at a temperature of $121^{\circ}C$ for 3–20 min. Meat removal of king crabs is done by shaking or blowing with water under pressure and sometimes with rubber rollers. In blue and dungeness crab, meat is removed manually.

Crabmeat is delicately sweet, firm but flaky and is categorized as white body meat and claw meat. The white meat includes lump, backfin and flake, or regular. Lump meat is the finest and most expensive. It consists of large, choice chunks of body meat. Backfin is smaller pieces of the body meat and flake is white meat from any part of the body (http://www.seafoodhandbook.com/harvest/crabmeatforms.html). Cut meat pieces are packed into cartons or trays for freezing. The meat in blocks of cartons is given an ice glaze before packing and shipped to cold storage having temperature between $-18^{\circ}C$ to $-23^{\circ}C$.

85.2.4 Oysters

Oysters differ from other crustacean shellfish due to higher carbohydrate and lower total nitrogen content in their flesh (Wheaton and Lawson 1985a; Jay 1992) (Table 85.1). Species such as Eastern oyster (*Crassostrea virginica*), Pacific oyster (*Crassostrea gigas*), and Olympia oyster (*Ostrea lurida*), are of economic importance. Oysters can be harvested by picking, tonging, and dredging. Picking is generally confined to the area exposed due to low tide. Tonging and dredging are common techniques adopted to capture the oysters as they collect the animals in larger numbers. Tongs consist of two poles crossed like scissors and possess toothed iron baskets at the end of the poles. They are lowered to the seafloor to scoop up the animals and then are closed before raising the tongs from the bottom (Wheaton and Lawson 1985b). Similar to the former gear, a dredge is a metal rake that is dragged across the bottom of the ocean, scraping up oysters in its path. The oysters are carried up from the bottom either by a conveyor belt or flowing water through a large diameter hose (Banks and others 1977).

If the oysters are marketed in the shelled form (unshucked), only washing, packing, and chilling is required. Though most oysters, however, are sold as shucked meat, which is prepared by manual labor. After shucking, oysters are preliminary rinsed as the pieces of shell and torn or discolored and culled out. Then they are aerated in blowing tanks to remove sand, silt, and shell fragments. The washed meat is graded by size and packed into suitable packaging (Wheaton and Lawson 1985c), which is dependent on the freezing method. For example, compression plate freezing are suitable for meat packed in waxed cartons and overwrapped while blast tunnels are suitable for meat packed in cans. Freezing rates should be high and freezing temperatures should be as low as possible. Recommended temperature of freezing is -18°C, although oyster meat may remain in good condition for more than 9 months when stored at -29°C (Peter 1968). However, storing oyster meat for more than 6 months degrades the raw material quality, especially if the storage condition is not easily consistent.

85.2.5 Clams

Clams may be hard-shelled or soft-shelled and the edible portion consists of the muscles, the siphon, and the feet. Clams are generally sweet and a bit chewy. Several varieties are available in the market and their flavor and tenderness depend on the size and species. Some of them are hard clam or quahog (*Venus mercenaria*), sea clam or skimmer clam, or surf clam (*Spisulla solidissima*) and soft clam (*Mya arenaria*). These bivalves are scooped from the sand at low tide and from beds in deeper water on Atlantic and Pacific coast by dredging operation. Live clams after capture should be tightly closed, with a fresh smell. The neck of soft shelled clams retards when touched (http://www.seafoodhandbook.com/safety/quality.html). After harvesting, the clams are first washed to remove sand and silt and the shell is then removed. In some processes, the clams are eviscerated by squeezing the meat that removes the stomach and other soft tissues. The shucked animal should not dry out, shrivel or discolor or its quality is degraded substantially. Clams may be chopped, sliced into strips, or left whole before packing and freezing. Like other shellfish, storage and freezing type are also dependent on the type of container used. Smaller packages (2 kg) are best frozen by compression plate method and larger cans are recommended to freeze by either blast or shelf coil methods.

85.3 FREEZING METHODS

Freezing and subsequent cold storage is an excellent process for preserving the quality of shellfish as long as 18 months or more. During this period, a complex series of chemical, physical, bacteriological, and histological changes takes place. The factors that must be considered while adopting a freezing or storing technique are listed below (Banks and others 1977).

- Type of product to be frozen;
- Allowable freezing time for products of average weight;
- Handling requirements;
- Source of available power;
- Space requirement;
- Amount of raw material;
- Cost of equipment and operation.

85.3.1 Sharp Freezing

Sharp freezing is generally considered as slow freezing method because it takes 3–72 h, depending on the quantity of the product to be frozen. The procedure consists of placing the products in a cold room where temperatures are maintained in the range of $-20^{\circ}C$ to $-40^{\circ}C$. The disadvantage of this method is its low freezing rate and high labor cost. In addition, the cooling coils may frost during the loading and unloading of the products. Therefore, defrosting is required at least once every 6 months. Sharp freezer consists of an insulated room with multishelf racks for holding the product, which are stacked one above another. Each shelf is constructed of pipe formed into a horizontal flat coil. Refrigerant, especially ammonia is expanded through the coils lowering its temperature to the desired level.

85.3.2 Plate Freezing

Plate freezer is accomplished by direct contact between a cold plate and the products. Pressure applied to the plates on each side of the products improves contact and increases the heat transfer coefficient between the plate and the products. The pressures applied by an hydraulic press, in the range of 1 and 10 bar. Since the pressure exerted is constant expansion takes place as the product freezes. Consequently expansion takes place inside the package until all voids are filled. Approximately 7% expansion occurring in the products during freezing is sufficient to fill voids and compress the products into single block during freezing. The two most common types of plate freezers are the horizontal plate freezer and vertical plate freezer, both made from extruded aluminium. Both types efficiently freeze only regular-shaped packages or blocks. Horizontal-plate freezers are likely used to freeze prepacked retail flat cartons of shrimps, both with and without shell. The products are usually wrapped in plastic film and then packed in cartons or directly on to aluminum freezing trays, which are in turn, placed on the freezer shelves (Garthwaite 1997). Plate freezing is also applied to spiny lobsters and clams.

85.3.3 Blast Freezing

Blast freezing is a method where cold air having a temperature between $0–40^{\circ}F$ is used to remove the heat from the products before transporting it to the refrigeration coils.

Although the general operating principles, there are several types of blast freezers, varying in airflow, loading method, and capacities. Most blast freezers use average air velocities of 2.5–7.5 m/s, while 2.5–5.0 m/s is reported as the most economical velocity range. Blast freezing is done either by tunnel freezing or fluidized bed freezing.

In tunnel freezing method, the products are placed on trays, either loose or packaged. The trays are placed on a moving mesh belt passing through a tunnel or enclosure where the cold air is blown from the opposite end. In some designs, cold air is circulated on both top and bottom ends of the entire length of the freezing belt so that a better distribution of the cold air is obtained. The main advantage of tunnel freezers is that they are versatile and are suitable for irregular-shaped, different-sized and nondeformable foods such as crustaceans, fish fillets, and added-value products. However, tunnel freezers have a slightly slower freezing rate compared with immersion freezing. Besides dehydration of the products may occur during the operation, which results in the constant need of defrosting the equipment. To reduce the moisture loss from the products, two or more stages of freezing are introduced. It is because when large volumes of air of high relative humidity are applied in the first stage, the products are frozen with minimum water loss. In the later stage, the temperature and vapor pressure differences are not so high. Therefore, the cold air has substantially less desiccating effect.

In some plants, where high capacity or extended freezing time is required, the use of spiral freezers is suggested. The single, continuous belt can be operated on a single- or twin-drum application in ascending or descending combinations. The whole system is enclosed in an insulated chamber. Blast freezing is suitable for many aquatic food products such as for king crab in the shell packed into tray or carton, whole dungeness crab in can and peeling and deveining shrimp on thin aluminum sheet. Due to high demand of IQF frozen products, fluidizing belt freezers are extensively used. The procedure requires a sufficiently powerful stream of cold air to keep the products in suspension. The advantages of fluidized bed freezing are short freezing time since each piece of food is kept loose and free flowing by the air pressure, resulting in higher yield. Retention time for freezing operation depends upon the size of the products, for example, small shrimps require 6–8 min as the large size shrimps require 12–15 min. Freeze-Pak fluidized belt freezer and Lewis fluidized bed freezer are the common type of fluidized freeze dries (Banks and others 1977).

85.3.4 Cryogenic Freezing

Cryogenic freezing is the ultra fast freezing process where the products are exposed to an extremely cold refrigerant. The products could be packed or thinly packed and the resulting quality of the products is very high. In this method, the heat removal is accomplished during a change of state by the refrigerant. The advantages of cryogenic freezing are rapid rate of freezing, simplicity, flexibility, and inexpensive equipment design. Refrigerants that are commonly used in plants are liquid nitrogen or carbon dioxide (Garthwaite 1997).

85.3.4.1 Carbon Dioxide Freezing. Carbondioxide exists in liquid state about its critical condition of $-31^{\circ}C$ and 7.35 MPa absolute pressure. Its triple point is at $-56^{\circ}C$ and 7.35 MPa absolute pressure. Freezing with carbon dioxide is done by passing the products under specially designed nozzles. Liquid CO_2 supplied to the nozzles at about 300 psi is sprayed toward the products as they move under the nozzles

on a conveyor belt. Due to the high pressure, the CO_2 changes its state as it leaves nozzles and absorbs large quantities of heat from the products.

The principle behind using carbon dioxide is that at atmospheric pressure and room temperature, solid CO_2 (dry ice) converts directly from a solid to gaseous state (sublimation) leaving no liquid residue. As sublimation of dry ice occurs at $-78.5^{\circ}C$, it is possible to freeze a product to a temperature as low as $-75^{\circ}C$ (Wheaton and Lawson 1985d). Freezing under these circumstances is very rapid and drip losses are reduced to less than 1% (Garthwaite 1997). A good example of using dry ice as cryogenic freezing is thermice process. The operation involves mixing of the comminuted dry ice with the products in the interior of a slowly rotating and insulated drum. The rotation of the cylinder turns the products over and over in dry ice and also break up the gas film on the product as well. It is noted that all of dry ice must be separated from the frozen products before the products are packed otherwise the package may explode due to the pressure of the gaseous CO_2 in headspace (Banks and others 1977).

85.3.4.2 Liquid Nitrogen Freezing. The critical point for nitrogen is much lower than that of carbondioxide, though it is achievable at $-147^{\circ}C$ and 3.39 MPa. The triple point occurs at $-210^{\circ}C$ and 12.6 kPa. Liquid nitrogen is nontoxic and relatively cheaper and is obtained as a by-product during production of oxygen from air. Liquid nitrogen freezing systems are divided into three types; that is, immersion type, spraying of liquid nitrogen and circulation of cold nitrogen vapor. However, the spray method is commonly applied in food industries in which the products are placed on a conveyor belt in a single layer moving in the opposite direction to the flow of nitrogen. Warm products entering the freezer are first subjected to a blast of cold nitrogen gas (typically at about $-50^{\circ}C$). This precooling prevents stress cracking in the products that can occur due to rapid cooling. Later, the products are headed to direct application of liquid nitrogen, which has a boiling temperature of $-196^{\circ}C$ at atmospheric pressure. In the last freezing section, equilibrium of temperature occurs between outside and the center of the products (Wheaton and Lawson 1985d).

The application of liquid nitrogen is commonly applied for shrimps and oysters. The frozen products have lower indole and trimethylamine contents (Bank and others 1977). In addition, the protein changes are less and the drip loss during thawing is low.

85.3.5 Immersion Freezing

Immersion freezing is a simple technique, in which the products are immersed into a low temperature liquid such as sodium chloride brine, sugar solution, or glycerol. Sodium chloride that has a eutectic point of $-212^{\circ}C$, is normally applied in the freezing process at a temperature of about $-15^{\circ}C$. Further reduction in temperature is achieved by transferring the products to cold storage. The limitation of immersion freezing is the suitability of refrigerating medium (Garthwaite 1997). The freezing medium should contain chemicals that should be edible and be capable of remaining unfrozen at $-17.8^{\circ}C$ and slightly below. The refrigerating temperature also needs to be carefully controlled. If the medium temperature is too high, it will enter the products by osmosis and if too low, the medium may freeze the products. Moreover, it is difficult to maintain the concentration of medium at a fixed value (Banks and others 1977). Crabs and shrimps are commonly frozen by brine immersion. Cooked whole and eviscerated crabs in shell are dipped into circulating brine of 88° salometer

at −18 to −15°C for 45 min then brought into fresh cold water to remove excess brine and provide an ice glaze (Garthwaite 1997).

85.3.6 Pressure Shift Freezing

Pressure shift freezing is carried out in a high pressure vessel where the temperature is controlled at subzero levels. The advantage of this technology is that it achieves uniform super-cooling in the products. The products are at first refrigerated under pressure and no ice crystals are formed in this step. The pressure is then released to atmospheric pressure. This phenomenon causes three significant phases. The first phase corresponds to cooling down the products without phase change. In the second phase, a sudden temperature rises up to the phase change temperature at the current pressure. Finally, partial freezing is initiated due to the high super-cooling of the product (Chevalier and others 2000).

85.4 GLAZING

Glazing is the process of coating a frozen product with a layer of ice to retard the process of moisture loss and oxidation. Glazing is usually accomplished by dipping the frozen products into a tank of chilled water or by spraying a light coating of chilled water onto the frozen products. The low product temperature results in the formation of a layer of ice on the exterior of the product. The amount of ice per product varies based on the temperature of the frozen product and glazing water, and the residence time in the glazing tank. Dipping in tank could lead to the possibility of contamination, especially if the water is not so clean and therefore spray system provides an added advantage over the dipping method. Different additives are applied in chilled water for different purposes (Santos-Yap 1996). The most common additives are organic salt solution of disodium acid phosphate, sodium carbonate and calcium lactate; alginate solution; ascorbic, citric and glutamic acid and monosodium glutamate and other edible coatings such as corn syrup solids.

The additives help in preventing oxidation, improving the appearance of the products, and strengthening the ice layer. This prevents the product to become brittle and fracture when it is bumped or dropped (Pigott and Tucker 1990).

Glazed products have a shelf life of at least 6 months while products without a protective covering last only 3–4 months. During storage evaporation occurs from the glazed layer only. Other preferable technique is to subject the product to a moisture-vapor proof over-wrap on the product package. This ensures prevention of water loss during prolonged storage under freezing condition.

85.5 THAWING

Appropriate method and conditions of thawing are as important as selecting a suitable freezing method because it can affect the net weight of the products. Improper thawing under forced conditions of warm air or water may cause the products to release its natural juice, thus drying out the product and aid bacterial growth. Therefore, the frozen products should be thawed slowly at temperatures just above freezing

(http://www.seafoodhandbook.com/harvest/frozen.html). Special equipment has been devised for the purpose of thawing, so that the damage to the quality of the product is minimal. During thawing, the frozen blocks are subjected to dielectric heating, being conveyed on a rubber belt through a series of dielectric units. To get an even heat flow across the frozen pieces, blocks are first immersed in plastic trays of water to fill up the voids in the blocks. It takes one hour to thaw a 4-inch thick block (Dassow 1968). Alternatively, cross-flow air blast devices are also used to thaw the frozen blocks.

85.6 PACKAGING

Packaging plays a significant role in minimizing quality loss within the products during periods of frozen storage. The suitable packaging should provide an effective barrier to the ingress of moisture, gasses, and any contaminants from the environment to the products. The special requirements for frozen shellfish packaging are temperature stability and insulation properties. The package material should be physically as well as chemically stable over a wide range of temperatures. It should withstand each stage of production, distribution, and storage. Insulated packages may help to maintain a low temperature throughout the bulk of products during periods outside the freezer and to minimize temperature fluctuations within food products. The common materials used for the packaging of frozen shellfish are plastic materials, metal and paper.

85.6.1 Plastic Packaging Materials

One of the most important characteristic of packaging materials for frozen foods is the low permeability to water vapor. Table 85.2 demonstrates the properties of plastic materials which are commonly used. Low density and high density polyethylene (LD- and HDPE) provide relatively good barrier protection to water vapor but poor barrier protection from O_2 and CO_2. HDPE and polyester terephthalate (PET) can withstand high temperature so they are often used in the prepared foods market. Although polystyrene (PS) has relatively poor barrier characteristics to both water vapor and gases, it is a good thermal insulator and has high impact resistance at freezer temperature. Therefore, it is generally used as a secondary package material (George 2000). Laminate and coextrusion materials built up from two or more of these materials or other films are also used to gain the specific properties required.

TABLE 85.2 Permeability Coefficients ([cm^3][cm]/[cm^2][s][Pa]) of Water and Gases in Plastic Films.

Film Type	Temperature (°C)	Permeability Coefficient × 10^{13}			
		Water Vapor	O_2	N_2	CO_2
Polyethylene, LD	25	93	5.18	1.58	21
Polyethylene, HD	25	13.5	0.825	0.248	3.225
Polypropylene	30	51	1.7	0.33	6.9
Polystyrene	25	1350	1.9	–	–
Polyvinylchloride	25	206	0.034	0.0089	0.12
Polyvinylidene-chloride	30	7.0 (at 25 °C)	0.000383	0.000706	0.0218

Source: Piringer (2000).

The film materials can be used as wrappers (over-wrap and shrink-wrap), bags and liners while semirigid plastics are usually manufactured in the forms of trays and plates, covered by lids.

Recently, modified atmospheric technique has been introduced to improve the retention of quality of frozen food. This is by retarding microbial, physical, chemical, and biochemical changes associated with deteriorative process (Bak and others 1999). Other innovative form is intelligent or smart packaging. Temperature and time-temperature indicators attached to the package are designed to monitor the history of the products (Selman 1995). Other special devices are gas sensing dye, microbial growth indicators, and physical shock indicators.

85.6.2 Paper and Card Packaging Materials

The packages from these materials are in the form of both folded and rigid cartons. The corrugated fiberboard or vulcanized fiberboard paper are used as the shipping container. The materials are usually coated or laminated with wax blend (paraffin and microcrystalline composition) or plastic (polyethylene or polypropylene) to provide adequate barrier protection (Jiang and Lee 2004).

85.6.3 Metal Packaging Materials

The metal commonly used in frozen food packaging is steel and aluminum. Both of them provide highly effective barrier properties for water vapor, oxygen, and light. As cited by George (2000), aluminum becomes more attractive because it can be used safely within microwave ovens. The frozen foods in form of ready meals or ready to cook products are usually packed in aluminum trays, dishes, or cups which offer good rate of heat transfer. These packages are covered with crimped-on aluminum sheet or a sheet of aluminum foil laminated to paperboard (Jiang and Lee 2004).

85.7 PHYSICAL PROPERTIES AS AFFECTED BY FREEZING TREATMENT

Changes in physical characteristics of products such as color, flavor, and texture occur immediately after harvest. If the products are not properly handled during freezing, frozen storage, and thawing, they undergo quality changes hence making the products unacceptable to market and consumers. When the product is to be exported to European or American markets, then the quality standards are more critical. The most common quality parameters that affect the marketability, the price and acceptability of shellfish products are described in the following section.

85.7.1 Changes in Odor and Flavor

Processing conditions of freezing, storing, thawing, and cooking have maximum effect on the flavor and odor of shellfish. Since the flavor and odor components are usually volatile, a slight change in the temperature of processing, be it any stage effects the taste of the shellfish, which is the most important criteria for consumer acceptance. Shellfish have a mild and sweet taste, that is lost quickly when stored under unsuitable conditions.

Generally odor changes occur in three phases, that is, gradual loss of flavor due to loss or decrease in concentration of some flavor compounds; the detection of neutral, bland, or flat flavor; and the development of off-flavor due to the presence of acids and carbonyl compounds from lipid oxidation and degradation of trimethylamine oxide (Santos-Yap 1996). Flavor and odor components found in shellfish are mostly classified as nitrogenous compounds. Those nitrogenous compounds comprise free amino acids, low-molecular weight peptides, nucleotides, and organics.

Shrimps and crabs possess high level of amino acids such as taurine, proline, glycine, alanine, and arginine but only traces of peptides are detected. Nucleotides serving as important palatable taste producing factor are found in shellfish as adenosine monophosphate (AMP). Small amount of adenosine diphosphate (ADP), inosine monophosphate (IMP), guanosine monophosphate (GMP), and uracil monophosphate (UMP) are detected in the leg meat extracts of boiled crab as well (Konosu and Yamaguchi 1982). Trimethylamine oxide (TMAO) is a common base usually found in muscle of fish and shellfish. In postmortem stage, this compound is reduced from trimethylamine which provides fish odor by bacterial strains of Enterobacteriaceae including, *Escherichia coli*, *Achromobacter*, *Micrococcus*, *Flavobacterium*, nonfluoresscent *Pseudomonas*, *Clostridium*, *Alcaligenes*, and *Bacillus* spp. (Regenstein and others 1982). As cited by Konosu and Yamaguchi (1982), TMAO is detected in crabs and shrimps in the range of 65–140 and 172–213 mg/100 g, respectively. The other important quaternary ammonium base is glycine betaine found in crabs and shrimps in amount of 357–711 mg/100 g and 251–961 mg/100 g, respectively. The variations depend upon species, growth, freshness, parts and tissue, season as well as environment condition. Other decomposed odor in shrimps is indole. This strong odor is a result of highly proteolytic, indole positive bacteria such as *Aeromonas* and *Proteus* spp. These microorganisms attack muscle protein and convert tryptophan to indole. The reaction is aggravated when the shellfish is stored under high temperatures therefore, high level of indole may be used to indicate temperature abuse (Smith and others 1984).

85.7.2 Color Change

Among all the shellfish, shrimps are more prone to color changes. The binding of protein with asthaxanthin, the dominant color component results in grayish color to shrimp. As soon as the shrimp is subject to heat, such as boiling, the attached protein degenerates, and pink color of the shrimp appears. Many a times, there is a rapid formation of black pigments which is referred to as melanosis, occurs within few hours after death and is enhanced by exposing the shrimps to air. This reaction is the result of phenol oxidation in the internal shell surface and can occur within 2–12 h of exposure to air (Banks and others 1977). The reaction can occur even at 0°C, however, at −18°C, no visible spots are detected for 3 months (Garthwaite 1997). The discoloration starts at both the ends of overlapping shell segments and then it develops into black bands or zebra appearance. In advanced stage, the oxidation reaction of tyrosinase on tyrosine results in melanin pigment on the underlying shrimp meat. Copper and other metallic irons can accelerate the reaction. Thawing at even 0°C could lead to melanosis due to the unnecessary exposure of the shrimps to air thus leading to oxidation.

In crabs and lobsters, too, the development of blue or black discoloration referred to as blueing is one of the most common and severe problems. Blueing may occur after freezing or during frozen storage, after thawing or even shortly after cooking. This bluish-black

curd-like discoloration appears to be related to biuret-type reaction, which occurs due to the copper pigments in the circulating fluid and the heat denatured protein. In crab as well, blueing relates with the change of phenolic compounds in crab as well (Babbitt 1982). Tyrosinase and phenol oxidase in live crabs initiate oxidation reaction followed by nonenzymatic oxidation and polymerization. The oxidation particularly occurs under alkaline conditions and or in the presence of metals such as copper and iron. Molting stage can aggravate the incidence since the phenolic compounds are involved in the formation of the new shell. Blueing discoloration in king crab meat could be reversed by using a reducing agent such as sodium sulfite solution (Banks and others 1977). Antioxidants such as ascorbic acid and metal chelating substances like phenylthiourea are also active in inhibiting the action of oxidases in crab (Babbitt 1982). Heating the crabs at 100°C for 20 min inactivates all enzyme activities. However, the best way to reduce the blueing discoloration is processing only live crabs that are properly harvested and handled.

In addition to blueing, yellowing, and fading of the red or orange-red carotenoids also occurs in crab and lobster. Both infer the degree of oxidation during processing or prolonged cold storage, which solely depends upon the retention time of exposure to air and temperature, freezing, and storage conditions. Microorganisms also cause discoloration in some shellfish, for example, Asporogenous yeast can grow and produce pink pigment when contaminated in oyster (Jay 1992).

85.7.3 Free Liquor or Drip

Free liquor or dripping occurs during thawing of the frozen shellfish products. The drip or exudate formation is directly related to the capacity of the animal protein to hold moisture (Garthwaite 1997). A cloudy liquid occurs due to the rupturing of cell walls caused by ice crystal formation during freezing. During cooking, there is an increase in the release of liquor resulting in the loss of water-soluble proteins, particularly sarcoplasmic protein, vitamins, and minerals. This indicates inappropriate handling, prolonged ice storage prior to freezing, improper cold storage or thawing technique. For example, frozen oyster could have a drip loss of over 20% depending on the conditions of blowing (Banks and others 1977).

85.7.4 Texture Changes

Texture is one of the most important parameters of cooked shell fish, though it varies with individual customer's acceptance. The textural changes are usually caused by protein denaturation. Frozen shellfish lose their juiciness and succulence after freezing and subsequent frozen storage. The muscle of the shellfish loses all its moisture at the first bite and this leads to a dry and slightly tough texture. Species and storage temperature are the main factors affecting the change in texture, for example; dungeness crab meat is less juicy than king crab meat when kept at −18°C. Lower storage temperature can also improve the storage quality of aquatic animals.

In some species of shellfish, mushiness or softening of the flesh occurs. These include sand crab (Slattery and others 1989), rock lobster (Wessels and Olley 1973), and blue legged shrimp (Baranowski and others 1984). This texture deterioration is due to the proteolysis of digestive enzymes from hepatopancreas (Nip and others 1985; Slattery and others 1989). Mushy shellfish is externally indistinguishable from the fresh animals and the condition becomes evident only after cooking. Poor handling can aggravate quality deterioration by accelerating the rate of degradation. Blanching can be used to lessen

the problem because enzymes are inactivated at temperatures higher than 70°C. Deheading is the other way to diminish the enzyme problem especially in shrimp. By doing this, the hepatopancreas, the major source of digestive enzyme, are removed. The disadvantage of deheading is that the product possesses less flavor because of the removal of the hepatopancreas which is the main source of flavor (Vongsawasdi and Noomhorm 2000). Moulting stage is also a crucial factor affecting the degree of mushiness. Pre- and postmoult shrimps are mushier due to a larger proportion of short fiber compared to the intermoult stage (Angel and others 1986; Slattery and others 1989). Moreover, the animal begins to absorb water upon entering the premoult stage. Such water may soften the tissue by disintegrating the interfiber connection within the muscle. After moulting, the amount of water in the tissues gradually decreases but it is enough to cause significant myofibrillar disruption and consequently mushiness occurs (Angel and others 1986).

85.8 MICROBIOLOGICAL QUALITY

Freshly caught shellfish are highly perishable due to accelerated bacterial activity at normal temperature. Due to this, the animals are either frozen or boiled immediately

TABLE 85.3 Microbial Spoilage of Some Shellfish.

Shellfish	Microorganisms
Shrimp	*Acinetobacter*[1] *Moraxella* (at 5–11°C)[1,2] *Vibrio*[1] *Pseudmonas* (at 0°C)[1,2] *Proteus* (at 16–22°C)[2]
Crab meat	*Pseudomonas*[1] *Acinetobacter*[1] *Moraxella*[1] *Proteus*[1]
Raw lobster	*Pseudomonas*[1] *Alcaligenes*[1] *Flavobacterium*[1] *Bacillus*[1] *Vibrio* (including *Vibrio parahaemolyticus*)[1]
Oyster	*Pseudomonas*[1,3] *Acinetobacter*[1,3] *Moraxella*[1, 3] *Serratia*[3] *Proteus*[3] *Clostridium*[3] *Bacillus*[3] *Escherichia*[3] *Enterobacter*[3] *Flavobacterium*[3] *Lactobacilli*[1,3] Yeasts[1,3]

[3]Jay (1992).

after capture. The incidence and number of microorganisms greatly depend on the quality of water from which these animals are harvested. The initial flora found in freshly caught oysters are *Alcaligenes*, *Flavobacterium, Moraxella*, *Acinetobacter* spp., while shrimps, crabs, and lobsters have a bacteria laden slime on their body surfaces including *Bacillus*, *Micrococcus*, *Pseudomonas*, *Acinetobacter*, *Moraxella*, *Flavobacterium*, *Alcaligenes*, and *Proteus* spp. (Frazier and Westhoff 1988). When the shellfish are frozen, these microorganisms are generally inactivated and microbiological changes in shellfish tissue are minimal. Although some microorganisms survive with their activity temporarily suppressed, bacterial numbers may be considerably reduced if recommended temperature is maintained. The temperature below which microbial growth is considered to be minimal ranges between -10 to $-12^{\circ}C$ (Matches 1982). However, the survival microorganisms, usually psychrotrophic bacteria, for example, *Pseudomonas*, *Acinetobacter*, *Moraxella*, *Alcaligenes*, and *Flavobacterium* spp., may grow after thawing and lead to microbial spoilage of the thawed products (Frazier and Westhoff 1988; Hayes 1992) (Table 85.3). The microbial activity depends on the degree of freshness of the raw material, natural microflora in the shellfish tissues and the thawing technique adopted.

85.9 BY-PRODUCTS OF FROZEN SHELLFISH

The meat is the most important component of shellfish, however waste from these crustaceans could be extremely valuable too. The shellfish waste from shrimp, crab, squid, cuttlefish, oyster, clams, and lobsters is rich in chitin, a biopolymer with innumerable applications (Knorr 1984). The shellfish such as shrimps also consist high quantities of protein as well as minerals (Rao and Stevens 2005). In many countries the biowaste obtained from the crustacean processing factories is released in the environment resulting in severe pollution of soil and surface water. In some countries the biowaste is sold to the feed mills at low prices. Realizing the potential application of chitin and its derivatives, many companies utilize the waste by processing immediately for chitin production or sell to other companies at better prices, to be eventually converted to chitin. To preserve the quality of waste, it needs to be sold or processed in frozen conditions.

The chitin content in crustaceans is very high varying from 11% in shrimp heads, 27% in shrimp shells, 12–18% in commercial shrimp waste, 24% in snow crabs, and 30–35% in squid pens. Chitin is a naturally occurring polymer constituting of N-acetylglucosamine units, some of them being deacetylated (Sannan and others 1976). The deacetylated derivative of chitin is known as chitosan, which has many applications in different sectors. The monomer of chitin is 2-acetamido-2-deoxy-β-D-glucose and that of chitosan is 2-amino-2-deoxy-β-D-glucose.

The free amine group gives chitosan its primary properties useful in natural polymer application development. When dissolved in dilute acid, chitosan becomes a cationic polymer, linear in structure, with a high positive charge density. This electronic charge can then be used in flocculation process, film forming, or immobilization of various biological reagents including enzymes. Other chemical properties of chitosan include its ability to act as a moisturizing agent in cosmetics, chelation of multivalent cations and an encapsulation agent when positive charge is removed (Ornum 1992). Chitosan fibers or granules applied to skin seem to keep fungi and microorganisms from growing, and therefore it has found application in textile industry. It even appears to stimulate the growth of beneficial bacteria in the digestive tract (Pennisi 1993). These polymers are

further used in wound healing, blood clotting, cholesterol lowering drugs, and controlled release of drugs in the body.

Besides chitin and chitosan, the shellfish could be a source of high value protein and minerals. Protein and mineral hydrolysate could be obtained by Lactobacillus fermentation of shrimp waste, where lactic acid produced during fermentation dissolves the minerals and the proteases produced contribute to proteolysis (Rao and Stevens 2005). This dual phenomenon results in a liquor rich in protein and minerals with a strong shrimp flavor. The liquor could also be converted into powder or paste for further applications.

The specific applicability of chitin and chitosan and other derivatives depends on its various properties such as molecular weight, viscosity, degree of acetylation, transparency, particle size, and solubility. The properties of chitin and chitosan are affected by the source and quality of raw material. This value addition to shellfish indicates that appropriate storage is not only important for food applications, but also for utilization of the so-called waste product of the shellfish industry.

85.10 QUALITY CONTROL AND ASSURANCE

Quality control is the process concerned with sampling of the products and measurement of quality indices to ensure that the products meet the required standards. Quality assurance, which is different than quality control, emphasizes on the processes and procedures which assure food safety and quality. In addition, this system is less dependent upon end product testing.

The examples of chemical indices for quality control are K value, total volatile basic nitrogen (TVB-N), trimethylamine (TMA), hypoxantine, and indole. Many researchers suggest that TVB-N and TMA are excellent indicators for determination of shellfish freshness (Fatima and Qadri 1985; Noomhorm and Vongsawasdi 1998; Shamshad and others 1990). Indole is considered a useful chemical index of shrimps however it should not be used solely as decomposed shrimps do not necessarily contain indole (Botta 1995).

The important element used as a means to assure food safety is Hazard Analysis and Critical Control Point (HACCP) which contains seven principles of identifying the potential hazards, determine the critical control points (CCPs) for the identified hazards, establish the target levels/tolerances for controlling the CCPs, establish/implement monitoring systems for controlling CCPs, identify corrective actions when a deviation occurs at a CCP, verify that the HACCP system is working and establish a documentation system for procedures and records (Pierson and Corlett 1992). The system must apply to the whole process, from raw materials to finished products otherwise an unacceptable food safety risk may occur. Generally, the procedures in developing the HACCP consist of two parts. The first part copes with hazard analysis which includes the determination of the critical limits and the identification of CCPs. Table 85.4 shows the hazard analysis of frozen shellfish. The possible hazards associated with the handling of fresh shellfish are physical damage, chemical contamination, microbiological contamination, autolysis, and other biochemical reactions. During freezing process and storage, there are further opportunities for physical, microbiological, and biochemical degradation as well. The second part of the procedure concerns with monitoring and verification. In this section, the CCPs can be defined as locations, procedures or processing steps at which hazards can be controlled. Table 85.5 represents a HACCP plan for frozen shellfish. Since the information from Table 85.4 indicates that metal inclusions may threat consumer

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

86.1 INTRODUCTION

Formulated fish and fish products are available in the frozen and dried forms. Two classes of these products exist; one that is formulated with high percentage of protein and the other is formulated with relatively high percentage of starch. Manufacturing of the formulated fish products has become increasingly important due to the varieties it can offer and also due to the abundant of alternative resources. It has been reported that in UK and European waters alone, approximately 100 species are harvested for food (Bayliss 1996). Morales and others (2001) had also reported the abundance of low value warm-water fish species such as Atlantic croaker (*Micropogon undululatus*), Mexican flounder (*Cyclopsetta chittendeni*), and Northern kingfish (*Menticirrhus saxatilis*) having the potential for surimi production.

Frozen entries can be nonbreaded or breaded. The breading materials differ in color, texture, and physical appearance. They can have a whitish to strong orange hue with a breadcrumb or flaky appearance. "Tempura type" coatings are cream in color and flaky. Examples of these products are the fish balls, fish cakes, fish rolls, fish filaments, fish fingers, fish sausages, and nuggets. These products can also be of squid, shrimp and crab flavors. These products are popular in the Asian countries and are gaining popularity in the West, which is perhaps due to their nutritional contents and increasing exposure to the products. They can be deep-fried, boiled, or steamed prior to their consumption. These formulated products are consumed as a menu or part of a dish during dinner and supper or as snacks during tea times. In some regions of the Asian countries, they are also prepared at breakfast. The value adding of the lower quality fish could be the factor that contributed to their growth and development in the Asian countries. The formulated products come in different shapes, sizes and flavors, which depend on the preference of the region. A fish finger in Japan is considered sweet to the South East Asian taste buds. Sugar content in kamaboko (Japanese fish cake) can be as high as 3% and in between 1–1.5% for fish cakes in the South East Asian countries. Aggressive product development has been carried out for these frozen entries. Fish balls formulated with mixed vegetables, corn, and spices are available in the market.

Fish and shrimp crackers are examples of the dried formulated product. They are also distributed in fried ready-to-eat form. "Keropok lekor," a product resembling sausage in texture, is also a formulated product, but it is cannot be categorized as dried product. It can be deep-fried or eaten as it is. Keropok lekor may be known only to the Asean countries. Both fish crackers and keropok lekor are high in starch (as high as 60%). The starch allows the fish crackers to expand during the deep-frying process and gives the crispy characteristics of the products.

86.2 QUALITY PARAMETERS OF THE FORMULATED PRODUCTS

Good Manufacturing Practices and Good Hygienic Practices are always insisted in the manufacturing of all these products. These products when marketed often have to comply with strict regulations impost by local authorities or importing bodies. However, special specifications have to be identified for individual product for in-house quality control. For frozen products, the good freezing practices must be adhered to during the freezing process for the assurance of a high-quality frozen product. Dried products are very sensitive to fluctuations in relative humidity and exposure to light.

Therefore, role of packaging becomes very significant. Storage temperature and duration are other parameters that must be control for the best shelf-life.

Factors that can affect the quality of the products during processing are the (1) ingredients, (2) quality control during the processing proper, (3) type of packaging, and (4) storage. The quality of the product can deteriorate during the distribution and retailing. Abuse in the temperature during transport and retailing are detrimental to product quality, especially the frozen products. Dried or prefried products are more prone to rancidity development.

86.2.1 The Ingredients

86.2.1.1 Fish and Mince Meat Quality. Whole fish is the raw ingredient for the manufacturing of formulated products. Good quality raw material is the first important key in the processing of these products. Raw material must always be fresh and handled at chilled temperature or iced, at the minimum. Studies have shown that poor quality fish are associated with the disintergration of the tissues, the development of spoilage odor, the accumulation of protein breakdown constituents such as the bioactive amines, and discoloration. The rate of deterioration is governed by species and the origin of catch as demonstrated by Johnston and others (1973) in their comparative study of 19 species of fish, whereby the myosins of warm-water species are found to be more stable at temperatures of 0–18°C as compared to fish from temperate waters. Freshness of the raw materials affects their organoleptic properties such as their taste-active compounds (Konosu and Yamaguchi 1990). The rate of freshness loss was reported to be generally slower for warm water fish in 82 species of fish comprising of species from tropical, subtropical, and temperate waters (Tsuchimoto and others 1986). Estimation of fish freshness based on physical attributes such as the eyes, gills, and the skin texture and luster can be carried out by experienced worker or through elaborate procedures such as the K-value determination. A group of researchers have reported the potential of a multivariate approach for freshness evaluation through the combination of the electric nose and the dielectric TDR method (Kent and others 2004). The concentration of biogenic amines has become a major concern of late due to their reported toxicity. Histamine, putrescine, and cadaverine have been suggested as spoilage indicators in fresh food (Saccani and others 2005). In 10 biogenic amines studied in tuna, it was found that the storage temperature had a crucial effect on the amount and the intensity of amine production (Veciana-Nogues and others 2004). Textural characteristics of the final product in products like fish nuggets are dependent on the nature and state of the initial fish tissue. Once general spoilage such as autolysis and microbial spoilage sets in, the quality of the raw material will decrease and this has a negative effect on the final product. No additive or preprocessing treatments can rectify this defect.

Prerigor muscle is always the best starting material for further processing since this is the stage where inosine monophosphate (IMP) is at its highest concentration. The concentration of IMP has been related to the natural sweetness of fish flesh. During rigor, the muscle goes through the natural contraction process, which resembles a tensed up muscle and has its water holding capacity at the lowest. These structural changes have been well demonstrated through electron microscopy in Blue grenadier (*Macruronus novaezelandiae*) (Bremner and Hallett 1985) and in bighead carp (Jamilah 2004). Structural changes of the fish flesh and related biochemical changes such as proteases activities

after postmortem had been discussed by Bremner (1992). This will affect the gelling ability in the fish protein and will be reflected in the lower springiness of the product.

Formulated products are preferred for their unique taste as well as their textural identity. Kyaw (2004) had identified that textural characteristic is the most important criteria in the marketability of these products and the taste factor becomes the second element. The thermal gel forming ability of the myosin in the presence of salt to dissolve the myosin filaments into myosin monomers dictates their textural properties (Tomoko and others 2006).

The raw material for the formulated products can be the mince fish meat or surimi. Minced meat obtained after deboning are not stable as compared to intact fish muscle due to the disruption of the tissue and the exposure of the meat to air (Babbitt 1986). Microbial and chemical stability of mince fish meat deteriorates at a faster rate than a piece of fish meat due to the increase in surface-volume ratio. Discoloration and odor development have been observed in these mince meats which can be due to the oxidation of the blood pigments, if improper handling such as temperature abuse and delay in processing occurred. Complete use of minced meat usage is more common in small-scale production as compared to surimi, which is used in large volume and continuous production line. In some processing line, a precalculated ratio of the minced fish meat is mixed into the formulation to impart taste and color characteristics of the fish species to the product. However, the fish cracker industries prefer the use of mince fish meat since using surimi will incur the need to add flavorings and colorings to overcome the bland characteristics of surimi. The use of minced fish meat renders natural variations in flavor and texture of the finish product. Better control in the overall quality and product uniformity can be expected when surimi is used instead of the minced fish meat, although with the constraints mentioned above. Frozen surimi blocks of 20 kg are common raw material traded and accounts for approximately 95% of all the surimi produced today. These frozen blocks come in varying grades. Traditionally, surimi is processed from Alaskan Pollock (*Theragra charcogramma*), although in South East Asia, threadfin bream (*Nemipterus japonicus*) surimi is commercially produced. Other species that are utilized for the surimi production in the ASEAN countries are bigeye snapper (*Priacanthus* sp.), jewfish (*Sciaena* sp.), and lizardfish (*Synodu*s sp.) (SEAFDEC 1996). Attempts to produce surimi from other fish species such as Pacific whiting (*Merluccius productus*), menhaden (*Brevoortia tyrannus*), sardines (*Sardinops* sp.), capelin (*Mallotus villosus*), and herring (*Clupea harengus*) have been reported. We have also found that red tilapia (*Tilapia nilotica*) make excellent surimi with hardly any trace of its characterisitic freshwater odor and flavor. In our experience, the use of fatty freshwater fish such as *Pangasius* sp. and the *Clarius batricus* will produce product with poor color and texture.

86.2.1.2 Hydrocolloids and Nonfish Proteins. Hydrocolloids are the next important ingredients that contribute to the texture characteristics and the juiciness of the formulated products. They are added to modify texture and the juiciness of the products. Solid fat are incorporated into burger and sausage formulations to influence the juiciness of finished product. In formulated fish products with relatively high starch contents, these hydrocolloids could act as antistaling agents. Nonetheless, different hydrocolloids will influence these properties to a different extend due to their own inherent properties. Cornstarch, modified starches, tapioca starch, and sago starch are added to varying degree in the formulations since these hydrocolloids have different cold water binding capacities. This

is reflected indirectly in their protein contents, hardness and the springiness of the products. In a market survey of 13 brands available in the Malaysian market of the central zone, the protein content of fish balls ranged from 14.7% to 6.8% and the hardness of the respective products had positive correlations to the protein content (Ismail 2004). Guar gum and *i*-carrageenan are also texture modifiers used in the fish sausage processing industry. They have been demonstrated to attribute to the protection of globular proteins against aggregation during heating through blockage of their hydrophobic binding sites by the bulky polysaccharide moiety thus offering stability to the product (Ibanoglu 2005). In formulated products like keropok lekor where the fish : starch ratio varies from 1 : 1 to 1 : 2, the texture is dependent on the heat-induced gel structure formed by the starch-fish protein interaction. In keropok lekor the addition of locust bean gum, carrageenan, and xanthan gum increased the gelatinization temperatures of sago starch by 4–6°C and the hardness of the gel and the vicsoelastic properties of keropok lekor dough were significantly dependent on the water binding ability of the gel as seen in the change of the loss (G″) and the storage (G′) moduli of the dough (Kyaw 2004). The addition of these hydrocolloids also affects the proneness of the deep-fried products to experience structural collapse after deep-frying and this is evident in their microstructures (Kyaw 2004). Figure 86.1 shows the SEM micrographs of keropok lekor dough formulated with the addition of 3% selected hydrocolloids to highlight the differences in the characteristics of the matrix formed and the different in the size of the cavities which leads to the different structural stability (Kyaw and others 2005). The incorporation of hydrocolloids such as guar and locus bean gums was reported to improve the stability of tapioca starch in products like bread (Guarda and others 2004; Temsiripong and others 2005).

All forms of soy proteins are also added in fish burgers, sausages, rolls and nuggets. In burgers, textured vegetable proteins are preferred. The amount incorporated into these products varies since they have different hardness characteristics. The percentages

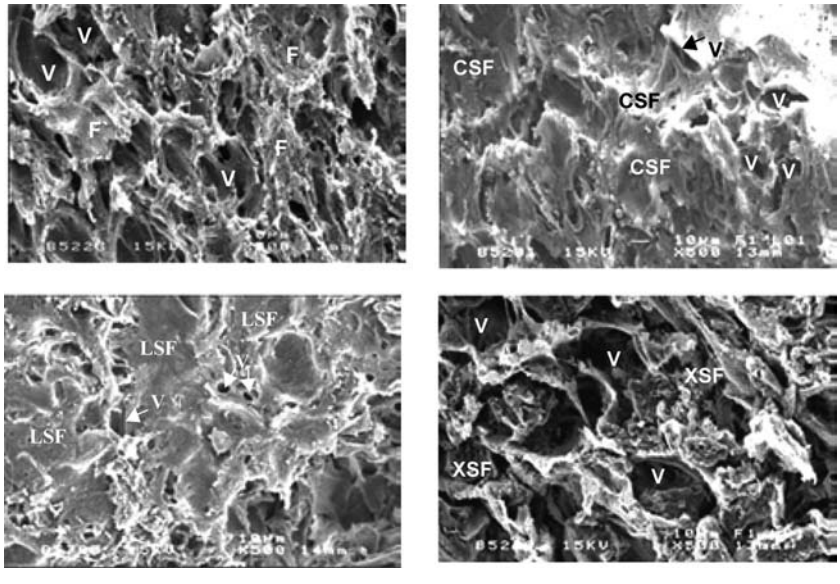

Figure 86.1 *Texture and microstructural characteristics of keropok lekor as affected by 3% incorporation of Food Grade Biopolymers (clockwise: control, carraneenan, xanthan, locust bean gum).*

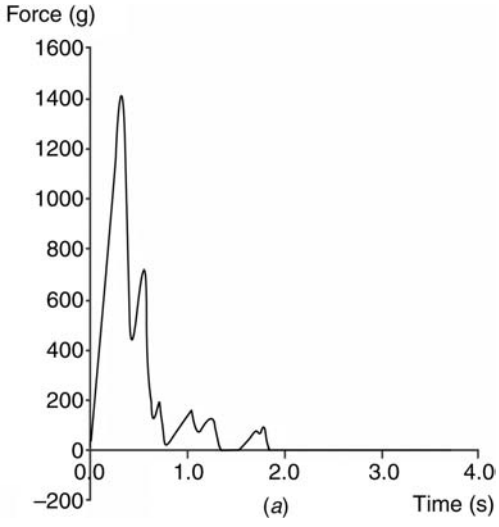
incorporated in these products are lower than those reported for beef-based products. Fish meat has a lot milder taste and aroma and easily override by the beany flavor of the soy protein. Excess amount of soy protein could result in hard textured products and not within the acceptable range of fish-based products. In our laboratory, we have found that soy protein can be incorporated from 3% to 10% by wet weight of the formulation. Lower range is more applicable to fish sausage since this product has a softer texture when compared to the springy texture of fish balls.

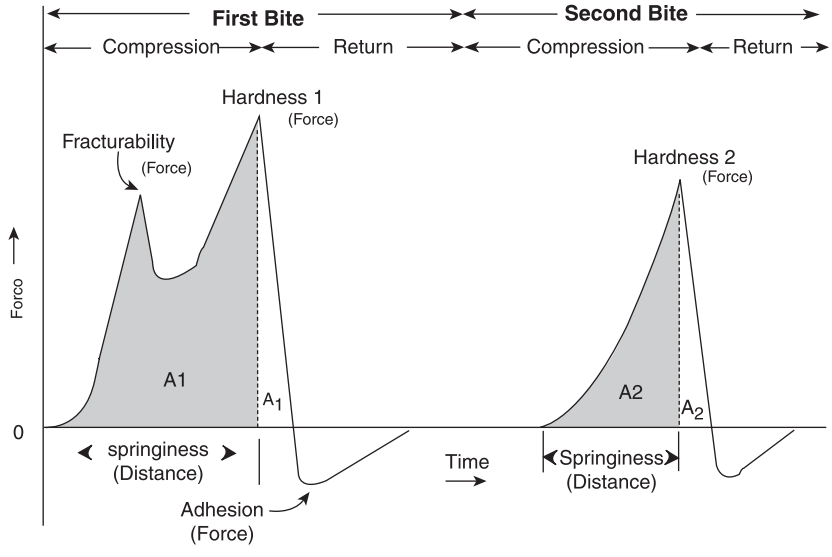
86.2.1.3 Chloride Salts. Sufficient amount of salt is required to help in the solubilization of the fish protein to form the gel. Salt content in the formulated products of high protein content are usually in the vicinity of 2%; beyond which the product may be salty. Optimum concentration of salt in keropok lekor was found to be at 2.5% (Kyaw and others 2003). Using response surface methodology (RSM), the influence of salt and sugar on the textural characteristics of keropok lekor has been demonstrated by Kyaw and others (2003). The salt and sugar concentrations significantly affect the penetration force and springiness in the first order relationship. For the formation of good surimi gels, the addition of 0.2% calcium chloride to Atlantic croaker, Mexican flounder, and Northern kingfish has been recommended (Morales and others 2001).

86.2.1.4 Batters and Breading Materials. Texture of these formulated products is also affected by the freezing techniques and the rates of freezing. In battered products, the batter and the breading material play crucial role in the overall texture perception of the product. Ingredients for batter and breading materials differ from one manufacturer to another. Crude fat and protein content of four local breading materials showed that the fat and protein content varied from as low as 1.14% to as high as 27.7% for fat and 4.1 to 7.7% for protein (Tay 2005). The amount of batter pick up will affect the total cooking loss and the fat uptake by the product. The coating characteristics will also influence the fat uptake during frying.

86.2.2 Quality Control During the Processing

The quality control during the processing can be looked at as four separate components, that is, the formulation, the processing stage proper, the freezing process or the drying stage and the storage and retailing. Quality control (QC) of each product line has to be identified. In any production line the QC is developed to ensure that the specifications and the standards of the products are maintained within a prescribed tolerance limits during all stages from raw material receiving until the product leave the production line. In one frozen reformed seafood processing company, the QC program include checking process at in-coming, in-process, and preshipment, laboratory and sensory test (personal communication). The in-process checking (color, texture, physical attributes such as uniformity of size), chemical analysis and microbial count can be carried out at preidentified intervals. Texture analysis and color monitoring are routinely carried out in frozen and dried products. An example of an instrumental texture profile analysis using Texture Analyser TA-XT 2i (Stable Micro System 1999) for tilapia fish chips (Ho 2003) can be seen in Figure 86.2(*a*) the hardness and the general texture profile for fish chips and other fish products and (*b*) is the sketch for springiness and gumminess calculation for products like keropok lekor. From the deformation curve, the highest peak





Cohesiveness[1,2] = A2/A1 (Ratio)

Gumminess = Hardness x Cohesiveness (Force)
Chewiness = Gumminess x Springiness (Energy)

Notes: 1 Areas as defined by Bourne = A1 and A2
2 Areas as defined by Friedman = (A1 + A_1) and (A2 + A_2)

(*b*)

Figure 86.2 *(a) The texture profile of tilapia chip after frying (profiles were obtained using Texture Analyzer Stable Micro Systems, TA-XT2, England). (b) Force-time curve of texture profile analysis instrument.*

recorded was the force required for breaking the fish chip and it represented hardness. The number of major peaks was considered as an indication of crispiness.

In products like the fish crackers, the crispiness of the product and its linear expansion after frying are important and monitored. Figures 86.3, 86.4(*a*) and (*b*) give an example of a flowchart for the processing of fish balls, fish crackers, and keropok lekor, respectively.

The quantity and the type of binders and texture modifiers incorporated in the formulations are important. Texture of these formulated products is also affected by the freezing techniques and the rates of freezing.

The mixing time, the setting time and temperature (for fish balls), the cooking time or the time required for gelatinization of protein, starch, and the sufficient development of the protein–starch linkages to obtain a desirable texture, the drying time and the thickness (for fish crackers) which will affects its linear expansion and crispiness are among the control points during the processing stage. Variations in the mixing time of these products are mainly due to the size of the processing batch. The setting time and temperature for fish ball type products are dependent on the species. This is because each fish species has an endogenous transglutaminase, which is a calcium dependent enzyme that catalyzes an acyl transfer reaction between gamma-carboxyamide groups of glutamyl residues in proteins and primary amines that is responsible for the setting characteristics of surimi (An and others 1996). In our laboratory, the setting time is 20–25 min and the temperatures are set at 45°C and 55°C for the first and second setting steps when working with surimi from seabream. However, the recommended setting time for some selected fish species surimi from Gulf of Mexico is at 40°C for 30 min and followed by another setting at 90°C for 15 min in the presence of 0.2% calcium chloride (Morales and others 2001). A bigger variation in the cooking time is sometimes obtained which is

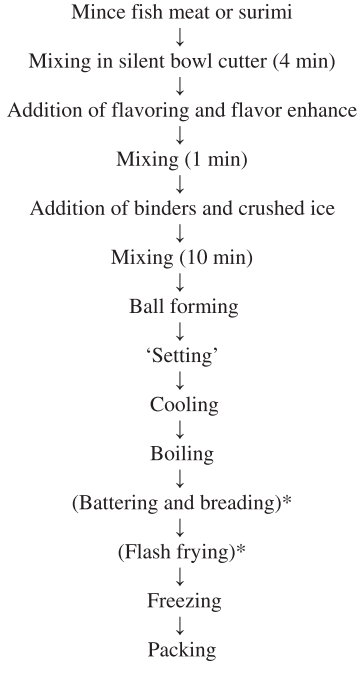


Figure 86.3 *The flowchart for the processing of fish balls. *Only for breaded fish balls.*

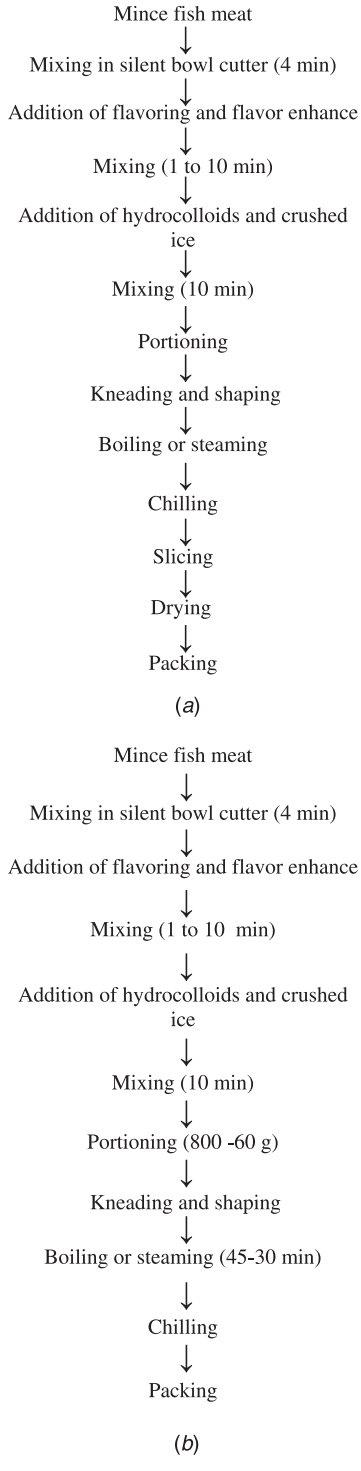

Figure 86.4 *(a) The flowchart for the processing of fish crackers (b) The flowchart for the processing of "keropok lekor."*

due to the variation in the actual ingredients and the physical dimension of the products. The later is more obvious in formulated products with higher starch contents, which may be due to the need for the starch granules to expand prior to their gelatinization.

86.2.3 Freezing Process

The freezing process for formulated products is similar to other food commodities. Ramaswamy and Tung (1984) had documented the review on the mathematical approach of predicting freezing rates of food. Differences may exist in the actual freezing point and the super-chilling phenomena. Freezing rate, which is influenced by the temperature difference between the product and the cooling medium; the modes of heat transfer to, from, and within the product; the size, shape, and type of package containing the product; and the size, shape, and thermal properties of the product (Fennema and Powrie 1964) is important to the products. The knowledge in the heat transfer parameters in terms of thermal diffusity and heat transfer coefficient as well as the estimation of temperature profiles are essential to attain an optimum cooling operation (Abbas and others 2006). A study on the freezing rate of tilapia (*Oreochromis* sp.) muscle by airblast and liquid nitrogen freezing has found that the freezing rate of the muscle is strongly correlated to the freezing temperature, that is, the lower the temperature, the faster is the freezing rate; regardless of the technique used (Chen and Pan 1995). In the manufacturing of fish nuggets, freezing process can also be done prior to packaging and this will reduce the freezing time.

Fast freezing has always been advocated for superior quality product, although freeze-cracking, a condition associated with crust formation, may happen in some cases, for example, freezing whole fish cryogenically has been reported to induce thermal stress and cause a radial cracking and a shattered structure upon thawing (Laverty 1991). However, several reports had implicated that fast freezing will ensure a better storage stability of the fish during frozen storage (Lee 1982; Semenov and others 1986; Yay and Bonie 1997). To date, no report on thermal stress for formulated products is found. Although very rapid freezing techniques can be employed to freeze these products, due to the economics of the production, they are often blast frozen with the exception of the seafood analogs, such as imitation crabmeat and abalone, which are individually quick frozen (IQF).

Rate of freezing determines the rate and size of ice crystals formation. Rapid freezing has always been associated with small ice crystals and thus causing minimal textural damage upon product thawing. Ice crystal formation and moisture migration during freezing was further minimized by the addition of locust bean gum and carboxymethyl cellulose (CMC) for these products with high starch content (Yap 2005).

86.2.4 Frozen Storage and Retailing

86.2.4.1 Changes in Texture and Physical Appearance. During storage and retailing, factors of concern are the general appearance of the product such as the presence of excessive ice crystals in the package and on the product surface, surface discoloration, and integrity of the package. Ice formation in the package and on the product surface is due to moisture migration from inside the product to the outside environment due to the temperature and the vapor pressure difference in the package (Fennema and others 1973; Reid 1997). Quality attributes such as textural

changes, change of flavor and odor are only recognizable upon consumption and prolong storage. An example of textural changes due to excessive storage period was reported for hake (*Merluccius merluccius*) that had been frozen for 2 years at −12°C (Montero and Borderias 1992). Textural changes during frozen storage are in part due to the unfolding of the myosin (Wagner and Anon 1985). The other factor that could cause the textural changes is due to the aggregation of the collagen and the formaldehyde (Montero and Borderias 1989, 1990). The electrophoretic pattern of myosin denaturation of white and red muscles from cod (*Gadus morhua*), tusk (*Brosme brosme*), and capelin (*Mallotus villosus*) also pointed to the different sensitivity of the myosin molecule of different fish species and tissue (Martinez 1992). Product rancidity is only obvious upon prolong storage which may be accompanied by textural changes (Jamilah and Wong 1996). It is also important to have a careful monitoring of warehouse temperature, duration of storage, and logistic. Improper retail handling and display can cause quality deterioration. It has been observed that temperature fluctuation of the frozen product happens quite often during the defrosting of the display refrigerators. The extent of the quality deterioration depends on the number of the freeze–thaw cycles experienced by the product. Freeze stability of these products is also dependent on the water binding agents added such as the addition of natural biopolymers and cryopectants that were incorporated in the surimi (Herrera and others 2000). Loosening of breading material or distorted product shape in formulated products has been observed in the local hypermarkets. Battered products that are frozen after prefrying or cooking require strong coatings to resist subsequent handling steps (Suderman 1993). Prolonged frozen storage for 52–54 weeks at −20°C are more detrimental to fish species from cold water as compared to those from warm water environment based on the enthalpies of the transitions of their myosin in a differential scanning calorimetry (DSC) study (Davies and others 1994). This is perhaps also true for the products derived from them.

86.2.4.2 Lipid Oxidation. Lipid oxidation can cause the development of off-flavor and off-odor or textural changes or the combination of all the changes to a varying degree. During frozen storage, lipid oxidation occurs at slower rate. For products that are battered and prefried or unbreaded but prefried, the lipid oxidation may be relatively more rapids than others. Generic mechanisms for off-flavor development in frozen fish have been proposed, however, the process is too complex; therefore, no generalization should be made (Hedges and Nielsen 2000). Khayat and Schwall (1983) suggested that the lipid oxidation in seafood can be catalyzed by metal ions and the oxidized lipids bind with protein to form lipid–protein complexes that are responsible for the change in quality such as toughening, development of unacceptable flavor and odor. Lipid oxidation and enzymatic peroxidation have been demonstrated to be temperature dependent as seen in the work on whole and minced rayfish (*Raja clavata*) muscle where more significant changes at −18°C was obtained as compared to that at −40°C for their respective lipid compositions (Fernandez-Reiriz and others 1995) and in catfish (*Ictalurus puntatus*) was enzymatic activities were reported to be inhibited at frozen temperatures below −10°C (Eun and others 1994; Haard 1994). Cold-store flavor developed in frozen cod (*Gadus morhua*) was attributed to the lipolysis in the phospholipid fraction to produce hept-*cis*-4-enal (Hardy and others 1979). However, extensive lipid oxidations in formulated products are not reported since their market turnover is normally within a few months.

86.3 SHELF-LIFE

Textural changes are often the main limiting factor for frozen formulated products; however, in products with high percentage of starch, the development of rancidity and staling are often the deciding factors. Shelf-life of the formulated products is the cumulative effect of their ingredients, preservatives added, the processing protocol, and the quality control of postprocessing handling. For example, Jamilah (1983) had reported a reduction in the microbial load and chemical changes when steaming was adopted instead of boiling for the processing of keropok lekor. Whey protein concentrate and soy protein isolate were reported to improve textural property and suppressed lipid oxidation in cooked meatballs (Ulu 2004). However, no similar study has been reported for formulated fish products. Conventionally, frozen surimi is stabilized by the addition of cryopectants such as sorbitol, sucrose, and polyphosphates; however, research on lizard fish (*Saurida wanieso*) surimi had proved that fish protein hydrolysate exhibits similar cryoprotective effects (Khan and others 2003). Therefore, the use of surimi as the base ingredient instead of mince fish meat indirectly gives an added advantage to the product. Studies on the mechanism of quality deterioration and factors affecting shelf life in frozen storage been published and it is reckoned that sensory studies using panelists are required to supplement this information (Jul 1984). Jamilah (2004) had summarized the shelf-life of the formulated products. The approximate shelf-life of these products is in the vicinity of 6–12 months at storage temperatures of $20 \pm 2^{\circ}$C. For frozen entries, the shelf-life of these products can be extended by the proper choice of packaging for physical protection as well for reduction of negative chemical reactions. In some retail packages of 250 g, a rigid thermoforming plastic tray is used to support the product. Vacuum packaging has been used for these products, but they are not popular; possible product deformation may occur. Theoretically, metal laminates are excellent barrier for gaseous and moisture transfer, yet it is not commonly used.

Concern of safety issues in all seafood and their products are of public interest. Ready-to-eat fish or fishery products, scombrotoxin-forming species, stuffed seafood products, vacuum or modified atmosphere package fish, and raw fresh or frozen shellfish are listed in the "substantial risk potential" seafood (Kvenberg and others 2000). However, freezing the seafood make it less vulnerable as a source of food pathogen if strict quality control is adhered to and the cold-chain is not been broken. Negligible microbial damage to the frozen food during frozen storage can happen since at these temperatures growth rates are very slow and generation times may be more than 100 h (Brown 1991).

86.4 PRODUCT THAWING DURING RETAILING AND HOME PREPARATION

Product thawing is not recommended for the formulated frozen products prior to preparation. This is because during thawing, the product temperature experiences a gradual drop; hence, it passes through a temperature range similar to those temperatures of chilled storage, which can harbor a host of pathogenic bacteria (Brown 1991). For example, *Listeria monocytogenes* showed ability to initiate growth in thawing condition even though the cells were injured during frozen storage (Golden and others 1988). The present principle of handling prior to the final preparation that is "from freezer to cooking." During retailing, unwanted thawing should be avoided

in all occasions. Loosening of the breading material breaded products could take place in excessive thawing.

86.5 SUMMARY AND FUTURE TRENDS

Formulated fish and fish products are definitely going to be one of the products that are processed globally in the future. This is based on the trends that are observed in consumer consciousness in eating healthier foods, omega-3 intake and the globalization of food consumption due to increase exposure to these products. An analogy of this situation is the burger (beef), fries, sausages, and potato chips industry, whereby, it is no longer limited to the Western hemisphere. However, the development of the local industries may evolve into processing formulated products that are adopted and adapted to the local preference for flavor and preparation style. The growth in this industry is also perpetuated by need to increase utilization of underutilized and low value fish.

87.1 INTRODUCTION

The flavor of seafood is influenced by a variety of volatile and nonvolatile flavor components formed via complex reactions caused by enzymatic reactions, lipid autoxidation, microbial action, and process-related heat induced reactions (Lindsay 1990; Kawai 1996; Olafsdottir and Fleurence 1998). Proteins and lipids are the main precursors for the flavor components produced during storage, processing, or cooking. Nonvolatile compounds such as free amino acids, peptides, organic bases and acids, nucleotides, sugars, and inorganic salts influence the taste whereas volatile compounds are responsible for the aroma. The degradation of polyunsaturated fatty acid by lipoxygenase is very important for the production of fresh seafood flavor (Josephson and others 1984a; Josephson and Lindsay 1986; Hsieh and Kinsella 1989), while Maillard and Strecker reactions play important role in developing the aroma of processed or cooked seafood (Baek and Cadwallader 1997). Desirable and most characteristic aromas of crustaceans are generated by thermal reactions during cooking (Spurvey and others 1998).

Flavorants with characteristic seafood flavor can be produced by enzymatic hydrolysis from for example seafood byproducts (In 1990; Pan 1990; Baek and Cadwallader 1999). Amino acids and peptides are released during hydrolysis and influence the taste of the flavorants, while volatile degradation compounds generated in the process give the aroma. An overview of the production of seafood flavorants and the development of key flavor components will be given herein. Examples of the production and characteristics of seafood flavorants will be given from a study done in collaboration with an Icelandic marine biotechnology company Primex ehf (www.primex.is). The aim of the study was to characterize the flavor compounds in seafood flavor powder products produced from, for example, fish cut-off, fish skin and bones, shrimp shell, scallop, and whey using different kinds of endopeptidases and exopeptidases.

87.2 SEAFOOD BYPRODUCTS

Utilization of fishery byproducts and under-utilized species is an important subject because of limited fish resources. Fish industry is economically very important in Iceland accounting for 62% of the value of exported products. The fisheries are divided into demersal fisheries, pelagic fisheries, and shellfish fisheries and the total catch was 2 million tons in 2001. The main commercial fish species belong to gadoids, that is, cod, haddock, pollock, and blue whiting, providing about 66% of the total catch value. Other important species are capelin, herring, ocean perch, Greenland halibut, and shellfish like shrimp, lobster, and scallop. Approximately 25–30% of total catch can be considered as underutilized (Venugopal and Shahidi 1995; Arason 2003). Fisheries byproducts and pelagic fish are a valuable source of digestible proteins of high nutritional quality but they are mainly used for low priced products like fish meal and oils. The fish byproducts are sources of components like lipids, proteins, flavorants, minerals, carotenoids, enzymes, and chitin, which can be used for different applications, including functional foods, healthcare products, pharmaceuticals, and cosmetics. A small percentage is processed into higher valued items, such as seafood flavorants, colorants, chitosan, and enzymes (Shahidi 2003). Enzymatic hydrolysis to produce fish protein hydrolysates and seafood flavorings from various sources of seafood byproducts is one of the approaches for upgrading byproducts. As an example, fish cut-offs from lean species brought to shore by

Icelandic freezing trawlers amounted to about 2000 tons in 2001 (Arason 2003). This raw material is an excellent source for the production of flavorants because problems of lipid oxidation are reduced in lean fish.

The biggest market for marine extracts and powder are fish soups and sauces, about 75% of the total market. Flavorants can also be used as additives in surimi-based products and cereal-based extrusion products like shrimp chips (Haard 1992). In 2000, the global food flavoring market was worth USD 6.5 billion. Savory flavors, including marine products (8–12%) were worth USD 1.5 billion. The market for marine extracts and powder was around 55,000 and 7000 tons, respectively. Industrial users of processed flavors are international food companies like Nestlé (Maggi), Unilever (including Knorr and Royco), Campbell, Kraft, IFF, and Mars (www.rubin.no; www.ubic-consulting.com).

87.3 FLAVORINGS PRODUCED BY ENZYMATIC HYDROLYSIS

Traditional enzymic processes of marine raw materials include fish fermentation, fish sauce, and fish silage production. In these processes endogenous proteolytic enzymes cause partial hydrolysis of the tissue (Gildberg 1993). The use of added chemicals or enzymes to prepare protein hydrolysates from fish and shellfish has been studied for decades. The functionality and the applications of fish protein hydrolysates (FPH) as ingredients for food formulations to improve nutritional value of protein sources in specialized foods is of increased interest (Skanderby 1994). FPH are proteins broken down into peptides of varying sizes with the aid of chemicals or enzymes (proteases). Kristinsson and Rasco (2000) give an excellent review of the production of FPH, and their biochemical and functional properties. Physicochemical and functional properties like solubility, water-holding capacity, emulsifying and foaming properties, fat absorption, and sensory properties are discussed. The main drawback for the use of FPH in food formulations is a problem with bitter taste.

A similar process as for FPH can be applied for the production of flavorants from seafood byproducts (In 1990). The use of seafood byproducts like fish cut-offs for the production of seafood flavorants powder with acceptable sensory properties and solubility has been developed by Primex. The flavorants are produced by controlled proteolytic hydrolysis coupled with other processing methods using different kind of commercial enzymes. Figure 87.1 shows an overview of the production of seafood flavorants and how proteins and lipids act as precursors for the development of components characterizing the taste and aroma of flavorants. The process consists of liquefaction of the raw material by enzymatic hydrolysis, thermal inactivation of the enzymes followed by centrifugation or filtration of bones and shells, and concentration of the flavorants. The final product consists of spray-dried powder of seafood flavorant. The details of the enzymes used and process parameters are not given herein since these are part of the products' specifications and recipes of the company.

The proteases used for the hydrolysis are characterized by their hydrolyzing mechanism into endopeptidases or exopeptidases. The endopeptidases provide peptides with different chain length while exopeptidases systematically remove amino acids (Shahidi 2003). The amino acids and peptides that are released by the proteases can give pleasant-tasting flavor compounds or act as precursors for desirable flavor. The Maillard reaction, including Strecker degradation, involves the reaction between reducing sugars and amino compounds and through numbers of reactions, flavor compounds are generated (Bailey 1998). Amino

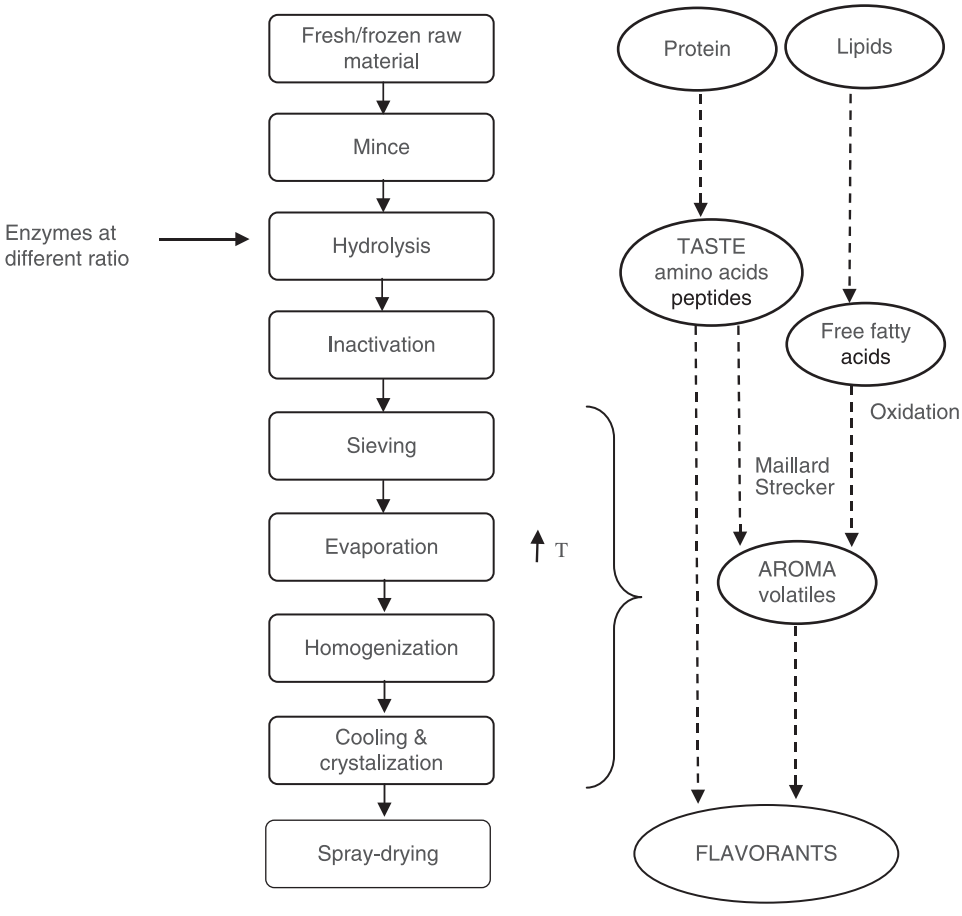

Figure 87.1 *A production scheme for seafood flavorants and the development of taste and aroma active components in the process.*

acids and peptides that are released during enzymatic hydrolysis are therefore important contributors to the flavor and aroma of seafoods. Baek and Cadwallader (1996) found a great amount of thermally generated aroma-active compounds via the Maillard reaction like pyrazines, in enzymatically hydrolyzed crayfish processing byproducts. Numerous volatiles derived from amino acids degradation, contributing to seafood aromas, have been identified in spiny lobster (Cadwallader and others 1995) and in blue crab claw meat (Chung and Cadwallader 1994, 1995).

The sensory quality of flavorants depends on several parameters where the specificity and the level of enzymes are important factors. Other factors such as the pretreatment of the raw material prior to hydrolysis, substrate to water ratio, pH, and temperature also play an important role. Besides the development of desirable flavors produced by enzymatic hydrolysis, formation of taste defects like bitterness caused by bitter amino acids and peptides, burnt taste and ammonia smell, can be a problem (In 1990; Kristinsson and Rasco 2000). Oxidation of fat can also cause off flavors especially in products from fatty species.

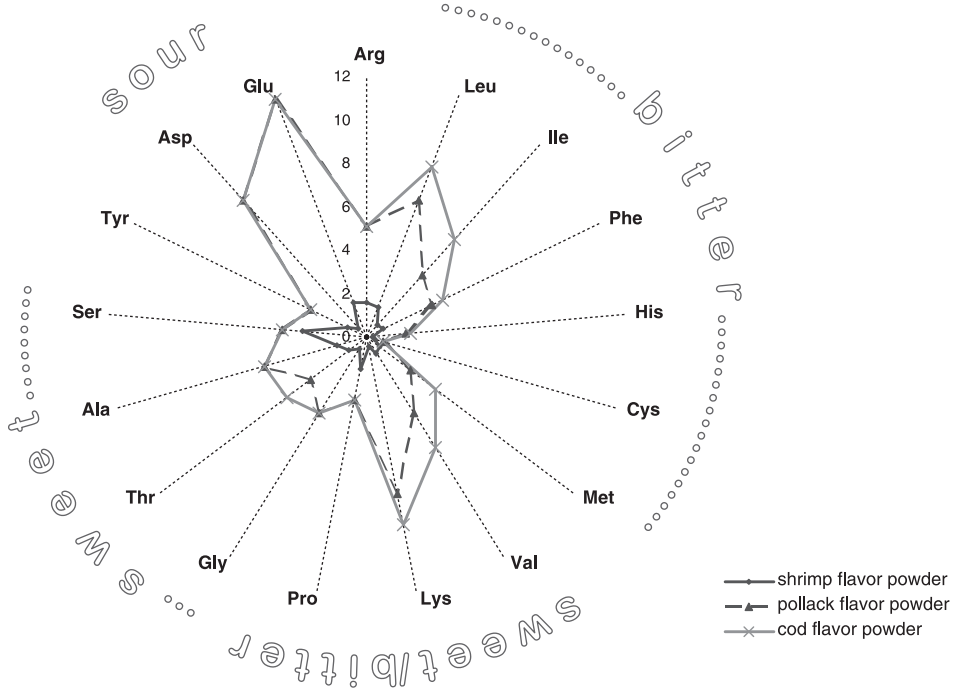

Figure 87.2 *Contribution and composition of free amino acids and their taste in flavorants produced from pollock, cod, and shrimp byproducts.*

87.3.1 Amino Acids

The free amino acids content of flavorants produced by enzymatic hydrolysis can vary greatly, depending on, for example, raw material and enzymes used, thereby influencing the flavor differently. Free amino acids can significantly influence the taste of foods. Individual amino acids have specific taste characteristics and usually they taste either bitter or sweet. Imm and Lee (1999) detected high percentages of free amino acids giving both umami and sweet tastes in hydrolysates from red hake. In the study of seafood flavorants, pollock and cod flavor powder contained about 85% of protein; thereof a very high content of free amino acids (78%) (Jonsdottir and others 2002). Shrimp flavor powder produced from shrimp byproducts contained 71% protein; thereof a much lower content of free amino acids (18%) compared to the cod and pollock flavorants as can be seen in Figure 87.2. The shrimp flavorant was hydrolyzed with endopeptidases but the pollock and the cod flavorants with a mixture of endopeptidases and exopeptidases resulting in a higher concentration of free amino acids.

Figure 87.2 shows that the amino acid composition of cod and pollock flavorants is very similar. The main free amino acids were glutamic and aspartic acid that can give sour taste and their salts give umami taste (Shallenberger 1993). Lysine and valine giving sweet taste with a bitter aftertaste (Haefeli and Glaser 1990) were in high concentrations. The content of leucine and isoleucine were also relatively high. Serine with sweet/bitter/sour characteristics was in the highest amount in the shrimp powder (3%) and proline with a positive sweet/bitter taste (Haefeli and Glaser 1990) was also found in a relatively high concentration. Glutamic acid, arginine, and leucine were detected in relatively high levels but

TABLE 87.1 Taste Assessment of L-Amino Acid Crystals with Respect to the Four Basic Tastes, Hedonic Assessment of Their Taste Attributes and Taste Threshold

Amino Acids	Abbreviation	Taste of L-[a]	Taste Threshold (in mM)
Arginine	Arg	Bitter (−)	2.65
Leucine	Leu	Bitter (−)	10.6
Isoleucine	Ile	Bitter (−)	13.0
Phenylalanine	Phe	Bitter (−)	10.0
Histidine	His	Bitter (−)	21.0
Tryptophan	Trp	Bitter (−)	3.38
Cysteine	Cys	Bitter/sweet (−, S)	1.98
Methionine	Met	Bitter/sweet (−, S)	12.7
Valine	Val	Sweet/bitter (−)	10.6
Lysine	Lys	Sweet/bitter (−)	2.97
Proline	Pro	Sweet/bitter (+)	16.1
Glycine	Gly	Sweet (+)	15.4
Threonine	Thr	Sweet (+)	25.4
Alanine	Ala	Sweet (+)	7.17
Serine	Ser	Sweet/bitter/sour (+)	11.4
Tyrosine	Tyr	Insipid (×)	7.65
Aspartic acid	Asp	Sour (+)	4.0
Glutamic acid	Glu	Sour (+)	4.0
Asparagine	Asn	Bitter/sweet (+)	67.0
Glutamine	Gln	Salty/bitter (−)	43.0

other free amino acids were in lower concentrations (<2%). Table 87.1 shows the taste assessment of L-amino acids from Haefeli and Glaser (1990) who studied of the D-, DL-, and L-forms of the 20 primary amino acids. The table summarizes the four basic tastes, hedonic assessment, and the taste-recognition thresholds of the taste attributes of the L-amino acids. The hedonic assessment of the amino acids give information about pleasant (+), and unpleasant (−) flavor perception. Glycine, alanine, and threonine have a sweet taste with pleasant perception but hydrophobic amino acids such as arginine, leucine, phenylalanine, and valine contribute to the bitter taste with unpleasant perception (Haefeli and Glaser 1990; Fuke 1994). The cod and pollock flavorants had mild sweet seafood like sensory characteristics while the shrimp flavorant had more predominant meat like character compromised with typical shellfish flavor. The amino acid composition of the flavorants can partly explain the sensory qualities, for example, high levels of glutamic and aspartic acid with sour taste contribute to a pleasant perception in cod and pollock flavorants. Leucine and isoleucine on the other hand contribute to the bitter taste and unpleasant perception in the flavorants. The complex taste perception of seafood flavorants can also be explained by the presence of peptides contributing to the flavor.

87.3.2 Peptides

Peptides have been recognized for a long time as important contributors to flavor in processed food. Peptides, released by enzymatic hydrolysis or by thermal degradation, can act as flavor precursor in thermally induced reactions (Rizzi 1989). Dipeptides can contribute to the organoleptic characteristics of food where the synergy of different

factors like pH, salt, and concentration of each taste or flavor enhancing component, that is, dipeptides and amino acids, play an important role (Kato and others 1989).

Peptides are polymers of up to 50 amino acids. When the degree of polymerization exceeds 50, the peptide is considered to be a protein (Shallenberger 1993). Kirimura and others (1969) characterized the tastes of 60 different peptides and classified them into three main groups: sour, bitter, and little or no taste. They reported that a relationship existed between amino acid composition and the taste of dipeptides. Dipeptides containing two acidic amino acids, acidic- and neutral amino acids, or acidic- and aromatic-amino acids tasted sour while dipeptides containing neutral amino acids with either large alkyl groups ($\geq$C3) or a combination of large and small alkyl groups ($\leq$C2), neutral and aromatic amino acids, or neutral and basic amino acids tasted bitter. Dipeptides having a little or no taste were composed of two amino acids with small alkyl groups, acidic- and basic amino acids, or two aromatic amino acids. Almost all peptides of hydrophobic L-amino acids evoke a bitter taste and the amino acid sequence of peptides also play an important role in the intensity of the bitter taste (Kato and others 1989; Saha and Hayashi 2001). Ney (1979) reported that the bitterness of peptides depended on their hydrophobic value Q. He suggested to obtain average hydrophobicity Q by summing the hydrophobicities of the amino acid side chains of a peptide and dividing by the number of the amino acid residues. Peptides with Q-values below 1300 are not bitter, whereas peptides with Q-values higher than 1400 are bitter. This principle is valid for molecular weights up to approximately 6000 Dalton, above this limit peptides with Q 1400 are also not bitter.

Uncontrolled or prolonged hydrolysis during the development of FPH and flavorants may cause taste defects like bitterness caused by bitter amino acids and short-chain peptides (Venugopal and Shahidi 1995). Hevia and Olcott (1977) identified basic bitter tripeptides that contributed to off-flavor in fish protein hydrolysates. The tripeptide had aspargine as the middle amino acid and lysine as the C-terminus, with leucine or glycine as the N-terminus. By using exopeptidases N-terminal amino acid residues can be selectively released from polypeptides or proteins resulting in reduced bitterness of protein hydrolysates (Saha and Hayasi 2001; Raksakultahi and Haard 2003). Addition of exopeptidases to modify food is becoming increasingly common, where commercial exopeptidases produced by microorganisms or exopeptidases naturally occurring in foodstuff are applied. Haard (1998) reported that the mid gut gland of marine invertebrates contains a wide range of amino- and carbopeptidases which may find use in debittering of protein hydrolysates.

87.3.3 Volatiles

Numerous volatile compounds have been identified in enzymatically produced seafood flavorants, for example, aldehydes, alcohols, ketones, sulfur containing compounds, and pyrazines (Pan and Kuo 1994; Baek and Cadwallader 1996). During processing a series of changes caused by thermal degradation, lipid oxidation, and Maillard reaction play important roles in generating complicated volatile compounds contributing to the processed flavor. The role of lipid derived unsaturated aldehydes, alcohols, and ketones in seafood flavors are well known. Compounds derived from lipoxygenase initiated oxidation of polyunsaturated fatty acids contribute to the characteristic fresh fish flavor (Josephson and others 1984a), in oxidized fish oils these compounds cause rancid odor (Karahadian and Lindsay 1989) and they also contribute to boiled odor of fish

(Milo and Grosch 1995). Volatile compounds characteristic for processed seafood odors such as alkyl-pyrazines and sulfur-containing compounds have been found in cooked crustaceans, and furans have been found in spray-dried shrimp powder and shrimp hydrolysate (Pan and Kuo 1994). Various methods have been used for isolating and analyzing volatile components from seafood. Gas chromatography is commonly used and the efficiency of the analysis depends on the sampling techniques (i.e., the extraction or concentration methods) and the detection approach. Gas chromatography-olfactometry (GC-O) is very useful for analysis of volatile components with low odor thresholds but gas chromatography-mass spectra (GC-MS) for verification of the components (Jensen and others 1998).

Table 87.2 shows the characteristic odors and volatile compounds identified in the cod, pollock, and shrimp flavorants by GC-O and GC-MS together with odor thresholds and possible precursors. The low flavor threshold of some of the compounds make them potential flavor substances even in trace amount. Aldehydes appear to be the main contributors to the odor but ketones, alcohols, and sulfides were also detected. The most characteristic odors of the seafood flavorants were potato-like odor, popcorn-like odor, cucumber- and green-like odors, caramel- and sweet-like odors, and mushroom-like odor. Some of the compounds responsible for these odors were present in very low concentrations and the quantification was only possible by using GC-O because of their low odor threshold. Figure 87.3 shows the relative odor impact of the key aroma compounds found in cod, pollock and shrimp flavorants.

87.3.3.1 Potato-Like Odor. The most characteristic odor of all the flavorants was identified as potato-like odor (Fig. 87.3). The compounds contributing to this odor were identified by GC-MS as a combination of *cis*-4-heptenal and methional. Methional (3-(methylthio)-propanal), the Strecker aldehyde produced from methionine, has been identified as an important contributor to the aroma of various crustaceans and flavor concentrates (Chung and Cadwallader 1995; Baek and Cadwallader 1997; Kim and others 2000). It has a characteristic potato-like odor and a very low threshold value (Table 87.2). McGill and others (1974) described the odor of *cis*-4-heptenal being similar to that of boiled potatoes. It is a lipid derived compound that can have a cardboard-like odor but in higher concentrations it gives a painty, putty- or linseed oil-like odor (Lindsay 1990). *Cis*-4-heptenal can also contribute to potato-like odor when detected in a low concentration (Josephson and Lindsay 1987). Thus, *cis*-4-heptenal together with methional have been identified as the major contributors to the characteristic potato-like odor of, for example, cooked mussel extracts (Le Guen and others 2001), cooked spiny lobster tail meat (Cadwallader and others 1995), and cooked blue crab claw and lump meats (Chung and Cadwallader 1995).

87.3.3.2 Popcorn-Like Odor. 2-Acetyl-1-pyrroline, giving a popcorn-like odor, was detected as one of the key aroma compounds in the cod, pollock, and shrimp flavorants (Fig. 87.3). Characteristic popcorn-like odor in shrimp was suggested to originate from the shell since 2-acetyl-1-pyrroline was only identified in unpeeled shrimp in a study comparing the volatile profiles of peeled and unpeeled shrimp (Jonsdottir and others 2002). 2-Acetyl-1-pyrroline can be thermally generated and may be formed via the Maillard reaction of glucose and proline (Baek and Cadwallader 1997). 2-Acetyl-1-pyrroline has been identified as an important character-impact aroma compound in enzyme hydrolyzed oyster cooker effluent (Kim and others 2000), cooked spiny lobster tail (Cadwallader and others 1995) cooked blue crab claw and lump meats (Chung and Cadwallader

TABLE 87.2 Volatile Compounds Identified in Cod, Pollock, and Shrimp Flavorants by GC-MS and GC-O Using a Purge and Trap Technique (Tenax)

Compounds	Odors	Precursor[a]	Odor Threshold[b]	Id[c]	RI[d]

1994), and boiled crab meat of American lobster (Lee and others 2001). 2-Acetylthiazole, also giving a popcorn-like odor, was detected in the flavorant samples derived from shellfish. Many desirable compounds are generated by thermal reactions during cooking of crustaceans, that is, pyrazine and thiazole that give meaty-, nutty-, and popcorn-like odors (Pan and Kuo 1994). Many pyrazine compounds were detected in flavorants produced from crayfish byproducts (Cha and others 1992; Baek and Cadwallader 1996).

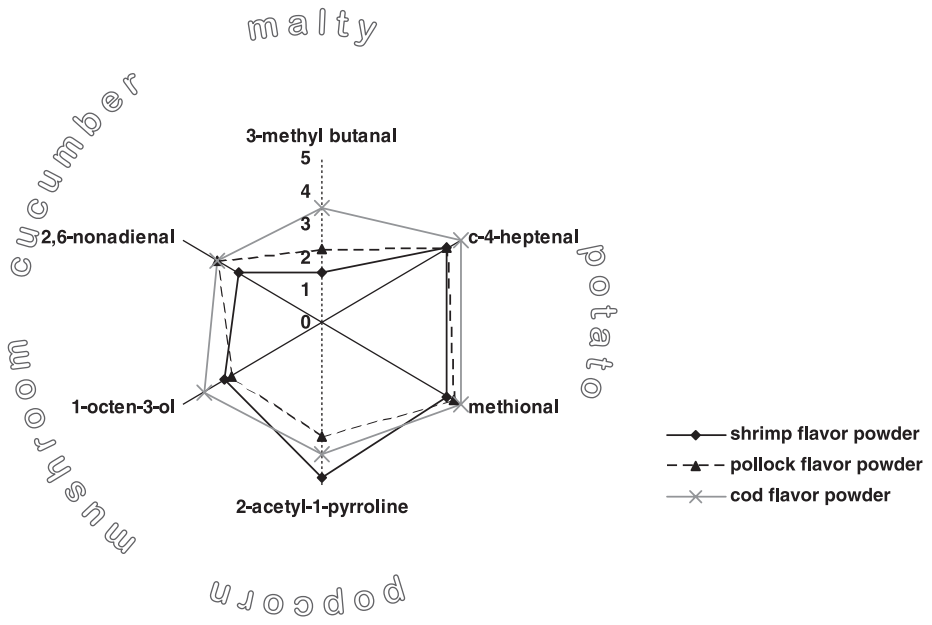

Figure 87.3 *Key aroma compounds and their characteristic odor in flavorants produced from pollock, cod, and shrimp byproducts. Identification by GC-MS and quantification by GC-O (odor scores from 0; not present to 5; strong odor).*

Pyrazine and thiazoles are also important in the development of popcorn-like odor of lobster (Cadwallader and others 1995).

87.3.3.3 Cucumber and Green-Like Odors. Lipid-derived compounds are known to contribute to the aroma of both cooked and fresh crustaceans (Baek and Cadwallader 1997). A desirable sweet, cucumber-like aroma was contributed by *trans*,*cis*-2,6-nonadienal in the flavorants. The compound was present in a low concentration but the aroma impact of the compound was however high because of its low odor threshold (Table 87.2). 2,6-Nonadienal is derived from omega-3 fatty acids via lipoxygenase activity and has been identified in various fish species contributing to green, fresh fish-like, cucumber odors (Josephson and others 1983; Zhang and others 1992; Olafsdottir and others 1997).

Lipid-derived compounds can also cause an undesirable aroma, for example, 2,6-nonadienal can be readily converted to *cis*-4-heptenal through the retro-aldol degradation reaction (Josephson and Lindsay 1987; Cha and others 1997). Other compounds produced because of autoxidation like hexanal, 2,4-heptadienal, and 2,4-decadienal can cause the oxidized, rancid, and painty flavors in fish oils (Karahadian and Lindsay 1989). These compounds were detected in low concentrations in the flavorants and may influence the overall aroma but were not perceived as rancid or undesirable in the flavorants. Other authors have identified similar unsaturated aldehydes in flavor concentrates (Baek and Cadwaller 1996) and hydrolyzed oyster cooker effluent (Kim and others 2000).

87.3.3.4 Malty, Caramel, and Sweet-Like Odors. 2-Methylpropanal, 2-methylbutanal, and 3-methylbutanal are short branched chains that were among the

aldehydes detected in the flavorant samples. These aldehydes give malty-, chocolate-, and sweet-like odor and together with other short chain aldehydes, ketones, and alcohols give a characteristic sweet mild caramel-like odor. Low molecular weight compounds with high volatility are likely to influence the first flavor perception. These compounds can also react further and contribute to the development of other flavor components. 2-Methylpropanal, 2-methylbutanal, and 3-methylbutanal are known as Strecker or microbially derived aldehydes from valine, isoleucine and leucine, respectively. Figure 87.2 shows that the levels of leucine and isoleucine were relatively high in cod and pollock flavorants compared to the shrimp flavorant and as expected their volatile degradation compounds 3- and 2-methyl butanal, respectively, contributing to sweet-, caramel-, malty-like odor were also higher in the cod and pollock flavorants than in the shrimp flavorant (Fig. 87.3). 3-Methyl butanal has been identified as an important contributor to boiled crab meat of American lobster (Lee and others 2001).

87.3.3.5 Mushroom-Like Odor. 1-Octen-3-ol was identified in all the flavorants and contributes to the overall seafood-like odor. Alcohols are generally minor contributors to flavor unless present in relatively high concentrations or if they are unsaturated. The odor threshold for 1-octen-3-ol is 10 ppb (Table 87.2). Is has been detected in low concentrations in seafood flavorants (Baek and Cadwallader 1996) and gives the pleasant mushroom fresh fish odor. Unsaturated alcohols are derived from long chain polyunsaturated fatty acids and contribute to the characteristic fresh mushroom-like odors found in freshwater and seawater fish (Josephson and others 1984b; Lindsay 1990).

87.3.3.6 Other Odors Contributing to Seafood. *Meaty and roasted-like odors*: Pyrazines and sulfur-containing compounds have been shown to play important roles many thermally processed foods. They have been found in both roasted and boiled shrimp and in snow crab cooker effluent and effluent concentrate giving meaty and roasted-like odors (Cha and others 1993; Baek and Cadwallader 1997).

Flowery and fruity-like odors: Many ketones were identified in the flavorant samples, some of them giving a sweet flowery and fruity characteristic often detected in shellfish (Cha and others 1992). Ketones can be oxidation products of polyunsaturated fatty acids or microbial degradation products of amino acids. They have a low odor threshold and can therefore influence the sensory characteristics of food, for example, 1-octen-3-one and 1,5-octadien-3-one, contributing a geranium like odor, have a great impact on the aroma of fresh fish (Josephson and Lindsay 1986). Numbers of ketones have been detected in boiled and roasted shrimp. 2,3-Butandione or diacetyl and 2,3-pentanedione give a buttery-like odor characteristic of shellfish. Diacetyl is generated through the Maillard reaction and is characteristic for cooked seafood (Le Guen and others 2001). Diacetyl was detected as one of the key aroma compounds in cooked spiny lobster tail meat (Cadwallader and others 1995).

Cabbage and onion-like odors: The sulfides detected in the flavorants were dimethyl sulfide (DMS), dimethyl disulfide (DMDS), and dimethyl trisulfide (DMTS). DMDS and DMTS are derived from sulfur-containing amino acids. They all have a very low odor threshold and are therefore likely to influence the overall aroma of food. Sulfides have been detected in most thermally processed crustaceans like shrimps and crabs. Concentrations of DMDS and DMTS in flavor concentrates produced from crayfish-processing byproducts, increased after enzymatic hydrolysis (Baek and Cadwallader 1996).

Fishy-like odor: Production of TMA (trimethylamine) from TMAO (trimethyl amine oxide) via microbial metabolism is well known contributing to fishy aroma and flavors in marine fish and shellfish. The odor of TMA is described as crab-like, old fishy, or fishhouse-like (Lindsay 1990). TMA was detected in some of the flavorant samples. TMA and ammonia develop because of microbial degradation of TMAO and amino acids, respectively, during refrigerated storage of fish and contribute to the stale ammonia like odor of stored seafood products. DMA (dimethyl amine) is produced by endogenous enzymes in the fish and is known to cause flavor problems in frozen fish. These compounds are commonly used as indicators for microbial growth and freshness of fish raw material (Oehlenschläger 1991). The contribution of TMA to the overall odor of the flavorants is believed to be low and Kim and others (2000) showed that the amount of TMA was only a minor part of the extractable nitrogen content in hydrolyzed oyster cooker effluent.

87.4 SUMMARY

The controlled production of seafood flavorants by enzymatic hydrolysis of lean fish cut-offs and byproducts from shrimp processing resulted in cod, pollock, and shrimp flavorants with a characteristic seafood odor and taste. GC-O and GC-MS results indicate that the key aroma compounds identified in the seafood flavorants are produced via Maillard reaction and Strecker degradation of amino acids during enzymatic and thermal processing of the flavors. Lipid derived components also contribute to the aroma of the flavorants. Amino acids and peptides play an important role in taste of the flavorants. To gain more knowledge and understanding of the formation of the flavors the industry can link together information on process parameters, the details of the enzymes used and the composition of key volatiles. It is thus possible to control the process and the development of the key flavor components. The information gained can be used for product formulation and development of recipes. By selection of raw material and variation of process parameters the formation of the desirable aroma of the flavorants can be achieved. The use of byproducts for the production of value-added seafood products like flavorants is a feasible way to reduce the amount of valuable under-utilized raw material.

88.1 BACKGROUND INFORMATION

The U.S. national regulatory authority for public protection and seafood regulation is vested in the FDA. The FDA operates an oversight compliance program for fishery products under which responsibility for the product's safety, wholesomeness, identity, and economic integrity rests with the processor or importer, who must comply with regulations promulgated by the FDA. In addition, FDA operates the low-acid canned food (LACF) program which is based on the hazard analysis critical control point (HACCP) concept, and is focused on thermally processed, commercially sterile foods, including seafood such as canned tuna and salmon.

The seafood processing regulations, which became effective on December 18 1997, require that a seafood processing plant (domestic and exporting foreign countries) implement a preventive system of food safety controls known as a HACCP plan. HACCP essentially involves: (1) identifying food safety hazards that, in the absence of controls, are reasonably likely to occur in the products; and (2) having controls at "critical control points" in the processing operations to eliminate or minimize the likelihood that the identified hazard will occur. These are the kinds of measures that prudent processors already take. HACCP provides a systematic way of taking those measures that demonstrates to the FDA, customers, and consumers, that the firm is routinely practicing food safety by design. Seafood processors that have fully operating HACCP systems advise us that they benefit in several ways, including having a more safety-oriented workforce, less product waste, and generally, fewer problems.

Most FDA in-plant inspections consider product safety, plant/food hygiene and economic fraud issues, while other inspections address subsets of these compliance concerns. Samples may be taken during FDA inspections in accordance with the agency's annual compliance programs and operational plans or because of concerns raised during individual inspections. The FDA has laboratories around the country to analyze samples taken by its investigators. These analyses are for a vast array of defects including chemical contaminants, decomposition, net weight, radionuclides, various microbial pathogens, food and color additives, drugs, pesticides, filth and marine toxins such as paralytic shellfish poison (PSP), and domoic acid.

In addition, FDA has the authority to detain or temporarily hold food being imported into the United States while it determines if the product is misbranded or adulterated. The FDA receives notice of every seafood entry, and at its option, conducts wharf examinations, collects and analyzes samples, and where appropriate, detains individual shipments or invokes "automatic detention," requiring private or source country analysis of every shipment of product when recurring problems are found, before the product is allowed entry.

Further, FDA has the authority to set tolerances in food for natural and man-made contaminants, except for pesticides, which are set by EPA. The FDA regulates the use of food and color additives in seafood and feed additives and drugs in aquaculture. FDA also has the authority to promulgate regulations for food plant sanitation [i.e., good manufacturing practices (GMP) regulations], standards of identity, and common or usual names for food products.

FDA has the authority to take legal action against adulterated and misbranded seafood and to recommend criminal prosecution or injunction of responsible firms and individuals.

FDA conducts both mandatory surveillance and enforcement inspections of domestic seafood harvesters, growers, wholesalers, warehouses, carriers, and processors. The frequency of inspection is at the agency's discretion, and firms are required to submit to these inspections which are backed by federal statutes containing both criminal and civil penalties.

FDA provides financial support by contract to state regulatory agencies for the inspection of food plants, including seafood.

The FDA also operates two other specific regulatory programs directed at seafood – the Salmon Control Plan and the National Shellfish Sanitation Program (NSSP), recently augmented by the Interstate Shellfish Sanitation Conference (ISSC). These are voluntary programs involving the individual states and the industry.

The Salmon Control Plan is a voluntary, cooperative program among the industry, FDA, and the National Food Processors Association (NFPA). The plan is designed to provide control over processing, plant sanitation, and to address concerns about decomposition in the salmon canning industry.

Consumer concerns about molluscan shellfish are addressed through the NSSP. It is administered by FDA and provides for the sanitary harvest and production of fresh and frozen molluscan shellfish (oysters, clams, and mussels). Participants include the 23 coastal shellfish-producing states and nine foreign countries.

The NSSP was created upon public health principles and controls formulated at the original conference on shellfish sanitation called by the Surgeon General of the U.S. Public Health Service in 1925. These fundamental components have evolved into the National Shellfish Sanitation Program Manual of Operations. A prime control is proper evaluation and control of harvest waters and a system of product identification which enables trace back to harvest waters.

FDA conducts reviews of foreign and domestic molluscan shellfish safety programs. Foreign reviews are conducted under a Memorandum of Understanding (MOU) which FDA negotiates with each foreign government to assure that molluscan shellfish products exported to the United States are acceptable.

FDA's regulations on HACCP for seafood processing have been in full force since 1997. HACCP, in addition to other scientific and technical considerations, is an extension of the basics of food processing sanitation which uses FDA's current good manufacturing practice regulations (CGMPR) and the Food Code as frames of references. The FDA considers such sanitation compliance a prerequisites to HACCP planning and implementation.

This chapter discusses those prerequisites of basic sanitation for seafood processing. If you are a seafood processor and you are planning to start the HACCP program, you must first examine the current practices of your operation to ascertain that it complies with such prerequisites.

The information presented in this chapter has been modified from the CGMPR of the FDA and USDA, the Food Code, and other documents issued by the FDA on inspection of seafood processing plants.

The format and style used in this chapter reflects the instructional process between a teacher (e.g., a training supervisor) and student (e.g., a company personnel).

88.2 FRESH AND FROZEN FISH

88.2.1 Sanitation Critical Factors

The critical factors to remember when a company officer performs a sanitation inspection of a processing plant for fresh and frozen fish.

1. Look for evidence of rodents, insects, birds, or pets within the plant.
2. Observe employee practices including hygenic practices, cleanliness of clothing, and the use of proper strength hand-dip solutions.
3. Check to see if fish are inspected upon receipt and during processing for decomposition, off odor, parasites, and so on.
4. Check for decomposition and parasites during EI.
5. Ascertain if equipment is washed and sanitized during the day and at the beginning and end of the daily production cycle.
6. Check if the fish are washed with a vigorous spray after eviseration and periodically throughout the process prior to packaging.
7. Determine the method and speed of freezing for frozen fish and fish products.
8. Check use of rodenticides and insecticides to assure that no contamination occurs.
9. Observe handling from boats to finished package and observe any significant objectionable conditions.

Specific details on the sanitation are as follows.

88.2.2 Raw Materials

1. Determine what tests are conducted on incoming fish for decomposition, parasites, chemical contamination, and so on.

2. Determine disposition of incoming fish which have been found to be decomposed, contain excessive parasites or contaminated with mercury, pesticides, and so on.
3. Conduct organoleptic examination of incoming fish or fish products, especially those which have been thawed for processing or held for prolonged periods of time at room temperature during processing.
4. Give attention to fish arriving at the plant, as to effectiveness of elimination of decomposed fish, and check fish actually being packed. Determine percentage of decomposed units encountered, classifying each as passable (class 1), decomposed (class 2), or advanced decomposed (class 3).
5. Examine susceptible fish for parasitic infestations (e.g., white fish, rose fish, tullibees, ciscos, inconnus, bluefish, herring, etc.).
6. Check other raw materials and storage areas for rodents, insects, filth, or other contaminating factors.
7. See required specification on other raw materials for bacterial load, and so on (e.g., received under a Salmonella-free certificate issued by a recognized government or private agency).
8. Check for misuse of dangerous chemicals including insecticides and rodenticides.
9. If fish is received directly from boats, see if hook is used for loading and unloading, or for that matter, if a hook is used for any handling of the fish.

88.2.3 Manufacturing

1. Study manufacturing procedure. Include flow plan.
2. Study type of equipment used as to construction, materials, ease of cleaning, and so on.
3. Observe equipment cleaning and sanitizing procedures, and evaluate its adequacy.
4. Observe evisceration procedure, filleting procedure, or other butchering procedures used.
5. Determine source of water used in operation. Check that only potable water from an approved source is used.
6. If, during processing of fish, there are long delays at room temperature, check for decomposition.
7. Examine all handling steps and intermediate steps in processing that could lead to the contamination of the fish with filth and/or bacteria.
8. Study holding times and temperatures during the processing operation.
9. If battering and/or breading fish is involved, check process carefully. In addition, check times and temperature, and for other possible routes of filth and/or microbial contamination.
10. Evaluate compliance with good manufacturing practices.

88.2.4 Controls

1. Check coding system. If no code marks are used, mark suspect lot packages with fluorescent crayon for later sampling.

2. Review records regarding finished product assay for decomposition, parasites, microbial load, pesticides, mercury, and for other quality factors.
3. Study labeling used on products.
4. Check use of preservatives on fish or ice.

88.2.5 Summary and Checklist

Check on

1. Compliance with CGMP.
2. Use of adequate and proper strength hand and equipment sanitizing solutions.
3. Proper cleanup.
4. Evidence of rodents, insects, birds, domestic animals, or any other source of contamination.

Use the following list of indicators of sanitation to make a valid assessment of the operations at different stages of the process flow.

Stage	Assessment
Receive (unload fish)	1. Determine condition of the fish (acceptable or decomposed). 2. Separate work area.
Store	1. Suitable storage area (sanitation). 2. Time/temperature (icing) (quality). 3. Separate work area.
Wash	1. Remove surface slime and dirt (sanitation). 2. Use of potable water.
Filet	1. Personnel sanitation. 2. Equipment sanitation. 3. Separate work area.
Skin (either hand or machine)	1. Personnel sanitation. 2. Equipment sanitation. 3. Separate work area. Same area as fillet operation.
Rinse	1. Potable water. 2. Equipment sanitation. 3. Time/temperature (quality).
Pack (either retail or block)	Equipment sanitation. Personnel sanitation. Suitable packaging materials. Time/temperature (quality). Separate work area.
Freeze	Time/temperature (quality)

88.3 CANNED TUNA

88.3.1 Sanitation Critical Factors

During a sanitation inspection, use the following critical factors:

1. Check adequacy of firm's controls and review records covering the receipt of tuna fish. Ascertain if only tuna below the mercury guidelines and not decomposed is processed. Determine disposition of decomposed or over tolerance tuna.
2. Conduct organoleptic analysis of incoming tuna and of tuna being processed.
3. Check food additives to determine that only those permitted by the standards are used.
4. Check usage of insecticides and rodenticides to determine that they are used properly and do not become incidental food additives.
5. Study controls over the canning operation to assure that only good quality tuna is canned and that it is canned in accordance with FDA requirements.

88.3.2 Raw Materials

1. Determine adequacy of firm's controls for assuring that they are not canning decomposed tuna or tuna with excessive mercury.
2. Determine disposition of lots of tuna which are rejected because of excessive mercury.
3. Review firm's assay records and controls regarding mercury analysis of raw, in-process, and finished canned tuna.
4. Ascertain adequacy of controls firm utilizes to assure that the species of tuna canned are those allowed by standards.
5. Conduct organoleptic analysis of incoming raw tuna, frozen tuna which has been thawed for canning, and of any tuna being held for excessively long periods at room temperature.
6. Determine disposition of any tuna which is found to be decomposed (destruction, diversion, etc.).
7. Check raw material storage area for presence of insects, rodents, or other possible contaminants.
8. Check food additives in storage to ascertain if they are allowed in canned tuna as per 21 CFR 161.190(a) – Canned Tuna Standards.
9. Check firm's storage of rodenticides and insecticides to determine that they are used in accordance with instructions and are not becoming secondary food additivese.

88.3.3 Processing

1. Check firm's can seamers to determine if they are functioning properly.
2. Determine adequacy of firm's check on can seaming.
3. Determine if firm's retorts or continuous cookers are functioning properly.
4. Review recording charts from retorts and continuous cookers to ascertain if tuna was processed at proper time and temperature relationship.
5. Determine firm's postprocessing can handling. How cans are cooled, and whether water is clean and chlorinated.

6. Examine fish at critical points in the processing procedure, for organoleptic quality such as:
   a. In butchering state–prior to precook;
   b. After precook before being canned (no long holding time after precook);
   c. After any period the tuna has been held excessively long at room temperature.
   d. Evaluate firm's canning operation for compliance with the GMPR's for low acid foods (21 CFR 113).
   e. Check plant for proper screening and rodent proofing to eliminate insects and/or rodents.

88.3.4 Sanitation

Check:

1. Firm's operation for compliance with GMPR's Human Foods (Sanitation) 21 CFR 110.
2. Firm's equipment cleaning and sanitizing operation and determine its effectiveness.
3. If adequate hand washing and sanitizing facilities have been provided and that signs are posted directing employees to use them.
4. Employees use of hand sanitizing solutions and whether solutions are maintained at proper strength.
5. Firm's usage of insecticides and rodenticides so they do become incidental food additives.
6. Freezers for proper storage temperatures and for sanitary storage.
7. Review firm's records regarding assay of finished product for mercury, decomposition, and other quality factors.
8. Review firm's assay records to determine if the canned tuna complies with the Standard (21 CFR 161.190).
9. Ascertain if the food additives used are permitted by the Standards and other legal requirements.

88.4 OYSTERS

Most oyster shucking operations are handled by state inspection agencies. For procedures see FDA standard guidelines on interstate shellfish sanitation. Microbiological considerations are of prime importance in any shellfish gathering and processing plant. Time-temperature abuses enter into most problems with the products. However, the high value of these products has made economic violations even more profitable to the unethical operator. During an evaluation of sanitation, use the critical factors as follows:

1. Check for evidence of contamination from the presence of cats, dogs, birds, or vermin in the plant.
2. Check results of any testing conducted on incoming oysters including filth, decomposition, pesticides, or bacteria.

3. Check for possible incorporation of excessive fresh water through (a) prolonged contact with water or (b) by insufficient drainage.
4. Determine if employee sanitation practices preclude adding contamination (clean dress and proper use of 100 ppm chlorine equivalent hand sanitizers).
5. Determine if equipment is washed and sanitized about every 2 h.
6. Check for time-temperature abuses that may cause rapid bacterial growth.

88.5 BLUE CRAB (FRESH AND PASTEURIZED)

88.5.1 Sanitation Critical Factors

During a sanitation evaluation, use critical factors as follows:

1. Check for evidence of contamination from rodents, insects, flies, birds, and domestic pets.
2. Determine if employee sanitation practices preclude adding contamination (clean dress and proper use of 100 ppm chlorine equivalent hand sanitizers) particularly during pick out of shells from crabmeat.
3. Determine if equipment is washed and sanitized about every 2 h.
4. Check for time-temperature abuses which may cause rapid bacterial growth.
5. Check testing of incoming crabs for decomposition, bacterial load, pesticides, and dead crab removal prior to processing.
6. Check firm's usage of rodenticides and insecticides to determine that they do not contaminate the in-process crabs.

Let us look at the sanitation aspects of the different stages of operation.

88.5.2 Raw Materials

1. Check receiving and handling process prior to cooking.
2. See if firm discards all dead crabs prior to cooking. If not estimate percentage of dead crabs utilized.
3. Note any rodent or insect activity in the receiving area.
4. If the firm refrigerates the live crabs prior to cooking, see if they are kept in a separate cooler from the processed crabs.
5. Check results of any testing of incoming crabs including bacteriological results and pesticides.

88.5.3 Manufacturing Process

To evaluate the sanitation of the manufacturing process, check on the following:

88.5.3.1 Cooking. Check product flow and determine time and temperature of cooking and type of cooker.

1. Retort.
2. Live steam. Check boiler compound used.

3. Review recording charts for retorts.
4. Determine venting procedures.

88.5.3.2 Cooling. Check time and temperature relationship and:

1. How long cooked crabs are held at room temperature.
2. Any processing delays between cooking, cooling, and picking.
3. Whether cooled crabs are refrigerated until picked.
4. Whether cooked crabs are stored in same baskets as cooked in or are transferred to another container.
5. If refrigerator is used for storing cooled crabs, it is used only for this purpose.

88.5.3.3 Picking. Check on the following sanitation aspects:

1. If picking table is cleaned and sanitized prior to use, at appropriate times during the day, and at the end of the day.
2. If the picking table is not cleaned and sanitized between each new supply of crabs, if all crabs on the table are picked prior to the addition of new crabs. Check handling of crab claws prior to picking.
3. Pickers hands for cuts, sores, and so on.
4. That picking utensils are of proper construction.
   a. See if all metal knives without wooden handles are used.
   b. Check to see that the workers do not wrap the handles of the knives with paper towels, cloth, or string.
   c. See if all stainless steel or other metal shovels with steel handles and shafts are used for placing the crabs onto the picking table. Check shovel storage and see whether it is used for anything besides crabs.
5. If claws are picked mechanically, obtain procedure and check operation.
6. Check on how often pickers deliver the picked meat to the packing room.

88.5.3.4 Packing

1. See if picked crab meat is placed directly into the can or into holding pans. If the crab is "deboned" prior to packing, check on how long it is held.
2. See if weighed crabmeat weighed into final can is closed and iced at frequent intervals. Determine if pickers do their own weighing and final packing.
3. Check on how finished packaged crab meat is stored or if it is shipped the same day it is packaged.
4. See if ice used is from an approved source. Check storage of ice.

88.5.3.5 Pasteurization

1. Check the can closing system and can handling prior to pasteurization.
2. Check time-temperature of pasteurization process.
3. Check on how pasteurized cans are cooled and stored.
4. See if the finished canned crabmeat is stored in a refrigerator prior to shipping and how long it is held prior to shipment.
5. Determine shipping operation: refrigerated trucks iced baskets, and so on.

88.5.3.6 Lighting, Ventilation, Refrigeration, Equipment

1. Determine if building is adequately lighted and ventilated.
2. Check if the cooling and refrigerating facilities are adequate to do the job.
3. See if equipment is of proper construction.

88.5.4 Overall Sanitation

1. See if the building provides for a separation of the various processes.
2. See if building is so constructed to be free from rodent or insect entry points or harborages and whether there are rodents or insects in plant.
3. Check if product contact surfaces (tables, carts, pans, knives, etc.) are of proper construction. See if seams are sealed to avoid product buildup.
4. Obtain in detail the firm's plant and equipment cleaning and sanitizing procedures and check if all equipment is cleaned and sanitized as necessary.
5. Determine if employee toilets and hand-washing facilities are provided, maintained, and supplied and if handwashing facilities are located in various processing areas.
6. Determine if hand sanitizing solutions are provided at appropriate locations, maintained at proper levels at all times, and used when necessary. Check hand-sanitizing solutions, strength at various intervals during the inspection. Check to see if employees use hand dips when necessary.
7. Evaluate the firm's operations and employee practices for compliance with the Human Food (Sanitation) GMPR's, CFR part 110 and the Food Code.
8. Document any insanitary conditions noted that could lead to the contamination of the firm's crabs ox crabmeat with filth and/or bacteria.
9. Check storage and disposal of solid waste, for example, shells.

88.5.5 Checklist for Crustacea Processor

Use the following to obtain the information necessary to make a valid assessment of the sanitation of a processor's operation.

Receiving (unload)	1. Determine condition (acceptable or decomposed)
Control aspect	2. Separate work area
Sorting	1. Remove miscellaneous species of incidental fish
Control aspect	2. Further determination of condition (quality)
Age	1. Sanitation
Control aspect	2. Time/temperature
Peeling (mechanical,	1. Sanitation
types (Model A)	2. Potable water
(PCA-1.5″ cook)	3. Separate work area (for peeling, washers,
(choice for freezing)	separators, and, if applicable, shaker-blower)

Washers	1. Sanitation
Control aspect	2. Potable water
	3. Shell and debris removal (quality)
Shaker-blower (options)	1. Sanitation
Control aspect	2. Shell removal (quality)
In-house inspection	1. Sanitation
Control aspect	2. Shell removal.
	3. Separate work area for freezing
Size graded (machine or manual)	Sanitation
Package (cans or plastic)	Sanitation
	Personnel sanitation
Control aspect	Suitable packaging materials
	Time/temperature
	Separate work area
Freeze	Time/temperature (quality)
Control aspect	

88.6 SCALLOPS

88.6.1 Background Information

The scallop industry encompasses three primary species.

1. Sea scallops
2. Bay scallops
3. Calico scallops

The processing of sea scallops is accomplished on board the vessel actually harvesting the product. Boats which process sea scallops remain at sea from 3 to 12 days depending on area and catch. In most cases, the calico scallops are harvested daily and processed at shore processing plants rather than on board the vessel. The trend, however, is toward on-board processing for this species also. Bay scallops pose a unique problem in that they may be processed in a commercial plant or at home.

88.6.2 Sanitation Critical Factors

During the evaluation of food plant sanitation, use the following critical factors:

1. Check for evidence of contamination from rodents, insects, birds, or from domestic animals.
2. Determine if equipment is washed and sanitized about every 2 h.
3. Check for time-temperature abuses which could cause rapid bacterial growth and/or decomposition.

4. Determine if employee practices preclude the addition of contaminants. Clean dress and proper use of 100 ppm chlorine equivalent hand sanitizers.
5. Determine method of icing or freezing of the scallops.
6. Ascertain if incoming scallops are tested for bacterial load, decomposition, pesticides, and so on. Review results of these tests.
7. Check usage of pesticides and rodentcides by firm, to ascertain that they do not become incidental food additives.

88.6.3 Raw Materials

Determine:

1. Geographical area where the scallops are harvested.
2. Type of scallops harvested and processed by common or species name.
3. How scallops are handled between harvesting and processing.

88.6.4 Processing

1. Observe in detail the scallop processing operation. Make a flow-plan.
2. Check shucking and evisceration process, and see if this process is physically separated from the packaging and other operations.
3. Determine source of water used in the scallop washing and rinsing operations. If treated by the processor, determine nature and extent of treatment.
4. See if equipment used in processing operation is of proper construction and design.
5. Check firm's equipment cleaning and sanitizing operation.
6. Determine time and temperature of processing operation. Check:
   a. How long between harvest and chucking and the temperature of the scallops;
   b. How long scallops are held at ambient air temperature and determine the ambient temperature;
   c. How long between shucking and rinsing and the temperature of the scallops;
   d. After being iced, how long before scallops reach an internal temperature below 40°F.
7. Check finished product packaging.
8. Determine source of ice used in icing operation and if bagged ice is used, source and: type of bag; condition of bags; conditions of storage.
9. Check finished product storage facilities and condition.
10. Check on the use of any food additives to determine if used at allowable levels.

88.6.5 Overall Sanitation

1. See if building or vessel is free from rodent or insect activity.
2. Check that toilets and hand-washing facilities provided are properly located and maintained.
3. Determine strength and type of hand-sanitizing solutions used and the sanitizer's location.

4. Note any employee practices that could lead to the contamination of the scallops with filth and/or bacteria.
5. See if water and ice used in the process is from an approved source and list source.
6. Determine method of shell and waste material disposal.
7. Evaluate the firm's operation for compliance with the Human Foods (Sanitation) CGMPR's,21 CFR 110 and the Food Code.
8. Document any insanitary conditions noted which could lead to the contamination of this firm's products with filth and/or bacteria.

88.7 SHRIMPS

88.7.1 Sanitation Critical Factors

Breading of shrimp has long posed a problem from an economic standpoint. In addition, the time-temperature abuses present a great potential for food poisoning organisms. The growing scarcity and consequential high value of the raw material make the breading standards even more important. Review Breaded Shrimp Standards (21 CFR 161) prior to evaluate plant sanitation.

During a sanitation assessment, use critical factors as follows:

1. Check for the presence of cats, dogs, birds, or vermin in the plant.
2. Review testing of incoming shrimp. Check results of tests for decomposition, bacterial load, pesticides, and other possible adulterants.
3. Evaluate operation for compliance with 21CFR 12.1- Raw Breaded Shrimp.
4. Watch for any time-temperature abuses in the handling of seafood.
5. Determine that employee hygienic practices are satisfactory, for example, clean dress, washing of hands, and use of 100 ppm chlorine equivalent hand sanitizers.
6. Note any equipment defects which cause seafood to lodge, decompose, then dislodge into the pack.
7. Observe breading operations for suspected excesses (21 CFR 161.175/6), lack of coolant to keep batter mix below 50°F in an open system and below 40°F in closed system.

Note the misuse of pesticides, abuse of color or food additives, deviations from standards, and so on.

88.7.2 Raw Materials: Receipt and Storage

Determine if:

1. Shrimp and other raw materials are inspected upon receipt for decomposition, microbial load, pesticides, and filth.
2. Raw materials susceptible to microbial contamination are received under a supplier's guarantee. Raw material specifications exist and only wholesome raw materials are accepted into active inventory. Determine disposition of rejected raw materials.

3. Shrimp receiving and storage facilities are physically adequate.
4. Frozen shrimp are stored at 0°F (−18°C) or below.
5. Fresh or partially processed shrimp are iced or otherwise refrigerated to maintain a temperature of 40°F (4°C) or below until they are ready to be processed.
6. Decomposed shrimp are being processed.
   a. Examine shrimp as received, and again after sorting, for decomposition. Classify as passable (class 1), decomposed (class 2), or advanced decomposition (class 3). Less experienced inspectional personnel should submit some of class 2 and class 3 shrimp for confirmation by the laboratory.
   b. Prompt handling and adequate sorting is necessary to prevent decomposition. Check times and temperatures.
   c. Where decomposed shrimp are going into canned or cooked-peeled shrimp, collect investigational samples of the finished pack. Give attention to disposition of loads showing a high percentage of decomposition which cannot be adequately sorted, and to disposition of reject shrimp. Make certain that "bait shrimp" is denatured.

1. Fresh raw shrimp are washed and chilled to 40°F (4°C) or below within two hours of receipt. Frozen shrimp should be held at 0°F (−18°C) or below. Determine if they are examined organoleptically when received.
2. Peeled and deveined shrimp are promptly chilled to 40°F (4°F) or below.

88.7.3 Plant Sanitation

Determine if:

1. The water (ice) is:
   a. From an approved source;
   b. Disinfected and contains residual chlorine;
   c. Sampled and analyzed for contamination;
   d. Handled in a sanitary manner.
2. Drainage facilities are adequate to accommodate all seepage and wash water.
3. The plant has readily cleanable floors which are sloped and equipped with trap drains.
4. The plant is free of the presence of vermin, dogs, cats, or birds.
5. The screening and fly control is adequate.
6. Offal, debris, refuse is placed in covered containers and removed at least daily or continuously.
7. Adequate hand-washing and sanitizing facilities are located in processing area and are easily accessible to the preparation, peeling, and subsequent processing operations.
8. Signs are posted directing employees handling shrimp and other raw materials to wash and sanitize their hands after each absence from the work station.
9. Employees actually wash and sanitize their hands as necessary (before starting work, after absences from the work station, when hands become soiled, etc.).

10. Hand-sanitizing solutions are maintained at 100 ppm available chlorine or the equivalent and are used.
11. Persons handling food or food contact surfaces wear clean outer garments, maintain a high degree of personal cleanliness, and conform to good hygenic practices.
12. Management prevents any person known to be affected with boils, sores, infected wounds, or other sources of microbiological contamination from working in any capacity in which there is a reasonable probability of contaminating the food.
13. The product is processed to prevent contamination by exposure to areas involved in earlier processing steps, refuse, or other objectionable conditions or areas.
14. Food contact surfaces are constructed of metal or other readily cleanable materials.
15. Seams are smoothly bonded to prevent accumulation of shrimp, shrimp material, or other debris.
16. Each freezer and cold storage compartment used for raw materials, in process or finished product is fitted with required temperature indicating devices.
17. Unenclosed batter application equipment is flushed and sanitized at least every 4 h during plant operations and all batter application equipment is cleaned and sanitized at the end of and the beginning of the days operation.
18. Breading application equipment and utensils are thoroughly cleaned and sanitized at the end of the days operations.
19. Utensils used in processing and product contact surfaces of equipment are thoroughly cleaned and sanitized at least every 4 h during operation.
20. All utensils and product contact surfaces excluding breading application equipment and utensils are rinsed and sanitized before beginning the days operation.
21. Containers used to convey or store food are handled in a manner to preclude direct or indirect contamination of the contents.
22. The nesting of containers is prohibited.

88.7.4 Processing

Determine if:

1. Raw frozen shrimp are defrosted at recommended temperatures (air defrosting at 45°F (7°C) or below, Or in running water at 70°F (21°C) or below in less than 2 h).
2. Fresh raw shrimp are washed in clean potable water and chilled to 40°F (4°C) or below.
3. Fresh shrimp are adequately washed, culled, and inspected.
4. Every lot of shrimp that has been partially processed in another plant, including frozen shrimp, is inspected for wholesomeness and cleanliness.
5. Shrimp entering thaw tank are free from exterior packaging material and substantially free of liner material.
6. On removal from thaw tank. shrimp are washed with a vigorous potable water spray.
7. Shrimp are removed from thaw tank within 30 min after they are thawed.

8. During the grading, sizing, or peeling operation the:
   a. Equipment is cleaned and sanitized before use;
   b. Water is maintained at proper chemical strength and temperature;
   c. Raw materials are protected from contamination.
9. Sanitary drainage is provided to remove liquid waste from peeling tables.
10. Firm prohibits the practice of salvaging shrimp (i.e., repicking the accumulated hulls and shells for missed shrimp or shrimp pieces).
11. Peeled and deveined shrimp are promptly chilled to 40°F (4°F) or below.
12. Peeled shrimp are transported from peeling machines or tables immediately, or, if containerized, within 20 min.
13. Peeled shrimp containers, if applicable, are cleaned and sanitized as often as necessary, but in no case less frequently than every 3 h.
14. When a peeler is absent from his duty post, his container is cleaned and sanitized prior to resuming peeling.
15. Peeled shrimp that are transported from one building to another are properly iced or refrigerated, covered, and protected.
16. Shrimp are handled minimally and protected from contamination.
17. Shrimp which drop off processing line are discarded or reclaimed.
18. Shrimp are washed with a low-velocity spray or in unrecirculated flowing water at 50°F (10°C) or below just prior to the initial batter or breading application, whichever comes first, except in cases where a predust application is included in the process.
19. Removal of batter or breading mixes or other dry ingredients from multiwalled bags is accomplished in an acceptable manner.
20. Batter in enclosed equipment is assured a temperature of not more than 40°F (4°C) and disposed of at the end of each work day, but in no circumstances less often than every 12 h.
21. Batter in an unenclosed system is maintained at or below 50°F (10°C) and disposed of at least every 4 h and at the end of the days operation.
22. Breading reused during a day's operation is sifted through a 1/2 in. or smaller mesh screen.
23. Breading remaining in the breading application equipment at the end of a days operation is reused within 20 h and is sifted as above and stored in a freezer in a covered sanitary manner.
24. Hand batter pans are cleaned, sanitized and rinsed between each filling with batter or breading.

88.7.5 Finished Product Process and Quality Assurance

Determine if:

1. Processing and handling of finished product is:
   a. Performed in a sanitary manner;
   b. Protected from contamination;
   c. Arranged to facilitate rapid freezing.

2. Manual manipulation of breaded shrimp is kept to a minimum.
3. Aggregate processing time, excluding the time required for thawing frozen material, is less than 2 h, exclusive of iced or refrigerated storage time.
4. Breaded shrimp are placed into freezer within 30 min of packaging.
5. Breaded shrimp are frozen in a plate or blast freezer at -20°F (-29°C) or below.
6. Storage freezer is maintained at or below 0°F (-18°C).
7. In-line, environmental, and finished product samples are analyzed and evaluated at least weekly for microbial conditions. Review these analytical records if available.
8. Firm has established microbiological specifications for the final product. If so, review and report these specifications.
9. Firm withholds from distribution lots which do not meet their established microbiological standards.
10. Finished product is handled and stored in a manner which precludes contamination.
11. Labels bear a cautionary statement to keep product frozen.

88.8 SMOKED FISH

88.8.1 Sanitation Critical Factors

During an evaluation of the sanitation of a smoking fish operation, use critical factors as follows:

1. Check sanitary conditions under which firm is operating, including any evidence of insanitation and contamination associated with insects, rodents, microorganisms, chemicals, or other possible sources. Check raw material and packaging material storage areas as well as other susceptible locations in the plant.
2. Review raw material receiving records for DDT and other pesticides, decomposition, and bacteriological quality.
3. Check food and color additives to ascertain that they are allowed for use and are being used properly.
4. Observe employee practices to make sure that they are not acting as routes of contamination.
5. Ascertain if the various operations including raw material receipt and storage, defrosting, brining, and so on, are acceptable.
6. Review recording charts to ascertain what time/temperatures of smoking have been, this may vary depending on the desired salt content the firm is trying to achieve.
7. Check finished stored product (i.e., any smoked chubs in which nitrite is used) to ascertain the internal temperature based on the time since smoking. (Temperature within 3 h of cooking and again within 12 h of cooking.)

88.8.2 Plant Sanitation and Facilities

1. Check method(s) for cleaning and sanitizing utensils, conveyors, smoking racks, and other food-contact surfaces used in daily operations.

2. Check the strength and adequacy of hand-sanitizing and equipment-sanitizing solutions. The minimum effective chlorine concentration for hand-sanitizing solutions is 100 ppm and for equipment-sanitizing solutions 200 ppm. Iodine solutions should be 15 ppm for hand-sanitizing solutions and 25 ppm for equipment-sanitizing solutions. Determine if maintained at proper levels.
3. Determine method used to separate finished product cooling, packaging, and storage areas from the uncooked product and processing areas.
4. Determine the adequacy of plant waste disposal operations.
5. Check if hand-washing, toilet, and sanitizing facilities have been provided and that signs have been posted directing the employees to wash and sanitize hands following use.

88.8.3 Raw Materials

Determine:

1. Source (area and distributor) and species of fish processed by the firm including the type selected for full coverage during this inspection.
2. Process condition in which bulk fish is supplied (e.g., fresh, frozen, mild cured, brined, etc.).
3. Quality of fish received. Organoleptic examination should be performed and results reported.
4. Raw fish handling procedures (e.g., defrosting, draining procedures encountered).
5. Available chlorine or iodine concentrations in hand dip or equipment sanitizing solutions, if used.
6. Time/temperature intervals for each step in the raw fish handling operations.
7. If incoming fish are sampled and analyzed for the presence of DDT and other pesticides.

88.8.4 Processing

88.8.4.1 Salting and Brining. Determine:

1. Size of fish or pieces of fish brined noting variations of fish size and sizing procedures.
2. Form and grade of salt (NaCl) used in the brining.
3. Ratio of brine to fish. Determine actual or near estimates of weight of salt, volume of water and weight of fish being brined.
4. Concentrations of brine (NaCl) solutions in degrees Salinometer at the initiation of brining, during brining, and at the conclusion of the brining operation. A reduction in salt concentration in the brining solution after brining may indicate salt uptake by the fish during brining. [CAUTION: If Salinometers are made of glass, the degree of salinity should be read in a plastic graduate. DO NOT put the salinometer directly into the tank with fish. It could break and contaminate the fish with glass.]
5. Time/temperatures of brining solutions at different intervals during the brining process. Include total brining time.
6. Method of agitation of brine solution during brining, if employed, noting number of times agitated and length of each agitation.

88.8.4.2 Heating, Cooking, and Smoking Operation

1. Check equipment used during heating, cooking, and smoking operation. Include oven type, source of heat, type of smoke generators, product temperature monitoring equipment, humidity regulators, and so on. (Temperature recording devices should have an accuracy of $\pm 2^{\circ}$F.).
2. Determine the methods and procedures used in drying, cooking, and smoking. Include time/temperature data, results of temperature monitoring by the firm, location of their temperature probes, and product rotation practices.

88.8.4.3 Cooling

1. Monitor time/temperature relationships during cooling to determine how long it takes to reach an internal temperature of 38°F.
2. Determine method of cooling.
3. Check observable procedures and conditions which can contribute to the microbiological contamination of the processed fish. Include observations such as extended cooling time and optimum incubation temperature, exposure to airborne contamination, improper handling, or poor in-process storage conditions.
4. Determine if firm separates cooling facilities from raw processing and cooking operations.

88.8.4.4 Packaging. Determine method and types of packing including:

1. Time/temperature relationships during any use of additives or prepackaging additive treatment. Include name of quantity added, method of application, and so on.
2. Observable practices and conditions which can contribute to the microbiological contamination of the processed fish. Include lack of required facilities, excessive product handling, improper storage, and so on.

88.8.5 Storage and Distribution

1. Check type of equipment used for determining, recording, and maintaining storage temperatures.
2. Determine actual storage compartment temperatures. Refrigerated storage temperatures should be 38°F or below.
3. Determine method of distribution (e.g., refrigerated, iced, frozen, etc.).

88.8.6 Laboratory Controls

Check or determine:

1. Method and frequency of sampling. Salinity testing operations and evaluate testing procedures and frequency. Microbiological testing of processed fish, how often, methods used, adequacy of testing, and so on.
2. Checks made on in-process controls and laboratory equipment.
3. Use of outside laboratories, consultants, and so on. Include name, location, and tests each firm performs and how often tests are conducted.
4. Results of analysis from previous lots.

88.8.7 Overall Sanitation

1. Evaluate the firms operation for compliance with 21 CFR 110-GMPR's Human Foods (Sanitation).
2. Evaluate the firm's cleaning and sanitizing procedures.
3. Check if adequate handwashing and sanitizing facilities are provided and if signs directing their use are provided. Evaluate the employees use of hand dips and if they are used when necessary.
4. See if hand dips and equipment sanitizing solutions are maintained at the proper level and changed when necessary.

89.1 INTRODUCTION

Aquaculture has existed for several thousands of years and in many different forms (Beveridge and Little 2002). It is hugely diverse and involves the production of both aquatic animals and plants in fresh, brackish, and marine waters from near polar to tropical environments. It has the longest history in China where earthen pond culture of common carp was recorded over 3000 years ago (Landau 1991; Li 1994). Polyculture of Chinese carps and other fish species in ponds still accounts for much of the World's aquaculture production and is a tribute to the methods developed by practitioners over thousands of years as well as to recent technological advances. A key characteristic of polyculture, partly explained by the name, is that several species are farmed together in the same body of water. This is possible because the different fish species exploit different food sources within the pond and because feeding activity and resultant fish wastes return inorganic and organic nutrients that stimulate production of plankton at the base of a

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

pond's food web. Depending on the level of management and inputs into the pond, this type of aquaculture is described as extensive or semi-intensive. Within the last half of the 20th century a new approach has emerged and shifted aquaculture into an industrial phase based on the intensive monoculture of a few high value species. Intensive aquaculture is well established for several salmonid species, including rainbow trout (*Oncorhynchus mykiss*) and Atlantic salmon (*Salmo salar*), as well as for channel catfish (*Ictalurus punctatus*) and increasing numbers of marine finfish such as European sea bass (*Dicentrachus labrax*) and gilthead sea bream (*Sparus aurata*). All types of aquaculture continue to expand as does their share of the global fishery, this share has increased from less than 4% in 1970 to 32% in 2003 (FAO 2004). In 2003 aquaculture of finfish, and of molluscs and crustaceans (shellfish) produced 41.9 million tonnes, finfish accounted for approximately half with crustaceans and molluscs accounting equally for the majority of the remainder (FAO 2004). Although aquaculture production is based on at least 210 different plant and animal species, the majority comes from a few groups and mostly from extensive and semi-intensive farming (FAO 2002). Carp dominate aquaculture production and nine of the top 20 aquaculture species in 2000 were carp or other finfish species used in pond based polyculture (Fig. 89.1). Monetary value reflects the socioeconomic and technical basis of a particular aquaculture sector so that of the top 20 species, prawns and salmonids had a larger share of total value than they did of production (Table 89.1). In 2003, nine countries produced more than half a million tonnes of aquaculture product, including plants: China (27.7 million tonnes) dominated, India (2.2 million tonnes), Indonesia (0.9 million tones) and Bangladesh (0.8 million tonnes) were the next largest (FAO 2004). These countries used mainly semi-intensive methods where as Japan, Norway, and Chile used mainly intensive methods to produce over 0.5 million tonnes each. Aquaculture has great potential to expand further and to meet an increasing human demand for protein but to do this there may have to be dramatic changes in current structures and practice, the debate on sustainable aquaculture is only just beginning (Bardach 1997; Naylor and others 2000; Tidwell and Allan 2001; Costa-Pierce 2002). There are many ways to farm finfish and aquaculture is very broadly divided into extensive and intensive forms. It has been proposed that whilst there is a continuum from extensive to semi-intensive systems intensive aquaculture is distinct. This is primarily because, under intensive aquaculture, water provides physiological support for the fish but all

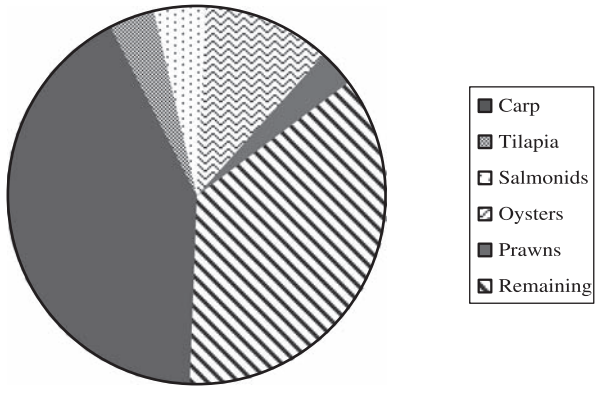

Figure 89.1 *Distribution (% of total production weight) of major aquaculture groups in 2000 (FAO 2002). Categories detailed in Table 1.*

TABLE 89.1 Major Aquaculture Species Ranked by Production in 2000.

Group	Name (US$ rank)[b]	Scientific Name	Production (Million Tonnes)
Bivalve	Pacific oyster (2)	*Crassostrea gigas*	3.94
Carp (Chinese major)	Silver carp (3)	*Hypophthalmichthys molitrix*	3.47
Carp (Chinese major)	Grass carp (4)	*Ctenopharyngodon idella*	3.45
Carp	Common carp (5)	*Cyprinus carpio*	2.72
Other (bivalve)	Small neck clam (7)	*Ruditapes philippinarum*	1.69
Carp (Chinese major)	Bighead carp (10)	*Hypophthalmichthys nobilis*	1.64
Carp	Crucian carp (13)	*Carassius carassius*	1.38

other means of sustaining life are provided from external sources, the most obvious being the supply of nutritionally complete feeds. The aim of this chapter is to provide an overview of the range of finfish species and systems used in intensive aquaculture.

89.2 INTENSIVE AQUACULTURE SYSTEMS

The principles that drive intensive aquaculture are based around maximizing production in the shortest length of time. Intensive aquaculture is most often based on monoculture of high value and usually carnivorous species in developed countries. Fish at high densities are contained in a wide variety of structures including net-cages, tanks, raceways, and earthen ponds (Fig. 89.2). Nutritionally complete compound feeds are fed at maximum rations, and usually manufactured at specialized feed mills as pellets containing a large variety of ingredients. Arguably, for a species to be an aquaculture species the lifecycle should be closed so that it is bred under culture and all stages of its lifecycle are farmed. This is the case for salmonids (salmon and trout), cyprinids (carp), and catfish as well as for increasing numbers of marine finfish. Reproduction and propagation of major freshwater (carps and catfish) and anadromous (salmonids) farmed finfish is relatively straightforward and achieved with a high success rate. One important characteristic of these finfish is the large size and robust nature of their eggs and the ease of feeding compound feeds immediately, or soon after, the time the larvae are able to take external foods. This is in marked contrast to marine species which have far smaller eggs and larvae, consequently first-feeding larvae are not fed on compound feeds and far greater investments in

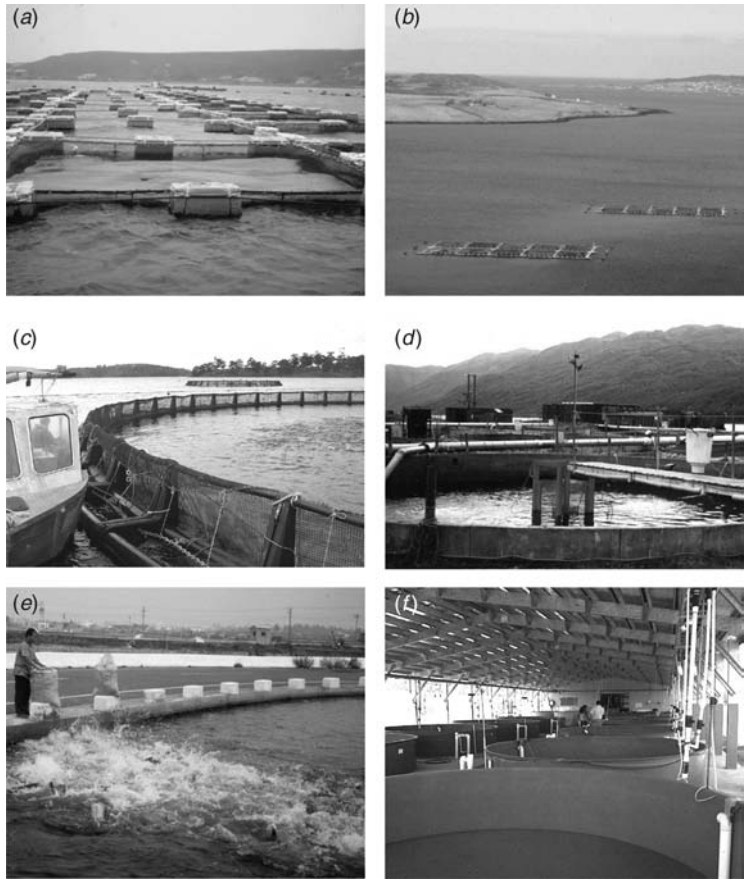

Figure 89.2 *Different forms of intensive aquaculture (a) small 4 m square-cages for grouper farming in Taiwan, (b) 24 m square-cages for Atlantic salmon farming in Scotland, (c) ring-cages for Atlantic salmon farming in Tasmania, (d) concrete tanks for turbot in Scotland, (e) road-side ponds for cobia farming in Taiwan (f) tanks used for intensive rearing of Asian sea bass fry in Australia.*

technologies for intensive larval rearing and for supplying live feeds have been made. Although, some industries may use extensive pond based production of fry as a more economic approach. Barramundi or Asian sea bass (*Lates calcarifer*) is one example of this practice, although intensive hatchery methods have been established some farms use extensive ponds to produce fry for intensive rearing and grow-out (Tucker and others 2002).

Maintaining fish health and disease control is clearly important to all sectors of aquaculture. Unfortunately, there are examples of large losses in production due to disease. The Atlantic and Pacific salmon industries have suffered from major viral (e.g., IPN, infectious pancreatic necrosis; ISA, infectious salmon anemia), bacterial (e.g., furunculosis; bacterial kidney disease), and parasitic (e.g., sea lice; ameobic gill disease) diseases. Atlantic salmon suffered from major outbreaks of furunculosis in the early 1990s that resulted in yearly losses of US$77 million, fortunately the disease has declined since 1993 due to the use of effective vaccines (Holm 1999). Vaccination against a variety of potential

pathogens is now a major management procedure in the salmon industry, over 90% of all Norwegian stocks are vaccinated by injection (Holm 1999). Vaccination is only a part of the healthcare management programs now in place. These recognize the need for trained personnel, routine monitoring and quick diagnosis; to minimize stress through appropriate stocking densities, careful and minimal handling; site rotation to break the disease cycle; cooperation between farms to ensure single-year class stocking at a location in order to prevent vertical transfer and break disease cycles (Holm 1999). Aquaculture is also vulnerable to environmental impacts that include toxic algal blooms, contamination from land run-off and disasters such as oil spills. Offshore marine finfish aquaculture is increasingly being considered as a realistic approach to make dramatic increases in aquaculture production and reduce some of these risks (Ytterland and Kvalheim 2005). It has the advantages of both avoiding and not contributing to costal pollution as well as minimizing conflicts with numerous commercial and recreational groups (Bridger 2001). Technology required for holding and servicing stocks must be far more resilient than for inshore farming and greater mechanization is needed to reduce the need for manual intervention, this technology is developing rapidly but not yet fully available (Bridger 2001; Ytterland and Kvalheim 2005). Large robust cages for offshore locations are under development for several aquaculture sectors including salmon, flatfish, sea bass, and sea bream (Lien 1993). Examples include various designs and one of the main features is that they can be fully submerged to reduce damage from wave action at the sea surface (Lien 1993; Ytterland and Kvalheim 2005). Individual units can be linked to central stations, for example, decommissioned oil and gas platforms have been under trial. There have also been significant advances in closed-water systems, these are usually indoor tank-based systems that place reliance on technology to reduce water use and maintain its quality with advanced physical and biological filtration.

Finfish nutrition and aquafeed development currently face important issues, aquafeeds use large amounts of fish meal and fish oil. Although it is argued that aquaculture has not caused any increase in fish meal production, existing production has been increasingly allocated to the aquafeed market from other feed sectors (Tidwell and Allan 2001). In the 10 years between 1988 and 1998 the proportion of the global fish meal supply used in aquafeeds increased from 10% to 35% and is predicted to increase further (Tidwell and Allan 2001). This is not sustainable and considerable research and development is focused on developing alternative protein and oil sources from various plants and microorganisms (Hardy 1996; Carter and others 2003). Experimental feeds that do not contain marine products have been developed for large channel catfish, in fact the total animal meal now used in commercial catfish feeds is less than 2% (Robinson and Li 2002). However, channel catfish is omnivorous and one of the few noncarnivorous finfish farmed intensively. The complete replacement of marine ingredients in aquafeeds for carnivorous species poses more challenges that include plant meals being low in digestible protein, high in carbohydrates, high in antinutritional factors and having poor essential amino acid profiles. For example, salmonids have limited ability to both digest and metabolise dietary carbohydrate and the optimum dietary inclusion ranges between 10–20% (Hemre and others 1995). Milled but relatively unprocessed plant meals can contain over 70% carbohydrates and less than 20% protein and this clearly restricts their inclusion level in aquafeeds. For many years soybean (*Glycine max*) meals from which oil has been extracted have proved an excellent source of digestible high quality protein for aquafeeds but other suitable highly processed ingredients manufactured from plant sources are both limited and expensive. Consequently, a number of microbial as well as plant sources are

being developed to produce ingredients that are more suited to inclusion in aquafeeds, important characteristics are higher digestible protein, a more suitable essential amino acid profile and lower levels of carbohydrate and antinutritional factors. Products made from lupins (*Lupinus* sp.), canola (*Brassica* sp.), and field peas (*Pisum* sp.) and from unicellular sources such as bacteria, yeasts and algae show considerable promise (Storebakken and others 1998; Carter and Hauler 2000; Metailler and Guillaume 2001).

Arguably, the replacement of fish oil with terrestrial oils in aquafeeds is more urgent that the replacement of fish meal. For example, Atlantic salmon aquafeeds contain a high proportion of fish oil (over 38%) and their high global production means aquafeeds are the major user of global fish oil. This level of use and the probability of increased competition for fish oil from other sectors (e.g., nutraceuticals) have the potential to severely restrict further expansion of salmon aquaculture. Animal fats are unsuitable due to the abundance of saturated fatty acids and low concentrations of unsaturated fatty acids, particularly omega-3 series (Metailler and Guillaume 2001). Fortunately, it now appears feasible to replace at least 75% of the fish oil in Atlantic salmon feeds with a blend of plant oils (Torstensen and others 2005). The majority of oils used to replacement fish oil have been of plant seed in origin such as canola (rapeseed), linseed, soybean, and sunflower (Bransden and others 2003). The major issue is that plant oils are low in the omega-3 fatty acids that confer the health benefits to humans, fish oil is rich in omega-3 fatty acids, particularly the long chain polyunsaturated omega-3 fatty acids eicosapentaenoic (EPA, 20: 5*n*-3) and docosahexaenoic (DHA, 22: 6*n*-3) acids (Sargent and others 2001; Bransden and others 2003). One approach is to look at ways of minimizing the inclusion of fish oil over the production cycle, for example, the amount of dietary fish oil may be increased towards the end of production to boost omega-3 flesh levels prior to harvest. However, fish have their own requirements for omega-3 and omega-6 fatty acids so that the correct dietary inclusion levels and balance between the different fatty acid series are required throughout production. Linseed oil, unlike other plant seed oils, is rich in long chain omega-3 fatty acids and has been investigated specifically to supply these in fish oil replacement studies (Bell 2000). Microorganisms such as thraustochytrids and marine bacteria show potential for production in large batch culture, because they can be very high in EPA and DHA they would make excellent replacements for fish oil (Lewis and others 1999; Carter and others 2003). Freshwater fish and salmonids readily convert linolenic acid (LNA) to longer chain EPA and DHA. Recently, a dietary source of stearidonic acid (SDA), a possible intermediate between LNA and EPA, was used by Atlantic salmon to increase their EPA and DHA content (Miller and others 2005). Considerable success has been achieved in replacing fish oil but further solutions are urgently required. One issue of importance in the replacement of fish meal and fish oil, particularly with plant oils has the potential to affect taste and consumer preferences. Interestingly there may be a preference for salmon flesh that is less "marine," salmon fed a blended plant oil for the entire production cycle were preferred over salmon fed entirely fish oil by a trained taste panel (Torstensen and others 2005). Encouragingly, all the fish oil could be replaced without compromising flesh quality and 75% could be replaced without compromising the long chain omega-3 composition in relation to human health (Torstensen and others 2005).

89.2.1 Salmonids

Around 10 salmonid species (members of the family Salmonidae) are farmed in 60 countries (Purser and Forteath 2003): rainbow trout, Atlantic salmon, and coho salmon

(*Oncorhynchus kisutch*) account for over 90% of production. These species are endemic to temperate seas of the northern hemisphere, *Oncorhynchus* species from the Pacific and *Salmo* species from the Atlantic. Export for use in recreational fisheries and aquaculture makes them global species with a considerable southern hemisphere presence (Willoughby 1999). Rainbow trout have been cultured for many years and Denmark pioneered pond based production of plate sized fish at the end of the 19th century (Willoughby 1999). In the last 10 years Atlantic salmon has become the major salmonid species due to a huge expansion in sea-cage farming in Norway and several other countries. Atlantic salmon are typically anadromous (return from the sea to spawn in freshwater) with freshwater and seawater phases in their lifecycle. Adults of up to 30 kg famously migrate up the rivers and streams that they last swam down as immature parr several years previously. Mature males and females return to freshwater sometime in the 12 months before they spawn, the female makes a hollow redd in a gravelly stream bed and the male fertilizes the eggs as they are released. The buried eggs hatch into a yolk-sac stage (alevin) and emerge as fry that start feeding on animal prey. The fry grow into parr that then undergo smoltification, a metamorphosis taking several months, to enable migration into the sea. After 2–5 years at sea (sea-winters) the fish return as mature adults, grilse mature early and return after only one sea-winter. Aquaculture followed this natural lifecycle but increased environmental control and manipulation, intense nutritional regimes, coupled with selective breeding, now maximize production over as much of the year as possible.

Selective breeding programs are at various stages of development throughout the world, in Norway it is estimated that 65% of farmed Atlantic salmon and rainbow trout originate from the National Breeding Program that started in 1971 (Gjedrem 2000). Growth rate and then increased time to maturation were used as key selection characteristics. More recent selection characteristics have used disease challenge to increase disease resistance and measurements of flesh color, fat content, and fat distribution to improve meat quality (Gjedrem 2000). There has also been development and testing of genetically modified or transgenic fish. Genetically modified Atlantic salmon parr containing a growth hormone transgene (chinook salmon growth hormone gene attached to an antifreeze protein promoter sequence from ocean pout) grew at over two and half times the rate of control fish due mainly to increased feed intake (Cook and others 2000).

Straightforward and effective procedures are followed to ensure high fertilization rates and efficient production of parr, ready for transfer as smolts from fresh to sea-water (Willoughby 1999). Smolts usually have to be transported from the hatchery to the grow-out site, this can be by land, air, or sea and care is taken to reduce stress. Only salmon parr that reached a minimum size during the "smoltification window" will be suitable for transfer, it is normally in the spring for Atlantic salmon but more variable for Pacific salmon. In contrast, successful sea-water transfer of rainbow trout, a nonsmolting species, is related principally to larger size (Purser and Forteath 2003). Controlling the supply of smolt enables stocking over more of the year and more even production throughout the year. This is particularly important when a large proportion of fish mature within one sea-winter as grilse which are smaller than older salmon (Purser and Forteath 2003). One-year smolt is the normal age category for smolt but half-year, one-and-a-half and two-year smolt are also produced and used (Willoughby 1999). Once in sea-water the on-growing phase is mainly in sea-cage systems, large bag-nets held on floating frames that are anchored to ensure the frames stay in the same place. Bag-nets are 5–20 m deep and their shape is maintained by devices such as metal rings around the circumference of

the net, weights, and lead-core ropes (Purser and Forteath 2003). Groups of cages are usually held and anchored together and can, depending on the design, be joined by walkways or only accessed individually by boat. Galvanized steel square-cages are typically available in 12–24 m^2 sections, a 24 m section would consist of a 15 × 15 m net surrounded by walkways with attached floatation devices (Fig. 89.2). The other main type of sea-cage is the circular ring-cage, buoyant circular ring structures are used to attach a circular bag-net, predator net, mooring cables and other ancillary structures such as bird netting or feeders (Fig. 89.2). These structures can range in circumference from 60 to over 120 m and are usually placed apart to allow greater water flow through a group of sea-cages, they are easier to manage independently of each other. There are a number of commercial variations of square- and ring-cages that may hold only a few tonnes to over 150 tonnes (Purser and Forteath 2003). Mature salmon are not desirable in a production run, mortality is higher in seawater, they partition feed resources into unwanted reproductive growth rather than somatic growth and develop many poor external and flesh quality characteristics that reduce marketability (Purser and Forteath 2003). Whether maturation occurs is highly influenced by size and nutritional status so that faster growing fish, often in warmer temperatures, will mature relatively quickly but be of a smaller size. Strategies to control the effects of maturation include the production of sterile triploid fish or the use of all female stock, since females show lower rates of maturity than males, and manipulation of photoperiod and lighting regimes (Pankhurst and Porter 2003; Porter and others 2003).

Several quality factors are considered of primary importance to the Atlantic salmon industry, the consumer emphasizes freshness, fat content, texture, and color whilst the producer also places priority on production yields (Torrissen and others 2001). The replacement of fish oils by plant oils and its effect on flesh quality have been discussed above. Two carotenoid pigments, canthaxanthin and astaxanthin, are mainly responsible for the pink coloration of salmon flesh. Species, lifecycle stage, and individual variation are key biological factors that influence carotenoid fixation in flesh. Salmonids, unlike some other aquaculture groups such as crustaceans, are unable to synthesize astaxanthin from precursors so it must be included in the diet (Choubert 2001). Lifecycle is important and salmonids have to reach a minimum size before carotenoids are retained in muscle, in addition carotenoids are remobilized from the muscle of maturing salmon and concentrated in the skin and in the orange eggs (Choubert 2001). Important factors that relate directly to aquafeeds are the pigment type, ingredient source, and dietary concentration. For example, carotenoids are lipid soluble and more digestible when contained in oils rather than in meals such as shrimp meal. Significant digestive and metabolic losses occur and carotenoids are deposited in many tissues besides the target muscle. Consequently, deposition in muscle occurs at an optimum dietary inclusion level, unfortunately, efficiency is generally less than 15% and decreases with dietary inclusion which further increases the cost of pigmentation. Crustacean meals, yeasts, and algae and other aquafeed ingredients are relatively rich in carotenoids but industrial synthesis of free forms of both canthaxanthin and astaxanthin allows more efficient inclusion in aquafeed formulations. Carotenoids are easily oxidized which means pigment sources that are protected from oxidation will be more effective. Recommended inclusion levels are 80 and 100 mg per kg of feed for canthaxanthin and astaxanthin, respectively (Choubert 2001). Pigments are very expensive and although only small amounts are used this increases the feed cost by 15–30% (Choubert 2001).

89.2.2 Marine Finfish

In many of countries that use intensive aquaculture product there is a premium on marine rather than freshwater finfish. Consequently, there is considerable interest in developing aquaculture for a variety of marine species, as yet there is no intensive aquaculture on the scale of Atlantic salmon. Good examples of intensive marine aquaculture in which the lifecycle is closed and that have high production, are European sea bass and gilthead sea bream in the Euro-Mediterranean region (Harache and Paquotte 1998), red drum (*Sciaenops ocellatus*) in the southern United States (Gatlin 2002), and red sea bream (*Pagrus major*) in Japan. Atlantic cod (*Gadus morhua*), Atlantic halibut (*Hippoglossus hippoglossus*), cobia (*Rachycentron canadum*), and grouper species (e.g., *Epinecphelus* spp.) show potential (Kilduff and others 2002; Tucker and others 2002; Rimmer and others 2004).

In marine finfish production bottlenecks are associated with larval stages and an extensive program of research and development, that includes validation at a commercial scale, appears necessary for each species. Rotifers (*Brachionus* sp.) and brine shrimps (*Artemia* sp.) form the basis of most larval rearing protocols, rotifers are smaller and always fed first and then alongside the larger brine shrimp in order to maintain a food source for smaller individuals, and to provide a new food source for larger individuals. As the larvae grow they are weaned off rotifers and then off the brine shrimp and onto compound feeds. Other variations include "greenwater" techniques, whereby microalgae are also grown because they appear to benefit both the live feed and the finfish larvae. Live feeds are often "enriched" by feeding them commercial preparations to increase concentrations of specific nutrients, particularly polyunsaturated fatty acids and vitamins. A simple larval rearing protocol such as one for red sea bream would be microalgae (days 3–25), rotifers (days 3–33), brine shrimp (days 20–40), and compound feed (days 20–60). On a few days, 20–25, all four feeds might be available.

European sea bass production has increased steadily over the last 10 years and all aspects of production, from larval rearing to broodstock management, are well developed and commercial hatcheries produce over 180 million juveniles for sea-based on-growing of around 45,000 tonnes per year (Kaushik 2002). Propagation is based on a relatively standard larval rearing protocol and the sequence of live feeds, rotifer followed by brine shrimp, before weaning onto a compound feed (Kaushik 2002). European sea bass larvae first-feed 4 or 5 days after hatching, live feeds are gradually replaced by compound feeds and weaning is usually complete by 40 days. Recently, a compound feed has been used immediately at first-feeding and for the entire larval period. The use of ingredients that contain nutrients in highly available forms, such as phospholipids and hydrolyzed proteins, supplies essential nutrients in a form that can be readily assimilated and explains the diet's success (Kaushik 2002).

The large and important Japanese yellowtail industry produced 137,000 tonnes in 2000 (FAO 2002) but this was below production at the start of the 1990s. Farming yellowtail in Japan developed from holding wild-caught fish and intensified in the 1970s; unfortunately, a too rapid expansion and limitations due to disease and markets led to greater controls on the industry and a reduction in production (Doumenge 1990). Although hatchery based propagation is possible the Japanese industry is still largely based on small ($<$10 g) wild-caught fingerlings that are grown to 50–100 g before being sold for on-growing to reach 3 kg after 12 months (Masumoto 2002). Recently, the lifecycle of a bluefin tuna (*Thunnus* sp.) was closed, successful larval production from Pacific bluefin tuna (*T. orientalis*) that

had been grown in culture from larvae was achieved (Sawada and others 2005). Research started with the capture of juvenile tuna 8 years prior to their successful spawning in 1995 and 1996, the research program started many years before and demonstrates the complexity of closing the lifecycle of marine fish and the need for considerable economic and time investment to achieve success. Further development will be required because there may be key differences between wild-caught and domestic broodstock that could result in poor larval quality and a low success rate in the production of viable juveniles from this second generation of larvae (Sawada and others 2005). Bluefin tuna are very valuable fish and attempts at forms of aquaculture have been underway for many years in Japan, Europe, Australia, and across the continent of America (Carey and others 1984; Kaji and others 1996; Carter and others 1998; Sawada and others 2005). The few commercial tuna farms, located mainly in Australia and the Mediterranean, on-grow and recondition large wild-caught juvenile tuna to market size. In Australia, for example, juvenile southern bluefin tuna (*T. maccoyii*) shoals are caught using a purse-seine, towed back in specially designed ring-cages and transferred to moored cages for 4–8 months on-growing (Carter and others 1998). Tuna are usually 10–20 kg at catch and can treble their weight, farming increases the value of a fishery catch due to increased weight and because larger tuna are more valuable on a per kilogram basis. Tuna are largely sold into Japan where grading determines their price, grading for an individual fish relates to its external characteristics, flesh quality judged by a "tail-cut" sample of muscle, and it is also relative to the season and market conditions: the grade is notoriously difficult to quantify.

The aquaculture of Asian sea bass provides an interesting view of how one species has been highly adaptable and successful under many systems (Tucker and others 2002). Its natural range encompasses the northern Indian and tropical western Pacific Oceans and it is found from Iran to Australia (Tucker and others 2002). Although aquaculture production is relatively small (20,000 tonnes in 1999) there is great potential for a species that can be cultured using intensive and extensive methods, indoors or outdoors, and that can be grown over the full range of salinity (from fresh to sea-water) and even in brackish bore waters far from the sea and that have a wide temperature range (Katersky and Carter 2005). Barramundi are catadromous (opposite to salmon) and sea water is needed for the broodstock, eggs and the first half of the larval rearing cycle and the species is also a protandrous hermaphrodite so that individuals first mature into males (after 2 years) and then into females (after 3–5 years) (Tucker and others 2002). Barramundi are very fecund and females produce hundreds of thousands of eggs per kilogram on each spawning, males are stocked with females and the floating fertilized eggs are collected by nets or from the outflow water. There are many approaches to larval rearing that range from intensive to extensive. Intensive procedures can be carried out in small tanks using a rotifer and brine shrimp sequence, rotifers from day 2 to day 15 and brine shrimp from day 10. Production methods may also incorporate greenwater and the use of microalgae over the first part of larval rearing. Extensive procedures are carried out in large earthen ponds relying on natural plankton blooms initiated by fertilizing the pond. Juveniles are easily weaned onto compound feeds and transferred from the nursery to on-growing. In Southeast Asia this uses small ponds (0.08–2 hectares), coastal impoundments or smaller cages (1–300 m^3). In Australia on-growing may be in open freshwater ponds, small cages held in freshwater ponds, large sea-cages and, because barramundi command a high market price, indoor tanks. Production is based on plate-size fish although larger fish of around 2–3 kg for fillets or as "banquet" fish are becoming more popular.

89.3 SUMMARY

Over 200 aquatic species are cultured throughout the world and many species that are new to aquaculture will be under investigation at any one time (and often rejected after some period of research and development). In this overview I have concentrated on major finfish groups that are grown using intensive techniques. As noted in the introduction the majority of finfish are farmed using semi-intensive systems, in addition there is sizable aquaculture of other vertebrates (e.g., frogs, soft-shelled turtles), invertebrate (e.g., echinoderms, sea cucumbers), and seaweeds. Important challenges face aquaculture and ensuring it is sustainable and best practice clearly does not imply only the use of intensive aquaculture since considerable improvements can be made to all systems. Which ever species or system is appropriate more emphasis will be placed on increasing efficiency and maximizing the use of valuable resources. A broader view of resource use might encompass multiple users of a location and the environmental impact of aquaculture; disease prevention rather than control and limiting the use of chemical or antibiotic solutions, sustainable use of feed ingredients, and decreasing reliance on marine products. Global forces such as climate change will have important consequences in relation to which and where species are farmed, increased water temperatures may allow species to be grown in new regions but also end the culture of other species. Aquaculture has the capacity to make an invaluable contribution to human nutrition and it therefore vital that sustainable approaches are developed.

90.18.2 Recommended Proportions of Ingredients 995

90.1 INTRODUCTION

This book is not the proper forum to discuss the manufacture of every processed vegetable available in the market. However, regulatory agencies such the Department of Agriculture (USDA) and the Food and Drug Administration (FDA) have issued some minimal criteria for each processed vegetable such as: what they are, what types and styles are available, and so on. The information in this chapter describes each available frozen vegetable product and has been modified from the product grades (USDA) and product standards (FDA). Product standards and product grades are established to achieve two objectives: assure product safety and minimize economic fraud.

The information provided here has one major objective: to remind a commercial processor what each frozen vegetable is and other applicable criteria for this particular product.

90.2 FROZEN ASPARAGUS

Frozen asparagus consists of sound and succulent fresh shoots of the asparagus plant (*Asparagus officianalis*). The product is prepared by sorting, trimming, washing, and blanching as necessary to assure a clean and wholesome product. It is then frozen and stored at temperatures necessary for preservation.

90.2.1 Types

1. Green or all-green consists of units of frozen asparagus which are typical green, light-green, or purplish-green in color.
2. Green-white consists of frozen asparagus spears and tips which have typical green, light-green, or purplish-green color to some extent but which are white in the lower portions of stalk.

90.2.2 Styles

Spears or stalks style consists of units composed of the head and adjoining portion of the shoot that are 3 inches or more in length. Tips style consists of units composed of the head and adjoining portion of the shoot that are less than 3 inches in length. Center cuts or cuts style consists of portions of shoots (with or without head material) that are cut transversely into units not less than one-half inch in length and that fail to meet the definition for cut spears or cuts and tips style.

Cut spears or cuts and tips style consists of the head and portions of the shoot cut transversely into units 2 inches or less but not less than one-half inch in length. To be considered this style head material should be present in these amounts for the respective lengths of cuts:

1. $1\frac{1}{4}$ inches or less. Not less than 18% (average), by count, of all cuts are head material.
2. Longer than $1\frac{1}{4}$ inches. Not less than 25% (average), by count, of all cuts are head material.

90.3 FROZEN LIMA BEANS

Frozen lima beans are the frozen product prepared from the clean, sound, succulent seed of the lima bean plant without soaking, by shelling, washing, blanching, and properly draining. They are then frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

90.3.1 Types

1. Thin-seeded such as Henderson, Bush, and Thorogreen varieties.
2. Thick-seeded Baby Potato such as Baby Potato, Baby Fordhook, and Evergreen. Thick-seeded, such as Fordhook variety.

90.4 FROZEN BEANS, SPECKLED BUTTER (LIMA)

Frozen speckled butter (lima) beans are the frozen product prepared from the clean, sound, freshly-vined (but not seed-dry) seed of the speckled butter (lima) bean plant (*Phaseolus limensis*). The skins of the seed are pigmented and the external colors range from variegated speckling of green, pink, red, and/or lavender to purple. The product is prepared by shelling the pods; by washing, blanching, and properly draining the seeds that have

been sorted and blended or otherwise prepared in accordance with good commercial practice. They are frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

90.5 FROZEN BROCCOLI

Frozen broccoli is the product prepared from the fresh, clean, sound stalks or shoots of the broccoli plant [*Brassica oleracea* (Italica group)] by trimming, washing, blanching, sorting, and properly draining. The product is frozen in accordance with good commercial practice and maintained at temperatures necessary for its preservation.

90.5.1 Styles

1. Spears or stalks are the head and adjoining portions of the stem, with or without attached leaves, which may range in length from 9 cm (3.5 in) to 15 cm (5.9 in). The spears or stalks may be cut longitudinally.
2. Short spears or florets are the head and adjoining portions of the stem, with or without attached leaves, which may range in length from 2.5 cm. (1 in) to 9 cm (3.5 in). Each short spear or floret must weigh more than 6 g (0.2 oz). The short spears or florets may be cut longitudinally.
3. Cut spears or short spears are cut into portions which may range in length from 2 cm (0.8 in) to 5 cm (2 in). Head material should be at least 62.5 g (2.2 oz) per 250 g (8.8 oz) and leaf material should not be more than 62.5 g (2.2 oz) per 250 g (8.8 oz).
4. Chopped spears or short spears are cut into portions which are less than 2 cm (0.8 in) in length. Head material should be at least 12.5 g (0.4 oz) per 50 g (1.8 oz) and leaf material should not be more than 12.5 g (0.4 oz) per 50 g (1.8 oz).
5. Pieces or random cut pieces are cut or chopped portions of spears or short spears or other units which do not meet the requirements for cut or chopped styles.

90.6 FROZEN BRUSSEL SPROUTS

Frozen brussel sprouts are the frozen product prepared from the clean, sound succulent heads of the Brussel sprouts plant (*Brassica oleracea* L. var. gemmifera) by trimming, washing, blanching, and properly draining. The product is frozen in accordance with good commercial practice and maintained at temperatures necessary for its preservation.

90.7 FROZEN CARROTS

Frozen carrots are the clean and sound product prepared from the fresh root of the carrot plant (*Daucus carota*) by washing, sorting, peeling, trimming, and blanching, and are frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

90.7.1 Styles

Wholes (or whole carrots) retain the approximate confirmation of a whole carrot.

Halves or halved carrots are cut longitudinally into two units.

Quarters or quartered carrots are cut longitudinally into four approximately equal units. Carrots cut longitudinally or cut longitudinally and crosswise into six or eight units approximating the size and appearance of quartered carrots are also permitted in this style.

Slices or sliced carrots are sliced transversely to the longitudinal axis.

Diced carrots consist of approximate cube-shaped units.

Double-diced carrots consist of approximate rectangular shapes that resemble the equivalent of two cube-shaped units.

Strips are carrots that consists of approximate French-cut shapes, with flat-parallel or corrugated-parallel surfaces, one-half inch or more in length.

Chips are carrots that consist of predominately small-sized units (such as less than one-half cube) and variously shaped pieces or slivers in which the longest-edge dimension approximates not more than one-half inch.

Cut carrots consist of cut units that do not conform to any of the forgoing styles.

90.8 FROZEN CAULIFLOWER

Frozen cauliflower is prepared from fresh flower heads of the cauliflower plant (*Brassica oleracea botrytis*) by trimming, washing, and blanching and is frozen and maintained at temperatures necessary for preservation of the product.

90.8.1 Styles and Requirements

1. Clusters are individual segments of trimmed and cored cauliflower heads, which measure not less than 20 mm (0.75 in) in the greatest dimension across the top of the unit. A maximum of 10%, by weight, of clusters less than 20 mm (0.75 in) in the greatest dimension across the top of the unit are allowed.
2. Nuggets or small clusters are individual segments of trimmed and cored cauliflower heads, which measure from 6 mm (0.25 in) to less than 20 mm (0.75 in) in the greatest dimension across the top of the unit. A maximum of 20%, by weight, of clusters, 20 mm (0.75 in) or greater, and a maximum of 10%, by weight, of clusters less than 6 mm in the greatest dimension across the top of the unit are allowed.

90.9 FROZEN CORN ON THE COB

Frozen corn-on-the-cob is the product prepared from sound, properly matured, fresh, sweet corn ears by removing husk and silk; by sorting, trimming, and washing to assure a clean and wholesome product. The ears are blanched, then frozen and stored at temperatures necessary for the preservation of the product.

90.9.1 Styles

1. Trimmed. Ears trimmed at both ends to remove tip and stalk ends and or/cut to specific lengths.
2. Natural. Ears trimmed at the stalk end only to remove all or most of the stalk.

90.9.2 Lengths

1. Regular. Ears which are predominantly over $3\frac{1}{2}$ inches in length.
2. Ears which are predominantly $3\frac{1}{2}$ inches or less in length.

90.9.3 Colors of Frozen Corn-on-the-Cob

Golden (or yellow); white.

90.10 FROZEN LEAFY GREENS

Frozen leafy greens are the frozen product prepared from the clean, sound, succulent leaves and stems of any one of the plants listed below by sorting, trimming, washing, blanching, and properly draining. The product is processed by freezing and maintained at temperatures necessary for its preservation. Any functional, optional ingredient(s) permissible under the law may be used to acidify and/or season the product.

90.10.1 Types

- Beet greens
- Collards
- Dandelion greens
- Endive
- Kale
- Mustard greens
- Spinach
- Swiss chard
- Turnip greens
- Any other "market accepted" leafy green

90.10.2 Styles

1. Leaf consists substantially of the leaf, cut or uncut, with or without adjoining portion of the stem.
2. Chopped consists of the leaf with or without adjoining portion of the stem that has been cut into small pieces less than approximately 20 mm (0.78 in) in the longest dimension but not comminuted to a pulp or a puree.
3. Pureed consists of the leaf with or without adjoining portion of the stem that has been comminuted to a pulp or a puree.

90.11 FROZEN OKRA

Frozen okra is the product prepared from the clean, sound, succulent, and edible fresh pods of the okra plant (*Hibiscus esculentus*) of the green variety. The product may or may not be

trimmed, is properly prepared and properly processed, and is then frozen and stored at temperatures necessary for preservation.

90.11.1 Styles

1. Whole okra consists of trimmed or untrimmed whole pods of any length that may possess an edible portion of the cap. The length of a whole pod is determined by measuring from the outermost point of the tip end of the pod to the outermost point of the stem end of the pod, exclusive of any inedible stem portion that may be present.
2. Cut okra is trimmed or untrimmed whole pods, which may possess an edible portion of cap, and which have been cut transversely into pieces of approximate uniform length. The length of a unit of cut okra is determined by measuring the longitudinal axis of the unit.

90.12 FROZEN ONION RINGS, BREADED, RAW, OR COOKED

Frozen breaded onion rings, hereinafter referred to as frozen onion rings, is the product prepared from clean and sound, fresh onion bulbs (*Allium cepa*) from which the root bases, tops, and outer skin have been removed. The onion bulbs are sliced and separated into rings, coated with batter (or breaded), and may or may not be, deep fried in a suitable fat or oil bath. The product is prepared and frozen in accordance with good commercial practice and maintained at temperatures necessary for the proper preservation of the product.

90.12.1 Types

The type of frozen onion rings applies to the method of preparation of the product, and includes:

1. French fried onion rings that have been deep fried in a suitable fat or oil bath prior to freezing.
2. Raw breaded onion rings that have not been oil blanched or cooked prior to freezing.

90.13 FROZEN PEAS

Frozen peas is the food in "package" form, prepared from the succulent seed of the pea plant of the species *Pisum sativum* L. Any suitable variety of pea may be used. It is blanched, drained, and preserved by freezing in such a way that the range of temperature of maximum crystallization is passed quickly. The freezing process should not be regarded as complete until the product temperature has reached $-18^{\circ}C$ ($0^{\circ}F$) or lower at the thermal center, after thermal stabilization. Such food may contain one, or any combination of two or more, of the following safe and suitable optional ingredients:

For more details see:

1. Chapter on Frozen peas: standard and grade.
2. Appendix B.

90.14 PEAS, FIELD, AND BLACK-EYE

Frozen field peas and frozen black-eye peas, hereafter referred to as frozen peas, are the frozen product prepared from clean, sound, fresh, seed of proper maturity of the field pea plant (*Vigna sinensis*), by shelling, sorting, washing, blanching, and properly draining. The product is frozen and maintained at temperatures necessary for preservation. Frozen peas may contain succulent, unshelled pods (snaps) of the field pea plant or small sieve round type succulent pods of the green bean plant as an optional ingredient used as a garnish.

For more details see:

1. Chapter on Frozen peas: standard and grade.
2. Appendix B.

90.15 FROZEN PEPPERS, SWEET

Frozen sweet peppers are the frozen product prepared from fresh, clean, sound, firm pods of the common commercial varieties of sweet peppers, which have been properly prepared, may or may not be blanched, and are then frozen in accordance with good commercial practice and maintained at temperatures necessary for the preservation of the product.

90.15.1 Types

Type I, green; Type II, red; Type III, mixed (green and red).

90.15.2 Styles

1. Whole stemmed: whole unpeeled pepper pods with stem and core removed.
2. Whole unstemmed: whole unpeeled pepper pods with stems trimmed to not more than $\frac{1}{2}$ inch length.
3. Halved: whole stemmed, unpeeled pepper pods which have been cut approximately in half from stem to blossom end.
4. Sliced: whole stemmed, unpeeled pepper pods or pieces of pepper pods which have been cut into strips.
5. Diced: whole stemmed, unpeeled pepper pods or pieces of pepper pods which have been cut into approximate square pieces measuring $\frac{1}{2}$-inch or less.
6. Unit: a whole unpeeled pepper pod or portion of a pepper pod in frozen sweet peppers.

90.16 FROZEN POTATOES, FRENCH FRIED

Frozen French fried potatoes are prepared from mature, sound, white or Irish potatoes (*Solanum tuberosum*). The potatoes are washed, sorted, and trimmed as necessary to assure a clean and wholesome product. The potatoes may or may not be cut into pieces. The potatoes are processed in accordance with good commercial practice which includes deep frying or blanching in a suitable fat or oil and which may include the addition of any

ingredient permissible under the law. The prepared product is frozen and is stored at temperatures necessary for its preservation.

90.16.1 Types

Frozen French fried potatoes are of two types, based principally on intended use, as follows:

1. Retail type. This type is intended for household consumption. It is normally packed in small packages that are labeled or marked for retail sales. It may be otherwise designated for such use.
2. Institutional type. This type is intended for the hotel, restaurant, or other large feeding establishment trade. Primary containers, usually 5 pounds or more, are often not as completely labeled as for retail sales.

90.16.2 Styles

They are grouped under: general, strips, slices, dices, Rissolé.

90.16.2.1 General. The style of frozen French fried potatoes is identified by the general size, shape, or other physical characteristics of the potato units. Styles with cut units may be further identified by substyles as follows:

1. Straight cut refers to smooth cut surfaces.
2. Crinkle cut refers to corrugated cut surfaces.

90.16.2.2 Strips. This style consists of elongated pieces of potato with practically parallel sides and of any cross-sectional shape. This style may be further identified by the approximate dimensions of the cross-section, for example: $\frac{1}{4} \times \frac{1}{4}$ inch, $\frac{3}{8} \times \frac{3}{8}$ inch, $\frac{1}{2} \times \frac{1}{3}$ inch, or $\frac{3}{8} \times \frac{3}{8}$ inch.

Shoestring refers to strip, either straight cut or crinkle cut, with a cross-section predominantly less than that of a square measuring $\frac{3}{8} \times \frac{3}{8}$ inch.

90.16.2.3 Slices. This style consists of pieces of potato with two practically parallel sides, and which otherwise conform generally to the shape of the potato. This style may also contain a normal amount of outside slices.

90.16.2.4 Dices. This style consists of pieces of potato cut into approximate cubes.

90.16.2.5 Rissolé. This style consists of whole or nearly whole potatoes.

Any other individually frozen French fried potato product may be designated as to style by description of the size, shape, or other characteristic that differentiates it from the other styles.

90.16.3 Length Designations

General. The length designations described in this section apply to strip styles only.

Criteria for length designations of a sample unit. Frozen French fried potato strips are designated as to length in accordance with the following criteria. Percent, as used in this section, means the percent, by count, of all strips of potato that are $\frac{1}{2}$-inch in length, or longer.

1. Extra long. Eighty percent or more are 2 inches in length or longer; and 30% or more are 3 inches in length or longer.
2. Long. Seventy percent or more are 2 inches in length, or longer; and 15% or more are 3 inches in length or longer.
3. Medium. Fifty percent or more are 2 inches in length or longer.
4. Short. Less than 50% are 2 inches in length or longer.

90.17 FROZEN POTATO, HASH BROWN

Frozen hash brown potatoes are prepared from mature, sound, white, or Irish potatoes (*Solanum tuberosum*) that are washed, peeled, sorted, and trimmed to assure a clean and wholesome product. The potatoes so prepared are blanched, may or may not be fried and are shredded or diced or chopped and frozen and stored at temperatures necessary for their preservation.

90.17.1 Styles

1. Shredded. Shredded potatoes are cut into thin strips with cross-sectional dimensions from 1 mm × 2 mm to 4 mm × 6 mm and formed into a solid mass before freezing.
2. Diced. Diced potatoes are cut into approximate cube shape units from 6 mm to 15 mm on an edge and loose frozen. They contain not more than 90 g, per sample unit, of units smaller than one-half the volume of the predominant size unit.
3. Chopped. Chopped potatoes are random cut pieces predominantly less than 32 mm in their greatest dimension and loose frozen.

90.18 FROZEN VEGETABLES, MIXED

Frozen mixed vegetables consist of three or more succulent vegetables, properly prepared and properly blanched; may contain vegetables (such as, small pieces of sweet red peppers or sweet green peppers) added as garnish; and are frozen and maintained at temperatures necessary for the preservation of the product.

90.18.1 Kinds and Styles of Basic Vegetables

It is recommended that frozen mixed vegetables, other than small pieces of vegetables added as garnish, consist of the following kinds and styles of vegetables as basic vegetables:

1. Beans, green or wax: cut styles, predominantly of $\frac{1}{2}$ inch to $1\frac{1}{2}$ inch cuts;
2. Beans, lima: any single varietal type;

3. Carrots: diced style, predominantly of $\frac{3}{8}$ inch to $\frac{1}{2}$ inch cubes;
4. Corn sweet: golden (or yellow) in whole kernel style;
5. Peas: early type or sweet type.

90.18.2 Recommended Proportions of Ingredients

It is recommended that frozen mixed vegetables consist of three, four, or five basic vegetables in the following proportions:

1. Three vegetables. A mixture of three basic vegetables in which any one vegetable is not more than 40% by weight of all the frozen mixed vegetables.
2. Four vegetables. A mixture of four basic vegetables in which none of the vegetables is less than 8% by weight nor more than 35% by weight of all the frozen mixed vegetables.
3. Five vegetables. A mixture of five basic vegetables in which none of the vegetables is less than 8% by weight nor more than 30% by weight of all the frozen mixed vegetables.

91.1 INTRODUCTION

In Mexico, as in other producing countries, avocados are eaten fresh in salads made up of different greens and vegetables, or in a typical Mexican sauce called "guacamole." Mexico is the principal producer and exporter of Hass avocados. However, processed avocado (avocado paste, guacamole and halved), is not exported to the same degree. Another avocado byproduct is oil extract that is becoming more popular in some markets and must therefore be taken into consideration for future export.

91.1.1 History

The avocado originated in the mountainous regions of Mexico and Central America and has been consumed for around 10,000 years. This has been confirmed through carbon testing. The West Indian species did not originate in the Caribbean Islands as the name implies, but rather in the lowlands of Central America. The avocado expanded from there to other areas of Central and South Americas and eventually to Spain in 1601, to Jamaica around 1650, to Mauricio in 1780, and to Asia in approximately 1850. Avocados were first noted in Florida in 1833 and in California in 1856 (Samson 1991).

The word avocado (fruit of the *Persea americana* tree) comes from the Nahuatl word ahuacacuáhuitl which means testicle tree. Archeological evidence, fossil remains and signs of human consumption dating back 7000 to 8000 years ago, and found in Tehuacan, Puebla, indicate that this fruit has been present since 10,000 years ago (León 1987). It was probably a very popular item in the diet of pre-Columbian cultures due to its nutritional and medicinal values (ASERCA 2002). The most ancient examples were found in Peru dated 3500 to 4000 years ago (León 1987).

Commercial exploitation of avocados in California and Florida began in 1932 and later expanded to Chile, Brazil, South Africa, and most recently, to Israel. That is to say, avocados are now grown in tropical and subtropical areas where ecological conditions suitable for the optimal development of this fruit exist.

Smith and others (1992) reported that the original "Fuerte" variety avocado tree first gave fruit in Atlixco, Puebla, Mexico in 1908 and died at the end of the 1940s. These same authors indicated that in 1920 Rudolph Hass discovered the Hass variety in La Habra Heights, California. He patented it in 1935. This variety still yields excellent quality fruit to this day. The Hass variety is grown and commercialized with great success in Mexico.

91.1.2 Biology

The botanical name of the avocado is *Persea americana* and belongs to the *Lauraceae* family. Other known members of this family are the laurel and cinnamon trees. The English name avocado is derived from the Spanish word abogado, an adaptation of the Aztec word ahuacatl. This word in Nahuatl became avocat in French and advokaat in Dutch. The name palta is still used in Peru, Ecuador and Chile (Samson 1991).

Three ecological races are recognized (subspecies or botanical varieties): the Mexican, the Guatemalan, and the West Indian which are considered to be subtropical, semitropical, and tropical, respectively. The physiological differences among the three races are commercially important and related to the time to maturity, fruit size, peel texture, flavor, oil content, disease tolerance, storage characteristics, climate, and cold tolerance of the tree. Mexican cultivars are well adapted to the cool climates of the tropics and subtropics and are the most cold tolerant of the three types. The Mexican cultivars produce fruit with thick peel or rind which is usually smooth and glossy and that mature earlier than, or simultaneously with, the West Indian cultivars (Salunkhe and Desai 1986; Samson 1991).

The absence of a sterility barrier between population types and the mechanism of floral biology favor the formation of hybrid populations. Many of the commercial crops that are vegetatively propagated come from interracial crosses.

The avocado tree has a very shallow root system, leaves that are alternately arranged, and bunches of buds. The inflorescences are found in the thousands, each with hundreds of flowers: these are green and are 1 cm wide and deep, have verticils with three stamens, and an ovary. It is therefore a complete flower and opens twice, closing in the interim: the first time it acts as a female; the second, as a male (Samson 1991). *Persea americana* produce thousand of flowers per plant: the panicles open for long periods, from weeks to months. Nevertheless, the number of flowers which are fertilized and produce fruit is low (León 1987).

The characteristics of the fruit vary considerably, depending on the type and race and cultivar. Pear shaped fruit is the most dominant, although there are also spherical and elongated oval shaped fruit. They are generally asymmetrical, with a thicker side which is more fibrous or has vascular bundles. The external color varies from yellowish green to purple or almost black. The surface can be smooth and shiny, or rugged pebbly brown-black. Hass avocados have a thick, rough, bright green peel, varying from dark green to almost black, depending on its degree of ripeness (Fig. 91.1). Its pulp is pale green and creamy textured and has a characteristically delicious taste.

The external tissue, epidermis and hypodermis of the fruit, separates easily from the meaty mesocarp which is rich in oils and makes up the edible part. The epidermis, consisting of strong walled isodiametric cells, has numerous stomas and is covered by a waxy layer. There are also lenticels, small lighter colored protuberances that frequently open, forming breaks on the peel of the fruit that are later covered with a corklike substance. The hypodermis is composed of parenchyma cells, full of chloroplasts and resins (Biale and Young 1971). There is a discontinuous layer of esclerenchyma underneath composed of groups of very thick walled cells which give the rind its characteristic grainy texture that in certain types is very easily pierced. This is the reason why the peel is separated from the rest of the fruit and what determines the thickness of the former. The mesocarp is rich in oil that can constitute up to 30% of the total weight. This oil is very nutritious, easy to digest, and increases as the fruit matures, completely filling many of the cells in the mesocarp while also appearing in other spherical

Figure 91.1 *Hass avocado* (*Persea americana*).

bodies (Fig. 91.2). The endocarp consists of several layers of thinned walled cells called parenchyma which often adhere to the seed testa (Biale and Young 1971; León 1987).

The ovoid shaped seed takes up a great part of the fruit: it is made up of two meaty cotyledons and a small embryo; it does not contain endosperm. The testa is made up of five external layers of sclerenchyma and various layers of parenchyma; the layer closest to the sclerenchyma layer is filled with tannin which gives it its characteristic dark color. The cotyledons are mainly made up of parenchyma which contain starch and tannins (León 1987).

91.1.3 Growth, Harvesting, and Cultivars

The fruit of the avocado tends to grow continually on the tree and matures after it is harvested. This characteristic has been used to store the fruit on the tree for a few months.

It is climacteric: its pattern of respiration is characterized by the so-called "climacteric increase." Ripening is triggered by endogenous ethylene and it has been established that a

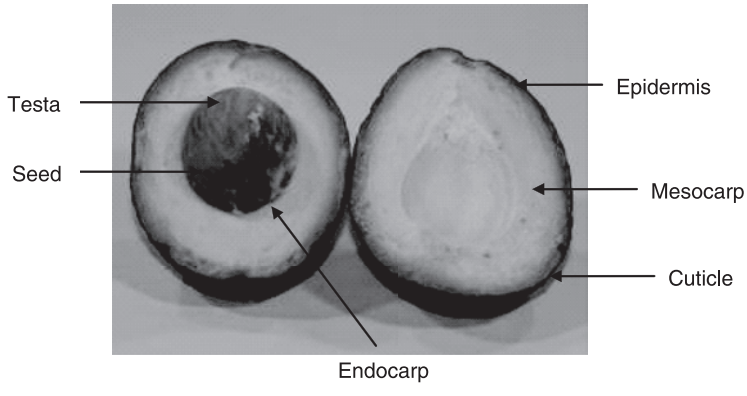

Figure 91.2 *Cross-section of an avocado.*

concentration of 10 ppm of ethylene at 15–17°C is enough to begin ripening in "Fuerte" avocados (Yahia and Báez 1992).

There are physiological differences in the three types (Mexican, Guatemalan, and West Indian) which include size and shape of the fruit, taste, oil content, disease tolerance, climate adaptations, and storage requirements. Mexican cultivars are adapted to cool climates and have the largest highest oil content of the three. The Mexican cultivars are "Gottifried" and "Pernod"; the "Fuerte" avocado is a hybrid of the Mexican and Guatemalan. The most important variety cultivated in Mexico is "Hass," and of lesser importance are the "Fuerte," "Booth 7," "Booth 8," "Azteca," "Zutano," "Bacon," "Atlixco," "Duke," "Perfecto," "Sinaloa," "San Sebastián," and "Colin V33" varieties (Yahia and Báez 1992; ASERCA 1999).

The "Fuerte," which originated in Atlixco, Puebla, is grown in other producing states. Its main characteristic is its resistance to cold, but sensitivity to heat. In Coatepec de Harinas, Mexico, the new V33 selection of the Fundación Salvador Sánchez Colín CICTAMEX is a variety of low stature which permits the efficient control of diseases and production through a greater ease in pruning and similar labor on each tree (ASERCA 1999).

The state of Michoacan produces 87% of the avocado production in Mexico and is the principal exporter to the United States (SIAP 2006). Creole avocados were grown in Michoacan until 1941 when the Fuerte variety was successfully introduced, triggering it to become the most productive avocado region in the world. Nevertheless, years later, the Fuerte variety was displaced by the Hass cultivar, originating in California and Florida. This variety had higher competitive advantages. The Hass avocado was preferred by producers because of its:

- Sustained productivity;
- Low, crop alternation;
- Compact growth pattern;
- Tolerance to handling and transport;
- The excellent quality of its pulp.

Once its quality was proven, the orchards were quickly grafted again with the Hass variety and new plantations are now established with this variety (ASERCA 1999).

Avocados are found all year round because there are different varieties, predominantly of the Hass cultivar. The harvest seasons are in two stages: the high season occurring from October to January, and the low season from February to September. There are four flowerings so it is recommended that the harvest be done in the following manner: (1) the fruit of the crazy flowers in August and September, (2) the fruit of the advantaged which has a head start, is harvested from October to December, (3) with the normal flowers, the fruit is harvested from January to February, (4) with the "march flower," the fruit is harvested beginning in March (ASERCA 1999).

With regards to avocado exports, the Unites States Department of Agriculture (USDA) has established a strict and costly import program which began on February 5 1997; on this date the Federal Register published the authorization for Mexican avocados to be exported to 19 east coast states in the United States.

The packinghouses are supervised during the entire export season to the United States, under the verification stage of the import program established by the USDA. The avocado

is transported from plantation to the packinghouse with shipment being covered with mesh and lots are not mixed. Once a lot has been packed, all the equipment used for processing in the packinghouse is cleaned before beginning with another lot.

The Michoacan Association of Producers, Packers and Exporters, A.C. in charge of the export program to the United States, is organized and has strict rules which has successfully permitted it to place excellent quality avocados in the North American market with confidence.

The harvest is done through a planned program to order the fruit picking for export. This is a complex process where various factors such as the economic needs, the climate (the orchards are located in hot areas, as well as where frost is a risk), the ripeness of the fruit and quality specifications, among others are considered (ASERCA 2002).

91.1.4 Production Statistics

Avocados are harvested all year round and grown in 28 states of Mexico. Nevertheless, in 2003, 95.5% of the national production was concentrated in five states in decreasing order, Michoacan, 88.44%; Morelos, 2.65%; Nayarit, 1.71%; Puebla, 1.40%; and the state of Mexico, 1.30% (Table 91.1, INEGI 2005). Michoacan has advanced technology for the growth and postharvest handling of Hass avocado and is therefore the state that exports this fruit to the United States of America, Japan, and Europe.

At the world level, Mexico is the principal avocado producer, after the United States, Indonesia, Brazil, Colombia, and Chile. These six countries produced 61.74% of the world production in 2004 (Table 91.2; FAOSTAT 2005).

The first export season of Mexican avocado to the United States was 1997/1998 comprised by November 5 1997 to February 22 1998 when 348 shipments for a total of 6031.7 tons. Avocado exports to this country have increased from this date. France was previously the main market for fresh and processed Mexican avocado (ASERCA 2002). The principal exporting countries in 2004 were Mexico, Chile, Israel, Spain, and South Africa. The main importers during the same year were the United States, France, the Netherlands, the United Kingdom, and Japan (FAOSTAT 2005).

Avocado consumption is concentrated in the major producing areas; for example, Mexico, the United States of America, Brazil, and so on. Mexican per capita consumption is about 7–8 kg per person, compared with U.S. consumption of less than 1 kg. Mexico is the main consumer at the world level (USDA 1997).

TABLE 91.1 Principal Avocado Producing States in México, 2003.

State	Area Harvested (1000 Ha)	Production (1000 Metric ton)	Participation (%)
National	103.3	905	100
Michoacan	80.9	800. 4	88.44
Morelos	2.5	24.0	2.65
Nayarit	2.2	15.5	1.71
Puebla	2.3	12.6	1.40
Mexico State	1.6	11.7	1.30
The others	13.8	40.8	4.50

91.1.5 Nutritional Value

The composition of an avocado is affected by the variety, ripeness, climatic growing conditions, light, temperature, soil, fertilization, and irrigation. Its pulp is 73.2% water, has a high oil content (14.7%), is rich in proteins and contains vitamin A and C, has a relatively low sugar content, and contains minerals such as calcium, magnesium, potassium, and phosphorus (Table 91.3; Cano and others 2005).

91.2 FROZEN AVOCADO PASTE AND GUACAMOLE: PROCESSING OPERATIONS

In Mexico avocados are mainly eaten fresh in salads and in a sauce called guacamole. The term *guacamole* comes from the Nauatl *ahuaca-mulli* which means avocado paste. In Mexico, the oldest and most basic form of guacamole is avocado flesh, some coriander leaves, onion, garlic and chopped jalapeño peppers ground together in a "molcajete" (stone mortar and pestle). It was always served as a sauce for meat or simply rolled inside a "tortilla." Guacamole, the paste, and frozen avocado halves are exported to the United States and Europe. The main industrial avocado processing plants are located in Michoacan. In 2001, Mexico exported 42,980 tons of guacamole (ASERCA 2002). Other producing countries besides Mexico such as the United States and Spain make the guacamole salsa taking into consideration the Mexican style of the sauce.

91.2.1 Harvesting

Avocados are manually harvested; the fruit in the lowest parts of the tree are cut with scissors and placed in harvesting bags. Hooks with knives are also used to separate the fruit from the higher tree branches. The harvesting bags are emptied into boxes in the field where the fruit is selected for fresh export and for processing.

91.2.2 Sorting and Grading

Sorting is the separation of fruit into categories on the basis of measurable physical properties. Like washing, sorting should be done as early as possible to ensure a uniform product for subsequent processing. The four main physical properties used to sort avocados are size, shape, weight, and color. Grading means the assessment of a number of attributes to obtain an indication of overall quality of a fruit or vegetable. Sorting (that is, the separation on the basis of one characteristic) may therefore be used as part of a grading operation (Fellows 1997). Trained operators grade avocados (Fig. 91.3).

91.2.3 Washing

The avocados are transported on a moving belt to an immersion tank where they are washed and subsequently brushed. Thorough washing removes dirt, mold, and other contaminants. In order to improve the washing efficiency, detergent or chlorine is also added to decrease the microbial load.

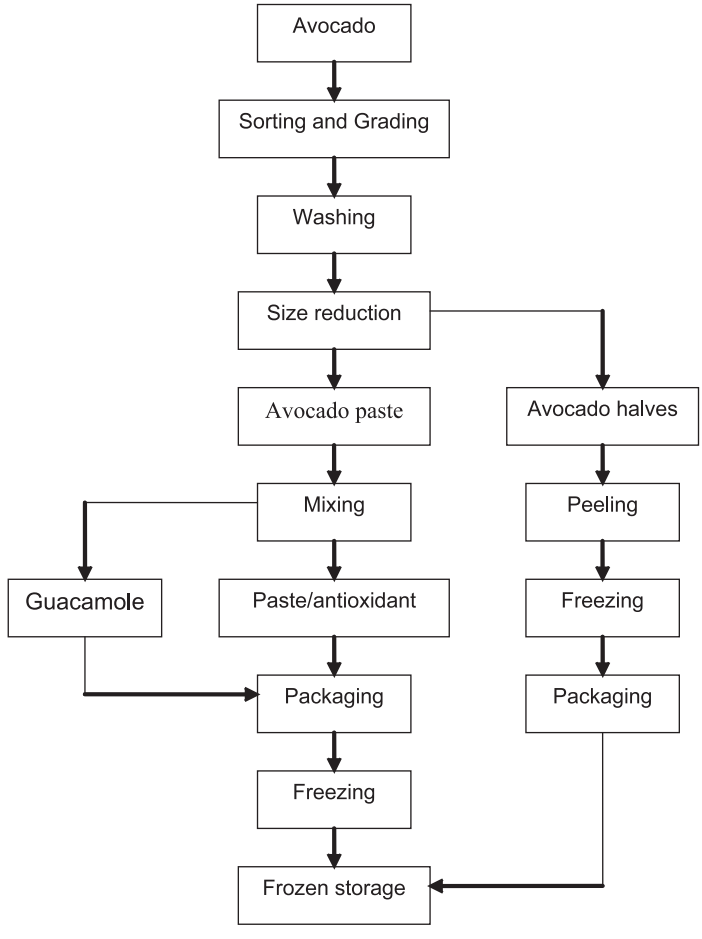

Figure 91.3 *Flow chart for avocado paste and halves, and guacamole.*

91.2.4 Size Reduction

Size reduction is the unit operation in which the average size of solid pieces of food is reduced through grinding, compression or impact forces. This operation has benefits in food processing such as: (1) there is an increase in the surface-area-to-volume ratio of the food which increases the drying, heating, or cooling rate and improves the efficiency and extraction rate of soluble components (for example juice extraction from cut fruit); (2) a similar range of particle size allows ingredients to be mixed more thoroughly (Fellows 1997). Avocado paste and additives are examples of such mixtures.

Different methods of size reduction are classified according to the particle size range produced:

1. Chopping, cutting, slicing, and dicing;
2. Milling to powders or pastes of increasing fineness;
3. Emulsification and homogenization.

Most fruits and vegetables fall into the general category of fibrous foods, have a firmer texture, and are cut at room or chilled temperatures. Avocados are cut in half with slicing equipment that consists of rotating or reciprocating blades that cut the fruit. The seeds are manually removed from the avocado halves by operators (Fig. 91.4).

91.2.5 Avocado Paste

Avocado halves are sent to a hammer or roller mill where the pulp is separated from the peel and the particle sizes are homogenized to make the paste.

In the roller mill, two rollers revolve towards each other and pull the avocado halves through the “nip” (the space between the rollers). The main force is compression, but if the rollers are rotated at different speeds, or if the rollers are fluted, there is an additional shearing force exerted on the fruit (Brennan and others 1980; Fellows 1997).

In the hammer mill, avocados are disintegrated mainly by impact as the hammers drive the avocado against the breaker plate. A horizontal cylindrical chamber is lined with a

Figure 91.4 *The selection of avocado halves by operators.*

toughened steel breaker plate and a high-speed rotor inside the chamber is fitted with hammers along its length.

91.2.6 Mixing

Mixing or blending is a unit operation in which a uniform mixture is obtained from two or more components by the dispersion of one into the other. This operation has very wide applications in many food industries where it is used to combine ingredients to achieve different functional properties or sensory characteristics. Antioxidants such as ascorbic acid or citric acid are added to the avocado paste that is then conveyed to the packing line. Antioxidants must be added to the avocado paste to inactivate the polyphenoloxidase.

91.2.7 Guacamole

Guacamole is prepared in the mixer with avocado paste, onion, garlic, coriander, jalapeño peppers, and salt. The product is conveyed to packaging line.

91.2.8 Packaging

Guacamole or avocado paste packaging is done in semi-rigid containers. Plastic cans are made from laminated polyvinylidene chloride-coated polypropylene-polyethylene film (Fig. 91.5; Fellows 1997) which is sealed with easy-open aluminum ends. The excess air is mechanically removed from the containers which are sealed under vacuum.

91.2.9 Freezing

Freezing is the unit operation where the temperature of a food is reduced to below its freezing point, and a proportion of the water is transformed into ice crystals. The immobilization of water into ice and the resulting concentration of dissolved solutes in unfrozen water lowers the water activity of the food. Preservation is achieved by a combination of the low temperatures, reduced water activity and in vegetables, pretreatment through blanching (Fellows 1997).

Figure 91.5 *Plastic packages for avocado paste and guacamole.*

Freezing is an effective means of preservation that maintains the quality of fruits or vegetables similar to the fresh product. Though this method is not cheap, the product retains more nutrients. Fruits and vegetables retain their natural color, flavor, and texture better when they are frozen. Although this unit operation delays the enzymatic activity, it does not stop it. In the case of avocado paste, it cannot be blanched due to its oil content. The color and flavor of avocado paste undergo damage when the paste was heated at 73–85°C for 4.6–10 min (Ortiz and others 2003). The addition of antioxidants such as ascorbic acid is an alternative method (Ramírez and others 1992).

The freezing process is dependent on freezing rate, heat transfer coefficient, and amount of heat removed from the food product. The freezing time depends on freezing rate, amount of heat removed, packaging and freezing methods used, initial and final temperature desired, thickness of the product, and food ingredients (Martinez-Romero and other 2004).

91.2.9.1 Blast Freezer. Avocado products are frozen in the food industry using different methods. Avocado paste and guacamole are frozen in a blast freezer. Air is recirculated over the packaged avocado paste at between −30°C and −40°C at a velocity of 1.5–6.0 m/s. In batch equipment, the product is stacked in trays in rooms or cabinets. Continuous equipment consists of a conveyor belt that carries the food through an insulated tunnel.

91.2.9.2 Cryogenic Freezer. A cryogenic freezer is also used to freeze avocado paste and guacamole. Freezers of this type are characterized by a change of state in the refrigerant (or cryogen) as heat is absorbed from the freezing food. The cryogen is in direct contact with the food and rapidly removes energy from the food to provide its latent heat from vaporization or sublimation, to produce high heat transfer coefficients and rapid freezing. The two most common refrigerants are liquid nitrogen and solid or liquid carbon dioxide. In a liquid-nitrogen freezer, packaged avocado paste travels on a perforated belt through a tunnel, where it is cooled by gas nitrogen and is then frozen by liquid-nitrogen sprays. The temperature is allowed to reach the required storage temperature (between −18°C and −20°C) before the product is removed from the freezer (Fellow 1997).

91.2.10 Frozen Storage

Avocado products will maintain high quality for 18–20 months at −18°C to −20°C. However, during frozen storage, the number of ice crystals will be reduced, while their size increases. These changes are affected by fluctuations in storage temperature, which in turn can cause migration of water vapor from product to surface of the container. The increase of ice crystals during prolonged frozen storage induces drip loss. Also, physical and chemical changes can occur. Main physical changes in fruits and vegetables products during frozen storage are due to recrystallization and sublimation phenomena related to the stabilization crystals inside the product and on the outside surface (Reid 1991; Martínez-Romero and other 2004). The recrystallization rate decreases at low temperatures, with no ice crystal growth at temperatures below −20°C (Reid 1991).

91.2.11 Quality Standard

There is only one quality norm for fresh Hass avocado (NMX-FF-016-SCFI-1995). This norm takes into account the minimum quality requirements that the fruit (a minimum of

21.5% dry material) must meet, three grades of quality (supreme, class I and class II), tolerances, testing methods, marking and labeling, packaging, and storage. This Mexican standard is in concordance with the international avocado norm of the Codex Alimentarius Commission (CODEX STAN-197-1995). International specifications such as: pH, oil content, salt content, viscosity, microbiological analysis, and product temperature are taken into account with processed avocado products.

91.3 FROZEN AVOCADO HALVES: PROCESSING OPERATIONS

The sorting, grading, washing, and size reduction operations are the same as used to make avocado paste and guacamole.

91.3.1 Peeling

Operators remove the peel, or rinds, from the avocado halves which then frozen.

91.3.2 Freezing

The avocado halves can be frozen using an IQF belt freezer, blast freezer or cryogenic freezer.

91.3.2.1 IQF Belt Freezer. The avocado halves are inspected, and frozen on an IQF belt freezer: the avocado halves are fluidized and quickly crust frozen in the first zone. Freezing of the product is completed on a second belt at $-18^{\circ}C$. Frozen avocado halves are packed into bags in boxes (polyethylene-in-polypropylene/carton).

91.3.3 Frozen Storage

Frozen avocado halves are stored in a freezer at a range of $-25^{\circ}C$ and $-30^{\circ}C$. The product must have a temperature of $-18^{\circ}C$. Frozen avocado products have a shelf life of 18–20 months and 1–2 days when refrigerated after removal from storage.

91.4 COLD CHAIN

It is important to consider the cold chain in the production-distribution of frozen avocado products to maintain their quality and safety until they reach the consumer.

The cold chain is composed of all the processing phases from rapid freezing until the product reaches its final consumer. This chain is established based on the fact that the frozen product must maintain a temperature equal or lower than $-18^{\circ}C$ throughout its entire commercial distribution process (Rodríguez and others 2002). Each link in the commercial cold chain follows the guides below:

- Freezing installation for freezing the product at $-18^{\circ}C$;
- Freezer storage at a range between $-25^{\circ}C$ and $-30^{\circ}C$, until the frozen product is shipped;

- Freezer vehicles used for transport to the distribution deposits at $-25^{\circ}C$;
- Distribution deposits' temperature of $-20^{\circ}C$;
- Distributor vehicles to the selling center at $-20^{\circ}C$;
- Selling centers' temperatures between $-18^{\circ}C$ and $-20^{\circ}C$.

The transport and household cold must also be considered as links in the cold chain. That is these noncommercial links should keep the temperature of the frozen product below or equal to $-18^{\circ}C$. Otherwise, the texture of product can be damaged by recrystallization.

91.5 RECOMMENDED INTERNATIONAL CODE OF PRACTICE FOR THE PROCESSING AND HANDLING OF QUICK FROZEN FOODS OF THE CODEX ALIMENTARIUS COMMISSION (FAO/WHO)

The countries that are members of the Codex Alimentarius Commission are revising the recommended international code for the processing and handling of quick frozen foods. The United States, as the host country of the Committee on Processed Fruits and Vegetables and the Committee on Food Hygiene (Codex Alimentarius Commission 2005), is coordinating the work.

The code considers the application of a program to control the dangers or defects identified throughout the cold chain. The concept of defect correction points, (DCP), was introduced and makes a clear distinction between the aspects related to quality and those involving safety (critical control points). It also includes temperature control as part of the management of the cold chain (freezing chambers, quick freezer, transport, retail sales) (Codex Alimentarius Commission 2001).

Defect: a defect is defined as the condition of a product that does not meet the essential dispositions of quality, composition and/or labeling which correspond to the Codex standard for products.

Defect correction point (DCP): the defect correction point is the stage where it is possible to apply control and avoid, eliminate or reduce a defect to an acceptable level, that is, eliminates the risk of an incorrect description.

The Practices Code incorporates the focus of Hazard Analysis and Critical Control Point System (HACCP); and establishes the technological directives and essential hygiene requirements for the processing of harmless quick frozen food products for human consumption which satisfy the corresponding norms of the Codex about these products.

91.5.1 Cold Chain Control: Safety and Quality (HACCP and DCP)

In the case of fruits and vegetables, these are some stages that can present defect correction points.

Some varieties of fruits and vegetables are more suitable for freezing than others (since they suffer less loss through exudation, or have a more adequate texture after thawing). To test for the correct varieties being received can constitute a DCP.

Blanching is more frequently used in the production of frozen vegetables, which reduces the microbiological charge, though its main objective is the deactivation of the enzymes that cause quality defects (taste, color) during freezer storage. Blanching constitutes a DCP and is considered to be a critical control point (CCP) in only some cases.

When it is necessary to store fruits or vegetables (fresh or intermediate products) before further processing, the storage condition, particularly temperature, must be appropriate for the given product. This stage could be a CCP or a DCP.

91.5.2 Safety

When large lots of vegetables or fruits are frozen it is necessary to leave space or canals that permit air circulation between the product in bulk or the containers. If such areas are not available, freezing will be slow.

It is important that the heat center of the product be cooled as quickly as possible to avoid the development of pathogenic microorganisms or the production of microbiological toxins. The freezing time can constitute a CCP.

91.5.3 Quality

The temperature must be quickly reduced in order to retard spoilage in quick frozen fruits and vegetables. Generally speaking, the faster the freezing takes place, the smaller the size of the crystals formed and the quality is not affected. The freezing time can constitute a DCP.

91.5.4 Transport and Distribution

Quick frozen fruits and vegetables are transported in vehicles that maintain the product at a temperature of $-18^{\circ}C$ or less. The temperature of the product while being transported and distributed constitutes a DCP.

91.5.5 Retail

Quick frozen fruits and vegetables must be sold in freezer units that maintain the product temperature at $-18^{\circ}C$. The freezer unit temperature constitutes a DCP.

92.1 INTRODUCTION

This chapter describes the general process of manufacturing frozen French fried potatoes and some aspects of quality assurance of the products. The information has been derived from grading and inspection documents issued by the U.S. Department of Agriculture.

92.2 PRODUCTS COVERED

The principal products covered are the traditional “French fries” potatoes cut into strips, partially deep fried, and frozen. The standard also may be applied to any potato product, regardless of shape or composition which is similarly processed and frozen. This includes products fabricated primarily from mashed, crushed, cut, or shredded potatoes and which are preformed into units prior to frying and freezing. Because of the difficulty of keeping oils in suitable condition, deep frying has not been popular with home cooks. With the discovery and development of frozen French fries, home consumption has increased rapidly. Institutional use also is increasing yearly. Some believe that yearly production now far exceeds any other frozen vegetable.

92.3 PRODUCTION

92.3.1 Areas of Production

The white potato is the world's most important vegetable crop. It is grown to some extent in all agricultural areas in the United States. Certain types of potatoes particularly those of low solids content are not always suitable for manufacturing. Therefore, extensive production of frozen french fried potatoes is limited principally to those areas where the raw product is most suitable. They are in general the Idaho, Eastern Oregon, and Washington areas, the San Joaquin Valley of California, the state of Maine, with some sizeable production in New Jersey, Eastern Pennsylvania, Michigan, and the Red River Valley of Minnesota.

Because of varietal differences and growing conditions potatoes from these widely separate areas have their own characteristics particularly with respect to flavor and mealiness. Very mealy French fries are produced principally from the Russett varieties in the Pacific Northwest. In other sections of the country the solids of the raw product are generally lower and the finished French fries have a slightly different flavor and are less mealy than those from the Northwest region. These regional differences have given rise to claims of superiority of the product based principally on the degree of mealiness. This is partially a matter of personal preference. Good quality French fries are produced in all the leading producing areas.

92.3.2 Varieties

There are several dozen recognized market varieties of potatoes grown in the United States and more are being developed each year. The Irish Cobbler is probably the most widely grown and the Katahdin is grown in the greatest volume. Among the more popular varieties are the Russet Burbank (Idaho), Cobbler, Katahdin, White Rose, Green Mountain, Bliss, Triumph (red), Russett Rural, Kennebec, Norgold, and Pontiac. Various varieties of potatoes have their own cooking qualities. Some are more popular for one quality than for another, that is, bakers, boilers, and fryers. The characteristics of the various varieties are not distinct and they are not always the same in all growing areas and all seasonal conditions. Therefore, no one variety or varieties is used entirely for the production of frozen French fried potatoes.

92.3.3 Receiving

Frozen French fries are usually produced fairly close to the source of supply but occasionally the raw product may be drawn from any of the principal potato producing areas of the country. At time of harvest most late varieties of potatoes have a total sugar content of less than 1% of total solids. Such potatoes are usually suitable for manufacturing into frozen French fries. After the potatoes are stored for a period of time at 40° or less the starch content partially changes to sugar and the potatoes if used immediately out of storage maybe unsatisfactory because of the high sugar content. Sugar in excess of 2–3% (based on dry potato weight) may render the potato practically worthless for deep frying. Such potatoes subjected to high temperatures develop black or brown areas, spots, or streaks, due to carmalizing and burning of the sugar.

They also may have a burnt or sweet taste. Most potatoes can be "conditioned" by storing for a period of time, at least 2 weeks, at near 60 or 70° temperature. In "conditioning" the potato starts to respire, a process which uses the sugar and converts a portion of it back to starch. If the potatoes have been subjected to excessive cold storage, that is down to 32–34° or lower, trouble in conditioning may be encountered, such as tissue breakdown leading to rotting.

92.3.4 Determining the Quality and Condition of Raw Potatoes for Frying Purposes

Processors try to evaluate and classify the quality of the raw product prior to purchase or processing. Two of the most important characteristics that indicate quality are specific gravity, closely associated with moisture content, and the degree to which starch has been converted to sugar. These will affect the texture and the color of the product. The size and shape of the potatoes is also important because of the cost of operations, the yield, the length of the units, and the number of slivers and irregular-shaped pieces. The presence of off-odors and off-flavors such as those caused by some insecticides is at times very serious.

No entirely satisfactory method seems to have been developed to predetermine the cooking quality of potatoes. Specific gravity tests, which to some extent indicate the degree of mealiness, are sometimes made. Picric acid color tests may also be made. These indicate to some extent the relative amount of sugars present. The objectionable flavor of benzine hexachloride – an insecticide – can be detected by boiling and mashing a sample of the potatoes.

Probably the most satisfactory method of determining the quality of the raw product is to subject a representative sample of the lot to a cooking test similar to the process which will be used in manufacture. The USDA in cooperation with the state of Maine and certain potato processors have developed a series of color photographs which show various degrees of darkening after a standard fry. Comparison of actual samples of cooked potato to the photographs provides a fairly accurate means of evaluating the quality of a load of potatoes for the purpose of making French fries. Some large users base their raw potato contracts on the fry colors shown in the USDA Color Standards for Frozen French Fried Potatoes.

92.4 MANUFACTURE

Each processor of frozen French fried potatoes has his own particular methods of manufacture. However, there are a number of things common to all processors. The following outline describes the principal steps in manufacture. These steps may vary with different manufacturers. The principles given here are basic.

After receiving potatoes or having withdrawn them from storage bins or "conditioning" cellars frying and/or suitable chemical tests are made from representative samples of the lot to determine whether potatoes are in condition to be processed.

92.4.1 Washing

If potatoes are in condition suitable for processing they are washed and may be run through hot water to remove some of the dirt and to loosen the peel. The potatoes may then be sized prior to peeling. Some plants flume the potatoes from place of storage to the peelers thus accomplishing the preliminary washing in this manner.

92.4.2 Peeling

After washing off excessive dirt the potatoes are dropped into peeling machines. These may be steam, lye, abrasive, or roller type peelers. The steam and lye peelers give a quick cook which loosens the skin or peel but does not penetrate deeply into the potatoes.

The peelings are then removed by passing the potatoes through rubber rollers and water sprays. In abrasive, roller type peelers the skin or peel is removed without the addition of heat.

92.4.3 Trimming

The potatoes after leaving the peeling machines are trimmed on wide moving belts. In the better plants these belts are arranged in sections so that each potato is picked up by an operator, examined for defects, trimmed if necessary, and tossed over a barrier onto another section of the belt. This procedure is much more satisfactory than trying to stir the potatoes on a single belt because many potatoes may miss any examination at all on the single belt. At this time the potatoes may also be sorted for size; the larger ones going to institutional lines; the smaller ones into the retail and by-product lines.

In some plants electric eye sorters are installed after the slicing operation to eliminate blemished units, thus cutting down on the amount of hand sorting and trimming of the whole potatoes.

92.4.4 Slicing

After the potatoes are trimmed and sorted to size they go to the slicing machines. These slicers usually consist of two set of knives either rotary or fixed. One set of knives slices the potato to the desired thickness. The potato slices are then passed through another set of knives, which cut the slices to strips if desired. The size of the strips depends on the wishes of the management. It may vary from one-quarter by one-quarter inch to one half by one half inch in cross-section. The usual size for retail sales is $\frac{3}{8}$ by $\frac{3}{8}$ inch. Poor slicing may be caused by small or irregular-shaped potatoes, by poor machinery, or good machinery not properly used or adjusted. The knives may be straight or corrugated.

92.4.5 Sizing

In the process of cutting potatoes into strips, there is always a certain amount of slivers and otherwise irregular shaped pieces. A certain number of these more or less irregular shaped pieces are expected in this product and are allowed for in the tolerances contained in the grade standards. It is usually necessary, however, to pass the cut potatoes over some type of shaker screen to remove a portion of the small pieces and slivers. The amount of chip material removed depends to some extent on the wishes of the purchaser. Processors do not like to remove any more than they have to because of the loss in yield.

92.4.6 By-products

The excessive loss of potato material because of the peeling, trimming and screening operations causes processors to consider by-products to utilize this material. Often this material is wasted; however, a large number of products, such as patties, puffs, shreds, diced, and mashed have been developed to utilize this material. Dehydrated flakes is also an important use. Where satisfactory use is made of screenings and sound throw-outs, there is less tendency to keep this material in the frozen French fry pack.

92.4.7 Desugaring

Sugar in excessive amounts or irregular quantities of sugar between units may cause French fried potatoes to have dark or irregular color, poor texture, and/or unpleasant taste. Proper harvesting, good storage, and conditioning after storage helps in the control of the sugars. However, conditioning and storing potatoes is an expensive process and is avoided whenever possible. Reasonably satisfactory methods of rapid equalization of sugar content has been developed. The methods used vary between manufacturers. However, the basic principle is to run the sliced potatoes through a water bath leaching out a portion of the surface sugar and then replacing the sugar to the desired level by blanching in a sugar solution (partially cooking the product) so that upon frying the color between units will be uniform. This method, based on a patented process, evens the surface sugar content between units. The sugar content of the whole slice is not greatly affected.

92.4.8 Blanching

The sliced potatoes are usually run through a hot water blanch which partially cooks the product. This may or may not be a part of a desugaring process referred to previously. After blanching the product may pass beneath heating units, under forced draft, which tends to remove most of the excessive moisture before entering the fryer.

92.4.9 Frying

Frying of the potatoes is usually a continuous process. The potatoes enter the hot oil on or under a draper-chain type belt traveling a certain distance and being removed, or by an undulating type belt moving the potatoes in and out of the oil; the oil flow carrying the potatoes along from one end of the fryer to the other. Some manufacturers use a double fry. That is, after the first fry, approximately 350–370°F, the potatoes fall onto another belt and enter another fryer at about the same temperature. There are several reasons for this; the principle one being that there is more even coloring because of the stirring of the potatoes as they fall from one belt to another.

92.4.10 Fat or Oil

The term "fat" refers to a product that is plastic at room temperature such as lard or the usual vegetable shortenings. Oils are liquid at ordinary temperatures. The terms are here used to mean the same thing. Any animal or vegetable fat or oil which does not impart an unpleasant flavor to the French fries is suitable for the purpose. Different processors use different oils. However, peanut oil, cotton-seed oil, or mixtures of vegetable oils including some amount of soybean oil are also used. Lard, which is hog fat imparts a flavor to the French fries that is particularly desirable to some people. Soybean oil in large amounts may impart a flavor that is usually disliked. Hydrogenated lard is tasteless.

One of the biggest difficulties in proper frying is to maintain the fat or oil in good condition. Fats and oils deteriorate rapidly with the addition of water under high temperature, also when in contact with bronze or brass fittings. When the frying oil deteriorates it darkens in color, develops unpleasant odors which are imparted to the product. Dark

bits of burnt carbon maybe deposited on the French fries giving them an unpleasant appearance, Quality control people often use the amount of free fatty acid present in the oil as an indication of degree of deterioration. A range in the area of 0.4–1.0% is regarded as normal.

Potatoes lose up to 30–40% of their weight, principally water during frying. Water is removed from the oil by a partial vacuum created by the upward draft in the hood and attaching stack covering the frying vat. Condensation from the hood is carried away by troughs along the edge of the hood. The tendency to deteriorate may be checked by eliminating bronze or brass fitting, adjusting size of fryer to volume of potatoes, using oil that will stand the highest temperature in the system, and by adding new oil from time to time.

In the better processing methods the amount of oil used is very small and is usually heated by super-heated steam in a heat exchanger rather than by direct flame. This keeps the oil in all parts of the system well below the scorching point. Usually the oil is filtered continually to remove charred materials and is thus kept clean.

92.4.11 Time and Temperature

There are many variants to be considered in determining the time and temperature of the fry. Potatoes of high specific gravity require less time to lose their excess moisture than those of low specific gravity. Different varieties of potatoes and potatoes in different conditions with respect to reducing sugars may require different cooks to attain a uniform degree of color. Certain markets seem to want potatoes fried much lighter in color than do other markets. French fries packed for institutional use, where an additional fry is to be given by the users, are usually fried to a much lighter color than are retail packs where the cooking is usually completed by the oven method. These light colored fries are usually designated as "oil-blanched" or "par-fried."

Probably the most satisfactory means of arriving at the correct time and temperature for frying is to actually fry representative sample batches of each new load. If samples come out too dark either the time or the temperature, or both, of the cook may be reduced; if too light they may be increased. In most plants quality control people watch the color of the fries as they leave the fryer, both for overall color and for uniformity of color and recommend suitable adjustments of the process. These recommendations may be based on experience or on actual color plates or models which are provided as guides for the operators. The USDA color standards may be used for this purpose. Immediately after coming from the fryer heat may be applied to drive off excess surface oil. In many plants the potatoes are cooled quickly after the fry by a blast of air. This air blast maybe designed to blow off the outer oil which clings to the hot potatoes.

92.4.12 Packaging

Packaging is usually accomplished by automatic machinery which places the proper amount of the French fries into each package. The packages are usually weighed individually and adjusted for exact weight. This packaging operation may take place before freezing or, if belt freezing is used, after the potatoes emerge from the freezer. The resulting end product of the belt freezing method is easier to handle because the units separate

easily where as the plate frozen product may emerge as one solid unit. Broken units are more common when the product is belt frozen.

92.5 INSPECTION DURING PACKING OPERATIONS

The basic principles of in-plant inspection apply in general to inspection during manufacture. Processing operations as outlined above and as observed in the plant will suggest observation to be made and the best points to make them.

Good sanitation, particularly with respect to conveyors, belts, cutting machines, and machinery that comes in contact with cut potatoes is particularly important because yeasts, molds, and bacteria thrive in a potato-water medium and odors develop quickly. Also, there may be a build-up of oil or grease between fryer and packaging lines.

Samples checked for color at the discharge end of the fryers will indicate whether the potatoes are in proper condition for frying. Samples taken over the last shaker and just prior to packaging can be checked for defects (including defectives per pound). Cooking tests should be made as soon as practical after freezing in order to develop all the information necessary for the In-plant Inspection Report.

92.6 INSPECTING THE PRODUCT

92.6.1 Sample Unit Size

Any change in sample unit sizes from those specified in the standards changes the probability of the lot of passing or failing the intended grade. The size of the sample unit used is, therefore, very important. The sizes are:

- In Retail Type – 16 ounces of product selected either from a production line or from one or more market packages.
- In Institutional Type – 32 ounces of product selected either from a production line or from one market package.

CAUTION: Make every effort to obtain a representative sample. French fries, particularly strip styles, tend to stratify themselves with vibration. Therefore, try to take from the full depth on the belt or package rather than from the top. Often a "sweep" across the entire width of a belt would be better than from just one spot.

92.6.2 Initial Fry Color, Types, Styles, and Length Designations

These items provide much needed standardized language for trading since these terms – previously widely used – were subject to much individual interpretation. Accurate identification of the fry color, type, style, and length designation is very important. They should be reported on all certificates.

92.6.2.1 Fry Color Definitions. Color changes caused by frying require special consideration. Keep in mind the following definitions: (1) Fry color refers to the color change which occurs in the potato units solely because of the initial frying or oil blanch process.

(2) Fry color of the individual units is ascertained by comparing them with the USDA Color Standards for Frozen French Fried Potatoes. The range of color includes the "color space" up to but not including, the next darkest color. (3) Fry color of the sample unit is the range of colors that occur in the frozen product before any additional heating.

92.6.2.2 Fry Color Designations. Fry color designation of a sample unit is the fry color designation appropriate to the ranges specified in the Standards.

The USDA color standards referenced are a series of colors which depict changes that occur solely because of the frying process. They are numbers 0, 1, 2, 3, and 4.

These designations are further amplified as follows: USDA No. 0 in the color standards has no browning caused by frying. The background colors of all these illustrations is yellow. Background colors of potato strips are usually basically white. They may be creamy-white, yellow-white, or any other characteristic color (see Table 92.1).

92.6.2.3 Refry Color Definitions. "Refry color" means the actual color of a potato unit after heating – either deep frying or in an oven.

"Refry color of the sample unit" is the range of colors that are present after heating in preparation for grading.

"Refry color designation" is the color designation which may be given to the sample unit after heating. The appropriate criterion for this designation is given in Refry or (after heating) Color Range Guide in later discussion.

92.6.2.4 Types. Many plants pack primarily for retail and others primarily for the institutional market. Some pack an identical product for both types. For retail, however, the fry process usually has progressed to the extent that there is some color change and sufficient oil is retained that French fried potatoes of characteristic texture may be prepared by heating the product in an oven. For institutional use the units are usually processed very lightly, resulting in little color change and often not enough oil

TABLE 92.1 USDA Colors.

USDA Color	Optional Fry Color Designation	Application to a Sample Unit
No. 0	Extra light	A sample unit may be designated "extra light" if almost all of the units have no fry color at the edges as in USDA No. 0.
No. 1	Light	A sample unit may be designated "light" if most of the potato units are lighter than USDA Color No. 2.
No. 2	Medium light	A sample unit may be designated "medium light" if most of the potato units are lighter than USDA Color No. 3 but may include Color No. 1.
No. 3	Medium	A sample unit may be designated "medium" if most of the potato units are darker than USDA Color No. 2 and may further range in color as dark as Color No. 4.
No. 4	Dark	A sample unit may be designated "dark" if most of the potato units are darker than USDA Color No. 3. This designation may contain units similar to No. 4, and darker. Sample units designated No. 4 "dark" fry color are not allowed in Grade A.

retention for proper preparation in an oven. This is often referred to as oil blanched or par fried.

The determination of type is based on intended use. You must make this determination on the information available to you.

Guidelines for this decision are as follows:

1. Small packages (5 pounds or less) which are labeled or marked as is customary or required for retail sales, and particularly those bearing official USDA marks, are considered to be "retail type." Five-pound packages which are so marked, however, may be considered to be institutional type if declared by the applicant to be intended for such use.
2. Packages of any size which are not labeled or marked as is customary or required for retail sales and display are considered to be "institutional type" unless specifically declared to be retail by the applicant for inspection.
3. If the product is unpackaged, as on belts or in tote bins, or if the packaging does not indicate the intended use, it is considered to be "retail type" and the retail type defective allowances apply. Such a lot, however, may be considered to be "institutional type" if so requested by the applicant.

92.6.2.5 Styles

Strips. This style should be designated as either:

- Straight cut;
- Straight cut-shoestring;
- Crinkle cut.

The cross-sectional dimensions of the strips are also important to the buyer. Because of the nature of the product these are not very uniform. Designate the cross-sections, therefore, as "approximate" and to $\frac{1}{8}$ inches as approximately $\frac{5}{8} \times \frac{5}{8}$ inch, or $\frac{5}{8} \times \frac{3}{4}$ inch, and so on. The cross-sectional dimension of crinkle cut strips are normally measured from "hill" to "valley."

Slices, Dices, Rissolé, Other. See chapter on "Frozen vegetables and product description."

92.6.2.6 Length Designations. (Applies only to strips). Length in French fries is closely related to quality and value for many purposes. "Extra long", for example, is usually considered a "premium" pack for institutional use. It is seldom packed for retail since it presents difficulties in packaging in retail size containers, and often requires sizing of the uncut potatoes. "Long" is packed in both retail and institutional type and is often considered a "premium" pack for retail. "Medium" is the usual retail size.

With the exception of "short" lengths which are specifically excluded from U.S. Grade A, the length of units is not considered to be a factor of quality under the U.S. standards. "Short" lengths may, however, be designated "U.S. Grade A Short" if the strips meet the other requirements of U.S. Grade A.

The lengths designated in the standards are intended to provide workable and much needed definitions for terms which are regularly used in trading.

Determining the length. The length designation may be determined readily by isolating the strips that are 3 inches in length or longer and those that are less than 2 inches in length. The percentages "2 inches in length or longer" and "3 inches in length or longer" may be readily calculated. Chips, slivers, pieces, and strips which are less than $\frac{1}{2}$ inch in length are not considered in the total count.

See USDA File Code 130-A-75 for description and scale drawing of the Vegetable Strip Sizer, a very effective device for sizing the strips.

Minimum equipment for inspecting frozen French fried potatoes:

1. Grading scale
2. Large flat trays
3. Ruler (size and length grading plate)
4. Percentage calculator
5. Authorized visual USDA color standards for frozen French fried potatoes
6. Vegetable strip sizer
7. Oven of suitable type, or deep frying equipment.

92.6.3 Preparation of Sample

The factors of color and defects are partially evaluated before the product is heated. Often when a package is opened there is a film of frost on the units which masks the color or if storage conditions have not been good there may be a crust of ice or a heavy coating of ice crystals. If there is any appreciable condition of frost, ice crystals, or icing in the sample, thaw until the condition disappears to the extent that the color may be properly evaluated. Icing is usually not serious; however, the thawing of the sample in the oven may add enough moisture to the potatoes so that they are soggy when cooked, also cause an explosion when put into hot frying oil (see Texture).

The sample should be examined for color designation using the USDA Color Standards as a guide, as discussed under Color.

92.7 QUALITY EVALUATION

92.7.1 Grade Factors Which are not Scored

92.7.1.1 Flavor. The flavor of French fried potatoes is affected by the conditions of the potatoes with respect to sugar or sunburn, the condition of the fat or oil used, and, to a certain extent, by the variety of the potatoes, the type of soil, and climatic conditions; whether or not certain insecticides have been applied to the growing potatoes.

Good flavor is required in Grades A and A Short and at least reasonably good flavor in Grade B. Sweetness, bitterness, rancidity of oil, and pronounced scorched or caramelized flavor and odors are the usual reasons for lowering the evaluation of flavor from "good" to only "reasonably good." Any definitely objectionable flavors or odors would be cause for lowering the grade of the product to Substandard. After the product has been heated in a suitable manner, taste and smell it and classify its flavor as "good," "reasonably good," or "poor."

92.7.2 Color Designation of a Sample Unit

The exact color of good quality potatoes varies considerably because of varietal differences, physical differences, types of fat used, areas of production, and other causes. It also varies because of the amount of color change induced by the frying process. These values are important to buyers because certain markets and certain important customers have strong preferences as to the lightness or darkness of the brown coloring.

Two separate and distinct color determinations are required:

1. Classifying the "fry color of the sample unit" as to its value (that is, its lightness or darkness) in order to establish the proper fry color designations; and
2. Evaluation and assigning the score points for color in compliance with the standards, giving consideration to color changes in the refried product.

Grade A, Good Color (27–30 points). This color is bright and typical of the product and meets the uniformity of fry color given for:

- No. 0 – extra light
- No. 1 – light
- No. 2 – medium light
- No. 3 – medium

and meets the uniformity of refry color given in the Refry Color Range Guide.

Grade B Reasonably Good Color (24–26 points) (Limiting Rule). This color must be characteristic of French fried potatoes – not dull or off color. It may exceed the fry color variation given for any of the USDA colors – including No. 4 – dark. After heating, the variation in the refry color may exceed those indicated in the guide but may not seriously detract from the appearance of the product.

Substandard (0–23 points) (Limiting Rule). Lots that darken quickly – before the interiors are cooked, or very irregular would fall into this classification.

92.7.3 Uniformity of Size and Symmetry

Uniformity of length of normal shaped strips is not considered under this factor. Consideration is given to the effect of any "chips" as defined on the appearance of the product and the percent by count of "small pieces," "slivers," and/or "irregular pieces." In assigning score points be guided by the following:

Grade A

20 points – almost no chips and/or:

Strips – no more than 5% of small pieces, slivers, and/or irregular pieces.

Other styles – almost perfect uniformity in size and shape of the units.

18 points – chips present but not to materially detract from appearance, and/or;

Strips – more than 5–15% of small pieces, slivers, and/or irregular pieces.

Other styles – high degree of uniformity in the size and shape of the units.

19 points – by interpolation.

Grade B

17 points – chips present materially detract and/or:

Strips – more than 15–20% small pieces, slivers, and/or irregular pieces.

Other styles – reasonably uniform in size and shape.

16 points – chips present that approach serious appearance, and/or:

Strips – more than 20–30% small pieces, slivers, and/or irregular pieces.

Other styles – variation in the size and shape of the units detracts noticeably from the appearance of the product.

92.7.4 Defects

Defects are carefully defined in the standards as: Insignificant imperfections, minor defects, and major defects.

Defectives are potato units affected with defects – as defined in the standards as "minor defective" or "major defective." It is defectives rather than defects which are scored against.

92.7.4.1 Considerations. For each grade three separate types of deficiencies are considered under this factor. While the principal consideration is major and minor defectives, all three must be considered in assigning the scores for the sample units. They are:

1. The total effect of all faults which might be present whether specifically mentioned. This is the "overall clause." Among such are extraneous materials, insignificant imperfections, and carbon specks or defects (as defined), and obnoxious blemishes which are much worse in appearance than usual major defect;
2. The effect of any carbon specks on the appearance of the product; and
3. The allowances for minor and major defectives as specified in Tables 92.2 and 92.3 of the standards.

92.7.4.2 Defect Tables in the Standards. Defectives allowed in these tables are not averages. Sample units that fail the applicable requirement are allowable in the sample only as regular deviants.

92.7.5 Assigning the Score for Defects

92.7.5.1 Procedure

1. Segregate the minor and major defectives in the sample unit and record them on the score sheet as (1) total (major and minor) and (2) major.
2. Assign a tentative score for defects as indicated by the following guide.

TABLE 92.2 Standards – All Styles Except Shoestrings and Dices.

Grade	Point	Defective	Possible Combinations of Defectives			
Retail type						
A	20	Total	0–3			
		Major	0			
	19	Total	4–5	1–3		
		Major	0	1		
	18	Total	4–5			
		Major	1			
B	17	Total	6–9	6–9	2–5	
		Major	0	1	2	
	16	Total	6–9			
		Major	2			
Institutional type						
A	20	Total	0–6	1–4		
		Major	0	1		
	19	Total	7–18	5–18	2–12	3–8
		Major	0	1	2	3
	18	Total	13–18	9–18	4–18	
		Major	2	3	4	
B	17	Total	19–28	5–23	6–18	
		Major	0–4	5	6	
	16	Total	24–28	19–28	7–28	
		Major	5	6	7–8	

TABLE 92.3 Standards – Shoestring, Strips, and Dices.

Grade	Point	Defective	Possible Combinations of Defectives			
Retail type						
A	20	Total	0–5	1–2		
		Major	0	1		
	19	Total	6–9	3–5	2–5	
		Major	0	1	2	
	18	Total	6–9	6–9		
		Major	2	1		
B	17	Total	10–18	3–15	4–8	
		Major	0–2	3	4	
	16	Total	16–18	9–18	5–18	
		Major	3	4	5	
Institutional type						
A	20	Total	0–10	1–8		
		Major	0	1–2		
	19	Total	11–28	9–28	3–21	5–18
		Major	0	1–2	3–4	5–6
	18	Total	22–28	19–28	7–28	
		Major	3–4	5–6	7–8	
B	17	Total	29–36	9–30		
		Major	0–8	9–10		
	16	Total	31–36	11–36		
		Major	9–12	11–12		

Groups are inclusive i.e., $\frac{3-5}{1}$ *means* $\frac{3}{1}\ \frac{4}{1}$ *or* $\frac{5}{1}\ \frac{Total}{Major}$.

3. Adjust the score point if appropriate by giving consideration to the "overall clause" and the effect of any carbon specks present. This becomes the defect score for the sample unit.

Guide for assigning tentative score for defects – subject to adjustment for "overall clause" and for carbon specks.

92.7.5.2 Texture. Texture is evaluated within three minutes after heating the product as specified, and while it is well above room temperature.

Heating the Product

OVEN METHOD. The method of reheating specified in the standards is similar to that employed by the housewife. The crumpled foil is placed in the bottom of the pan in order to prevent excessive burning of the potatoes where they touch the metal pan. Fifteen minutes at 400° is a minimum for most potatoes. The time depends on the size of the units, the sugar content, and the type of oven – whether gas or electric – the number of samples in the oven, and how well it is ventilated. Trial runs are usually necessary to determine the proper time to cook any lot of potatoes in the available equipment. Potatoes are properly cooked when the interior of the largest units has lost the raw potato taste. This method should be used when it is obvious that the product is intended for home use and cooking directions call for the oven method. Exceptions may be made when test runs have shown that the "deep fat" method gives results comparable to the oven method on the particular potatoes.

DEEP FAT METHOD. Frozen French fried potatoes prepared for institutional use usually have a lighter fry color than those prepared for the retail trade. This is because the institutions using these potatoes will give them a short fry in oil. This additional fry can be adjusted in time and temperature so that the finished French fries will have the desired color. This desired color may be light or fairly dark depending upon the preference of the cooks. Also the directions on some retail packages provide for an additional cook in hot oil rather than an oven cook. For this reason provision is made in the U.S. standards for heating the product by any other method which will give comparable results.

Deep fat frying is probably preferred for inspection use because of the speed with which the samples can be run. It should always be used where the product is light in color and/or obviously intended for institutional use. Where large numbers of samples are to be inspected a deep fat fryer of the type marketed for household use and provided with an automatic heat control is very useful. If only an occasional sample is to be inspected equally good results maybe obtained by using a small stew pan with a wire dipper. With this equipment it is necessary to have an emersion thermometer capable of registering up to 600°F. Also, new automatic frying pans can be obtained with heat control units.

Heat at least 100 units to determine the score for character. The temperature of the oil is very important. The temperature must be high during the entire refry time or the results will be in error. One-hundred units in a very large tank such as may be available in-plant inspection would not lower the temperature significantly. With a quart or pint of oil only a few units can be fried at a time without lowering the oil temperature. Good texture varies somewhat with the varieties used and the area of production. It

may vary from a somewhat cheese-like, very fine grained texture to a coarse-grained almost powdery texture.

Usual Variations from Acceptable Texture

SOGGINESS. As the name implies this refers to a wet pasty or mushy condition either loaded with water or oil. It may be a basic characteristic of the potatoes or it may be induced by frying at too low a temperature. Often only a portion of the potato becomes soggy. Both the amount of the unit affected and the degree of sogginess must be considered in estimating the effect on texture. Score the unit only if 50% of its length (or less if very objectionable) is so affected.

HARDNESS. Interior portions that are very firm, sometimes oily to touch and raw in taste even if well cooked. Often – as with sogginess – only a portion of a strip or slice is hard. Score such units only if 50% (or less if very objectionable) of its length is so affected.

PULL AWAY. Interior portion of a strip that has withdrawn from the outer shell voiding $\frac{1}{3}$ of the cross sectional area of a regular strip or $\frac{2}{3}$ of the cross section of a shoestring.

CRISP OUTER SURFACE. Really crisp outer surfaces is a texture fault in any grade. A slight crispness is expected in Grade A and the surfaces may be slightly hard or slightly tough in Grade B. Keep in mind that excessive cooking will increase the crispness of the outer surfaces.

SUGARY ENDS. A unit that has a dark and often soft rubbery end, caused by excess sugar.

EXCESSIVE OILINESS. For reasons which are not always explainable an unusual amount of oil is sometimes retained by the fries. It is very objectionable to buyers as it affects the texture adversely. Excessive oiliness can often be detected by the feel of the units prior to the heating. If excessive oiliness does not disappear with normal preparation, lower the texture score to reflect this condition.

Score Points. The exact score points to assign requires careful preparation of the sample. Consider all the factors affecting texture and assign scores as indicated in the following guide: Scoring Procedure: Heat 100 strips to determine the Texture Score. The number of points deducted from a possible 30 points will depend on the overall excellence of the sample. Consideration must also be given for those units in a sample that have a soggy or hard texture, or show pull away, or have excessively oily outer surfaces. Sugary ends not serious enough to be considered defects would fall into this category. The sample shall be practically free of such units to score in the Grade A range. Percentages ranging from 0–10% by count depending on the seriousness of the defective units, are acceptable in this grade.

Prepared French fried potatoes that are scored 24–26 points for texture must be reasonably free from soggy or hard texture, pull away, or sugary ends, or those which do not have a crisp outer surface.

Score 26 points if there are 11–15% by count of these scorable units, or if the units with slightly soggy or hard interior portions, or soft or slightly hard exterior surfaces materially affect the overall appearance or eating quality of the product.

Score 25 points if there are 16–20% by count of the scoreable units and 24 points if there are 21–25% by count.

93.1 INTRODUCTION

Since the discovery of the New World, red pepper fruits spread widely to the rest of the world. Today, this fruit is grown for commercial purposes in the United States, Brazil, India, Taiwan, South Africa, Zimbabwe, and through all Europe, with Hungary and Spain as the most representative producers of paprika. Pepper plant (*Capsicum* genus)

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

belongs to the *Solanaceae* family as well as potato, tomato, tobacco, and petunia, and even coffee. This genus includes 22 wild species and five domesticated species: *C. annuum*, *C. baccatum*, *C. chinense*, *C. frutescens*, and *C. pubescens*, with *C. annuum* and *C. frutescens* being the most economically important. Fruits of these plants are used in the manufacture of selected commercial products known for their color and pungency respectively, mainly paprika and paprika oleoresins. *Capsicum frutescens* L. plant is cultivated in the tropics and warmer regions of the United States, and its fruits are used to provide pungency in tabasco sauce. *Capsicum annuum* L. plant is extensively cultivated, producing fruits that vary in length, color, and pungency depending upon the cultivar. The nonpungent cultivars are used for direct consumption, either fresh or dried, whole or ground. They are also widely used as color additives to improve or provide that organoleptic attribute in other foodstuffs.

Fruits of these plants are berries, with different shapes (rounded or elongated) and size (few grams up to 250 g) depending on the variety. Seeds are straw-colored and placed on the placenta. During ripening, color of fruits changes from green to red due to a massive de novo biosynthesis of carotenoid pigments, which is accompanied by a catabolism of the chlorophylls originally present in the unripe fruits.

Coloring power is the main characteristic in determining commercial value for paprika and derived products, and this property is directly correlated with the carotenoid content. Selection and breeding of varieties have been performed in order to increase carotenoid content of fruits (Hornero-Méndez and others 2000, 2002). Other selection criteria are fruitful ability of plants, resistance to rot, and finally, grouped ripeness and plant morphology to facilitate mechanical harvest. As mentioned before, selection of fruits and economic evaluation of their processed products will be made in terms of coloring capacity, and these attributes are measured with the appropriate methodology. The compounds responsible for color of these fruits are carotenoids as discussed in the next section.

93.1.1 Description of Carotenoids as Components Responsible for Fruit Color

The fruits of *C. annuum* owe their intense red color to carotenoid pigments that are synthesized massively during fruit ripening. Carotenoids are isoprenoid compounds with an extensive system of conjugated double bonds (polyene chain) which is responsible for their physical and chemical properties. This characteristic structure is the primary cause for their lipophilic behavior, as well as for their distinctive light-absorbing properties and therefore of their coloring capacity. In the case of red pepper fruits, the main carotenoid pigments responsible for the final red color of the fruits are capsanthin, capsorubin, and capsanthin-5,6-epoxide, which are almost exclusive to the genus *Capsicum* (Davies and others 1970; Mínguez-Mosquera and others 1984; Mínguez-Mosquera and Hornero-Méndez 1994a).

Carotenoids are essentially C40 terpenoid compounds formed by the condensation of eight isoprene units. Their biosynthesis is an important branch of the complex isoprenoid pathway. The basic carotene structure (i.e., lycopene) undergoes several structural modifications namely cyclization, hydroxylation, epoxidation and rearrangement, giving way to the great variety of carotenoids in Nature (more than 650) (Britton 1998). During ripening of the pepper, there is a spectacular *de novo* biosynthesis of carotenoid pigments.

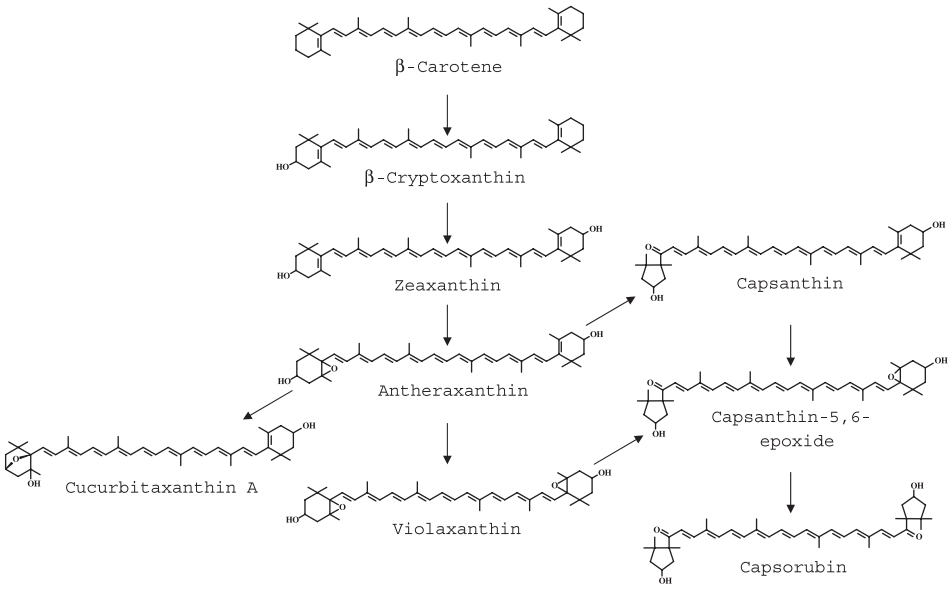

Figure 93.1 *Scheme of the basic biosynthetic pathway of carotenoids in red pepper fruits (Capsicum annuum L.). Red fraction comprises capsanthin, capsanthin-5,6-epoxide and capsorubin. Yellow fraction includes rest of carotenoid pigments.*

Figure 93.1 shows the basic route for the biosynthesis of carotenoids found in red pepper fruits. All the carotenoid pigments present in the pepper contain nine conjugated double bonds in the central polyene chain. The presence of different end groups (β, ε, κ, 3-hydroxy-5,6-epoxide), changes the chromophore properties of each pigment, allowing them to be classified in two isochromic families: red (R) and yellow (Y). The red fraction contains capsanthin, capsanthin-5,6-epoxide, and capsorubin, while the yellow fraction comprises the rest of the pigments (zeaxanthin, violaxanthin, antheraxanthin, β-cryptoxanthin, β-carotene, and cucurbitaxanthin A), which act as precursors of the former.

An important characteristic of the group of xanthophylls is that they are esterified with fatty acids, a fact that takes place during ripening of pepper (Camara and Monéger 1978). Several functions or benefits result from the esterification of xanthophylls, such as the increase of liposolubility, enhancing the stability of these pigments towards enzymatic and nonenzymatic oxidative reactions, and that they may be used as indicators of ripeness index (Hornero-Méndez and Mínguez-Mosquera 2000). Yellow xanthophylls are mainly esterified with unsaturated fatty acids like oleic and linoleic while saturated fatty acids esterify the red xanthophylls (Biacs and others 1989; Mínguez-Mosquera and Hornero-Méndez 1994b). Besides the coloring capacity, two properties of carotenoids must be remarked. First, β-carotene and its isomeric forms, and β-cryptoxanthin show provitamin A activity. Second, all carotenoids perform antioxidant capacity, independently of the provitamin A activity. The antioxidant capacity of carotenoids could be displayed in the food where they are added or in human body, once these pigments are ingested. The antioxidant properties displayed by the carotenoids are also indicative that these pigments will be easily degraded under oxidative conditions, such as increased light and temperature,

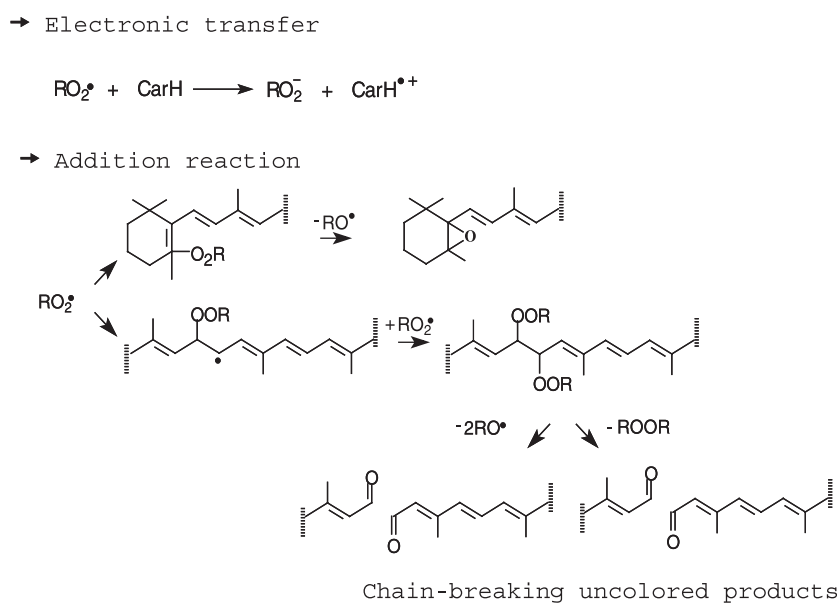

Figure 93.2 *Radical reaction pathways affecting the polyene chain of carotenoids that modify and disrupt the coloring properties.*

presence of free radicals, and reactive oxygen, through which carotenoids have been demonstrated to be effective quenchers (Foote and Denny 1968). Frequently, these conditions are promoted during fruit processing. The interaction between carotenoids and prooxidants takes place mainly through the polyene chain (Fig. 93.2) and any reaction or excess of energy of the environment affecting this chain will modify coloring properties of the pigment. Consequently, coloring capacity is diminished through oxidative processes and thus economic value of the product will decrease. This correlation is considered during processing of red pepper fruits for paprika, as the unit operations applied may considerably increase the progress of oxidative reactions affecting carotenoid concentration of fruits and their later stability. Hence, the suitability of the type of processing and conditions applied will be assessed in terms of minimal degradation of the carotenoid content and its maximal stability during the storage of the final product.

93.2 INDUSTRIAL PROCESSING OF RED PEPPER FOR PRODUCTION OF PAPRIKA

Paprika is a fine, brilliant, highly colored powder resulting from the application of two unit operations to mature red pepper fruits, dehydration and milling. Dehydration of fruits reduces the water content from 70–85% to 10%. This operation increases the shelf-life of fruits from days to months and allows application of the second unit operation: milling. This size reduction is necessary to homogenize the color of the dry fruits batches, and facilitate its use as colorant.

Dehydration could be considered as the main processing step in paprika manufacturing because conditions (temperature and time regime) may produce profound changes in the

carotenoid content as a consequence of the degradative reactions that either directly or indirectly degrade pigment profile of fruits. And these changes may be denoted immediately after processing or triggered during storage of the product. Therefore, in this processing step is where more technological innovations have been implemented, nowadays even more, with the trend to reduce impact of thermal processing on food constituents. Current techniques and emerging technologies of dehydration are described in the next sections.

93.2.1 Current Techniques Applied for Dehydration of Red Pepper Fruits

Traditionally, two conventional dehydration techniques have been used, via direct exposure of fruits to sunlight in open air, a characteristic process of Murcia (Spain) or in drying chambers where the heat source is the burning of oak logs, the traditional process carried out in La Vera (Spain). The first form of traditional drying has been employed in Spain, Turkey, and Tunisia. But the rain damage, dust and insect contamination, and quality of dry peppers, affected by oxidative degradation promoted by sunlight (Mínguez-Mosquera and others 1996), are serious drawbacks that have made this easy technique to be disregarded. However, economically and environmentally, this dehydration method is very attractive and some efforts are now conducted to improve the technique. The main innovation is to perform the dehydration under shelter, in greenhouses and some trials have been made to obtain mathematical models for moisture evolution of fruits. Even the possibility of introducing forced convection in the greenhouses has been explored. These studies are still performed only from the physical point of view, so they should be complemented with the analysis of the quality of the product (Passamia and Saravia 1997; Ratti and Mujumdar 1997; Condori and Saravia 1998).

Industrial processes, with alternative heat sources have replaced the solar dehydration technique. Traditionally, the combustion of oak logs has been the heating source to increase temperature of air going into drying chambers. Heat is generated in the first floor of the cottages and the fruits are piled on the second one, the surface of which is a wooden lattice that allows hot air and smoke to circulate through the mass of fruits. This method of dehydration is characterized by continuous rises and falls in temperature associated with the combustion of wood, a manual process without technical equipments. Thus, the temperature–time profile is very irregular, but with a cyclic period of rise and fall of temperature coinciding with the fire up and fire down during the 7–10 days of dehydration (Mínguez-Mosquera and others 1996; Pérez-Gálvez and others 2001). The final product, dry husks, presents flavor features highly prized and appreciated by both the consumer and food producers, as the flavor will provide unique organoleptic characteristics to a meal or the product where this kind of paprika is included as well as the coloring properties.

However, this low temperature–time regime has two special considerations: variability, and a lack of modern technology to control this traditional process. As a result, conventional industrial dryers become more suitable for the dehydration step. The temperature–time regime is more uniform, the residence time of fruits is reduced from days to 4–6 h, and moisture content of the dry product is even lower (4–6%). Moreover, the process is frequently made in a continuous flow fashion, using tunnel dryers (Chung and others 1992; Levy and others 1995). The hot air (60–80°C) circulates through the tunnel while fresh fruits, deposited on trays, move intermittently through it (McGaw and others 2001). One improvement is the use of vacuum dryers that would considerably

reduce the thermal stress, and the temperature–time regime could be reduced, decreasing pressure, using vacuum roller dryer (Zhang and others 2003).

93.2.2 Emerging Technologies and Processing Strategies Applied for Dehydration of Red Pepper Fruits

Although preprocessing techniques of raw material before dehydration are not generally used, some studies show that application of pretreatments to fresh fruits reduces temperature–time regime by increasing the rate of water transfer (Lazarides and others 1999). Combination of techniques such as washing, chemical peeling, cutting, and steam blanching considerably decreases processing time and consequently the degree of thermal stress (Doymaz and Pala 2002).

Undoubtedly, osmotic dehydration has become one of the reference techniques to be applied for reducing the negative impact of conventional convective dryers, thus improving the organoleptic properties of the fruits, mainly the color, but also original composition in other components, such as vitamin C, so that nutritional value observed in fresh fruits could be preserved. This technique consists on placing the fresh fruits into highly concentrated salt or sugar solutions. Control variables are composition of the dehydration solution, immersion time and temperature of the pretreatment. The concentration gradient makes water from fruits to diffuse into the solution. The dehydration level of the fruit material is later reduced to the desired level by application of a conventional dehydration technique. This preprocessing step decreases the energy requirements of the dehydration operation.

Osmotic dehydration may also be combined with high intensity electric field pulses that disrupt the cell material and produce pore formation that modifies skin permeability properties, or with application of high hydrostatic pressure that affects cell wall structures. Application of these preprocessing techniques considerably reduces temperature–time regime in convective dryers to reach the dehydration level of fruits (Ade-Omowaye and others 2002).

Novel thermal processes like infrared, microwave, ohmic, and inductive radio frequency and high heat infusion techniques might also be considered as alternatives to conventional dehydration. In general, these drying technologies enhance the diffusion of heat and mass. Microwave and radio frequency dehydration methods start to dry the product internally and the heat diffuses to the surface, enabling increased drying rates and improved product quality.

One strategy that could be implemented is to perform dehydration of fruits in an inert atmosphere or processing under vacuum that will diminish the oxidative effects over pigments, vitamins, and aroma, and therefore maintaining product quality features (Ramesh and others 1999).

93.2.3 Milling

The size reduction of dry fruits is achieved by milling. This process has the following profiles:

- Homogenizes the coloring capacity of different batches,
- Facilitates transport and storage, dosage of product in formulation of foodstuffs, and application of further processing for obtaining paprika oleoresins.

The dry husk is milled with the seeds of the fruit that enhances color surface and brightness. Seeds percentage in paprika is 30–35% and they act as a dilution factor because they do not contribute to any carotenoid pigmentation (Mínguez-Mosquera and others 1993; Pérez-Gálvez and others 1999a). A common particle size after milling is 40 μm.

Two types of mills are usually utilized: ball and hammer mills. Ball mills consist of a slowly rotating, horizontal steel cylinder, half filled with steel balls (2.5–15 cm in diameter). The final particle size depends on the speed of rotation and on the size of the balls. Hammer mills consist of a horizontal or vertical cylindrical chamber lined with a steel breaker plate and contains a high-speed rotor fitted with hammers along its length. The material is broken apart by impact forces as the hammers drive it against the breaker plate.

93.3 EFFECT OF PROCESSING AND STORAGE ON THE CAROTENOID CONTENT

93.3.1 Processing

The quality of processed fruits and vegetables is governed by a major factor. The original organoleptic and nutritional properties of the raw material should remain after processing. For red peppers, this means that the carotenoid content, that gives the nutritional value in paprika, and its main organoleptic property, the color, should be retained as close as possible to the initial levels. In addition, carotenoids provide this fruit with significant health attributes besides the color, for example, provitamin A level and antioxidant properties. Preserving the color during processing means that those nutritional characteristics are also preserved, a correlation schemed in Figure 93.3. Like in other fruits, vitamin C retention in red peppers after processing could be used as indicative of processing quality (Tijskens and others 1979) although carotenoids are the main markers (Mínguez-Mosquera and others 1992).

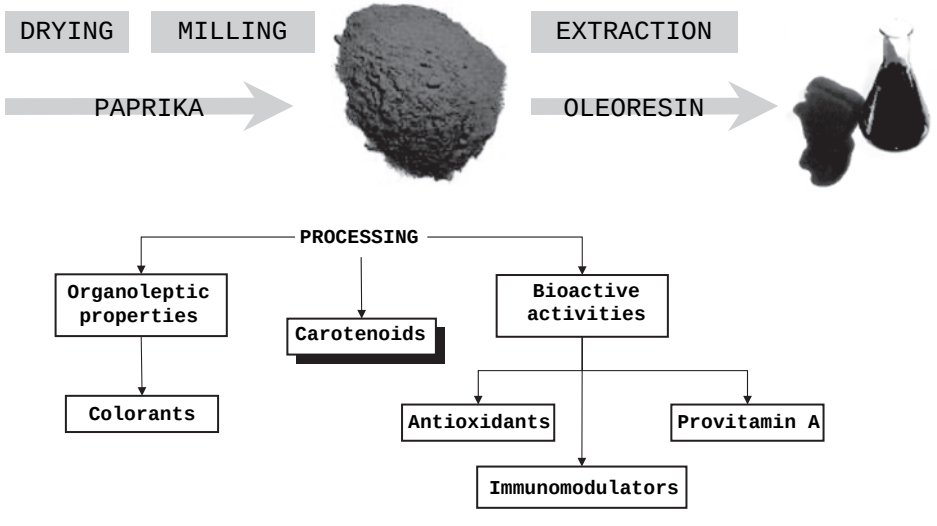

Figure 93.3 *Unit operations applied for manufacturing of paprika and paprika oleoresins and consideration of the effect of those processing steps on properties of carotenoids.*

Dehydration parameters, time, temperature, and moisture of fruits will define the outcome of carotenoid content. These pigments are sensitive to those factors that promote oxidative reactions and the thermal stress to which the fruits are subjected to during dehydration. They will determine the extent of changes in the carotenoid composition of the dry product (Mínguez-Mosquera and others 2000).

Current technologies applied for dehydration of processing have resolved the equation "temperature and time residence" in different means. While conventional industrial processes diminish the residence time by increasing the temperature, the traditional process extends the residence time and the processing temperature is considerably reduced. These different approaches will have different consequences in the color quality of the dry product obtained.

Dehydration conditions in convective dryers, (high temperature–time regime), facilitate nonenzymatic browning reactions and carotenoid loss (Lee and Kim 1989). Percentage of loss will depend on processing conditions. A report of Mínguez-Mosquera and others (1994a) shows a 25% of loss on the total carotenoid content when fresh fruits were oven-dried. A subsequent work (Mínguez-Mosquera and Hornero-Méndez 1994c) shows a 16% of loss after dehydration at 60°C during 8 h.

The traditional drying process carried out in the La Vera region (Spain) is milder, with a mean temperature of 40°C during the 7–10 days of processing. Several reports on this way of drying confirm that color quality remains unaltered in most cases. Of course, thermal stress and oxidative reactions take place. However, mild temperature conditions and low drying rates allow fruits to keep high moisture levels during the first phase of dehydration. This increases the over ripening of the fruits, activating the anabolic pathway for carotenoids (Mínguez-Mosquera and others 1994b, 2000; Pérez-Gálvez and others 2004). The biosynthesis of carotenoids compensates loss of pigments due to degradative reactions yielding a dry product with a total carotenoid content very similar to that of the fresh product. There is a correspondence between temperature profile, catabolism and anabolism of carotenoids, and moisture content (Pérez-Gálvez and others 2004, 2005). These results help us to establish, during the dehydration process, the operation conditions that will modify the carotenoid content towards anabolic and catabolic reactions.

Biosynthetic reactions are, therefore, the metabolic reply to the thermoxidative stress. This anabolic capacity makes possible a balance between anabolism and catabolism, hence keeping the characteristics of fruits. Moreover, it has been observed that the anabolic capacity is increased when fruits are harvested before total ripeness because they keep metabolically active and have more capacity to modulate the stress. The concept of cyclic time–temperature varying profile of this traditional processing is reproduced during dehydration of some food products to enhance quality and reduce drying time. The need for a lower drying time by using temperature–time varying profiles has been mathematically demonstrated by Devahastin and Mujumdar (1999). Chua and others (2000a) have used time-varying air temperature profiles to reduce the change in color parameters. The application of temperature fluctuations during dehydration also reduces the loss on other valuable components, such as vitamin C (Chua and others 2000b). Effect on quality during drying and degradation profile during storage after application of this dehydration strategy should be extensively studied.

Effect of novel technologies and pretreatments on the carotenoid concentration of red pepper fruits is a subject of research in recent years. The effort made to establish processing conditions for the application of osmotic predehydration, high intensity electric pulses and high hydrostatic pressure, and the analysis performed of physical variables

must be complemented with the effect of such techniques on chemical parameters of composition of valuable components, mainly carotenoids. The physical changes produced in cellular structure of fruits during osmotic dehydration facilitates the process, but still a variable percentage of loss is observed. The work of Ade-Omowaye and others (2002) reports a variable loss, ranging from 80% to 55% after the osmotic dehydration at different temperatures. It was observed that due to the permeability, a carotenoid fraction is lost by diffusing to the osmotic solution. Combination of osmotic dehydration with high intensity electric pulses diminished the losses. Composition of osmotic solution has been reported to have some effect on color characteristics of osmosed peppers (Torreggiani and others 1995).

High temperatures used in the steam blanching produce losses of carotenoids when this pretreatment is combined with the subsequent conventional hot air dehydration. Alternative use of inert gas atmosphere has shown to reduce carotenoid losses when blanched red peppers were dried with hot air. In any case, losses are lower in comparison with those achieved with hot air dehydration without any pretreatment or modification of the atmosphere (Ramesh and others 1999).

Few reports discuss over the effect of milling on the carotenoid content of dry fruits. Degradation arises from temperature increase due to friction and bruising from the mill hammers or balls. In the region of Murcia (Spain), production of paprika under PDO (Protected Designation of Origin) regulation specifies that temperature milling must not increase above 45°C. Residence time in mills takes no more than 3 h but losses of 10–15% have been reported (Mínguez-Mosquera and others 2000).

93.3.2 Storage

Stability of food components during storage is not only a direct consequence of storage conditions but also the result of content in compounds that may act as antioxidants and the presence of promoters of degradative reactions, and finally derived from processing parameters applied for manufacturing the final product. Degradation of the carotenoid profile during processing could be used as a marker of stability of the product at the store, as well as oxidation of the fatty acid profile, which would give the paprika undesirable flavor that would making the product inappropriate for trade and consumption (Biacs and others 1992). Additionally, it must be pointed out that although degradative reactions may initiate during processing, their consequences would not be noticeable immediately, but later during storage (Malchev and others 1982).

To avoid degradation during storage, different common strategies should be established. Vacuum packaging of paprika in red plastic bags avoids direct contact to air and light. Storage at low temperatures and appropriate water activities is also advisable as stated by Lee and others (1992). Like in other foodstuffs, progress of autoxidative reactions, which are responsible for the degradation of carotenoid pigments, could be delayed in paprika by addition of antioxidants (ascorbic acid, tocopherols, herbs extracts). These methods avoid exogenously the oxidation potential of the sample, which is mainly based on the polyunsaturated fatty acid profile of the paprika (Pérez-Gálvez and others 1999a,b) and promoted by excessive thermal stress during paprika processing (Malchev and others 1982, 1989), inappropriate storage conditions or a combination of both issues.

Addition of antioxidants is a common practice to increase stability of foodstuffs. In the case of paprika, the ascorbic acid content in the raw material (the red pepper fruits) could

be considered high (3–5 mg/g dry fruit), but during processing the fruit losses the main part of it (Daood and others 1996; Pérez-Gálvez and others 2004). Thus, addition of ascorbic acid to improve antioxidant capability of dry material could be considered as a reconstitution technique. This is useful in the sight of results described in some studies (Biacs and others 1992; Carvajal and others 1997). Other antioxidants used to improve coloring stability of paprika have been tocopherols, and rosemary extract, which showed different coloring protection properties depending on storage conditions. At temperatures higher than 25°C, the tocopherols display a marked protective effect, while at 5°C the rosemary extract has the strongest antioxidant action.

The protective effect of added antioxidants seems to depend on conditions used to store paprika like relative humidity and temperature. High humidity levels provide the proper environment where hydrophilic antioxidants (like ascorbic acid) could perform their antioxidant activity (Kanner and others 1978). When temperature increases, then the activity of the lipophilic antioxidants becomes the key as autoxidative reactions take place at higher rates. To achieve a wide range of antioxidant activity in different storage conditions, more than one antioxidant should be added (Ladrón-de-Guevara and others 2002).

In any case, addition of antioxidants is avoided due to labeling restrictions, mainly when the paprika is commercialized under PDO regulation. Moreover, use of other strategies to improve color stability should be more appropriate instead of reconstitution or adding antioxidants, in order to maintain authenticity of the product. One of these strategies could be the endogenous modification of the oxidation potential. If the lipophilic matrix of the food is prone to oxidation (high content of polyunsaturated fatty acids such as in paprika), changing that composition by a monounsaturated profile could minimize oxidative susceptibility (Pérez-Gálvez and others 1999b, 2000). This could be achieved by application of a breeding program where cultivars with a less polyunsaturated fatty acid profile should be selected.

The technological innovation in drying techniques and the study of the effect of dehydration on paprika compounds should not stop at the characterization of product immediately after processing, but also analyses during storage should be performed. Application of different techniques could change the behavior of stability as this highly depends on temperature–time regimes of dehydration (Ramesh and others 2001; Ade-Omowaye and others 2003). Therefore, quality of the product, in terms of carotenoid retention, should not only be based on coloring capacity but also on the stability of that quality attribute during storage. This point will be discussed below.

93.4 DETERMINATION OF QUALITY OF PAPRIKA

Measurement of color is the reference for determining economical value of paprika. The higher coloring capacity the higher price. Several straightforward standard procedures for determination of coloring capacity have been developed to obtain values of that capacity that allows ranking of different batches of paprika. Hence, "Standard" method determines the color value by measuring the absorbance of a 1/10,000 solution of a known weight of paprika in acetone at 462 nm, multiplying the result by 66,000 and divided by sample weight to obtain a standard color value (Guenther 1948). ASTA method consists of a color extraction of a weighed paprika sample with 100 mL acetone during 24 h. An aliquot of that solution (10 mL) is diluted again to 100 mL, and a portion of the diluted solution is used for the spectrophotometric measurement at 460 nm. ASTA units are

calculated by multiplying the absorbance by 164 and divided by sample weight (ASTA 1986).

Other spectrophotometric approaches have been achieved to obtain a more approximated carotenoid composition of paprika, as the abovementioned methodologies only give a global value of color provided by all carotenoids of the sample. The method developed by Hornero-Méndez and Mínguez-Mosquera (2001) allows a simultaneous quantification of the red and yellow fractions with low error in the determination and lower time analysis in comparison with that of chromatographic methods. But quality determination of a sample based on a spectrophotometric measurement gives only an isolated static idea of it without possibilities of prediction of its evolution with time. Measurement of promoter components of degradative reactions such as peroxides could help to infer the potential stability of paprika.

Hornero-Méndez and others (2001) have developed a simple spectrophotometric method for determination of peroxide value in paprika samples that may help to that purpose. Individual determination of carotenoid composition of sample by using chromatographic methods provides a more detailed information about the carotenoid profile, the provitamin A activity, and the extent of degradative reactions affecting yellow and red isochromic fractions. Ratio between the two fractions should remain invariable if the processing does not affect the two fractions, or to the same extent if it affects initial ratio value. This ratio has been proposed as a useful quality index either for the fruits or their processed products (Mínguez-Mosquera and Fernández-Díez 1981; Mínguez-Mosquera and others 1984, 1992). It is known that yellow fraction is more prone to oxidation than the red one, so a high value of the ratio should indicate that degradative reactions have taken place. Other predictive tools for assessing stability of carotenoids during storage have also been established (Jarén-Galán and others 1999). On the other hand, the red to yellow ratio may vary if commercial pigments, like canthaxanthin and β-apo-8′-carotenal, or other carotenoid rich sources like tomato, are added to enhance the red hue. In this case the application of HPLC methodologies has been demonstrated to succeed on this fraud detection (Mínguez-Mosquera and others 1995).

94.1 QUALITY ASSURANCE

94.1.1 Introduction

This section is not designed to explain how pickles are manufactured in the United States. Rather, it is designed to show you the critical factors you should look for in assuring the quality of your pickles. The information has been modified from a document issued by the United States Department of Agriculture: *United States Standards for Grades of Pickles*. Consult the original document for complete details.

This section contains 11 tables of reference data, numbering 94.1 to 94.11 and they do not appear in the same order as the text.

94.1.2 Product Description

Pickles means the product prepared entirely or predominantly from cucumbers (*Cucumis sativus* L). Clean, sound ingredients are used that may or may not have been previously subjected to fermentation and curing in a salt brine. The product is prepared and preserved through natural or controlled fermentation or by direct addition of vinegar to an equilibrated pH of 4.6 or below. The equilibrated pH value must be maintained for the storage life of the product. The product may be further preserved by pasteurization with heat, or refrigeration and may contain other vegetables, nutritive sweeteners, seasonings, flavorings, spices, and other permissible ingredients defined by the U.S. Food and Drug Administration (FDA). The product is packed in commercially suitable containers to assure preservation.

94.1.3 Styles of Pickles

1. Whole style means the pickles are whole and are relatively uniform in diameter as indicated in a latter discussion (Table 94.2).
2. Whole, mixed sizes style means the pickles are whole pickles of mixed sizes.

3. Sliced lengthwise style means the pickles are cut longitudinally into halves, quarters, or other triangular shapes (spears, strips, or fingers), or otherwise into units with parallel surfaces with or without ends removed.
4. Sliced crosswise, crosscut, or waffle cut style means the pickles are cut into slices transversely to the longitudinal axis. The cut surfaces may have flat-parallel or corrugated-parallel surfaces.
5. Cut style means the pickles are cut into chunks or pieces that are of various sizes and shapes.
6. Relish style means finely cut or finely chopped pickles containing no less than 60% of cucumber ingredient and may contain other vegetable ingredients (cauliflower, onions, pepper, tomatoes, cabbage, olives, mustard, or any other suitable vegetable).

94.1.4 Types of Pack

94.1.4.1 Cured Type. The pickles are cured by natural or controlled fermentation ina salt brine solution and may contain the dill herb or extracts thereof. The pickle ingredient may be partially desalted. The pickles may be further processed or preserved by the addition of vinegar and may contain other ingredients (spices, flavorings, firming and preserving agents) that constitute the characteristics of the particular type of pickle. The pickles are preserved by acidification to maintain an equilibrated pH of 4.6 or below. The characteristics of the various types of cured pickles are as follows:

1. Dill pickles (natural or genuine) are cucumbers that are cured in a brine solution with dill herb and other flavoring agents.
2. Dill pickles (processed) are brine-cured pickles that have undergone a freshening process and are packed in a vinegar solution with dill flavoring and other flavoring agents.
3. Sour pickles are cured pickles that are packed in a vinegar solution with or without spices.
4. Sweet pickles and mild sweet pickles are cured pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s).
5. Sour mixed pickles are cured pickles that are packed in a vinegar solution. The pickles may be of any style or combination of styles other than relish and may contain other vegetable ingredients as outlined in Table 94.1 or any other suitable vegetable.
6. Sweet mixed pickles and mild sweet mixed pickles are cured pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s). The pickles may be of any style or combination of styles other than relish and may contain other vegetable ingredients as outlined in Table 94.1 or any other suitable vegetable.
7. Sour mustard pickles or sour chow chow pickles are cured pickles of the same styles and ingredients as sour mixed pickles except the pickles are packed in a prepared mustard sauce of proper consistency with or without spices and flavorings.
8. Sweet mustard pickles or sweet chow chow pickles are cured pickles of the same styles and ingredients as sweet mixed pickles except the pickles are packed in a sweetened, prepared mustard sauce of proper consistency with or without spices and flavorings.

TABLE 94.1 Proportions of Pickle Ingredients in Certain Types and Styles.

	Cured; Fresh-pack; and Refrigerated Types	
	Sour Mixed; Sweet Mixed; and Mild Sweet Mixed; Sour Mustard or Sour Chow Chow; Sweet Mustard or Sweet Chow Chow	Sour Pickle Relish; Sweet Pickle Relish; Dill Relish; Hamburger Relish; Mustard Relish
Pickle Ingredients and Styles	Percent by Weight of Drained Weight of Product	
Cucumbers, any style other than relish	60–80%	–
Cucumbers, chopped or finely cut	–	60–100%
Cauliflower pieces	10–30%	–
Cauliflower, chopped of finely cut	–	30% maximum (optional)
Onions, whole (maximum diameter of $1-\frac{1}{4}$ inches), sliced or cut	5–12%	–
Onions chopped or finely cut	–	12% maximum (optional)
Green tomatoes, whole or pieces	10% maximum (optional)	–
Green tomatoes, chopped or finely cut	–	10% maximum (optional)
Red, green, or yellow peppers. or pimientos, cut, finely cut or pieces	Optional	Optional
Celery	Optional	Optional
Cabbage	Optional	Optional
Olives	Optional	Optional
Tomato paste	Optional	Required in hamburger relish
Mustard or prepared mustard	Required in chow chow and mustard pickles	Required in mustard relish, optional in hamburger relish

9. Sour pickle relish consists of finely cut or chopped cured pickles that are packed in a vinegar solution. Sour pickle relish may contain other chopped or finely cut vegetable ingredients as listed in Table 94.1, and may contain a stabilizer such as a starch or gum.
10. Sweet pickle relish and mild sweet pickle relish are finely cut or chopped cured pickles that are packed in a vinegar solution with a suitable nutritive sweetening ingredient(s). Sweet pickle relish and mild sweet pickle relish may contain other chopped or finely cut vegetable ingredients as listed in Table 94.1 and may contain a stabilizer such as a starch or gum.
11. Hamburger relish consists of relish style pickles and other chopped or finely cut vegetable ingredients as listed in Table 94.1 with tomato product added.
12. Mustard relish consists of sweet pickle relish with mustard and other chopped or finely cut vegetable ingredients as listed in Table 94.1.
13. Dill relish consists of relish style pickles containing dill flavoring and other chopped or finely cut vegetable ingredients as listed in Table 94.1.

94.1.4.2 Fresh-Pack Type. The pickles are prepared from uncured, unfermented cucumbers and are packed in a vinegar solution with other ingredients to produce the characteristics of the particular type of pack. The pickles are preserved by acidification to maintain an equilibrated pH of 4.6 or below. In addition, the pickles are sufficiently

processed by heat to assure preservation of the product in hermetically sealed containers. The distinguishing characteristics of the various types of fresh-pack pickles areas follows:

1. Fresh-pack dill pickles are pickles that are packed in a vinegar solution with dill flavoring.
2. Fresh-pack sweetened dill pickles are pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s) and dill flavoring.
3. Fresh-pack sweetened dill relish consists of finely cut or chopped pickles packed in a vinegar solution with suitable nutritive sweetening ingredient(s) and dill flavoring. The relish may contain other finely cut or chopped vegetable ingredients as listed in Table 94.1.
4. Fresh-pack sweet pickles and fresh-pack mild sweet pickles are pickles that are packed in a vinegar solution with nutritive sweetening ingredient(s).
5. Fresh-pack sweet pickle relish and fresh-pack mild sweet pickle relish consists of finely cut or chopped pickles that are packed in a vinegar solution with suitable nutritive sweetening ingredient(s). The relish may contain other finely cut or chopped vegetable ingredients as listed in Table 94.1.
6. Fresh-pack hamburger relish consists of relish style pickles and other chopped or finely cut vegetable ingredients as listed in Table 94.1 with tomato product added.
7. Fresh-pack mustard relish consists of sweet pickle relish with mustard and other chopped or finely cut vegetable ingredients as listed in Table 94.1.
8. Fresh-pack dill relish consists of relish style pickles containing dill flavoring and other chopped or finely cut vegetable ingredients as listed in Table 94.1.
9. Fresh-pack dietetic pickles are pickles that are packed with or without the addition of sweetening ingredient(s), salt (NaCl), or other suitable ingredient(s) as declared and permitted under FDA regulations.

94.1.4.3 Refrigerated Type. The pickles are prepared from fresh cucumbers and are packed in a vinegar solution with other ingredients to produce the fresh crisp characteristic of refrigerated type. The pickles are preserved by acidification to maintain an equilibrated pH of 4.6 or below. They are stored, distributed, and displayed under refrigeration and may or may not contain one or more chemical preservatives. The various types of refrigerated pickles are the same as the types listed for fresh-pack type in earlier discussion with respect to ingredients except that they conform to the requirements for refrigerated type.

94.1.5 Sizes of Whole Pickles

Sizes of whole pickles are based on the diameter and the relationship of diameter to the count per gallon. Size designations, applicable counts, and diameters are outlined in Table 94.2 of this subpart. The diameter of a whole cucumber is the shortest diameter at the greatest circumference measured at right angles to the longitudinal axis of the cucumber.

94.1.6 Definitions of Terms

For an interpretation of this standard, some definitions of terms are:

TABLE 94.2 Sizes of Processed Whole Pickles.

		Glass			Metal	
Word Designation	Diameter	1 qt.	$\frac{1}{2}$ gal	1 gal	No. 10	No. 12 (1 gal)
Midget	19 mm (0.75 in) or less	67 or more	135 or more	270 or more	202 or more	270 or more
Small gherkin	Up to 2.4 cm (0.94 in)	33–66	67–134	135–269	101–201	135–269
Large gherkin	Up to 2.7 cm (1.06 in)	16–32	32–66	65–134	48–100	65–134
Small	Over 2.7 cm (1.06 in) but not over 3.5 cm (1.38 in)	10–15	20–31	40–64	30–47	40–64
Medium	Over 3.5 cm (1.38 in) but not over 3.8 cm (1.50 in)	6–9	13–19	26–39	19–29	26–39
Large	Over 3.8 cm (1.50 in) but not over 4.4 cm (1.73 in)	4–5	9–13	18–25	13–18	18–25
Extra large	Over 4.4 cm (1.73 in)	2–3	6–8	12–17	9–12	12–17

94.1.6.1 Analytical Definitions. Analytical definitions refer to analytical laboratory requirements.

1. Acid means total acidity calculated as acetic acid in accordance with the Official Methods of Analysis of the Association of Official Analytical Chemists (AOAC).
2. Brix value (Brix) means the percent sugar, by weight, corrected to 20°C (68°F), as determined with a sugar scale Brix hydrometer or other instrument that gives equivalent results.
3. Degrees Baumé means the density of the packing medium determined with a Baume' hydrometer (modulus 145) corrected to 20°C (68°F).
4. Equalization means the natural (osmotic) or simulated blending between the soluble solids of the pickle ingredient and the packing medium.

Natural equalization means equalization brought about after a period of time has elapsed after processing as follows. Sweetened pickles are considered to be equalized 15 days or more after processing. If the pickles have been sweetened in a tank prior to packing, the pickles will be considered equalized 15 days after the sweetening process began. Sour and dill pickles are considered to be equalized 10 days or more after processing.

Simulated equalization means a method of simulating equalization by comminuting the finished product in a mechanical blender, filtering the suspended material from the comminuted mixture and making the required tests on the filtrate.

5. Total chlorides or salt means the salt content expressed as grams NaCl (sodium chloride) per 100 mL packing medium; except that total chlorides in mustard pickles and chow is determined and expressed in grams NaCl per 100 g of product.

94.1.6.2 Blemished. Blemished means any unit that is affected by discoloration, pathological injury, insect injury, or similar causes to the extent that the appearance or edibility of the product is adversely affected:

1. Slightly – those blemishes which detract only slightly from the appearance of the unit;
2. Seriously – those blemishes which strongly detract from the appearance or edibility of the unit.

94.1.6.3 Color.

1. Good color in cured type means the typical skin color of the pickles ranges from a translucent light green to dark green and is practically free from bleached areas. Not more than 10%, by weight, of the pickles may vary markedly from such typical color. In mixed pickles, chow chow pickles, and pickle relish, all of the ingredients possess apractically uniform color typical for the respective ingredient. The pickles and other vegetable ingredients shall be free of off-colors.
2. Good color in fresh-pack and refrigerated types means the typical skin color of the pickles ranges from an opaque yellow-green to green. Not more than 15%, by weight, of the pickles may vary markedly from such typical color. In pickle relish, all of the ingredients possess a good uniform color typical for the respective ingredient. The pickles and other vegetable ingredients shall be free of off-colors.
3. Reasonably good color in cured type means the typical skin color of the pickles ranges from light green to dark green and is reasonably free from bleached areas. Not more than 25%, by weight, of the pickles may vary markedly from such typical color. In mixed pickles, chow chow pickles, and pickle relish, all of the ingredients possess a reasonably uniform color typical for the respective ingredient. The pickles and other vegetable ingredients shall be free of off-colors.
4. Reasonably good color in fresh-pack and refrigerated types means the typical skin color of the pickles ranges from light yellow-green to green. Not more than 30%, by weight, of the pickles may vary markedly from such typical color. In pickle relish, all of the ingredients possess a good, fairly uniform color typical for the respective ingredient. The pickles and other vegetable ingredients shall be free of off-colors.
5. Poor color in all types of pickles means the pickles fail to meet the requirements for good or reasonably good color for the respective type.

94.1.6.4 Shape. (Also see the definition of misshapen.) Crooked pickles mean whole pickles that are curved at an angle greater than 60° as illustrated in Figure 94.1.

Curved pickles mean whole pickles that are curved at an angle of 35–60° when measured as illustrated by Figure 94.2.

Diameter in whole style means the shortest diameter measured transversely to the longitudinal axis at the greatest circumference of the pickle. Diameter in cross-cut style is the shortest diameter of the largest cut surface.

Defect means an imperfection such as curved, misshapen, mechanically damaged, discolored, and other imperfection that affects the appearance or edibility of the product.

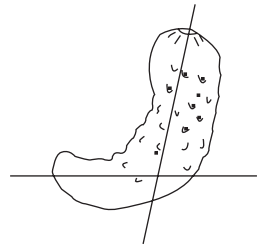

Figure 94.1 *Crooked pickles (also see the definition of misshapen).*

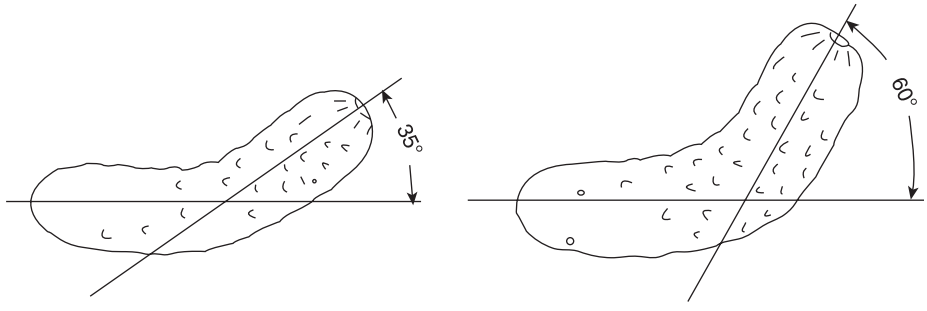

Figure 94.2 *Curved pickles.*

End cut means a pickle unit intended for crosscut (sliced crosswise) style that has only one cut surface.

Extraneous vegetable material (EVM) means any harmless vegetable material, other than stems, that is not normally part of the pickle ingredient. EVM such as leaves or other vegetable material not associated with proper pickle preparation or packaging is considered a defect if it affects the appearance or edibility of the product either:

Slightly – Practically free of EVM and does not more than slightly affect the appearance or edibility; or

Materially – Reasonably free of EVM and does not more than materially affect the appearance or edibility.

94.1.6.5 Flavor and Odor

1. Good flavor and odor means characteristic flavor and odor (e.g., characteristic dill flavor or the like) typical of properly processed pickles, for the type, that is free from objectionable flavor and odor of any kind.
2. Reasonably good flavor and odor means flavor and odor that may be lacking in characteristic flavor for the type but is free from objectionable flavor and odor.
3. Poor flavor and odor means flavor and odor that fails to meet the requirements for good or reasonably good flavor and odor.

Length in sliced lengthwise style means the longest straight measurement at the approximate longitudinal axis.

Mechanical damage refers to crushed or broken units that affect the appearance of the units. In relish, mechanical damage refers to units which are poorly cut and have a ragged or torn appearance.

Misshapen pickles mean whole pickles that are crooked or otherwise deformed (such as nubbins). Also see the definition for crooked pickles.

Nubbin is a misshapen pickle that is not cylindrical in form, is short and stubby, or is not well developed.

Texture means the firmness, crispness, and condition of the pickles and any other vegetable ingredient(s) and freedom from large seeds, detached seeds, and tough skins that may be present. The following terms also relate to texture:

1. Hollow centers in whole style, means the pickles, when cut transversely to the longitudinal axis, are missing $\frac{1}{3}$ or more of the seed cavity.
2. Soft, shriveled, and slippery units refers to pickles that are wrinkled, not crisp, slick, flabby, or lack firmness.
3. Good texture means the pickle units have been properly processed and possess a texture that is firm and crisp.
4. Reasonably good texture means the pickle units have been properly processed but lack some of the firmness and crispness that is characteristic for the style and type of pack.
5. Poor texture means the pickle units do not meet the requirements for good or reasonably good texture.

Uniformity of size (relish style only).

1. Practically uniform in size means the size of the units may vary moderately in size but not to the extent that the appearance or the eating quality is seriously affected.
2. Poor uniformity of size means the units fail the requirements for practically uniform.

Unit means one whole, half, slice, or piece of pickle as applicable for the style.

Units missing $\frac{1}{3}$ or more of the seed cavity in crosscut style means pickles that have lost a substantial portion of the seed cavity such as a crosscut unit missing $\frac{1}{3}$ or more of the seed cavity portion.

94.1.7 Recommended Fill of Container

The recommended fill of container is not a factor of quality for the purposes of these grades. Each container of pickles should be filled with pickle ingredient, as full as practicable, without impairment of quality. The product and packing medium should occupy not less than 90% of the total capacity of the container.

94.1.8 Quantity of Pickle Ingredient

The recommended minimum quantity of pickle ingredient is designated as the percentage of the declared volume of product in the container for all items except pickle relish. Minimum quantity of pickle relish is designated as a relationship of the drained weight of the pickle ingredient to the declared volume of the container. The minimum quantities recommended in Tables 94.3 and 94.4 are not factors of quality for the purposes of these grades.

TABLE 94.3 Recommended Pickle Ingredients: All Styles Except Relish.

Type of Pack	Minimum Fill (Volume)
Cured	55%
Fresh-pack	57%
Refrigerated	57%

TABLE 94.4 Recommended Drained Weight to Container Volume, Relish.

Type of Pack	Minimum Fill (Weight/Volume)
Cured	
Sweet	92%
Other than sweet	88%
Fresh-pack	
Sweet	85%
Other than sweet	80%

The percent volume of pickle ingredient is determined for all styles, except relish, by one of the following methods in accordance with the procedures prescribed by the USDA:

1. Direct displacement (overflow-can method);
2. Displacement in a graduated cylinder;
3. Measurement of pickle liquid;
4. Any other method that gives equivalent results and is approved by the USDA.

94.1.8.1 Drained Weight/Volume. The percent weight/volume (w/v) of relish shown in Table 94.4, is determined as follows: The drained weight of pickle relish of all types is determined by emptying the contents of the container upon a U.S. Standard No. 8 circular sieve of proper diameter containing eight meshes to the inch (0.0937 inch $\pm$ 3%, square openings) so as to distribute the product evenly, inclining the sieve slightly to facilitate drainage, and allowing to drain for 2 min. The drained weight is the weight of the sieve and the pickles less the weight of the dry sieve. A sieve 8 inches in diameter is used for 1 quart and smaller size containers and a sieve 12 inches in diameter is used for containers larger than 1 quart in size.

94.1.9 Sample Unit Size

For all styles of pickles and types of pack, the sample unit used in analyzing the quality factors is the entire contents of the container unless otherwise specified in CFR Part 7.

94.1.10 Grades

1. U.S. Grade A is the quality of pickles that meets the applicable requirements of Tables 94.5–94.11 and scores not less than 90 points.

TABLE 94.5 Analytical Requirements: [a]Cured Type Pickles, all Styles.

	Maximum		Minimum	
	Total Acidity Expressed as Acetic Acid g/100 mL, Unless Otherwise Indicated	Total Chlorides Expressed as NaCl g/100 mL, Unless Otherwise Indicated	Degrees Brix	Degrees Baumé
Cured type all styles		–	–	–
Dills (natural, genuine or processed)	1.1	5.0	–	–
Sour, sour mixed, dill pickle relish, sour relish	2.7	5.0		–
Sweet whole, sweet mixed, and sweet relish	2.7	3.0	27.0	15.0
Mild sweet, mild sweet mixed, mild sweet relish	–	–	20.0	12.0
Sour mustard or sour chow chow	2.7[b]	3.0[b]	–	–
Sweet mustard or sweet chow chow	2.7[b]	3.0[b]	28.0	15.5
Fresh-pack and refrigerated types, all styles	–	–	–	–
Dills and sweetened dills	1.1	4.25	–	–
Sweetened dill relish	1.1	4.25	–	–
Sweet and mild sweet relish	1.65	2.75	–	–
Sweet and mild sweet pickles	1.65	2.75	–	–
Dietetic	–	–	–	–

[a]All pickle products must have an equilibrated pH of 4.6 or below.
[b]Expressed as g/100 g.

2. U.S. Grade B is the quality of pickles that meets the applicable requirements of Tables 94.6–94.11 and scores not less than 80 points.
3. Substandard is the quality of pickles that fails the requirements of U.S. Grade B.

94.1.11 Factors of Quality

The grade of pickles is based on the following quality factors:

1. Analytical requirements in Table 94.5
2. Flavor and odor
3. Color
4. Uniformity of size
5. Defects
6. Texture

94.1.12 Requirements for Grades

See Tables 94.5–94.11.

TABLE 94.6 Quality Requirements: Whole Style Pickles.

94.2 ESTABLISHMENT INSPECTION

The United States Food and Drug Administration has issued guidelines for the inspection of a pickles processing plant. Some of the information is provided in this chapter. The quality control officer in such a plant should use the information to implement its in-plant inspection procedure.

The information is presented in the teacher/student format for ease of reference.

1. Direct special attention to the following areas when inspecting these types of food establishments. If the establishment is producing acidified Fresh Pack Pickles, determine if the establishment is complying with the requirements of 21 CFR 114, Acidified Foods.
2. Salt Stations and Salt Stock Tanks.
3. Insects which breed in decomposed pickles or other decaying organic matter such as the lesser or little house fly, the latrine fly, the house fly, the rat-tailed maggot, and

[a]Cannot be graded above U.S. Grade B, regardless of the total score.
[b]Total score is adjusted by dividing the total score by 0.80 to allow for the absence of the quality factor of uniformity of size in whole mixed sizes style.

drosophila are of major sanitary significance. Examine 25% of the tanks for insect filth.

4. "Mill run" salt may be used but workers should not walk in the salt.
5. Tanks should be skimmed daily for debris and insects and the skimmings should be properly disposed of.
6. Newly salted stock ferments – scum growth should be removed regularly and disposed of so that insects are not attracted.

94.2.1 Pickle Products

94.2.1.1 Examination of Raw Materials Used in Relish

1. Obtain the usual composition of relish in percent by weight of cucumbers as well as other ingredients to help appraise the filth load found in the sample.
2. Salt stock used for relish may consist of poor quality pickles, that is, deformed, bloated, or blemished. However, in the absence of filth, grit, or partly/wholly rotted pickles, there is no objection to their use. Mushy pickles are caused by certain pectin splitting enzymes during fermentation. Soft pickles may be invaded by bacteria and fungi, but it is frequently difficult to determine if any mold or bacteria are present by field examination.

TABLE 94.8 Quality Requirements: Sliced Lengthwise Style Pickles.

3. Examination of cucumber salt stock for relish – when whole pickles or large pieces are used, examine a representative sample of 100 units going to chopper.
4. Segregate and list objectionable pickles as follows:

94.2.1.2 Class

	Number	*Percent*
1. With rot spots over 1/2 in.	_____	_____
2. Insect infested or damaged	_____	_____
3. Mushy or very soft	_____	_____

4. For class 1 pickles, make a further determination of the surface area of the rot spots by size; up to 1 inch; from 1 inch to half of the pickle; and over half of the pickle. Take close-up color photographs of objectionable pickles. Collect exhibits of pickles showing typical rot and insect damage.
5. Laboratory examination of mushy pickles for mold is necessary to establish if they are objectionable. If over 5% of the units are mushy, cut a thin cross-section from each pickle. Place the slices in a quart jar with water and add 20 cc formaldehyde for later examination.

[a]Cannot be graded above U.S. Grade B, regardless of the total score.
[b]Pickles that are substandard for uniformity of size cannot be graded above U.S. Grade B, regardless of the total score.

6. When small pieces of salt stock cucumbers, cauliflower, and peppers are used, rot determination by count is impractical. If rotten pieces are observed, collect a separate quart of each pickled vegetable. Preserve the samples with 20 cc formaldehyde. At the same time collect a sample totaling half a gallon of finished relish.

94.2.2 Peppers

1. Check for insect larvae (maggots or larvae of pepper weevil) in fresh and salt stock peppers and figure percent of infestation on a representative sample. Examine any fresh pack peppers in which infested stock was used.
2. If peppers with rot are found, evaluate in the same fashion as for cucumbers.
3. Examine vinegar storage tanks for drosophila infestation and for vinegar eels.
4. Insect filth in sweet stock pickles – insects, particularly drosophila, are attracted to the sweetening tanks, and may be found in the finished sweet pickle products.
5. Sweet brine is frequently circulated within a tank and from one tank to another dispersing insects in the circulating brine. It is sometimes difficult to estimate the

number of insects and parts in such circulating brine. Close examination of the inside tank walls may reveal drosophila above the brine level. These are the best indices of infestation in a tank.

94.2.3 When Insects are Found in a Sweetening Tank

1. Determine whether sweet brine in the tank is an intermediate or finishing brine and if it is circulated within the tank or between sweetening tanks.
2. If the finishing brine is used as a packing medium, determine whether it is filtered prior to use and evaluate the filtration step.
3. If sweet stock is held in infested tanks, determine anticipated date of packing.
4. Evaluate tank covers used.
5. List quantitatively, the extent of insect infestation by the collection of representative samples of filth from a definite area, for example, square feet of the walls of the tank on the sweet stock and in a specified amount of brine from different areas of the tank if the infestation is widespread. If infestation seems to be isolated, collect specimens showing the types of insects.

94.2.4 Other Points of Interest

1. Grit in pickles – excessive grit is frequently found in fresh pack pickles and in midget sweet pickles. Salt stock may occasionally contain excessive grit. If dirty cucumbers are packed, collect in-line and finished product samples.
2. Use of color and preservatives – green artificial color is sometimes used in relish without label declaration. Ascertain if the color is permitted for use and declared on the label.
3. Sorbic acid may be used in salt stock, to prevent yeast growth, and in finished pickle products, as a preservative. Where sorbic acid is present in the finished product, determine if it is declared on the label.
4. Examination of warehouse stocks – examine for evidence of spoilage, particularly in fresh pack pickles which may have been inadequately pasteurized.
5. If heavy insect infestation is found, examine 24 jars of the pickle product (other than relish) most likely to contain insects by inverting jars under strong light. Collect jars containing insects as a factory sample.

94.2.5 Sample Collection

94.2.5.1 Bulk Salt Stock for Filth. If in barrels, collect a minimum of 12 half-gallon jars of salt with their brine; two from each of six previously unopened barrels to make six duplicate subs. Collect one sub from the top and the other sub from the bottom, if possible. If in tank cars, collect a minimum of $12\frac{1}{2}$ gallon jars of salt stock and brine. If live flies are observed inside tank during sampling, note and estimate their number.

94.2.5.2 Finished Pickle Product — All Types.

Filth and Grit

Quarts and smaller jars	Minimum to collect
Up to100 cases in lot	24 jars
More than 100 cases	48 jars

Gall on jars	Minimum to collect
Up to 100 cases	12 jars
More than 100 cases	24 jars

Undeclared Color and Chemical Additives. Collect 6 quarts or 12 pints for examination.

95.1 INTRODUCTION

Availability of soymilk and tofu has a long history, since the Han Dynasty in China about 2000 years ago. It has been an integral part of the Chinese food culture, and has also spread to Korea, Japan, and several Eastern Asian countries. It is generally believed that the absence of prolonged malnutrition in the China may be due to the regular consumption of soymilk, tofu, and other soyfoods in their diet. The consumption of tofu has gradually gained acceptance in the Western culture as some of its nutritional and health benefits are now known. It is also popular among vegetarian consumers.

The main components in soymilk and tofu are water, protein, fat, and minerals. Its protein profile is not as good as milk and egg proteins but is probably the best among foods of plant origin. Soymilk is often referred to as "poor man's milk." Dieticians also consider tofu made with calcium salts as a good source of calcium. The U.S. Food and Drug Administration approved a health claim for processed foods containing soy proteins that states "consumption of 25 g soy proteins per day in conjunction with a low cholesterol diet would reduce the risk of heart disease."

The availability of tofu in various parts of the world is credited to the migration of East Asian peoples to the different countries, and also to the development of semi- to fully-automatic machines to make tofu by the Japanese. Many people can claim they can make tofu. However, making tofu with consistent quality is not that easy, even though tofu making consists of only two basic steps: preparation of soymilk and coagulation of soymilk to form the curd which is then made into various types of tofu. Many processing factors are involved in the preparation of tofu and the raw bean components are also determinant factors on the quality of tofu.

Three books contain information on soymilk and tofu making, including the The Science of Tofu (Watanabe 1997), the Tofu & Soymilk Production, the Book of Tofu, Volume 2 (Shurtleff and Aoyagi 1990), and the 'Soybeans: Chemistry, Technology and Utilization,' (Liu 1997). Two recent reviews on the science and technology of tofu making are also available (Chang and Hou 2004; Chang 2006). Soymilk is an intermediate product for tofu making. The technology for making soymilk for tofu making is similar to that for making the unflavored plain soymilk products (Chen 1989). This chapter will focus on the basics in the making plain soymilk, which can be used as the base for flavored soymilk products, and on tofu and the factors affecting tofu production and quality from a different approach.

95.2 THE MANUFACTURE OF SOYMILK AND TOFU

There are many methods for producing soymilk (Chen 1989). There are several types of tofu produced nowadays. They are momen (firm or extra firm) tofu, soft tofu, silken (Kinugoshi) tofu, and fill-packed silken tofu. These tofu products are usually packed in trays with water, pasteurized and kept refrigerated in display chambers in retail stores for sell in developed countries. They have a shelf-life of about 3 weeks under proper refrigeration. However, in some countries, they may be sold as fresh tofu in plastic bags or containers with water, or even just cut into smaller blocks as ordered by the consumers. These types of tofu have a short shelf-life, 1–3 days under proper refrigeration. Filled silken tofu has been sterilized and is shelf-stable for 6 months or longer under refrigeration.

Figure 95.1 presents a generalized flowchart in the preparation of soymilk and Figures 95.2–95.4 are schematic diagrams on the manufacture of various types of tofu from soymilk.

95.2.1 Preparation of Soymilk

95.2.1.1 Cleaning and Soaking. Raw soybeans are first cleaned to remove all the foreign matters, followed by soaking the cleaned beans in water to allow the dry beans to absorb enough water before grinding. Soaking time is dependent upon soaking

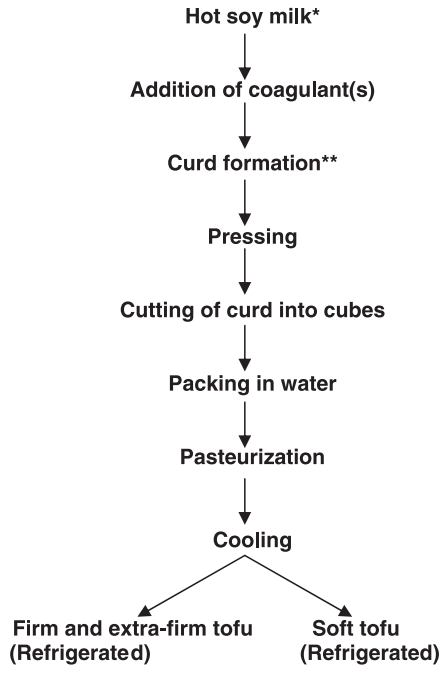

Figure 95.2 *Manufacture of momen tofu.*

temperature. Usually this soaking process takes 8–10 h at 15–20°C or 12–16 h at 10–15°C. This difference is due to ambient temperature difference at various locations of the manufacturing plant. On the other hand, soaking could be done at a low temperature

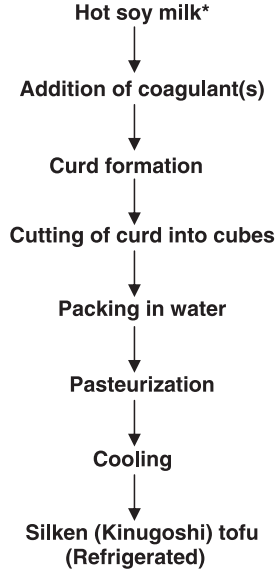

Figure 95.3 *Manufacture of silken (Kinugoshi) tofu.*

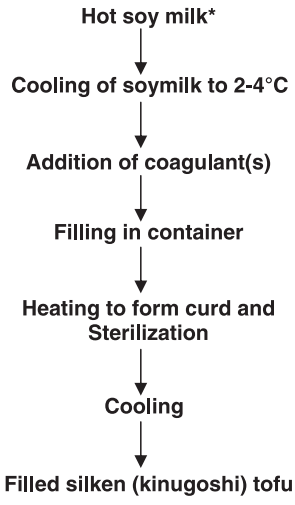

Figure 95.4 *Manufacture of filled silken tofu.*

(2–4°C) to prevent off-flavor development during soaking and grinding. After soaking, the beans weigh approximately 2.2–2.3 times their initial weight. When water is absorbed, it rehydrates the various components in the dry beans making it easy to be dissolved or dispersed in water during the grinding process. Soymilk for tofu making also could be made from soybean powder or soybean flakes (Moizuddin and others 1999) that require less time to rehydrate. In addition, dry unsoaked soybeans or dehulled soybeans can be partially soaked at high temperature for a very short time and milled with hot water (80°C) to extract soymilk with a low beany flavor (Wilkens and others 1967). However, such practice will reduce the yield of soymilk. In preparing consumer soymilk products by some manufacturers, dehulling soybeans prior to extraction also removes germs (hypocotyls), and is carried out to improve the flavor of soymilk and to extend shelf-life.

95.2.1.2 Grinding. Grinding of soaked soybeans breaks down the intact structure of the dry beans. The amount of water added in the grinding process should be carefully controlled to meet the requirements for the different type of tofu to be manufactured. For example, the water dosage for silken tofu, soft tofu and regular tofu is 5, 7–8, and 10 times of raw soybean weight, respectively (Watanabe 1997). This will give soymilk with 9–13 °Brix or higher (see Figs. 95.2–95.4). Grinding can be conducted using a stone mill or stainless steel grinder. Solids content in °Brix can be rapidly measured using a hand-held refractometer for quality control. °Brix is proportionally related to soluble solid content of the soymilk.

Water soluble components such as sugars, amino acids, and water soluble vitamins dissolved in the water added during the grinding process. Proteins and lipids are dispersed in the slurry and the fibers are broken down to smaller particulates. Proper grinding gives appropriate small particle sizes in the slurry and facilitates the extraction of solids and nutrients into the soymilk. It is understandable that the finer the slurry, the more components can be extracted, but it makes it harder for the separation of the soymilk and the residue (*okara*). This will also affect the yield of soymilk.

95.2.1.3 Grinding Temperature. Temperature during grinding affects not only the flavor of the soymilk, but also texture of the resulting tofu. Obata and Matsuura (1993) reported that tofu firmness decreases as the grinding water temperature increases between 0°C and 50°C. They found that this is related to the contents of sulfhydryl (—SH) groups in soymilk that is critical in the curd formation process. Lipoxygenases in soybean decrease the availability of —SH groups in soymilk and makes the tofu less firm.

95.2.1.4 Water Added During Grinding. Tofu contains about 88–90% water. It has long been claimed that water from certain sources such as mountains and streams are better for making tofu. Water containing proper amount (about 100 mg/L) and balance of minerals, including calcium, magnesium, sodium, potassium, iron, and manganese provides a harmonious and mellow taste (Watanabe 1997). The amount of water absorbed during soaking and the amount added during grinding constitute the water-to-bean ratio. For regular tofu, a ratio of 10 : 1 is considered the best with recovered soymilk having 6.0–6.3% solids and 3.0% protein (Watanabe and others 1964). However, ratios of 5 : 1 to 7 : 1 are required for making soft or silken tofu (Saio 1979). For making filled tofu, soy isolate can be added to increase protein content thereby increasing firmness of tofu since pressing is not carried out in filled tofu.

95.2.1.5 Heating and Separation. Heating of the slurry or after separation of the soymilk and the residue serves several purposes:

- Inactivation of microorganisms;
- Improvement of nutritional quality of soymilk by inactivating the trypsin inhibitor (TI);
- Denaturation of proteins to facilitate their curdling in the presence of coagulant(s);
- Improvement on yield of soymilk;
- Reduction of beany flavor.

Abundant of microorganisms are present during the soaking process and introduced during grinding. Mild heating of the soymilk serves as a mechanism to reduce its microbial load, even though it will not destroy all the microorganisms at this stage.

One of the major disadvantages of soybeans is the natural presence of trypsin inhibitor (TI) that affects the digestion of proteins by trypsin. Typsin inhibitor is heat resistant. Upon heating, activity of this trypsin inhibitor can be reduced considerably. Chang and Hou (2004) summarized the effect of various combination of temperature and time of heating to reduce the TI activity. Watanabe (1997) recommends that heating soymilk for 3–5 min at 100°C is adequate for tofu making. Heating temperature and time range of 80–105°C for 4–20 min are used by tofu manufacturers. These heat treatments can reduce the TI activity considerably and at the same time facilitates the separation of soymilk and *okara* (residue). UHT processing has been recently used to heat soymilk in a very short time within one min depending upon temperature (135–150°C) (Kwok and others 1993, 2002; Rouhana and others 1996). The optimal residual trypsin inhibitor activity is in the range of 4–10%. However, UHT heating could result in significant trypsin inhibitor activities if not heated properly (Guo and others 1997a; Xu and others 2004). UHT processing of soymilk has been used to produce aseptically packaged tofu products (Alan and others 1999).

Soy proteins in their nature state maintain their globular structure with the hydrophobic regions wrapped inside. Upon heating, soy proteins are denatured, subsequently unfolding the natural molecules with exposure of the hydrophobic groups to the outside. Thus, protein solubility decreases owing to aggregation. The viscosity of soymilk is affected by heating procedure. A two-step heating method (70°C for 5–10 min followed by heating to 90°C for 5–10 min) resulted in a higher viscosity than that heated by one-step heating (90°C for 5–10 min) (Liu and others 2004; Liu and Chang 2004a).

For small quantity of slurry, separation of soymilk and residue (*okara*) can be accomplished by filtering the slurry in a cotton cloth or nylon bag accompanied by manual pressing. For large volume, it is accomplished by drum pressing, screw pressing, centrifugation, or shake filtration.

The Chinese procedure in the preparation of milk is to separate the soymilk from the residue (*okara*) first followed by heating the soymilk subsequently. However, the Japanese procedure is to heat the slurry first before separation of soymilk and *okara*. It is claimed that the Japanese procedure can increase the soymilk yield and reduce beany flavor. The *okara* contains 17% and 29% of the original protein and solids in the original soybeans, respectively. When the *okara* is rewashed and repressed, additonal 15–20% soymilk can be recovered (Shurtleff and Aoyagi 1990).

Soy products including tofu usually carry a beany flavor that is not familiar to the Western consumers and is a barrier for consumption. The presence of lipoxygenases in soybeans is the major cause of beany flavor in soy products including tofu. The iron-containing lipoxygenases catalyze the oxidation of polyunsaturated fatty acids such as linoleic acid, producing fatty acid hydroperoxides which are then broken to produce hexanal, the major compound of beany flavor in soy products.

Soybeans are known to be the most abundant source of lipoxygenases, with four isozymes, L-1, L-2, L-3, and L-4 (Axelrod and others 1981). L-3 and L-4 are very similar in behavior and composition and they are sometime considered as one isozyme, L-3. Heating is known to be capable of inactivating enzymes in the raw soymilk. L-1 is heat stable, with loss of activity of 50% at 69°C for 25 min (Christopher and others 1970), whereas L-2 and L-3 are much less heat stable with loss of activity of 50% at the same temperature for 0.7 min (Christopher and others 1970). L-1 has optimal activity at pH 9 and L-2 and L-3 at pH 7. L-2 and L-3 have more activity on fatty acids and triglycerides with increased activity at the presence of calcium ions. However, L-1 is more active on fatty acids, but not activated by calcium ions. Even though L-2 is the least abundant but has the highest specific activity at the positions of 9 and 13 of linoleic acid and is mainly responsible for the beany flavor (Christopher and Axelrod 1971; Christopher and others 1972; Takamura and others 1991).

The beany flavor can be developed rapidly when the substrate is available and the temperature is appropriate. For soymilk, it is at the grinding step where the enzyme, fatty acids and triglycerides are liberated with excess of water present. Wilkens and others (1967) found that when the grinding temperature is at 80°C, no volatiles are formed. Several techniques are developed to overcome this beany flavor by heating the soybeans mildly, adjusting the moisture or pH, or using aqueous alcohol to soak the soybeans or their combinations (Hajika and others 1995; Trawatha and others 1995). Soybean cultivars with the absence of lipoxygeanses are also available (Wilson 1996). Soymilk

made from lipoxygenase-free cultivars has the same functional properties, less beany flavor and less astringency as compared to soybeans made from regular soybeans, but the soymilk is rated more yellow and darker (Torres-Penaranda and others 1998). Fatty acids also play an important role in generating beany flavor compounds in addition to lipoxygenases (Yuan and Chang 2007a). Hexanal can be produced by lipoxygenases-null cultivars by autoxidation of unsaturated fatty acids, particularly the linoleic acids (Yuan and Chang 2005a,b, 2007a).

Besides contributing to the beany flavor in soymilk, lipoxygenases have also been found to affect tofu texture (Obata and Matsuura 1993; Obata and others 1996). During grinding of soaked soybean at 2–50°C, lipoxygenases not only oxidize lipids to hydroperoxides, but also subsequently oxidize the free –SH groups liberated from the denatured proteins to disulfide bonds, and possibly cysteinic or cysteic acids. Oxidation of the –SH groups affects their availability to participate in the interchange of free –SH groups with disulfide bonds during heating to form the protein networks, thereby decreasing the firmness of the tofu products. Firmer tofu products can be prepared by grinding soybeans under anaeorbic conditions. Among the lipoxygenase isozymes, L-2 has the greatest SH-degrading capacity.

95.2.2 Coagulation of Soymilk

Coagulation of soymilk to form the curd is the most critical and difficult step in tofu manufacturing as there are many interdependant variables that can affect the outcome of coagulation. These are

- Solid content and pH of soymilk;
- Types and amount of coagulant(s) used;
- Temperature;
- Coagulation method;
- Cutting or breaking curd; and
- Pressing.

95.2.2.1 Solids Content and pH of Soymilk. Soymilk for tofu manufacturing has solid concentration ranging between 9–13 °Brix. For regular or firm (*momen*) tofu manufacturing, it is between 9–10 °Brix. For making silken (Kinugoshi) and filled silken tofu, it is 13° or higher, and for making soft tofu, it is 10–12°Brix. In the making of regular or firm tofu, even though it requires a lower solid content in the soymilk, it takes longer time to coagulate the curd and thus more solids can be coagulated. In addition, it requires pressing to firm the tofu. For making soft tofu, a higher solid content requires shorter coagulation time as compared to the regular or firm tofu. For silken tofu, the soymilk is coagulated without the excretion of whey and there is no pressing, the requirement for a higher solid/protein content in the soymilk is understandable. Soy protein isolate has been added to increase protein content in making filled tofu products. The pH of soymilk before coagulation usually is about neutral or slightly below as this is affected by the original pH of soaking and water added during grinding. This near neutral pH in soymilk is therefore most suitable for lipoxygenases to work on the substrate to produce the bean flavor compounds as indicated earlier.

95.2.2.2 Types of Coagulants Available. Hot soymilk is usually coagulated to form curd by the addition of a salt, and/or acid coagulant. Tofu coagulants are classified into four basic types:

- Chloride-type or *nigari*-type coagulant such as calcium chloride, magnesium chloride, and seawater;
- Sulfate-type such as calcium sulfate, and magnesium sulfate;
- Gluco-delta-lactone (GDL);
- Acid coagulants such as citrus juices, vingar, and lactic acid.

Each type of coagulant has its advantages and disadvantages. *Nigari* may be natural, or refined. Regular *nagari* is composed of mainly magnesium chloride hexahydrate ($MgCl_2 \cdot 6H_2O$, 92.3%) and the residual components in seawater (magnesium sulfate, 3.8%; sodium chloride, 1.7%; and calcium sulfate, 1%) after salt (sodium chloride) is removed and dried. Refined *nagari* is mainly magnesium chloride (99.5%). Calcium chloride is not found in seawater but it gives tofu an excellent flavor, almost identical to tofu made with regular or refined *nigari*. In addition, it is generally recognized as safe (GRAS) in the United States, available in food-grade and the cheapest chloride-type coagulant. Tofu made with *nigari*-type coagulant is considered the most delicious with subtle sweet flavor and aroma. However, compared with tofu made with calcium sulfate or GDL, they react very rapidly with soymilk, and therefore require skill and attention. They must be added slowly, and the curd is destroyed while agitation is going on. This type of tofu contains less water as compared to the sulfate-type, and the yield is less with a coarser texture. *Nigari* is not suitable for making silken tofu as the reaction is too fast for the high solid content and high temperature of the soymilk, making it very difficult to form uniform blocks of tofu. However, for filled silken tofu, this problem can be overcome by cooling down the soymilk to 2–4°C prior to coagulant addition followed by heating to slowly coagulate the proteins.

Calcium sulfate or gypsum is the most widely used sulfate-type coagulant in making of tofu in the world. Gypsum is not that water-soluble at room temperature (3.0 g/L), making it a determining factor on the coagulation reaction. It reacts slowly with the soymilk; consequently it allows formation of curds with higher water-holding capacity and soft and smooth texture. Thus, they give 15–20% higher bulk yield as compared to the *nigari* process. Calcium sulfate can be used in the making of regular, firm, soft, silken and even packed (packaged-filled) tofu, whereas as the last two types can not be easily accomplished with *nigari.* Calcium sulfate is easy to use, even with unskillful tofu manufacturers with fairly consistent yields and texture. Calcium sulfate-coagulated tofu has a mild or bland taste and the taste is slightly inferior to that of *nigari*-tofu. It should be noted that coagulation of soymilk using salts followed by pressing will remove the water soluble constituents not trapped in the final curd.

Glucose-delta-lactone (GDL) was first used in Japan to make silken tofu in the 1960s (Shurtleff and Aoyagi 1990). It differs from the chloride- and sulfate-type coagulated tofu in that it uses an acid to form the curd. In a water solution, GDL is slowly hydrolyzed into gluconic acid by water in 2–3 h with a pH drop from 3.5 to 2.5 for a 1% solution at room temperature. In the manufacturing of packed and silken tofu, GDL is dissolved in previously cooled soymilk to allow formation of gluconic acid gradually. Upon heating, the soymilk coagulates due to the action of gluconic acid with the formation of a

homogenous solidified curd without loosing any of the water in the container. GDL-coagulated tofu has a sour flavor and its sourness increases with the increasing concentrations used in making firm and extra firm GDL-tofu. GDL is often used together with calcium sulfate to improve the flavor of the final tofu product. This type of tofu contains all the components of the soymilk used to make tofu in addition to the coagulant.

The acid-type coagulant such as vinegar, lactic acid, and lemon juice can be used as natural coagulants. However, use of this group of coagulant produces low yield with slightly crumbly texture and a slightly tart flavor as compared with the *nigari*- and sulfate-type tofu.

95.2.2.3 Amount of Coagulant Used. The amount of coagulant required to reach the optimum coagulation varies with the solid content of the soymilk. It is also kind of proprietary to the tofu manufacturers. It greatly affects the yield, texture, taste, and aroma of the final product. In general, tofu makers can tell by observing the curd formed and whey produced during pressing whether appropriate amount of coagulant has been added. Whey usually is transparent and amber or pale yellow. When proper coagulation is achieved, the curds have a smooth and cohesive texture in traditional tofu making. If coagulation is incomplete (too little coagulant), the whey is cloudy containing some uncoagulated soymilk. When too much coagulant is used, the texture will become coarse and crumbly. There are some published methods for determining appropriateness of coagulation. Whey transmittance is one of the more reliable guide in determining the optimum amount of coagulant added for maximum yield. Watanabe and others (1964) reported that more concentrated soymilk requires 3–8% more coagulant to reach the same level of whey transmittance, and the dosage for calcium sulfate is 20% than that for *nigari*. Chang and Hou (2004) reported that the coagulant concentration required for reaching optimum coagulation of silken tofu increases linearly with the soymilk solid content in the range of 6–11%, and the concentration for magnesium chloride is about 13–15% more than that for calcium chloride. Kao and others (2003) reported in making firm tofu by calcium sulfate, 0.4% resulted in the most uniform and homogeneous microstructure and retained the highest protein and water in the tofu gel. Whey conductance is claimed to be a better indication for proper coagulation with faster and more reproducible results than whey transmittance (Beddows and Wong 1987a). A rapid titration method based on the flow properties of the soymilk during titration with coagulant was developed in our laboratory (Liu and Chang 2003a,b; 2004a,b) for determining optimal coagulants of the *nigari* type (calcium chloride and magnesium chloride). This method allows the manufacturer to determine coagulants rapidly for reducing waste that may be caused by improper use of *nigari* coagulants. The procedure can be modified for sulfate type of coagulants.

95.2.2.4 Coagulation Temperature. Coagulation temperature is another crucial factor in tofu making. The rate of soymilk coagulation and tofu quality are affected by the soymilk temperature. The yield and moisture content of tofu decrease as the temperature of coagulation increases, whereas hardness and elasticity of the resultant tofu increase (Wang and Hesseltine 1982). When soymilk is at high temperature, proteins possess high active energy. This can lead to fast coagulation, resulting in the formation of curd with low water holding capacity; consequently, tofu has hard texture and low bulk yield. The hotter the soymilk at the time of coagulation, the less the amount of coagulant required. When tofu is coagulated at a high temperature, a small increase in

the amount of coagulant may lead to a large decrease in yield. In the tofu industry, the temperature of coagulation varies from one factory to another, depending on the type of coagulant used. Generally, coagulation temperature ranges from 68°C to 95°C for those using *nigari*, while those using calcium sulfate prefer the range from 70°C to 80°C in Japan. Beddows and Wong (1987b) reported that the optimum coagulation temperature is 75–80°C for silken tofu with gypsum as coagulant in a small bench scale. Shih and others (1997) reported that the optimum coagulation temperature is 85–91°C for making soft tofu with $CaSO_4$ in a medium scale. The operational temperature of coagulation also varies from one region to another. In America, tofu makers prefer a relatively high temperature, 85°C, for using *nigari* and calcium sulfate, since less coagulant is required, the curd forms quickly, and the tofu has firm and dense texture but no significant drop in yield.

95.2.2.5 Coagulation Method. The coagulant addition procedure, the stirring speed, and the follow-up stirring after the coagulant is added have very definite effect on tofu yield and quality. Generally, the controlling techniques of this coagulation rely on the experienced tofu maker's judgement.

Traditionally, calcium sulfate in a suspension is added to soymilk, which has been stirred vigorously by hand with a paddle, and the mixture continues to be mixed six to eight more times.

Nigari-type coagulant could be divided to three portions and added in three steps in order to coagulate soymilk slowly and get high yield and smooth texture. The first portion of *nigari* is poured from a height of several feet into the soymilk being swirled with a paddle. Coagulation starts from the bottom of the container and slowly works up, while the uncoagulated soymilk constantly rises to the surface. The second portion is sprinkled over the soymilk surface. The content is covered and stands for about 5 min. Then, the last portion of the *nigari* is sprinkled over the surface. The curd is allowed to stand for 15–20 min to solidify completely (Shurtleff and Aoyagi 1990).

Optimum combination of stirring time and speed are critical in obtaining quality tofu with proper yield. This depends considerably on the experience of the tofu manufacturer and his desired yield and quality. Chang and Hou (2004) and Shih and others (1997) determined the optimum combinations of soymilk solids, coagulant concentration, soymilk temperature for adding coagulant, and stirring time after adding coagulant for soft tofu making by using a medium scale and a stirrer fixed at 285 rpm. Tofu yield is affected mainly by soymilk solid content and coagulant concentration. Tofu solids and protein content are affected by soymilk solids, coagulant concentration, and stirring time. Solid content of soymilk is the most important factor affecting textural properties of tofu. The optimum combinations are soymilk 11.8–12.3 °Brix, coagulant 0.27–0.32% of soymilk volume, stirring temperature 85–91°C, and stirring time 5–11.3 s (Shih and others 1997).

95.2.2.6 Cutting of Curd. Depending on the type of tofu manufactured, the curd may or may not be cut or break up before pressing to expel the whey. Cutting or breaking curd is required in the manufacturing of regular or firm and extra firm tofu, whereas filled silken and aseptically packaged tofu do not require cutting as they are the curd is formed inside the container.

95.2.3 Pressing

For tofu requiring a cutting step, a pressing step follows to expel the whey. The yield, moisture contents and texture in these final products therefore depend on the pressure applied during this pressing step and its length. It is obvious that longer time and higher pressure are needed for firmer tofu. Pressing usually is conducted in molds of various sizes depending on the volume of tofu to be produced. For research purposes, a mold for small-scale production has dimension of 12.5 L × 12.5 W × 5.5 H cm; a mold for medium-scale production has dimension of 25 L × 25 W × 7 H cm and a mold for large-scale production has dimension of 40 L × 40 W × 4.5 H cm. For industrial production, the molds are much larger. Widely inconsistent conditions of pressures and duration of pressing have been used by different researchers (Chang and Hou 2004) for making various types of tofu. Because of differences in soymilk and tofu making methodology, it is difficult to compare reported data and a standardized procedure is needed for determining the quality of soybeans in tofu making. As a general guideline, tofu manufacturers apply a light initial pressure of 2–4 g/cm^2 for about 5–10 min followed by a stronger pressure of about 5–15 g/cm^2 for 10–15 min to make soft tofu. For firm tofu, a pressure of 20–100 g/cm^2 is used for 20–30 min (Shutleff and Aoyagi 1990). Generally, silken tofu is not pressed, but Beddows and Wong (1987b) reported an optimum pressure of 4–6 g/cm^2 for pressing silken tofu until dripping ceased. Pressures above or below this range will produce unacceptable silken tofu.

95.3 EFFECT OF SOYBEANS AND COMPONENT ON SOYMILK AND TOFU MANUFACTURING AND QUALITY

95.3.1 Soybean Raw Materials

Soybean cultivar is one of the major factors influencing the quality of tofu. It is well known that good tofu can only be prepared from good soybeans. In addition, location (environment of growth) and handling practice at harvest, and storage practices postharvest together can also affect soybean chemical compositions, which in turn affect curd formation and sensory properties of tofu.

Over the years, substantial interest has been placed on the understanding of the quality of various soybean cultivars for tofu making. This is of practical importance in soybean trading since a good quality identity-preserved soybean cultivar developed especially for tofu making would commend a premium. Several researchers have reported the differences in the quality of various soybean cultivars for making tofu. Soybean cultivars with higher protein content have generally lower oil and total sugar content. The chemical composition of soybeans is closely related to that in soymilk and tofu (Wang and others 1983; Lim and others 1990). The higher protein content in soybeans, the higher protein content is retained in soymilk or in packed tofu. However, cultivars with higher protein contents may not produce tofu with harder texture, because protein content alone is not adequate to explain the observations related to hardness. Therefore, a thorough understanding of the composition in various cultivars and changes during storage is important to relate to tofu quality.

Unfortunately, there is no standard method to evaluate soybean quality for making tofu. It is important that an evaluation method using small scale production has the ability to detect the differences of soybeans with different quality characteristics, and such a method could produce a similar trend of results in a large-scale tofu manufacture

process. Since manufacturing processes of tofu vary from manufacturer to manufacturer, one evaluation method can not be applied to all manufacturers. However, for a simple purpose of comparison among different varieties/materials for tofu making, one method developed for a specific tofu product may be appropriate. Most methodologies reported for tofu making are small-scale methods and have not been described in details and they have not compared the reported small-scale method with a large-scale method. Our research results (Cai and others 1997; Chang and Hou 2004) revealed that the small bench and the large-scale method correlated significantly ($P > 0.05$) in tofu yield, color, texture, and chemical composition (moisture, protein, lipid, ash, calcium, and magnesium). The quality and yield of tofu were significantly affected by soybean cultivars and processing methods. Since tofu quality made by the small-bench scale was well correlated to the production method, the bench scale method may be used for determining the quality of soybeans for making tofu. Murphy and others (1997) also suggested a production-scale method for determining the soybean quality for suitability of commercial processing. However, the small bench-scale method developed in our laboratory is appropriate for evaluating soybean quality, since tofu quality made by the small-bench scale is well correlated to a production method.

95.3.2 Storage Conditions

Most soybeans are produced by a few major countries and shipped to other nonproducing countries for further processing into various soy products including tofu (Chang and others 2004; Hou and Chang 2005a). These beans may be stored up to one year or longer after harvest in a wide variety of environmental circumstances before they are processed. Prolonged postharvest storage of beans, generally called aging will decrease the quality of edible soybeans and the viability. The mechanism of soybean aging is not completely understood. A commonly acceptable hypothesis is that lipid peroxidation plays an important role in the initial stage of seed aging process (Parrish and Leopold 1978; Stewart and Bewley 1980; Wilson and McDonald 1986). Hydroperoxides resulted from lipid peroxidation of polyunsaturated fatty acids in the presence of oxygen not only destroy the lipid itself, but also damage cell membranes and other cellular components. In addition, they can break down to form secondary volatile oxidation products, which may contribute to the off-flavor formation in soy products during storage of soybean (Clark and Snyder 1991; Hou and Chang 1998). The magnitude of the quality deterioration of seeds depends upon storage conditions, including time, temperature, relative humidity (RH), and microbial contamination. Among these factors, relative humidity/water activity is the most important. Low humidity may effectively preserve the original bean qualities even at a high temperature (Saio and others 1980). In general, when the relative humidity increased to 80% and temperature is 30°C or higher, the soybean quality deteriorated quickly. Humidity has a higher impact on the soybean quality for soymilk or tofu making, whereas when humidity is low, temperature increase is important in soybean deterioration.

The reported changes of components in soybeans induced by storage include the following:

- Surface discoloration, Maillard reaction, loss in protein extractability (Narayan and others 1988; Thomas and others 1989; Chang and others 2004; Kong and others 2004; Hou and Chang 2005a; Kong and Chang 2006);

- Increase in the acidity or decrease in pH (Hou and Chang 1998; Chang and others 2004);
- Decrease in phospholipid content (Nakayama and others 1981; Mounts and Nash 1990; List and Mounts 1993);
- Changes in isoflavone forms with a decrease in malonyl forms and increase in aglycone forms (Hou and Chang 2002);
- Decrease in extractability of glycinin and β-conglycinin, and changes in the subunit-composition of glycinin and structures (Murphy and others 1997; Saio and others 1982; Chang and others 2004; Hou and Chang 2004; 2005b).

When soybeans are stored in adverse conditions, decrease in soymilk quality, and the yield and quality of tofu with off-flavor and a coarser texture are the results (Hou and Chang 1998, 2005a; Genovese and Lajolo 1992). However, soybeans in conditions of 57% RH 20°C, cool 4°C, or in an uncontrolled ambient temperature condition in North Dakota could remain their soymilk and tofu qualities for up to 18 months (Hou and Chang 2005a,b). In general, whole soybeans are more resistant to deterioration during storage than soy meal or damaged beans including split and seedcoat cracking. Usually, the amount of broken or damaged beans tends to increase with prolonged storage, especially when moisture content is low (<13%) (Genovese and Lajolo 1992).

Under the conditions of 30°C, 82% RH, reducing sugar content in soybeans was first reduced and later nonreducing oligosaccharides in the soybeans were hydrolyzed. A part of the reducing sugars formed by hydrolysis of the oligosaccharides may participate in the nonenzymatic glycosylation and in the Maillard reactions with the amino residues in the soy proteins (Wettlaufer and Leopold 1991; Locher and Bucheli 1998; Hou and Chang 2004, 2005a,b). Sugar content in soybeans and tofu has significance in color and sweetness of the products.

Phytic acid affects the coagulation of soymilk during tofu making by decreasing pH after calcium salt is added. Phytate in soybeans degrades gradually with storage time in the adverse environment. However, under the mild or cold conditions, hydrolysis of phytate also could occur, but at a lesser degree (Hou and Chang 2003). The hydrolysis of phytate in soybeans during storage contributes not only to the decrease of soymilk pH, but also to the loss in chelating ability with calcium ions, and subsequently affects protein coagulation behavior to lead to softer textural quality (Hou and Chang 2003). The effect of phytate on soymilk and tofu making and quality is discussed in the following Section 95.3.5.

95.3.3 Proteins

On a dry basis, about 35–40% of soybeans is made up of soy proteins (mostly globulins) and approximately 90% of these proteins is extractable with water or dilute salt solutions. Soy proteins consist of discrete groups of polypeptides that have a wide range of molecular size. A typical ultracentrifuge pattern of water-extractable soy proteins has four major fractions designated as 2S, 7S, 11S, and 15S on the basis of their sedimentation rates. Each fraction is a complex mixture of proteins. The 7S and 11S proteins are the two major storage proteins in soybeans, which comprise approximately 70% of storage protein. The 2S fraction accounts for about 20% of the extractable proteins, which

contain protease inhibitors (the Kunitz and the Bowman-Birk trypsin inhibitors) and cytochrome C (Steiner and Frattali 1969).

The 7S fraction has been classified into three major components with different physicochemical properties named β-conglycinin, γ-conglycinin, and basic 7S globulin (Catsimpoolas 1969; Hirano and others 1987). β-conglycinin is the most prevalent of these three and accounts for about 30–35% of the total seed protein, which is used interchangeably with 7S protein since it is the major 7S protein. The 11S fraction, designated as glycinin, accounts for an additional third of the total seed protein and is generally simple protein. The 15S fraction accounts for approximately 10% of the total seed protein, which is an aggregate of 11S protein (Wolf and Nelsen 1996).

Tofu is made from heated soymilk that is a turbid solution containing approximately 5% protein and 3% lipid. Soy proteins are the dominant components in tofu dry matter (more than 50% of the total solids on dry basis), which provide the major network structure of tofu gel. Soy proteins form an emulsion gel by a combination of heating and the addition of a coagulant, which is either an acid or divalent salt or a combination of both. This tofu emulsion is permanent since heating is not able to separate lipids from the protein system. Besides protein and lipid, other components in soymilk such as phytate, isoflavones, saponins, and lipoxygenases also may play important roles in coagulation of proteins during curd formation. Because of the complexity of the soymilk-tofu system, the mechanisms of tofu formation are also complex, and are not fully understood. Even though reports on understanding the interactions between nonprotein constituents (e.g., phytate and lipid) and proteins on the coagulating reaction in tofu making are available (Saio and others 1969; Kumagai and others 1998), there is a need for a comprehensive approach to put all factors together in one picture to understand the gel formation in tofu making.

Recent studies have shown that various soybean cultivars have various ratios of 11S/7S proteins that may influence the textural quality of tofu (Cai and Chang 1999; Poysa and Woodrow 2002; Mujoo and others 2003). We found that the β-conglycinin (7S) and glycinin (11S) contents in 13 varieties are 17.2–23.1% and 36.3–51.3% of total proteins, respectively, and the 11S/7S protein ratio varied from 1.64 to 2.51 among the varieties (Cai and Chang 1999). Furthermore, positive correlations existed between tofu firmness and the 11S/7S ratios in various (13 to 16) soybean cultivars (Zhang and Chang 1996; Chang and Hou 2004; Cai and Chang 1999). Processing methods also affect 7S- and 11S-protein content of tofu and their contribution to tofu hardness, yield and sensory quality. Thus, processing methods have an impact on the relationships between 11S/7S ratios and textural quality since different coagulation processes and pressing steps are used for preparing tofu (Cai and Chang 1999). However, conflicting results on the relationships between 11S/7S ratio and tofu firmness have been reported by other researchers (Murphy and others 1997; Skurray and others 1980; Utsumi and Kinsella 1985; Taira 1990). The conflicting report may be partly due to different methods used for processing, because of a lack of standard methods for tofu research.

95.3.4 Lipids and Phospholipids

Approximately 60% of total lipids in raw soymilk are associated with the protein particles, however, only 3% are found in the protein particles of cooked soymilk (Ono and others 1996). Significant amount of lipids in raw soymilk can be precipitated with large protein particulates by low speed centrifugation (Liu and Chang 2006). After being

heated to 65°C, part of the lipids and almost all α and α′ subunits of β-conglycinin in the particulate fraction begin to liberate to soluble fraction. Above 90°C, almost all neutral lipids in the protein particles of raw soymilk is liberated to a floating fraction, and one half of the phospholipids remains in the particles (Ono and others 1996; Guo and others 1997b). Coagulation of soymilk depends on the concentration of coagulant, the pH of soymilk, and temperature, the last being an external factor that accelerates soymilk coagulation. In fact, the addition of coagulant causes not only protein coagulation and gelation but also the incorporation of lipids into the protein gel with the lipid droplets being located in the networks of the protein gel (Saio and others 1969; Yamano and others 1981; Guo and others 1999).

Phospholipids (including lecithin) are polar compounds. More than 50% of these lipids extracted from hexane-defatted soy meal are phopsholipids. They are believed to play an important role in combining the particulate proteins with neutral lipids (Ono and others 1996). 11S and 7S proteins isolated from defatted soy meal contain about 0.8% and 2.3% phospholipids, respectively. Phospholipids bind to the hydrophobic sites of β-conglycinin (Ohtsuru and others 1979). 7S protein is more hydrophobic than 11S protein and therefore phospholipids bind stronger to the 7S proteins. Removal of lipids, particularly the phospholipids, from the surface of 7S proteins by extraction with chloroform:methanol solution makes 7S proteins vulnerable to form insoluble aggregates thus decreasing the ability to complex with protein particles. Adding phospholipids to soymilk increases the formation of protein particles. Lecithin-supplemented gels exhibit a fine network structure.

95.3.5 Phytic Acid

Phytic acid (phytate) content comprises 1~2% of soybeans on a dry basis and accounts for about 70∼80% of the phosphorus in seeds (Cheryan 1980). It is structurally integrated with the protein bodies as phytin, a mixed potassium, magnesium, and calcium salt of inositol (Erdman 1979). Phytate has strong chelating ability with multivalent metallic ions, especially zinc, calcium, and iron. According to Graf (1983), calcium ion can bind to phytic acid over a wide pH range (pH 4.8–10.4), the degree and tightness of binding being affected by pH, temperature, ionic strength, and size and valence of the cation. The affinity of phytic acid for calcium increases sharply with pH; the higher the pH (alkaline), the higher affinity; the affinity in pH 10.4 is a thousand-fold higher than in pH 4.8.

It is reported that phytate attaches to the glycinin at pH between 2.5 and 5.0, and the extent of binding increases with decreasing pH; above the pI (isoelectric point) of glycinin (pH 4.9), no binding is found (Okubo and others 1976). A portion of phytate in soymilk is bound to particulate and soluble proteins (about 35% and 23%, respectively). The others are present in the free form (about 42%) (Ono and others 1993). Therefore, when calcium is added to soymilk, it binds to phosphate groups of phytate and binds to proteins as well.

The role of phytic acid in the coagulation step during tofu-making has been related to a decrease in pH after calcium salt is added (Ono and others 1993; Tezuka and Ono 1995). When calcium is added, the phytate-calcium salts form at approximately the neutral pH (6.6). Hydrogen ions bound originally with phosphate groups in phytate, are liberated. Therefore, the pH decrease upon the addition of calcium may be mainly due to the formation of phytate-calcium salts. The decrease in pH of soymilk from approximately 6.6 to 5.8 after the addition of calcium chloride allows the use of a lower concentration of Ca salts for coagulation. When calcium is present, it binds simultaneously to proteins

and phytate, calcium binding to proteins can retard the decrease of pH because of less phytate-calcium formation. Tofu curd contains both types of calcium bound to protein or phytate.

Phytate is also very important in relation to the speed of coagulation during tofu making. It has been found that higher content of phytic acid results in a slower coagulation of soymilk during tofu making, and gives a higher tofu yield (Saio and others 1969). Therefore, the phytate content in soymilk can affect the textural properties of tofu. To understand the role of phytate on yield and textural properties of tofu, we conducted a series of experiments using Proto soybean as the raw materials that were stored under a series of environmental conditions to induce the changes of phytate (Hou and Chang 2003). Significant positive relationships exist between soybean phytate and tofu yield ($r = 0.93$) and between soymilk phytate and tofu yield ($r = 0.95$). Negative correlations between soybean phytate and tofu hardness and brittleness are observed ($r = -0.92$ and -0.84, respectively). Negative correlation coefficients are found between soymilk phytate and tofu hardness and brittleness ($r = -0.94$ and -0.86, respectively). Although statistical correlation between phytate content existed, phytate does not have a direct impact on tofu yield since when phytate changes in soybeans during storage, other components such as protein solubility, protein molecular structures, titratable acidity also are changed simultaneously (Hou and Chang 2004, 2005a,b). To understand the separate effect of phytate, phytase was used to hydrolyze the phytate in soymilk to that of the stored beans. Reducing phytate actually increases tofu yield but reduces firmness. Therefore, phytate plays a minor role in affecting tofu quality as long as the coagulant used is optimal. Besides its effect on texture of tofu, phytate has been recently reported to be responsible for the astringency of soymilk (Mahfuz and others 2004a,b). The astringency in soymilk disappears when the soymilk is coagulated with calcium salt to tofu. Therefore, the calcium salt form of phytic acid has no astringent taste.

95.3.6 Isoflavones and Saponins

Distribution of isoflavones, a subclass of the more familiar flavonoids, is extremely limited in nature. Soybeans and soy foods are the major foods containing significant amount of isoflavones. The main isoflavones found in soybeans are genistein, daidzein, and glycitein, each of which exists in four chemical forms, as an aglycone form (genistein, daidzein, and glycitein), a β-glucoside form (genistin, daidzin, and glycitin), a malonylglucoside form (6″-*O*-malonylgenistin, 6″-*O*-malonyldaidzin, and 6″-*O*-malonylglycitin), and an acetylglucoside form (6″-*O*-acetylgenistin, 6″-*O*-acetyldaidzin, and 6″-*O*-acetylglycitin).

Isoflavone content varies among soybean varieties, which contain approximately 1–4 mg/g soybean. The isoflavone content of soybeans is markedly affected by crop year and growing condition (Wang and Murphy 1994; Hoeck and others 2000). Isoflavones are quite heat stable. Wang and Murphy (1994) reported that cooking did not influence the isoflavone retention during tofu making, but alter the distribution of isoflavones by dramatically decreasing in malonylglucoside forms and increasing in acetylglucoside forms. Minimal heat processing can convert substantial amounts of malonylglucoside to the β-glucosides. Total isoflavone content in soy products decreased most likely due to leaching of isoflavones into water during processing. Wang and Murphy (1996) reported that 44% of total isoflavones were lost during the processing of tofu. Coagulant type and concentration affect the recovery of isoflavones in tofu (Kao and others 2004). The concentration of 0.3% calcium sulfate gives the highest tofu recovery as compared to that

made by calcium chloride. Isoflavones have several potential health benefits (Chang and Hou 2004). Liu and others (2005) reported that tofu has *in vitro* and *in vivo* antioxidant activity as high as that of 250 ppm isoflavone crude extracts.

Saponins are widely distributed in plants, and are glycosides composed of a sapogenin that makes up the aglycone and a sugar moiety. The sapogenin is a triterpeneoid alcohol. At least five sapogenins have been found in soybeans (Birk 1969). Xylose, arabinose, galactose, glucose, rhamnose, and glucuronic acid have been found in the glucoside portion of soy saponins. Saponins exist in two groups, A and B (Shiraiwa and others 1991a,b; Kudou and others 1992). The group A saponins consist of 6 different kinds of saponins (Aa, Ab, Ac, Ad, Ae, and Af), which are acetyl-soyasaponins. The group B saponins, on the other hand, consist of eight kinds of saponins (Ba, Bb, Bb′, Bc, Bd, Be, BdA, and BeA), which are not acetylated and are different from the group A. BdA is the major natural soybean saponin in soybean seeds (Kudou and others 1992). Saponins are polar compounds because of the associated sugars (oligosaccharides), which are found in the soybean meal in amounts of approximately 0.5% of the dry weight (Fenwick and Oakenfull 1981).

It is known that isoflavones and saponins impart the bitter and astringent after-tastes in the flavor of soy products. Glucoside forms of saponins and isoflavones are the major compounds that cause objectionable after-taste in soybeans, and saponin A group contributes most strongly to the undesirable taste. The undesirable taste becomes weaker when saponins decompose from glucoside forms to aglycone forms, while isoflavone glucosides show a reverse tendency. The aglycones of isoflavones have stronger objectionable after-taste than those of glucosides (Matsuura and others 1989; Okubo and others 1992).

Saponins, glycitin, and glycitin derivatives are present primarily in hypocotyl, and all of these substances can give objectionable aftertaste. In Japan, removal of these compounds by processing methods has been reported to produce good-taste tofu by the Namashibori technique (Watanabe 1997). In the method, the soybean is first cracked, and seedcoat and hypocotyl are removed. The resulting materials are soaked in water for a short period of time, ground to make the slurry "go" and filtered. The raw soymilk is boiled and the brown foams (which contain saponins) are scooped away to reduce aftertaste. However, in light of potential health benefits of these isoflavone and saponin compounds (Hasler 1998), a different strategy may be needed to preserve these compounds to produce soy foods with the maximum health benefits.

95.3.7 Lipoxygenases

Lipoxygenases and hydroperoxide lyase (Matoba and others 1985) are involved in the oxidation of polyunsaturated fatty acids such as linoleic acid and linolenic acids to hydroperoxides and secondary breakdown products, some of which have beany flavor. Heating can reduce the activity of lipoxygenases and hydroperoxide lyase (see earlier sections on Heating and Separation on reduction of beany flavor, and Grinding Temperature).

95.4 MECHANISM OF TOFU CURD FORMATION

There are several reviews on the mechanism of tofu curd formation (Saio and others 1969; Ono and others 1991, 1993, 1996; Tezuka and Ono 1995; Guo and others 1997a,b, 1999; Ono 2000; Tezuka and others 2000). It could be summarized into three steps.

- The total of the large and medium-sized particles constitutes more than 50% of the proteins in soymilk. Before heating the raw soymilk, most of the particles are still intact. Most lipids are present in the protein particles.
- When the soymilk is heated up to 90°C, the proteins denature and the lipid droplets are liberated to floating fraction. Approximate 75% of the large particles is degraded to supernatant proteins, but the amount of medium-sized particles increases due to the combination of β subunit of 7S and the basic polypeptide of 11S from the supernatant proteins that contain mainly 11S and 7S globulin.
- The addition of coagulant (calcium ion, magnesium ion and/or GDL) to the heated soymilk is the key step. At low concentration of coagulant(s), protein particles combine with lipid droplets and the gel network is first formed through the binding of calcium to protein particles to neutralize the negatively charged protein molecules and to cause protein aggregation due to a reduction in electrostatic repulsion. When about 50% of the proteins is coagulated with coagulant, almost all the lipids in soymilk are trapped and become inseparable by the association with particulate proteins. With the availability of more coagulant(s), it leads to a decrease in pH. The soluble proteins aggregate at a higher concentration of coagulant and bind to the protein particles-oil droplet complex to form a stable tofu-curd emulsion network.

95.5 FOOD QUALITY EVALUATION OF SOYBEANS, SOYMILK AND TOFU: TRADING AND INDUSTRY PERSPECTIVE

95.5.1 Soybean Quality

As discussed above, soymilk and tofu quality characteristics are affected by raw material characteristics, processing and storage. In trading, identity-preserved and organic food soybeans are preferred by the industry. Soybeans are alive and each lot of the soybeans may have unique properties and they can change over time. The seller and purchasers should maintain a record of the history of the soybeans with respect to variety (cultivar), production environment (location, soil, water, temperature, and sunlight of cultivation), harvest and storage conditions (humidity, temperature, and time), and shipping conditions. Mechanical drying after harvest should be done very carefully so that the proteins are not denatured.

The following are the factors that are commonly considered in trading soybeans for food uses.

95.5.1.1 Size and Hilum Color of Soybeans. Traditionally, large size is preferred for making tofu. However, our research shows that size is not a factor to affect tofu quality (Wang and Chang 1995). Size uniformity and % hard-to-soak beans (stone beans) are important. Clear hilum soybeans also have been preferred by the industry. However, our research shows that soymilk and tofu color is not related to hilum color. We have observed that a brown hilum color soybean produces soymilk with whiter color than some white hilum soybeans.

95.5.1.2 Chemical Composition as Related to Food Quality. Protein content and protein subunit patterns (11S and 7S subunit distributions) and lipid content affect the yield, composition, and texture of soymilk and tofu. Lipoxygenases, lipid and fatty acid content affect the flavor of soymilk and tofu. Sugar content affects the taste.

Phytate, saponins, and isoflavones may affect the bitterness and astringency of the soymilk products. However, the exact contributions of these compounds to food quality are not well established.

95.5.1.3 Storage Changes. Undesirable storage changes can be measured. Chemical changes include protein solubility, titratable acidity or pH of soymilk. Rancidity or oxidized off-flavor may be resulted from improper storage. Color is a good indicator of the changes of soybeans during storage and can be measured using a surface colorimeter such as the Minolta colorimeter with the Hunter's Lab scale. The optimal coagulant concentration for making tofu decreases with storage (Liu and Chang 2003a,b). Soymilk and tofu yield and texture need to be measured before trading. Soybeans should be kept in a low relative humidity and cool temperature to preserve the quality for food making (Hou and Chang 2005a).

95.5.2 Soymilk Quality

Indicators for soymilk include protein recovery, sugar content, color, beany aroma or off-flavor, and taste (sweetness, bitterness, astringency, aftertaste, and chalky taste). Instrumental analysis can be used to measure color, whereas chemical contents such as protein recovery and sugar content can be measured. Additional composition of interest could also be measured. Aroma and taste using hedonic or descriptive methods can be used.

95.5.3 Tofu Quality

In addition to yield of tofu such as g tofu made from 100 g soybean, color, texture, (firmness, cohesiveness, elasticity, and smoothness) and taste are important characteristics of tofu. Small-scale (Chang and Hou 2004) or pilot-scale making equipment (Figs. 95.5 and

Figure 95.5 *Tofu machine.*

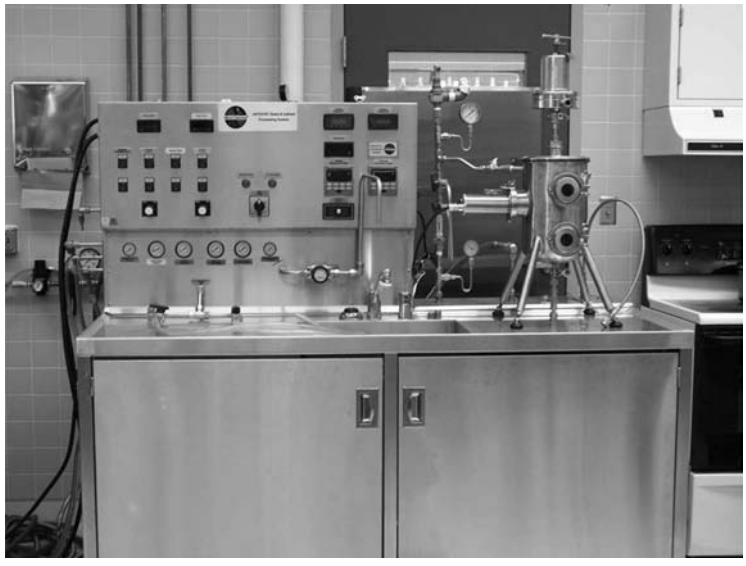

Figure 95.6 *UHT unit.*

95.6) are useful for processing tofu and soymilk for quality evaluation of soybean materials (Cai and others 1997; Chang and Hou 2004). Chemical methods and sensory methods are available for measuring the above characteristics. Instrumental methods are commonly used for textural analyses (Chang and Yuan 2005; Yuan and Chang 2007b). Hexanal, a major indicator of grassy, beany flavor compound commonly analyzed by gas chromatography, is strongly affected by raw materials and processing methods (Yuan and Chang 2005a,b, 2007a). Since tofu researchers use different parameters for textural analysis, the interlaboratory results are difficult to compare. The Instron universal testing equipment (Bourne 1982) is the most reported method for textural profile analysis of tofu (Chang and Hou 2004; Yuan and Chang 2007b). Yuan and Chang (2007b) investigated the optimal Instron settings for measuring textural qualities of 13 different types of tofu and found that the instrumental analysis using the selected parameters (75% plunger penetration and crosshead speed of 60–100 mm/min for cylindrical sample size of 44 mm diameter and 1.5 cm height) correlated very well with the results obtained from the human sensory testing methods.

ACKNOWLEDGMENT

Thanks are due to Professor Wai-Kit Nip, University of Hawaii at Manoa and Shaohong Yuan, North Dakota State University for their assistance in preparing the article.

96.1 INTRODUCTION

Fresh tomatoes are preferred over processed ones in Mexico just like in other parts of the world. Nevertheless, in the last few years the demand for tomato products, such as juices, purees, paste, and sauces, has increased due to technological advancement and the tastes and habits of the new generation.

Tomatoes and tomato products are considered to be healthy food for various reasons: they are low in fat and calories, free of cholesterol, and a good source of fiber and proteins. Tomatoes are also rich in vitamins A and C, ß-carotene, lycopene, and potassium. Tomato quality and its processed products are evaluated according to their redness that is due to their lycopene content. Therefore tomato and its products are the main source of lycopene which makes them important contributors of carotenoids to the human diet (Shi and Le Maguer 2000).

96.1.1 History

The tomato is a plant native to the American tropics that reached its greatest importance and development outside its area of origin and the tropics. The United States and Europe have introduced improved crops in the last few years, especially hybrids that have eliminated native crops of inferior quality. The tomato originated in the Andes region (Chile, Colombia, Ecuador, Bolivia, and Peru (Vavilov 1951) where the greatest genetic variability and abundance of wild types are to be found (Chávez 1980). Mexico is considered by the world, though, to be the most important domestication center of tomatoes. The word tomato comes from the Nahuatl word "tomatl." The Spaniards took this vegetable to Europe in 1554 and its commercialization began in the United States in 1835 (Chávez 1980).

96.1.2 Biology

The tomato (*Lycopersicon esculentum*) belongs to the Solanaceae family and is an annual crop. It can be semiperennial in tropical regions (Fig. 96.1) There are diverse crops with

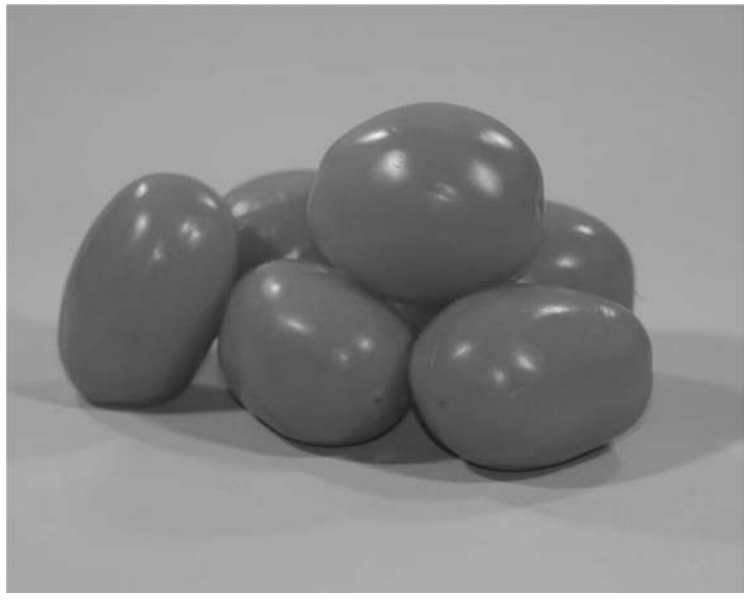

Figure 96.1 *Tomato* (*Lycopersicon esculentum*).

greater yield, resistant to pests and diseases, and that have a more adequate color, viscosity, and solid content. The fruit is a meaty berry composed of various lobules: from two (bilocular) to three or more lobules (multilocular). Commercial crops belong to the locular type (Valadez 1989).

The berry consists of skin over an external wall and internal radial walls of pericarp containing the locular material. The skin is composed of a cuticle over the epidermis. The cuticle contains cuticular acids and waxes that allow the berry to be resistant to attacks by insects and diseases; it also makes peeling by steam or with lye more difficult (Barringer 2004). The red flesh, made up of parenchyma rich in lycopene, is found beneath

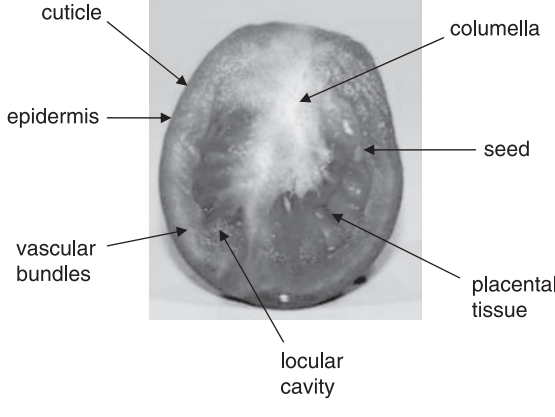

Figure 96.2 *Cross-section of a tomato.*

the skin in the form of crystals suspended in the liquid that fill the parenchyma cells. If the tomato is peeled too deeply, these tissues are lost and the yellow vascular bundles become visible. The seeds are found embedded in the gelatinous parenchyma inside the locular cavities (Fig. 96.2).

96.1.3 Growth, Harvesting, and Crops

The tomato is a warm climate vegetable that is frost intolerant; the temperature range of the soil should be from 12° to 16°C, with a maximum of 30°C, and the air temperature for its development should range from 21° to 24°C, with the optimum temperature being 22°C; growth is stunted at temperatures below 15°C and higher than 35°C. When there are high temperatures (greater than 38°C) for 5–10 days before the anthesis, there is little tying of the fruit because the grains of pollen are destroyed; if high temperatures continue for 1–3 days after anthesis, the embryo is destroyed. The tying of fruit is also low when night temperatures are high (25–27°C) before and after the anthesis. At a temperature of 10°C, or lower, a great percentage of the blossoms drop off (Valadez 1989).

The optimum temperature for fruit maturation is from 18° to 24°C. If the temperature is lower than 13°C, the fruits tend to mature poorly. On the other hand, when the temperature is higher than 32°C during storage, the red coloration (lycopene) is inhibited and the fruit turns yellow. It has been reported that optimum coloration is obtained at temperatures of from 22° to 28°C (Valadez 1989).

The fruit of the tomato is climacteric and may be harvested at different stages of ripening, from its green to red stage. Tomatoes produce small quantities of ethanol during their development and also undergo changes in the presence of exogenous ethylene (Wills and other 1989). Respiration and ripening increase in response to this gas. This last property is used by producers and distributors to accelerate ripening; ethrel is applied commercially.

Tomato crops may be grouped according to consumption type and market; there are markets for it fresh or for industrial production. Crops with lower acidity (pH), higher soluble solids, less viscosity, greater consistency and redness are used industrially (Gould 1992).

Tomato production has evolved in Mexico through the years as a result of the variation that its commercial demand has undergone. Its production has been established outdoors in the ground, in espaliers and lastly, in greenhouses. The genetic progress obtained is so important that new varieties appear each year which displace others that were developed a few years before. Hybrids that retain the most favorable characteristics of the preceding varieties are an important advancement. Some of the varieties grown in Sinaloa and Sonora are Rio Grande, Super Rio Grande, and Big Rio and the tomato hybrids are Saladette: Sauzalito, Brigade, Maya, Yaki, SXT-0289, Tequila, and Santa Fe (Borbón and Armenta 2000). Tomatoes are also classified according to their shape: round or ball, pear or guajillo (Valadez 1989). The round tomato and the saladette, or guajillo, are the most produced, while fewer cherry tomatoes are (ASERCA 1995).

96.1.4 Production Statistics

The tomato is the main export crop in Mexico, said to represent approximately 37% of the value of vegetable exports. Its production extends into 27 states, in the northern, central,

TABLE 96.1 Principal Tomato Producing States in Mexico, 2003.

State	Area Harvested (Ha)	Production (Ton)	Participation (%)
National	67,644	2,171,159	100
Sinaloa	21,908	742,685	34.21
Baja California	5,638	251,057	11.56
Michoacán	6,645	237,454	10.93
San Luis Potosí	6,757	208,798	9.62
Baja California Sur	2,657	122,045	5.62
Other	24,039	609,120	28.06

Source: SIAP (2006).

and southern regions of the country. Even so, approximately 71.94% of the national production is concentrated in five states.

The principal tomato producing states according to production volume are Sinaloa (34.21%), Baja California (11.56%), Michoacan (10.93%), San Luis Potosi (9.62%), and Southern Baja California (5.62%) (Table 96.1; SIAP 2006).

The geographic location of the country and intensive production technology permits exploitation in two known growth cycles: spring-summer, and fall-winter. The latter has the greatest production, for example Sinaloa, with its products sent to national and/or international market, depending on the market demand at harvest time. Production in this state is 61% tomato saladette, 39% round tomato, and 10% industrial (ASERCA 1998).

Sinaloa is the main seasonal exporter of tomatoes because the producers prioritize exports, programming their fields and crops in order to place high quantities of the crop on the market when the prices are high on the border; this situation causes the supply of tomatoes to be deficient in the national market. These market strategies are possible due to the Israeli seeds that are used to produce tomatoes. These seeds require technological packages that involve not only genetically improved seeds, but also drip irrigation and extensive use of greenhouses (ASERCA 1998).

At the world level, the principal tomato producers that produce 60.46% of the total world production (120,384,017 metric tons in 2004) are: China (25.04%), the United States (10.60%), Turkey (6.65%), India (6.31%), Italy (6.23%), and Egypt (5.63%) (Table 96.2, FAOSTAT 2005). Mexico with 1.78% is in tenth place. The principal countries that imported this vegetable in international commerce in 2004 were: the United States, Germany, France, the United Kingdom, and the Russian Federation. The greatest demand for Mexican tomatoes is from the southern and eastern regions of the United States (ASERCA 1998). The principal exporting countries for this same year were Spain, Mexico, the Netherlands, Syria, and Jordan (FAOSTAT 2005).

96.1.5 Nutritional Value

The composition of a tomato depends on the variety, stage of ripeness, climatic growing conditions, light, temperature, soil, fertilization, and irrigation. The water content ranges from 90% to 96%, while its total solids range between 5% and 6% (Table 96.3; Titchenal and Dobbs 2004). Approximately half of these solids are reducing sugars, with a slightly higher amount of fructose than of glucose. Sucrose is generally 0.1%. A quarter of the total

TABLE 96.2 2004 World Production for Tomatoes.

Country	Area Harvested (1000 Ha)	Production (1000 Metric Ton)	Participation (%)
World	4421	120,384	100
China	1255	30,142	25.04
United States	173	12,766	10.60
Turkey	220	8,000	6.65
India	540	7,600	6.31
Italy	135	7,497	6.23
Egypt	191	6,780	5.63

Source: Titchenal and Dobbs (2004).

solids are citric, malic, and dicarboxylic amino acids, lipids, and minerals. The other quarter is made up of proteins, pectic substances, cellulose, and hemicellulose (solids insoluble in alcohol). Tomatoes are an important source of nutrients and vitamins, mainly vitamin A and C (Barringer 2004).

Tomatoes are available all year round in Mexico. A basic crop in the Mexican diet, it is consumed fresh in salads or in food, in processed products such as paste, juice and canned. These products are used to prepare sauces and are eaten in soups, with meat, fish, and chicken. Hot chilli salsas and catsup are used as condiments. Tomato juice has recently increased in popularity.

96.2 CANNED TOMATOES: PROCESSING OPERATIONS

Tomatoes destined for industrialization are harvested at an advanced degree of ripeness, through the use of selected crops with adequate irrigation systems (Fig. 96.3).

96.2.1 Sorting and Grading

Whole canning tomatoes are selected and classified by color, firmness, defects, and size that are evaluated by experts. Red color should be uniform throughout all surface of fruit. Its classification is by color standards which are norms proper to the industry. A Hunter lab, Munsell or Agtron color spectrometer is also used, as well as cameras and infrared light. Firmness and color are parameters for determining the quality of the canned product.

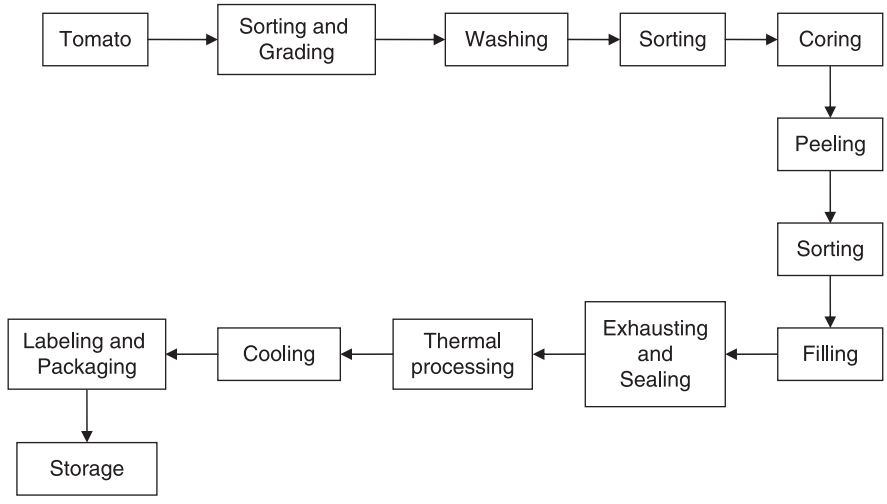

Figure 96.3 *Flow chart of whole canned tomatoes.*

96.2.2 Washing

The tomatoes are washed in agitation tanks for 3–5 min to eliminate dirt and contaminants and to reduce the microbial count. After the dust clinging to the tomatoes has been completely removed, the tomatoes are rinsed under streams of water.

96.2.3 Sorting

Selection can be made according to size, state of maturity, and firmness. Hydrosorter involves an immersion tank that is used to remove the immature fruit during the washing stage. The immature tomatoes float in the hydrosorter tank, while the ripe fruit sinks. The immature product is used for juice. The size sorters eliminate the small tomatoes and send them to the tomato choppers. Sorting according to firmness (texture) eliminates soft ones and sends them to the juice line.

96.2.4 Coring

This operation consists in extracting the peduncle and heart in the section closest to the peduncle. There is machinery that does this, though it can also be performed manually.

96.2.5 Peeling

Peeling is an unavoidable operation in the processing of the majority of fruit and vegetables and involves eliminating the least possible amount of the product. In the case of tomatoes, the peeling methods that are most used in the industry are steam peeling and peeling using lye. In the case of steam peeling, the tomatoes are placed on a moving belt and go through a closed section where steam is injected, and then continue with the next step in the process. Steam peeling is undertaken at 24–27 psi and 127°C for 25–40 s (Gould 1992). The high steam temperature rapidly heats the surface of the

tomato and when there is a sudden fall in pressure (upon exiting the steam chamber), the steam under the skin is released and the superficial cells burst. The majority of the material comes away when the steam is released and streams of water are needed to remove the remaining attached skin. The factors to be controlled during the peeling process are temperature and pressure. Higher temperatures and shorter time yield a more efficient peeling process. The steam peeling method is more commonly used in industry.

Peeling using lye consists of the tomatoes being transported on a belt to an immersion tank of hot lye where they remain for 25–30 s. The concentration is 12–18%, at a temperature of 88–93°C. This chemical peeling process involves chemical and diffusion reactions; the lye dissolves the cuticular wax and hydrolyzes the pectin, reacting with the organic acids in the cytoplasm, middle lamella, and cellular wall, and, as a result, separates the tomato skin (Gould 1992). After either steam or lye peeling, the tomatoes pass through a series of rubber disks or through a rotating drum under high pressure water sprays, to remove the adhering peel.

96.2.6 Blanching

Blanching is applied to destroy the enzymatic activity of the vegetables and some fruits that are to be canned, dehydrated, or frozen. This operation is also combined with the peeling and/or washing in order to save, not only in investment and space costs, but also costs in energy. In the case of tomatoes, steam peeling simultaneously inactivates the pectinmethylesterase (PME) and pectinpolygalacturonase (PPG) enzymes (Cheftel and Cheftel 1992).

96.2.7 Manual Sorting

The peeled tomatoes are inspected before being placed into cans by trained workers who separate the tomatoes that do not meet the quality requirements which has been established by the Mexican standard for canned tomatoes. The tomatoes cannot be spotted, or rotten. The overly soft products are sent to the juice line.

96.2.8 Filling, Additives, and Containers

Filling the can is done mechanically or manually. The drained weight must be a minimum of 50% and the cans must be 90% filled (including the medium used as covering), leaving 10% headspace for expansion during thermal processing (CODEX STAN 13-1981). Because of the acid nature of the tomato, enameled cans and lids are used. The packing medium is juice or salted tomato puree. The pH must not be higher than 4.5. Organic acids may be added for adjustment. The most commonly used is citric acid. Sugar may also be added to compensate for the acid due to the added acid. Calcium chloride tablets are added to maintain the firmness of the tomatoes. The limit permitted in the end product is 0.045% (CODEX STAN 13-1981). The calcium ions react with the methoxy groups in the pectin chains, forming calcium pectate (Cheftel and Cheftel 1992).

96.2.9 Exhausting and Sealing

The vacuum within the cans and sealing is done at the same time. Generally, rotating automatic fillers controlled by an operator are used at a preprogrammed velocity, for example,

1000 cans/min (Fellows 1997). Juice or tomato puree at a minimum temperature of 86°C is added to the cans filled with hot peeled tomatoes that are then sealed. When the can is sealed, steam is injected into the headspace which creates a vacuum after it is cooled. This vacuum assures that the ends of the cans are flat or slightly concave during storage and will maintain the cans' integrity when made available to the consumer (Hersom 1991).

96.2.10 Thermal Processing (Canning)

The thermal canning process is undertaken in a rotating retort in a generally semicontinuous process at 100°C for 30–40 min because tomatoes are a high acid-food. The temperature and length of processing time depend on the product being canned, the size of the can and the type of retort. There are other thermal systems that involve a long tunnel through which a belt transports the products through the heating and cooling areas. The steam tunnels have the advantage of taking up less space and heating faster therefore requiring a shorter processing time. Once the cans leave the thermal process, they are cooled at 30–40°C to minimize quality loss. The steam in the headspace condenses at this stage and a vacuum is formed.

96.2.11 Quality Standards

The Processed Fruit and Vegetable Committee of the Codex Alimentarius FAO/WHO has a quality standard for canned tomatoes (CODEX STAN 13-1981) which includes six presentations: whole tomatoes, whole and sliced tomatoes, sliced tomatoes, diced tomatoes, and wedges. Table 96.4 indicates some of the specifications that must be met by these tomato products.

This international standard also includes specifications for quality, hygiene requirements, labeling, and absence of contaminants.

TABLE 96.4 Specifications for Canned Tomatoes.

Specification	Limit
Filling	Not less than 90%
Drained weight	Not less than 50%
Packing media	Tomato juice, tomato puree or tomato paste
Others ingredients:	
Onion, peppers, celery, basil leaf	Not exceeding in total 10% of the product
Salt	—
Sweeteners:	
Sucrose, dextrose, glucose syrup	When acidifying agents are used
Acidifying agents:	
Acetic acid, citric acid, lactic acid, malic acid, L-tartaric acid	Limited by Good Manufacturing Practice
Firming agents:	
Calcium chloride, calcium sulfate, calcium citrate, mono-calcium phosphate, calcium lactate, calcium gluconate	0.08% total calcium ion content in the end product in the styles "diced," "sliced," and "wedges," 0.045% total calcium ion content in the end product in the styles "wholes," "wholes and pieces," and "pieces."

Source: CODEX STAN 13-1981.

96.3 DICED TOMATOES: PROCESSING OPERATIONS

The operations for sorting and grading, washing, sorting, coring, and peeling for diced tomatoes are similar to the operations for whole canned tomatoes.

96.3.1 Size Reduction

Size reduction is a unit operation in which the average size of solid foods is reduced by the application of grinding, compression, or impact forces. Generally, one of these forces tends to be more important than the other two for the process in question. Peeled tomatoes are diced at an average size of $\frac{1}{2}$ or 1 inch. An inspection to eliminate blemished dices is made at this stage (Fig. 96.4).

96.3.2 Filling, Additives, and Containers

Enameled cans are mechanically filled with diced tomatoes. A maximum of 0.08% calcium chloride tablets are added during the filling operation to increase the firmness of the diced tomatoes (CODEX STAN 13-1981). Calcium can also be added by conveying the dices through a calcium bath. The packing medium is tomato puree with salt. The pH must not exceed 4.5.

The exhausting and sealing of the can and thermal processing is done in the same way as with whole canned tomatoes.

96.3.3 Quality Standards

Quality standard for canned tomatoes includes diced ones CODEX STAN 13-1981 (Table 96.4).

Figure 96.4 *Diced tomatoes.*

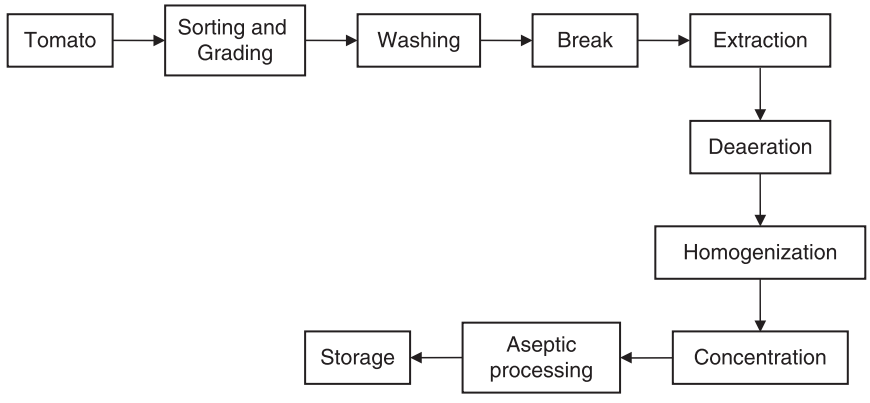

Figure 96.5 *Flow chart for tomato paste.*

96.4 TOMATO CONCENTRATE OR TOMATO PASTE: PROCESSING OPERATIONS

Tomato concentrate, or paste, is an important tomato product since it has great international demand. The paste is refined tomato pulp (juice) that is concentrated at 30–32°Bx or more (Fig. 96.5). This paste is used in sauces which can be marketed as such or as part of frozen meats and soups.

96.4.1 Sorting and Grading

The selection and classification is made by trained workers who take into consideration color, defects (worm damage, mechanical damage, anthracnose, fungi, and diseases) and soluble solids. The color is evaluated by the tomato's red surface or with a sample of tomato juice using a colorimeter. The industries generally apply specifications of quality to the raw material. Depending on the inspection results, the producer's lot is accepted or refused.

96.4.2 Washing

The tomatoes are washed in agitator tanks for 3–5 min to eliminate dust, fungi, insects, and drosophila eggs, and to reduce the microbial count. Some processing plants add chlorine to keep the concentration of spores low in the flume water. After completely eliminating the adhered dirt, the tomatoes are rinsed under water streams.

96.4.3 Break

Tomatoes for juice are processed by the hot break or cold break method. In the hot break method, the tomatoes are first chopped and then sent to the breaking up tank, which has a serpentine rotary to achieve uniform heating, where they are heated at 100°C. The hot pulp is pumped to the heating sterilizer where the pulp is heated up to 112°C to assure the inactivation of the pectinmethylesterase (PME) and polygalacturonase (PG) enzymes. The enzymes must be inactivated so that the juice will maintain its maximum viscosity. The juice is cooled within the tank to 100°C and then undergoes the extraction operation.

The largest juice production is obtained with the hot break method and is used to concentrate the paste with the high level of viscosity needed to prepare other tomato products such as sauces and catsup. Some breaking systems are done in a vacuum to reduce the degrading of the ascorbic acid.

The tomatoes are chopped and heated to 50–60°C in the cold break method to accelerate enzymatic activity. The juice thereby obtained has better color and taste, though less viscosity because of the activity of the enzymes. This low viscosity juice is adequate for the production of tomato juice, tomato soups, and dehydrated tomatoes.

96.4.4 Extraction

After the break system, the mashed tomatoes are sent to the extractor, pulper, or finisher to remove the seeds and skin. The extractor is a cylindrical perforated metal screen that has brushes or paddles inside which rotate at a high velocity. The tomato pulp is forced through the perforations in the screen by the brush action. The hole size of the screen determines the size of the pulp particles that affects the viscosity and texture.

96.4.5 Deaeration

Deaeration removes dissolved air incorporated in the flesh during breaking or extraction. This operation is done in a vacuum chamber. Foam is also prevented from forming during concentration. If the air is not eliminated, vitamin C is lost.

96.4.6 Homogenization

The juice is homogenized to increase viscosity and to reduce separation of the serum. The juice is forced through a narrow orifice at high pressure, shredding the suspended solids.

96.4.7 Paste Concentration

Concentration is the most important stage of the entire process. The water is partially removed from the juice through evaporation. The juice is pumped to the triple-effect evaporator where the puree is concentrated from 4.5% to 32% of the soluble solids (Bartholomai 1991). The triple effect vacuum system uses interconnected evaporators (effects); the steam obtained in an effect is directly used as a means of heating for the following effect. This steam can only be used so that the juice will boil at a lower temperature than the previous effect. In order for the difference between the juice temperature and the heating element to be maintained, the effects must function at progressively lower pressures.

The yield of the evaporators depends on a number of effects and brand. This can generally be between 300–600 ton/day of fresh tomatoes (Rossi Catelly T-30 and Manzini MV-1500, respectively). The juice also is concentrated to paste by inverse osmosis with yield of 350 ton/day of fresh tomatoes.

96.4.8 Aseptic Processing

The paste is pumped to a deposit tank and from there to a scraped surface or tube-in-tube heat exchanger where pasteurization takes place at 110°C for 2 min or at 96°C for 3 min (Barringer 2004). Afterwards the product is cooled (30°C) and filled into sterile containers

TABLE 96.5 Physical and Chemical Specifications for Tomato Paste.

Specifications	Limit	
Color	Minimum in Munsell units	
	Number disc	Area exposed
	1. Red	53%
	2. Yellow	28%
	3. Black	19%
	4. Grey	19%
	3. and 4.	9.5% and 9.5%
Soluble solids free of salt	Minimum	25%
Acidity (citric acid)	Maximum	1.0%
Chloride (NaCl)	Maximum	2.0%
pH	4.0–4.5	

Source: NMX-F-025-1982.

in aseptic filler. Pasteurization occurs before it is packed; after the thermal treatment, the product is cooled to conserve its color, aroma, and taste qualities. The aseptic containers are not resistant to heat higher than 38°C. The container used industrially is an aseptic bag of 235 kg within a metallic drum or an aseptic bag of 1250 kg located within a wooden bin. The shelf life of these products is two years at room temperature.

The Manzini aseptic fillers work at the rate of 10–12 ton/h of tomato concentrate, while the Flash Cooler aseptic fillers do so at 23 ton/h of tomato concentrate.

96.4.9 Quality Standards

96.4.9.1 Mexican Quality Standard. The Mexican standard of quality for packed tomato paste (NMX-F-025-1982) takes into consideration sensory, physical and chemical specifications (Table 96.5), microbiological and chemical contaminants, methods of analysis and sampling, labeling, container and packing.

TABLE 96.6 Specifications for Tomato Concentrates.

Specifications	Limit
Product designation:	
Tomato puree	Tomato concentrate that contains not less that 8%, but less than 24%, of natural tomato soluble solids.
Tomato paste	Tomato concentrate that contains 24% or more of natural tomato soluble solids.
Permitted ingredients:	
Salt, spices, natural vegetable products (onion, basil leaf, etc.)	—
Acidulants:	
Lemon juice	—
Sugars or other sweeteners	Not permitted
pH regulating agents:	
Sodium hydrogen carbonate	To raise the pH to a level not above 4.3
Citric acid, malic acid, lactic acid, L-tartaric acid	To maintain the pH at a level not below 4.3

Source: CODEX STAN 57-1981.

There also exists a Mexican standard for packed tomato puree (NMX-F-033-1982), which takes into account tomato puree containing a minimum of 10% of salt free soluble solids.

96.4.9.2 International Quality Standard. The Codex standard for tomato concentrates CODEX STAN 57-1981 (Table 96.6) covers only tomato puree and tomato paste. That is to say, it does not consider tomato sauce, chili sauces or catsup since they are seasoned in different concentrations and contain black pepper, onion, vinegar, sugar, and so on, in quantities that change the taste, aroma, and flavor of the tomato ingredients.

The tomato concentrate must have 8.0% or more of natural soluble solids without reaching the state of dehydration. The Codex standard determines the product type according to the percentage of natural soluble solids.

This international standard also includes the sampling criteria used for natural soluble solids, quality specifications, hygiene requirements, labeling, and limits for contaminants. The processors for tomato products handle the specifications shown in Table 96.7.

96.5 TOMATO JUICE: PROCESSING OPERATIONS

Juice is an intermediate product in the processing of tomato paste since it is obtained in the juice extraction stage that will, when the process continues, later result in tomato concentrate.

The tomatoes for juice making are selected, classified, and washed just as those used for tomato paste are.

96.5.1 Break

The tomatoes are chopped and heated to 50–60°C (cold break; Gould 1992). The juice obtained with this method has a better color and taste, though less viscosity due to the enzymatic activity. This juice with less viscosity is adequate for preparing tomato juice. The chopped tomatoes are heated at 83°C for 15 s to deactivate the enzymes in order to obtain juice with more viscosity (Figuerola 1992).

96.5.2 Extraction

After the breaking up system, the ground tomatoes are put through an extraction to remove the seeds and skin in a screen with paddles or pulper.

TABLE 96.7 Commercial Specifications for Tomato Paste.

Presentation	Soluble Solids °Bx	Texture (Screen)	Consistency (12°Bx, 20°C, 30 s) cm	Color (Hunter Lab)	pH
Hot break	30–32	0.033″/0.039″/0.045″	4.5–6.0	Fancy USA	4.1–4.5
Cold break	36–38	0.024″/0.033″	8.0–11.0	>2.2	4.1–4.5

96.5.3 Deaeration

Air is removed from the juice in a vacuum chamber to eliminate the oxygen dissolved in the product.

96.5.4 Formulation

The juice is formulated at this stage according to the characteristics demanded by the market: the most common is juice with salt and another more complex presentation with different spices. Organic acids, the most common being citric acid, is added to adjust the pH.

96.5.5 Homogenization

Homogenization retards the separation of the solids and liquid. The juice is forced through a narrow orifice at a pressure of 1000–1500 psi at a temperature of 66°C to shred the suspended solids (Gould 1992).

96.5.6 Aseptic Processing

The tomato juice is pasteurized at 130°C for 4–5 s. This short thermal treatment at a high temperature (high temperature-short time) is very efficient since it preserves the nutritional and sensory properties of the product. The heating and cooling takes place in the scraped surface heat exchanger or tubes. The cooling temperature is between 85–90°C.

The juice must be cooled to a temperature lower than 30°C for aseptic filling to take place. A 500 or 1000 mL capacity tetrabrik is used for packing. The container has six layers with an external layer and an internal (which is in contact with the product): (1) the external layer made of polyethylene, (2) paper and decoration, (3) polyethylene, (4) aluminum, (5) and (6) polyethylene (Richardson and Selman 1994). The combination of materials is especially adapted to preserve the sensory characteristics of the product and to prevent light and air from entering. The paper layer (2) makes the package rigid, while the aluminum layer (4) acts as an efficient barrier against oxygen and light. The polyethylene prevents leakage and permits the package to close well. The name of the company, information about the product, drawings, recommendations, and so on, is printed on the paper layer instead of a big label which is then protected by a polyethylene layer (1). At the aseptic filler, the material is shaped into a closed longitudinal roll under sterile conditions. The juice is added and the container is closed below the level of the liquid so that the package is now completely filled; the jaws cut and separate them. The packing is sterilized with peroxide (H_2O_2).

96.6 TOMATO CATSUP: PROCESSING OPERATIONS

This sauce is a product that is made with different vegetables, spices, and vinegar. It is used as a complimentary seasoning in everyday food. There are sauces in every country that vary according to its habits. Nevertheless, catsup is very well known. This product can be made from fresh tomatoes or from tomato paste, the latter being what is used industrially. The process consists of the mixing of tomato paste (30–32°Bx) with salt,

TABLE 96.8 Physical and Chemical Specifications for Tomato Catsup Sauce.

Specifications	Limit
Color, minimum (Munsell units)	Acceptable
Consistency, maximum (cm)	12
Moisture, maximum (%)	73
Total solids, minimum (%)	27
Protein, minimum (%)	1.5
Acidity as acetic acid, maximum (%)	2.5
Fiber, minimum (%)	0.4
Ash, maximum (%)	4.5
Total reducing, maximum (%)	24
Chloride as NaCl, maximum (%)	4
Pectin (dry base), maximum (%)	3.5
pH, maximum	4.3

Source: NMX-F-346-1980.

sugar, onions, vinegar, black pepper, mustard, mushroom, and bell peppers. The mixture is pasteurized at 96°C for 4–6 min. The pasteurization temperature varies depending on the equipment used and the end product desired. The sauce then goes through the stage of deaeration, after which it is cooled to filling temperature (25–75°C). The filling is done while hot in order to pasteurize the contents of the sealed container. The Mexican standard NMX-F-346-1980 for tomato catsup establishes the physical and chemical specifications shown in Table 96.8.

This Mexican standard also includes microbiological specifications (maximum limits of mesophyll aerobic bacteria and fungi), for permitted food additives, acidifying agents, sampling criteria, quality specifications, hygiene requirements, labeling, and storage.

97.1 INTRODUCTION

Drying is one of the oldest methods of preserving food products. Dried foods have a good preservation capacity because the moisture content is so low that spoilage organisms cannot grow and enzymes become inactive. Apart from its preserving function, drying also has other advantages, such as providing a wide variety of food products and avoiding the need of much storage space and refrigerating systems (Hayashi 1989).

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

Vegetables are a good source of minerals and vitamins, in particular thiamine (B1), riboflavin (B2), and niacine (B_3), and also provide useful amounts of the fiber (bulk) needed for a good functioning of the intestine (Multon 1992).

Vegetables that are traditionally dried include peas, corn, peppers, zucchini, okra, onions, tomatoes, and green beans. Usually vegetables are cut into pieces of suitable size before drying, since the increase in the superficial area will fasten significantly the drying process.

Almost all vegetables need to be blanched before drying, by scalding in boiling water for a short period of time. This operation stops the enzyme action, which drying cannot stop. In fact, if vegetables are not blanched, enzymes will destroy the color and flavor during drying and storage. However, when blanching is done in boiling water, some water soluble nutrients are lost in the process. To minimize these losses, steam blanching can be used although it is a slower process. The time of blanching must be carefully selected in order to minimize the losses in nutrients and ensure that the enzymes are effectively inactivated. In the case of tomatoes, blanching is not essential because of the richness of tomatoes in antioxidant substances.

The tomato (*Lycopersicon esculentum Mill.*) is native from South America, and is presently one of the most important crops grown worldwide. Mostly, tomatoes are consumed either fresh as salad or in food preparations. However, and since it is highly perishable, they are also used in the form of juice and canned varieties and in the manufacture of various products, such as puree, paste, ketchup, sauce, and soups, among others (Sogi and others 2003; Akanbi and Adeyemi 2006).

The dehydration of tomato has been practiced for many years as a means of preserving it, and offering an alternative way of commercialization. The most popular method used to dry tomatoes is convective hot air drying. However, this method has some important disadvantages related to physic and structural changes, such as migration of soluble solids, shrinkage, case hardening, loss of volatiles, and aroma. Other drying methods are used, that minimize the effects described earlier: freeze drying, air drying at low temperature, and vacuum drying (Akanbi and Adeyemi 2006). Some experiments were carried out to process tomatoes by the foam-mat technique (Ginette and others 1963) or by spray drying (Olorunda and others 1990; Zanoni and others 1999).

The drying, as well as the predrying treatments can affect substantially the quality of the final product. Also storage-induced changes affect the quality of dried products. Some of these involve alterations in the physical state of the material, like shrinking of cells, loss of rehydration ability, wettability, migration of solids, case hardening, and loss of volatile aroma components. On the other hand, chemical modifications, such as enzymatic reactions, nonenzymatic browning and oxidation of lipids, pigments, and vitamins are also affected by physical structure, mainly due to its influence on molecular mobility, which changes diffusivity of the relevant molecular species (Karel 1991; Nijhuis and others 1998).

The increasing consumer demand for processed products that preserve in a better way their original characteristics, as well as the higher industrial use of dried products, has increased the level of requirements, particularly in terms of "functional properties." Telis and Sobral (2002) studied the glass transitions of freeze-dried and air-dried tomatoes and concluded that for the osmotically treated, air-dried tomatoes, the glass transition temperatures were lower than those of the freeze-dried product. Moreover, no differences were observed between glass transition temperatures of samples dried at different air temperatures.

97.2 NUTRITIONAL ASPECTS

Tomatoes are low caloric (19 kcal/100 g of edible part) (Senser and others 1999) and rich in vitamins and minerals, making it a good food product from the nutritional point of view (see Tables 97.1 and 97.2).

Tomato contains not only the nutritional antioxidants like vitamins C and E, but also important quantities of nonnutritional antioxidants like β-carotene, carotenoid, flavenoids, flavone, and total phenolics compounds, and so on.

Some epidemiological studies reveal that the consumption of tomato and tomato-based products can help to prevent various forms of cancers (especially prostate, lung, pancreas, stomach, or digestive-tract cancers) as well as heart diseases (Rao and Agarwal 2000; Chang and others 2005; Toor and Savage 2006). This is the main reason for the increasing interest in the antioxidant components of tomatoes, such as lycopene, ascorbic acid, phenolics, and flavonoids, and the demand for ready-to-use products, which have similar health benefits to the original raw products (Dewanto and others 2002; Schieber and Carle 2005; Toor and Savage 2006).

Fresh tomatoes can be dried as halves, slices, quarters and powders, that are lately used as components for pizza, pestos, snacks, and various vegetable dishes (Lewicki and others 2002). Industrial processing of tomatoes to a final moisture content of less than 15% often involves high temperatures (ranging from 60°C to 110°C) for a period of 2–10 h in the presence of oxygen, and therefore, the products show some oxidative damage (Zanoni and others 1999).

Lavelli and others (1999) reported a reduction in the vitamin C content of tomatoes in drying and Dewanto and others (2002) have observed important losses of ascorbic acid during the production of dried tomato halves and tomato pulp using high temperatures. However, the losses of ascorbic acid are not only dependent on the drying temperatures used but also on the moisture content in the final product.

Air drying of tomatoes also leads to an increase in the 5-hydroxymethyl-2-furfural (HMF) content, which results in undesirable color and appearance changes of dried tomatoes (Zanoni and others 1999). It has been reported by Olorunda and others (1990) that for the air drying of tomatoes an increase in drying time and temperature result in tissue darkening, while other studies report an increase in darkness and decrease in redness (Kerkhofs 2003).

Lycopene is a C_{40} carotenoid polyene, and is the principal coloring matter responsible for the deep-red color that characterizes the ripe tomatoes and tomato products. However, its importance goes beyond its coloring properties, since its presence is associated with recognized health benefits. Although it has no provitamin A activity, lycopene is able to function as an antioxidant and to quench singlet oxygen in vitro. The quenching constant of lycopene

is more than two times that of β-carotene and more than 10 times that of α-tocoferol (Shi and others 1999; Goula and Adamopoulos 2005). The heating, and in particular the drying of tomato products under different processing conditions to manufacture tomato juice, pulp, powder or others, may cause a more or less important degradation of lycopene, according to the conditions used. The principal causes for lycopene degradation are isomerization and oxidation (Goula and Adamopoulos 2006). However, air drying is reported to have little effect on the lycopene content of tomatoes (Kerkhofs 2003).

The total phenolics and carotenoids of tomato have seem to be quite stable during processing under high temperature conditions, and thermal processing has been reported to release more bound phenolics due to the breakdown of cellular constituents (Dewanto and others 2002).

Oxidation increases during dehydration if the moisture content falls below the monolayer moisture content of the product (Zanoni and others 2000). To reduce oxidative damage in the final dried product, Zanoni and others (1999) propose a modification in the operating conditions during air drying of tomatoes, by using low temperature treatments, reducing tomato thickness (using tomato slices or quarters), and partial removal of water (producing tomatoes with an intermediate moisture content).

Color is better retained with low temperature treatments (Kerkhofs 2003), and for osmotic dehydration (Shi and others 1999). However, it is not known whether color and

the antioxidant components of tomatoes would be retained in a higher degree if lower temperatures were used and a higher moisture content product was produced.

Chang and others (2005) reported that the drying process could enhance the nutritional value of tomatoes by increasing parts of the total flavonoids, total phenolics, and lycopene contents. This is a demystification of the idea that the nutritional value of processed foods is lower than that of the fresh ones. Therefore, a proper processing to develop a new type of product could somehow be considered helpful to promote the nutritional value and extend the utilization of tomato. In fact, tomato could be regarded as source of food additives used for fortification and stabilization, even when submitted to technological processes that can eventually cause some degree of loss in the more labile hydrophilic antioxidants. From the economic point of view, the extract products from dried tomato could be further developed as food additives useful in other food applications such as instant food products.

Recently, a new method to produce semidried tomatoes has been developed by drying at 42°C for 18 h to a final dry matter content of about 19%. The bright-red semidried tomatoes obtained are then packed in airtight plastic bags after the addition of canola oil to extend their shelf-life. It is believed that these semidried tomatoes would retain high levels of antioxidant compounds.

97.3 PROCESSING

Tomatoes, like other vegetables, can be dried using various methods. However, in any technique used to dry tomato the time required for drying depends on many different parameters, some related to the product and others related to the drying conditions. As to the first, it is worth mentioning the tomato variety and its composition, in particular the soluble solids content (°Brix) of the fresh product. As to the second, the most important factors are: the size of the tomato segments, the air humidity, the air temperature, and velocity, and the efficiency of the drying system. As expected, the rate of drying directly influences the final quality of the dried product.

In general, dried tomatoes undergo the following process steps: predrying treatments (such as size selection, washing and tray placing), drying or dehydration, and postdehydration treatments (such as inspection, screening, and packaging).

The traditional sun-drying method is advantageous due to its simplicity and low cost, but on the other hand, it requires long drying times and has some disadvantages that can compromise the product quality, like the possibility of contamination from dust and insects or suffering from enzyme and microbial activity. As to industrial drying, when high temperatures are used (~90°C) the tomatoes loose quality regarding color and aroma and may suffer from case hardening (the formation of a hard outer shell), offering a resistance to moisture diffusion and impeding the drying of the interior part of the product. Therefore, the ideal conditions for drying tomatoes are mild temperatures (between 45°C and 55°C), because they allow the dried product to retain its nutrients (including vitamins and lycopene) and flavors.

97.3.1 Pretreatments

Before drying, tomatoes are peeled, mostly by dipping in boiling water, cut and then subjected to different pretreatments.

97.3.1.1 Washing. For small and medium production scales, and when the tomatoes are not peeled, washing can be done in washers by immersion, on three stages. For tomatoes, in the first washing the ideal is to immerse them for 20 min in a solution with 80 mg/L of chlorine. After this first bath, the tomatoes are placed in a second tank where the remaining impurities are removed. This second wash should last about 10 min and the water should be treated with a concentration of 50 mg/L of chlorine. The third and final washing stage is carried out with pure water, without the addiction of chlorine.

97.3.1.2 Cutting and Seeds Removing. Depending on the final usage of tomatoes and the drying method used, they may be cut in halves in the longitudinal direction, using stainless steel knives. Alternatively they may be cut in smaller portions.

The seeds are removed at this stage and those tomatoes not obeying quality standards must be rejected.

97.3.1.3 Osmotic Dehydration. The osmotic dehydration is a pretreatment used to minimize the decrease of nutrients (such as lycopene and vitamin C), allowing the retention of these compounds in the latter convective drying. This procedure has some important advantages, such as low energy requirements, the obtaining of a final product with better appearance (in particular in respect to color), the possibility of incorporating some components that may increase the preservation capacity and minimize the changes caused to color, texture, and flavor by the heat. These reasons contribute for the increase of interest for osmotic dehydration as a pretreatment for the processing of tomato in the most recent years.

This operation consists in the immersion of the product in a solution with a water activity lower than that of the food, which causes the dehydration of the product and at the same time some alteration in its composition. For the osmotic dehydration of tomato, the residual salt amount must be defined according to the products already commercialized, or in agreement with the demands of a specific client. Usually, the tomatoes are left for 30 min in a solution with 5% (w/w) of salt. Alternatively, the pretreatment can be done using sugar mixed with the salt, thus obtaining tomatoes with better organoleptic characteristics. For this, a 65°Brix syrup with one part of salt for 10 parts of sugar is used, at 45°C.

After this pretreatment, the tomatoes are quickly washed with potable water and are drained for 2 min for removal of the syrup in excess.

97.3.1.4 Application of Antioxidants. This treatment intends to minimize the oxidative processes during drying, and is done by immersing in a bath with ascorbic acid (1500 mg/L) and metabisulphite (100 mg/L) for 1 min. Although there is a general tendency to minimize or even to avoid the usage of metabisulphite, it is known that when it is used in small quantities together with the ascorbic acid, its effect is maximized, being more efficient than the two used separately, even in higher concentrations.

Other pretreatments include dipping in calcium chloride solution (Collins and others 1997), sodium chloride solution (Olorunda and others 1990; Sacilik and others 2006), sulphited starch solution (Tripathi and Nath 1989), or osmotic dewatering (Shi and others 1999). In other cases, tomatoes were just cut into halves, quarters or slices and subject to drying (Hawlader and others 1991; Zanoni and others 1999).

97.3.1.5 Effect of Pretreatments. The color of tomatoes dried in pieces is little affected by storage (Tripathi and Nath 1989). However, the powdered product is unstable. It was found that calcium chloride greatly increases the losses in carotenoid, but on the other hand, minimizes browning. Contrarily, the use of sodium chloride and metabisulphite has no effect on the browning of the powder (Baloch and others 1997). As to the effect on the carotenoid losses, sodium chloride has no effect, while metabisulphite decreases the losses.

Osmotic pretreatment proceeding air drying is found to be advantageous for quality of the product (Collins and others 1997; Shi and others 1999). Lycopene loss and isomerization are reduced compared to the conventional air drying process, and the final product properties are similar to those of typical dried fruits.

97.3.2 Sun and Solar Drying

Traditionally, farmers and housewives dried meaty tomatoes with few seeds. Tomatoes with these characteristics dry more quickly than other varieties while having great flavour. The drying of the excess production adds value and shelf-life to tomatoes while taking advantage of the off-season markets. Ripened tomatoes are firstly washed and halved and then they are spread into drying trays in the sun for 5–10 days. The result is a product with typically 12–24% moisture, robust in taste, and which darkens after some time (9–12 months). Products dried by this method require continuous supervision and do not allow homogeneity in the quality of the final product. However, the solar energy can be used without stringent conditions for drying purposes and overcomes many of the sun drying problems.

It is commonly known that the drying process can be conducted by using several solar drying methods. However, solar dryers with solar heater air provide a better control of the required drying air conditions. In addition, solar tunnel dryers, based on plastic tunnel greenhouses, have a good efficiency and do not require any other energy during the operation. Sacilik and others (2006) describe a solar tunnel which is covered by a plastic film of semitransparent polyethylene with 150 μm thickness, in order to incorporate UV and far infrared protection. Wire mesh trays are used to accommodate the tomato halves during the drying process. To compare the performance of the solar tunnel dryer with that of open sun drying the authors used control samples of tomatoes put on a tray near the dryer and dried simultaneously under the same weather conditions. The time to reach a final moisture content of 11.50% (w/w) in the solar tunnel was found to be between 82 and 96 h, while the drying time for open sun drying varied from 106 to 120 h. The higher drying rate obtained when using the solar tunnel, and compared with the open sun drying, could be explained by the temperature difference (more 12.6°C) and relative humidity differential (less 8.7%). In addition, the dried solar tunnel tomato samples had redder and lighter colour than those of the open sun drying.

Other design of a solar drying, a staircase solar dryer, was characterized by Hallak and others (1996) to dry tomato. Basically, it has a shape of metal staircase with its base and sides covered with double-walled galvanized metal sheets and the upper surface covered with a transparent polycarbon sheet. The air motion by natural convection is assured by air-entry points located in the base of the dryer and an exit through a chimney. The temperature inside the dryer must not exceed 70°C, to prevent cooking, and the time necessary to reach a moisture content of 19% is between 2.5 and 3.5 days, very fast when compared to the sun drying.

Sharma and others (1995) present the cabinet-type and multistacked natural convection solar dryers and, additionally, they also analyse a multishelf forced convection solar dryer for drying tomatoes, in which the air temperatures are between 40°C and 65°C along a drying period of 9–16 h. Although an indirect-type solar dryer needs a higher upfront investment cost and availability of electric power, this type of system presents a better performance when compared to the others, showing a higher efficiency and allowing the drying of a higher quantity of material over a given drying period. Moreover, the system can be improved on a semi-industrial scale and operated in a continuous mode trough an auxiliary energy resource.

Although it is true that the direct open-air sun exposure drying processes are the cheapest methods, their application for rural and commercial scales is limited to climates with hot sun and dry atmosphere, as well as with strong winds. Thus, these methods of preservation have been substituted by indirect drying methods using solar heated air.

97.3.3 Convective Air Drying

For the industrial drying, the tomatoes are distributed over trays with a load of approximately 8 kg/m^2. The control tray must have the same load, since it will be used to accompany the process and identify the end-point of drying.

The temperature of the drying air must be set to 60–65°C and the trays must be turned 180° every hour in order to reduce the drying time and to obtain a uniform final water content.

The end of the drying is when the weight of the product obeys the relation:

$$W_f = (W_s - W_i * X_i)/X_f$$

where W_f = final weight in the dryer; W_i = initial weight in the dryer; X_i = initial moisture content; X_f = final moisture content (desired).

Andritsos and others (2003) describe a system for the dehydration of tomato in a tunnel with convective air drying. The tomato dehydration process can be divided into three stages: a predrying preparation step, the drying step, and the postdrying treatment. In the predrying treatment the raw tomatoes are prepared for the dehydration process. This step involves firstly the selection of the tomatoes, in respect to their maturity and soundness (about 40–70% of the tomatoes are selected to proceed for drying depending mainly upon the climatic condition during tomato growth and harvesting). Then, the tomatoes are sorted into two sizes: tomatoes above 90 g and tomatoes of lower weight. Posterior, the tomatoes are placed in crates, washed to remove dust, dirt, plant parts, and so on, and finally cut into two halves and placed into stainless steel trays (mesh type, 100 × 50 cm^2).

The drying operation is carried out in a tunnel drier. This drying system consists of the following main components (Andritsos and others 2003):

- *Finned-tube coil air-water heat exchanger* (INTERKLIMA) for heating the drying air and having a capacity of 300,000 kcal.
- *Fan units.* Two fan units installed in the system, totaling a rated power of 7 kW. The drying system, operated with an air flow rate in the tunnel between 10,000 and 12,000 m^3/h, corresponding to a superficial air velocity of 1.7 m/s (without the trays loaded with product), used approximately 30% of its power capacity. However, in the presence of the loaded trays, which block partially the cross-section

of the tunnel the air velocity increases by 20–50%, depending on the location inside the tunnel.

- *Drying tunnel*. The rectangular tunnel (width a cross section of 1 × 2 m) is 14 m long and is constructed of polyurethane aluminum panels. In the tunnel, the heated air flows in counter current in respect to the movement of the trays. The trays loaded with tomato are placed at the entry of the tunnel and they are conveyed towards the end (where the hot air enters the tunnel) in a semicontinuous way: approximately every 45 min a series of 25 trays with dried product is removed from the end of the tunnel and 25 trays loaded with raw tomatoes are inserted at the entry, pushing the upstream trays towards the end. Each tray is loaded with approximately 7 kg of raw tomatoes. The temperature profile along the height of the tunnel is uniform, allowing the obtaining of a uniform product regardless of the tray position.
- *Measuring instruments.* The inlet and outlet temperatures are continuously monitored using thermocouples. The moisture content is measured by weighing certain marked trays at various locations in the tunnel.

The postdehydration step involves inspection and screening (the removal of dehydrated pieces of unwanted size, of foreign materials, etc.) and packaging in glass jars with olive or sunflower oil, wine vinegar, salt, garlic, and various herbs.

The weight of the processed product reduced about 10–12 times after drying, thus obtaining tomatoes with a moisture content of about 10% (w/w). The removal of the moisture content appears to be faster at the first half part of the tunnel. The residence time of the product in the drier is 30 h, and during that period about 4200 kg of raw tomatoes are introduced in the tunnel and the production of dried tomatoes reaches about 400 kg (Andritsos and others 2003).

Alternatively, the drying of tomato can be done with a wide variety of conditions. Hawlader and others (1991) dried tomato slices at temperatures between 40°C and 80°C with an air flow ranging from 0.7 to 1.8 m/s. Shi and others (1999) used higher temperatures (95°C), Olorunda and others (1990) used temperatures between 60°C and 80°C, Zanoni and others (1999) dried tomato halves at 80°C and 110°C and Lewicki and others (2002) dried tomato quarters at 60°C with an air velocity of 2 m/s. The drying times varied from a few hours to 10 h.

97.3.4 Spray Drying

Spray drying is an important method to dry heat sensitive products such as fruits and vegetables. It is a relatively efficient method that allows the conservation of the purity of the food particles. For the production of tomato powder by spray drying, is recommended the use of tomatoes with bright red color, thick walls, high solids, and pectin content.

97.3.4.1 Principles. The spray drying operation consists in the evaporation of moisture by atomization of a feed into a spray which contacts with a drying medium (usually hot air). The products that can be spray dried follow into two major categories: nonsticky and sticky products. The sticky products are normally more difficult to spray dry, because during the drying process they may remain as syrup or stick on the dryer wall, or even form unwanted agglomerates in the dryer chamber and conveying system resulting in lower product yields and operating problems. On the contrary, nonsticky products can

be dried using a simpler dryer design and the powder obtained is relatively less hygroscopic and more free flowing. Fruit and vegetable juice powders, honey powders, and amorphous lactose powder, are some examples of sticky products.

The problem of powder stickiness is mainly related to the low glass transition temperature (Tg) of the low molecular weight sugars present in such products, (mainly sucrose, glucose, and fructose) (Roos and others 1996). Tomato pulp is a typical example of a product that is very difficult to be spray dried due to the low glass transition temperature of the low molecular weight sugars present. The sugars found in tomato products are essentially dextrose and levulose with a Tg of 31 and 5°C, respectively (Bhandari and others 1997).

During spray drying, different amounts of additives are used depending upon the specific product in use. Tomato is most commonly used and can be dried with or without additives. Spray drying seems to be the most efficient process in obtaining high quality tomato powder at a low cost (Masters 1976).

Centrifugal or spinning disk type atomizers are the most adequate for fruit juices with discrete pieces of pulp (Van Arsdel and others 1973). Industrial dryers usually have multinozzles to deal with the high feed rate. It is important to consider the ease of accessing and removing the nozzles, uniformity of distribution, and their visibility (Barbosa-Canovas and Vega-Mercado 1996).

Special attention must be given to the chamber design, to the handling of the dried particles, and to the packaging of the product during drying, because of the thermoplastic and hygroscopic characteristics of fruits and vegetables.

97.3.4.2 Spray Drying of Tomato. According to Van Arsdel and others (1973), the best tomatoes for dehydration are those with thick walls, bright red color, and high solids and pectin content.

Fresh, ripe tomatoes are soaked in a vat and then transported by a rolling conveyor to a spray-washing vat. After this washing operation, the tomatoes are manually sorted and crushed in a chopper to obtain the pulp.

Tomato is spray-dried in large amounts from a concentrated paste. The powder is made from "hot break" paste or "cold break" paste. If the "hot break" paste is used, the tomatoes are firstly heated at 85–90°C and then crushed, and the seeds and skin are removed before refinement of particle size. However, Noyes (1969) refers that tomato puree which contains skin and seeds originates a more dryable product, recommending grinding the seeds to 325 μm. When a "cold break" paste is used, tomato pulp is held for a few seconds in order to obtain pectin decomposition, which will provide an easier-to-spread paste.

Usually, the powder obtained from the "hot break" is more desirable. The juice is then concentrated in a double effect evaporator and this product goes to a feeding tank to be pumped to the spray drying (Masters 1976). "Cold break" tomato pastes are spray dried at higher concentrations than "hot break" pastes (50°Brix for "cold break" and 45°Brix for "hot break").

A spray drying plant capable of producing a free-flowing product that when reconstituted compares favorably with tomato paste consists of a cocurrent drying chamber with a jacketed wall for air-cooling. If moderate drying air temperatures are used, the intake of cool air is controlled in order to maintain a desired temperature in the range 38–50°C.

The tomato heavy paste goes to a rotatory atomizer containing several vanes. The paste is sprayed into a stream of hot air (138–150°C) and then cooled (Gransmith 1971; Jayaraman and Das Gupta 1995). The cool chamber wall is favorable to minimize the

thermoplastic particles from sticking, because the outer surface of the thermoplastic particles coming in contact with the cold wall solidifies. This method, although improves the process, does not solve the problem, because the cold chamber wall also cools the surrounding environment and causes an increase in the relative humidity of the air close to the wall surface. Droplets of 600–800 μm are desirable for tomatoes with 28% solids constituents.

An alternative approach to the processes described earlier is the Birs Tower process, in which the drying takes place in a very tall tower into which the tomato juice is introduced as a spray at a predetermined height. The whole drying process relies on the time-delayed fall of the product droplets and the very low temperature (not exceeding 30°C) of the upward air flow. In this way the droplet expansion takes place very slowly and explosion-type evaporation is avoided. Therefore, the particles are not exposed to high temperatures likely to damage their organoleptic properties (Gransmith 1971). The volatile compounds present in the paste are better retained as well as the quality of tomato solids. However, the cost of building and operating such towers is very high (Bhandari and others 1997). The tomato powder produced has 10% moisture content, which is later reduced by using a fluidized bed attached to the base of the dryer (Masters 1976).

Another system capable of producing a free-flowing product is a scraped surface drying chamber. This method can be very useful for relatively less thermoplastic sugar such as lactose or sucrose. Karatas (1989) developed an experimental spray dryer with a chamber wall scraper specifically to dry tomato juice. The product recovery was up to 77% with a low inlet air temperature (115°C).

According to Karatas and Esin (1994), during air drying of tomato concentrate droplets the constant rate period lasts about half a minute. When the drying of the surface ends, the diffusional falling rate period shows discontinuities, with the drying rate falling to zero occasionally and then restarting with a drying rate different from the previous period. This behavior is a typical consequence of case hardening phenomena. When the rate of moisture migration from inside of the particle towards the surface becomes lower than the rate of the moisture evaporation from the surface, the surface becomes very dry and hard. Thus, a thin layer is formed, and since it is not permeable to water locks in the remaining moisture inside the particle or the drop. Therefore, drying stops and the average moisture content becomes constant. Though there is no net drying during the case hardened state, internal diffusion continues, and since the rate of output is zero, moisture accumulates in the hardened volume and plasticizing action proceeds outward. When the surface layer is plasticized to a sufficient degree, drying restarts and persists until the rate of internal supply plus moisture accumulated in the surface shell volume can meet the drying rate. To provide a smooth drying operation the drying rate must be low, which can be achieved either by operating at low temperatures or by increasing the moisture content of the drying air, or even a combination of both in order to keep the surface of the drying material plasticized (Karatas and Esin 1994; Szentmarjay and others 1996; Goula and Adamopoulos 2005a,b). However, prolonged drying could cause severe degradation in the sensory and the nutritional properties of the tomato.

97.4 PACKAGING

The tomato powder is packaged in an air-conditioned packing room (Masters 1976). Lumpiness decreases as cooling powder increases. However, the maximum powder temperature to

obtain a lump-free product during storage depends upon the type of the tomato. If the product is used within a few months and it is atmosphere packaged in dry air at low temperature, the product will suffice. Since tomato powder cannot contain more than 2% moisture content, nitrogen or carbon dioxide atmosphere packaging is the most appropriated. For this reason low moisture content of dried fruit juices is required for storage. In order to prevent lumpiness noncaking agents can be used: food gel, silica gel and other noncaking additives can be added to prevent caking (Van Arsdel and others 1973).
