Cream contains many desirable volatile components that contribute to flavor. For a detailed analysis on the volatile components found in cream and different cream fractions using gas chromatography, see Wong and Patton (1962) and Siek and Lindsay (1968).

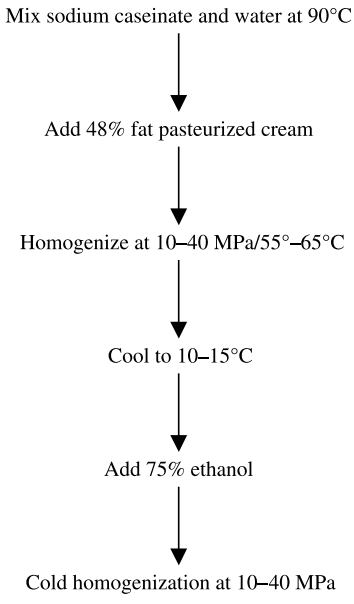

Figure 32.10 *Preparation of cream liqueur.*

32.8.1 Off-Flavors

Vacreation is a steam distillation process used to remove off-flavors and odors from cream. These undesirable components derive from the type of pasture eaten by the cows. In the vacreation process, steam is injected into cream and flash evaporated under reduced pressure. The undesirable volatiles are removed with the steam. This process has the potential to heat-induce coalescence of fat globules, and also to partially homogenize the larger globules through the turbulent action of the steam injection process. A more detailed description can be found in Towler (1994).

An alternative to vacreation, spinning cone technology, can be used to remove off-flavors and odors from fluid products under reduced pressure (Fig. 32.11). This apparatus consists of a series of alternating stationary and rotating concentric cones. Fluid is injected into the top of the column, flowing down the first stationary cone and onto the second cone, which is rotating. The fluid moves upwards and outwards as a thin film and onto the next cone, which is stationary (Fig. 32.12). This process is repeated as the fluid moves down the series of cones. The cones serve the purpose of increasing the total surface area of the injected fluid, hence increasing the efficiency of separation. At the same time, steam is injected into the bottom of the column and moves towards the top, stripping volatiles from the injected fluid product. Deodorized fluid is removed from the bottom of the stack of cones. The volatiles in the steam phase can later be retrieved by condensation.

32.9 SUMMARY

The fat in cream is emulsified in an intricate encapsulated package containing multilayers of enzymes, other proteins, and lipids that participate in these reactions. Despite the apparent simplicity of cream as a processed dairy product, there is an immense and hidden

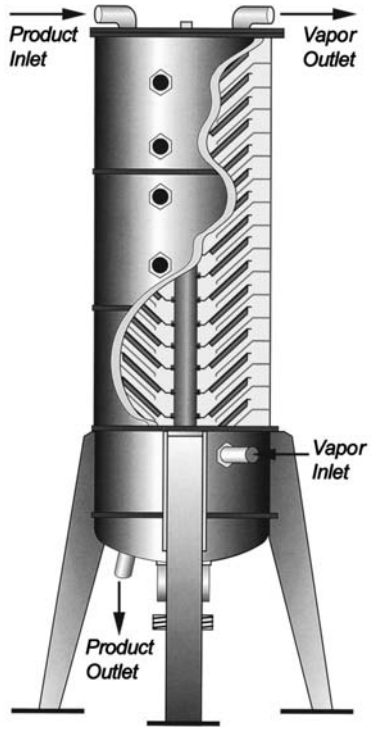

Figure 32.11 *Spinning cone device* (*used with kind permission from Flavourtech*).

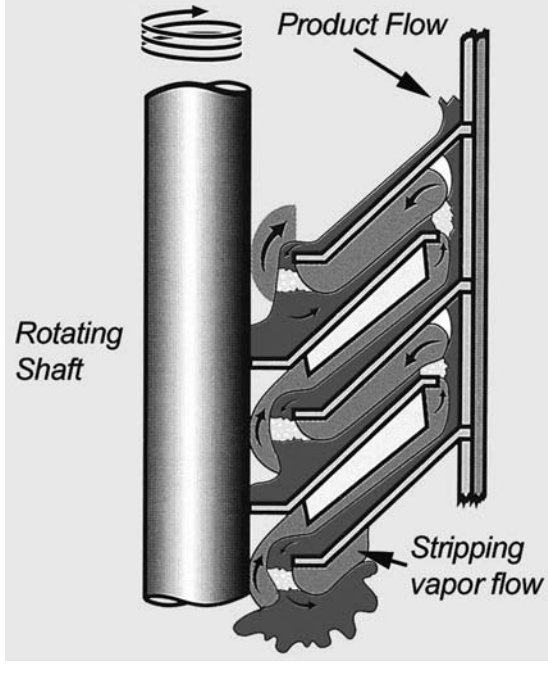

Figure 32.12 *Spinning cone internal configuration* (*used with kind permission from Flavourtech*).

complexity within this food. The many different components of cream interact and produce desirable flavor and texture through chemical and physical reactions. Processing conditions such as heat and shear flow induce other reactions that alter the physical stability of cream as an emulsion. These can be employed to produce many different types of cream with different flavor and textural attributes for use as food ingredients.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

33.1 INTRODUCTION

The olive tree, *Olea europaea* L., is the best known and most widely spread species of the Oleáceas family, its cultivation extending mainly to countries in the Mediterranean area. The tree blooms in May with small white flowers and, almost immediately after, in May or June, the fruit begin to form, culminating in maturation towards the end of autumn.

Its cultivation began more than 6000 years ago, making it one of the oldest cultivated plants in the Middle East, and spread west on both sides of the Mediterranean Sea. It reached Spanish shores with the Roman Empire, but it was the Arabs who promoted cultivation in Andalucia, making Spain the prime producing country in the world. The olive tree was brought along from the Mediterranean basin with the discovery of America in 1492. From Seville, the first olive trees were taken to the Antilles, and then to the continent. By 1560, olive groves were productive in Mexico and later in Peru, Chile, Argentina, and the state of California in the United States. In more recent times, olive growing has continued to expand to places far from its origin to southern Africa, China, Japan, and Australia (Civantos 2004).

There are some 850 million olive trees in the world, occupying an approximate surface area of 8.7 million ha, of which 95% is concentrated in the countries of the Mediterranean basin. Spain is the leading exporter of olive products, with some 170 million olive trees in more than 2.2 million ha of groves, of which 60% are located in Andalucía. Other countries with substantial populations of olive trees are Italy (125 million), Greece (120 million), Turkey (83 million), Tunisia (55 million), Portugal (49 million), and Morocco (33 million).

The fruit of the olive tree, "oliva" or "aceituna", is defined as a drupe and so exhibits a growth curve of the sigmoidal-double type, describing three stages. In the first stage, the weight of the fruit increases remarkably, followed by a stage of weight maintenance, and, finally, a fast growth phase due mainly to an increase in cell volume. Each one of these stages shows a variable duration according to variety (Roca and Mínguez-Mosquera 2003).

The component parts of the olive are the epicarp (or epidermis), the mesocarp (or flesh), and the endocarp. The olive mesocarp, which is also referred to as pulp, accounts for 70–90% of the olive weight (wet basis); the endocarp (stone or pit) comprises 30–10%, and includes the seed (1–3% of the whole fruit).

Olives differ from all other drupes in chemical composition, with a relatively low concentration of sugars, but a high oil content and a characteristic strong bitter taste. Composition depends on factors such as cultivar, latitude, climate, state of ripeness, and so on. The main constituents of the pulp are water (60–75%) and lipids (oil) (10–25%). Of the total oil weight, 98–99% consists of a mixture of triglycerides, free fatty acids, waxes, mono- and diglycerides, sterol esters and terpene alcohols, and phospholipids.

The earliest olive growers of each zone selected wild olives (acebuche) from woodlands for their productivity, fruit size, oil content, and environmental adaptation. Vegetative propagation maintains the characteristics of the initially selected first varieties. The repetition of this procedure (spread of cultivars/hybridization, selection of descendance/cloning) was responsible for a great diversity of autochthonous cultivars, products of chance in all the olive-growing zones throughout the world (Barranco 2004).

Close to 1500 olive cultivars are cataloged throughout the world, although some are the same cultivar under a different denomination. Cultivated olive trees are classified into three categories according to the use given to their fruits: table olive processing, oil extraction, or both purposes, also called double or dual-use cultivars.

The main varieties/cultivars of olive are different in morphologic, agronomic and technological characteristics, such as fruit weight, resistance to biotic factors, fat yield, and

adaptability to mechanical harvesting and pitting. The principal diseases of olive trees that affect production are repilo, caused by the mushroom *Spilocaea oleagina*, verticilosis, produced by *Verticillium dahliae*, and tuberculosis, caused by the bacteria *Pseudomonas syringae* pv. *savastoni*.

Of the 262 olive cultivars grown in Spain, 24 are classified as main varieties, occupying a considerable geographic area or dominant in at least one region. Only four varieties make up 60% of the olives grown, and one, the *Picual* variety, with more than 700,000 ha cultivated, produces practically half of all Spanish olive oil. Based on cultivated surface, *Cornicabra*, *Hojiblanca*, and *Lechín de Sevilla* are important.

The *Frantoio* cultivar occupies a cultivated surface of 100,000 ha and can be considered as the prototype of the Italian cultivars to produce an olive oil of good quality. *Koroneiki* is the main cultivar for oil production in Greece and occupies 50–60% of its cultivated surface. *Ayvalik* cultivar has a high percentage of oil and is considered as the Turkish variety for oil production because of its organoleptic quality. *Chemlali of Sfak* is the variety most important in Tunisia and represents 60% of the cultivated surface. The main Portuguese cultivar is *Galega Vulgar* or *Negrihna*, which represents about 80% of its olive production and is used primarily for oil production, although it is also appreciated as a Greek-style naturally black table olive. In Morocco, the *Picholine marocaine* cultivar occupies 96% of the cultivated surface and is a cultivar for dual use, as table olives and in oil production.

Of the annual world production of olive fruit – approximately 10 million tons – 10% is consumed as table olives, and the rest is processed for olive oil (Civantos 2004). The virgin olive oil is an excellent natural food obtained solely from fruits of the olive tree by mechanical or physical procedures like crushing, malaxing, centrifugation and decantation, and conditions, mainly thermal, that do not cause alteration of the oil. In these conditions, the olive oil has a very pleasant aroma and flavor, and can be used, without further treatment, for human consumption.

The excellent health properties (high monounsaturated fatty acid content, sufficient levels of polyunsaturated fats, antioxidants, and so on) of virgin olive oil are considered added values for the consumption of this oil. This has caused an increase in its market price. It is important for consumers to know the quality of the product and what they are paying for. This chapter focuses on the different studies made on the influences of processing conditions on certain components of virgin olive oil.

33.2 PROCESS OF EXTRACTION OF VIRGIN OLIVE OIL

The Spanish word *aceite* comes etymologically from the Arab word *az-zait*, meaning the juice of the olive. The oil obtained from olive fruits has served for centuries as a food, the prime material for lighting, a medicinal ointment, and a revitalizing liquid.

Today, olive oil is under great demand and has high profitability, thanks to the successful campaign that highlights its therapeutic and nutritive properties. It has an encouraging future and an increasing surface area of cultivation. Estimated world production for the 2005/2006 season by the International Olive Oil Council (IOOC) is 2,584,000 tons, with Spain (34.1%), Italy (23.2%), and Greece (16.4%) being the main producers.

Virgin olive oil has exceptional organoleptic characteristics and is practically the only vegetable oil that can be consumed raw, conserving intact its nutritive and functional properties. The deterioration in virgin olive oil is almost exclusively due to faulty handling of the fruit and of a poorly controlled production process. Independent of variety, only fruits

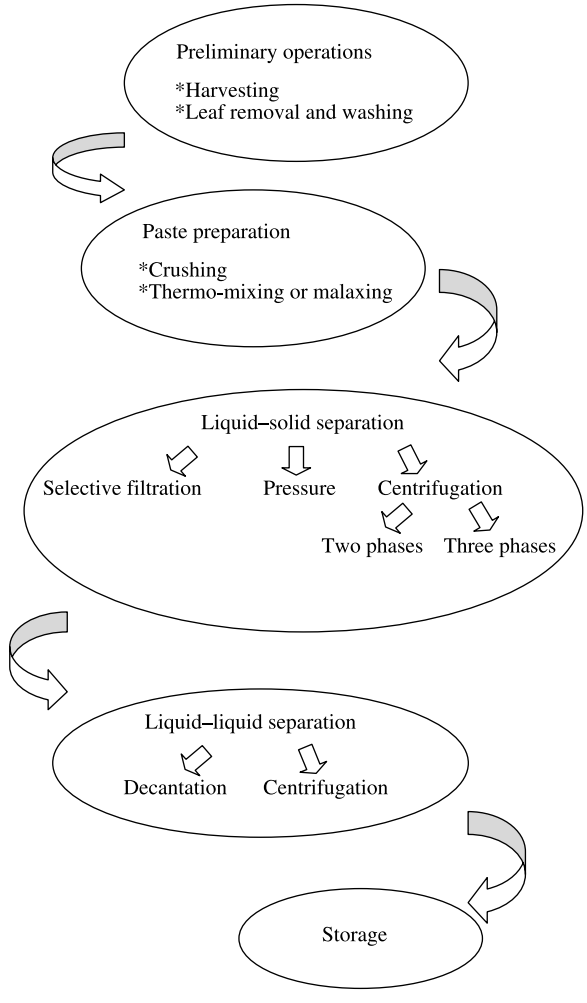

Figure 33.1 *Process of extraction of the virgin olive oil.*

that have suffered from the action of pests or diseases or have fallen on the ground before harvesting inevitably produce altered oil requiring refining due to its high free acidity and/or its disagreeable organoleptic characteristics. Figure 33.1 shows a general scheme of olive processing in order to obtain virgin olive oil (Alba 2004).

33.2.1 Preliminary Operations

The time of year at which the harvesting is carried out, as well as the system used, influences considerably the characteristics of the olive oil obtained. The fruit needs to be harvested at the optimum degree of ripeness, taking into account maximum oil content and best characteristics. The factors that have an impact on the optimum time of harvesting (Porras 1997), are:

- Resistance to the pull of the stalk of the olive;
- Oil content of the fruit;
- Changes in oil quality;

- Falling of the fruit; and
- Date of the previous harvest.

The resistance to stalk detachment is determined by the force necessary to break the pull of the fruit stalk, which can vary enormously throughout ripening and has a bearing on the performance of the operation if the harvest is manual. The harvest must coincide with the time that the green fruits disappear from the tree, which is also when the maximum oil content is reached.

The organoleptic characteristics of the oil deteriorate when the harvest of the fruit is delayed. If more fruity and aromatic oils are desirable, the harvest can be advanced by a few days. With a substantial percentage of green fruit, a better quality product is obtained, although the production yield of the oil is decreased. The natural fall of the fruit basically depends on the cultivar, although it can be influenced by climatic conditions and the health of the fruit. The end of the harvest should coincide with the time that the natural fall of the olive starts and would reach a percentage that would have a significant effect on the cost of harvest. A delay in the time of harvest also produces certain inhibition in floral differentiation of leaf buds, which can result in harvest losses the following year. Harvesting that spoils the fruit and produces damage, such as bruises, broken branches, or twigs, should be avoided.

In general, the fruit is brought down manually from the tree, known as hand picking, or mechanically, using a trunk shaker. The fruit is collected in cloth nets or plastic material that extends below the olive trees, occupying an area larger than the drop zone of the tree. Finally, the contents of these nets are poured into boxes or trailers for transferring to the olive-oil mill.

The daily capacity of oil extraction in the mill is normally lower than the rate of receiving the harvested fruit, requiring fruit to be stored in the so-called *trojes* (or silos) during a variable period of time. During this time, the olives can undergo various changes such as fermentation, enzymatic and microbial lipolysis, auto-oxidation of fatty acids, and so on. These changes will damage oil quality by increasing acidity, decreasing stability, and degrading the organoleptic characteristics. The fundamental objective during this preservation period is to maintain the fruit without changing the oil characteristics, and significantly increasing the cost of the process.

Leaf removal and washing is necessary to prevent contamination from impurities that affect the organoleptic characteristics of the oil, as well as reducing wear and tear on the mills. The winnowing machine is used as a cleaning system, which separates the impurities of lesser weight than the olive (leaves and twigs) using an adjustable airflow. Water is used for the wash that eliminates heavier objects such as mud, stones, and so on. There are washers that operate by density, adding common salt to the water until the olives start to float, and others that work by trawling, adjusting water circulation rate in such a way that it only carries the fruit.

33.2.2 Paste Preparation

A paste is produced by means of crushing and mixing operations with the objective of separating olive oil as a continuous oily liquid phase from rest of the components of the olive, without changing the composition and organoleptic characteristics.

The crushing breaks down cellular membranes to liberate oil droplets. These droplets group together in variable-sized drops that come into contact with the aqueous

phase present in the paste, which arises from the vegetation water and remains of the washing water. This operation is fundamental for the rest of the extraction process and influences industrial yield and quality of the oil. Today, metallic crushers, generally of the hammer type, have replaced the traditional mills with their cone-shaped millstones.

The olive paste obtained after crushing is mixed slowly (malaxing) with the objectives of gathering together the larger-sized drops of oil, combining into a continuous oily phase, and separating the solid phase and the aqueous phase (Martinez-Moreno and others 1957). To improve yield of this operation, mixers have a heating mechanism that helps to decrease the oil viscosity and makes outflow easier. The temperature in the thermomixer should not exceed 25–30°C to prevent loss of aromatic compounds and an increase in the oxidation process. In order to facilitate the separation of oil from the other components of the fruit (therefore increasing the yield), it is possible to use technological aids in this phase of the process. According to the European rules (Regulation EC 1513/2001) that took effect in November 2003, only one technological aid is allowed, hydrated magnesium silicate, because it has no chemical nor biochemical action, and is therefore commonly the denominated talc (Alba 2004).

33.2.3 Liquid–Solid Separation

This stage constitutes the fundamental part of obtaining oil with the objective of separating liquids contained in the olive paste, that is, the oil and residual water (liquid phase) and the solid mixture (skin, pulp, and broken pits), which is known as "olive-pomace". Three separation systems are used in the industry: selective filtration, extraction by pressure, and extraction by centrifugation.

After mixing, it is possible to obtain an important part of the freed olive oil contained in the olive paste by means of cold extraction (*selective filtration*). The first oil contained in the fruit is thus obtained, which has superior quality characteristics to that obtained later by mechanical extraction. This system is recommended for high-quality oil production but is little used due to its high cost (Hermoso and others 1991).

The *hydraulic press* has traditionally been the system used. It consists, in essence, of placing the paste, once mixed, over some filters made of esparto or synthetic fiber (or a mixture of both), known as pulp mat or olive mat, making up the pressing or load unit. This load, located over a trolley with a central spike, is installed in a container in the press in such a way that, by pressing a load over this container, the filtrate of the liquids contained in the paste is obtained. There are several fundamental steps or factors in the execution of the pressing: paste preparation, its distribution and thickness on the olive mats, the state of the olive mat, specific pressure of the press, and the speed and time of pressing (Martinez-Moreno and others 1964). This system is used in only 3% of Spanish oil mills, whereas in Italy 46% of the industry uses such a method.

The use of centrifugal force is the modern method to carry out the liquid–solid separation. It is carried out in dynamic phase systems where the solids are displaced along the draft shaft and continuously removed. The mixed paste is introduced (partially diluted in water) into a horizontal centrifuge called a decanter. This consists of a conical–cylindrical revolving rotor and a hollow bore helicoidal scraper, which revolves co-axially in its interior and at a different speed. By the action of centrifugal force, the solids are pushed to the interior wall of the rotor and are drawn to the furthest point from the axis of spin, that is to say, the space nearest to the wall of the worm gear motor. Separation continues in this manner until it runs out of liquid. The liquid phases (oil and aqueous)

form concentric rings, which, depending on their density, move further toward the middle. Two outlets, situated at a different level in the periphery of the decanter, are used as exits for the residual water and oil. Therefore, three phases are formed: a solid-olive pomace or *orujo*, and two liquids–oil and residual vegetable water. The system is known as three-phase centrifugation. In Italy it is the system used in 43% of the oil mills, whereas in Spain it only represents 10% (Alba and others 2004).

This system produces a final aqueous phase (residual vegetable water) of approximately 0.7–1.1 L/kg of olives. This effluent contains a high load of contaminants, as assessed by the chemical demand for oxygen, and spillage into public waterways negatively affects flora and fauna (Alba and others 1995). Government measures compel olive mills to put a purification system in place. The first system recommended as an emergency measure was the storage of the residual water in pools for natural evaporation. At the same time, exploitation and purification techniques were developed but were not generally accepted by the sector, due to the level of efficiency and installation and operational costs.

Due to this situation, the consumption of water now tends to be lower to minimize the volume of residual vegetable water produced and thus reducing the environmental problem caused by lack of purification. A variation of the process has been developed called a two-phase centrifugation system, which does not require the fluidity provided by the addition of extra water. The separation of the olive paste is achieved in only two phases, a solid-olive pomace and the other liquid-oil. In this system, the vegetable water of the olive is incorporated into the solid phase, which is distinguished from that obtained by the three-phase process in that it is a more moist and pliable consistency, and is now called two-phase olive-pomace or *alpeorujo* (Hermoso and others 1995). The level of final effluent in this production system is reduced to 0.25 L/kg of olives. In Spain, it is regarded as the system of excellence (87% of cases). However, in Italy it is used only in 11% of the industry.

33.2.4 Liquid–Liquid Separation

The oil obtained in the previous stage contains some amount of residual water and a few solids, in the same way that the residual water contains some oil and a large percentage of solids. It is necessary, therefore, to purify the oil (by freeing solids from the residual water) as well as the residual water to obtain the small amount of oil that it contains. Before separating the liquids, the solids, also known as "fines", are eliminated by using vibratory sieves or filters, to separate the highest possible quantity of "fines". Finally, oil separation from water is carried out by natural decantation, centrifugation, or a combination of both.

The difference in density between the oil (0.915–0.918) and the residual water (1.015–1.086) enables separation by natural decanting into vats or settling pits that are linked together. It is the oldest method, and even today it is still being used in some oil mills. However, it requires a large space and a long period of time, during which the contact of the oil with the aqueous phase can cause fermentation and changes in oil quality.

The use of a vertical centrifuge enables continuous and rapid liquid–liquid separation. By the addition of a specific quantity of water, separation of oil from the rest of the residual water is achieved and, in the same way, but independently, recovery of the oil fraction, which is in the aqueous phase. The factors to be considered in this operation are homogeneity and volume of the liquid to be centrifuged, temperature, volume of added water, and time taken between unloading. The oil that comes out of the centrifuge passes into small decanters for degassing and continues to the recipients, where its quality classification is derived.

33.2.5 Storage

The storage period is limited to a season or part of the following one. Longer periods are only anticipated in industrial mills, which include, as well as the extraction process, bottling and marketing operations. During storage, every possible precaution should be taken to prevent three causes of oil spoilage: contact with unsuitable materials, prolonged contact with aqueous impurities, and oxidation. It is advisable to use vats of a capacity of approximately 50 tons, for easier classification and marketing. Vats must be constructed with impermeable and inert materials so oil will not penetrate or react with the surface, as any absorbed oil that cannot be removed by cleaning will be altered and will compromise further use of the vat. The storage cellar must have minimum luminosity, with walls and floors that are easy to clean and maintained between 15 and 18°C without abrupt changes in temperature. Today, the vats that best accomplish these conditions are called "trujales" or traditional underground vats, which, thanks to an appropriate cover of vitrified refractory tiles, ensure the preservation of the oils. If surface vats are used, they must be covered and protected from atmospheric agents and variations in temperature. The most ideal material is stainless steel, although other materials can be used provided that an inert inner covering is used. Vats must have a conical bottom or a flat incline and a purge tap to facilitate sediment removal.

33.3 INFLUENCE OF PROCESSING ON MAIN CHARACTERISTICS OF VIRGIN OLIVE OIL

Considering the characteristics of the extraction process for virgin olive oil, the variables that can affect the final nature of the product are not very extreme. Among them are temperature and time of malaxing, the system of liquid–solid separation (pressure, two phases, or three phases), or the use of some aids, typically talc. Modifications in some of these parameters during the process originates changes in certain components of the olive that allow tracking of the process. In fact, some of the components of the oil are not present in the fruit, but have been formed during and as a result of the extraction process.

33.3.1 Volatile Compounds

In this group are found all compounds responsible for the characteristic aroma of virgin olive oil, although the volatile compounds can only explain 66% of the sensorial attributes (Morales and others 1999). More than a hundred volatile compounds have been identified, such as hydrocarbons, alcohols, aldehydes, ketones, esters, acids, phenolic compounds, terpene compounds, and furan derivatives. However, there is still no objective method of measuring the aroma, which requires evaluation by a panel of specialist tasters (Panel Test).

In good quality oils, the retained volatile compounds come from the actual fruit and are generated by biogenesis mechanisms. Some compounds are originally found in intact flesh of the olive, while others, called secondary or technological volatiles, are formed during breaking down of the cellular structure as a result of enzyme reactions that take place in the presence of oxygen. The principal biochemistry route is through the action of lipoxygenase, and precursors such as the 18-carbon polyunsaturated linoleic and linolenic fatty acids (Olias and others 1993; Sánchez and Salas 2000). When the harvest conditions of fruit and production or storage of virgin olive oil are defective, a whole series of disagreeable volatile compounds responsible for sensory defects (off-flavors) are generated. Very

different mechanisms are implicated in the genesis of these undesirable compounds. The majority is related to microorganisms (yeast, bacteria, and molds) during storage of fruit before oil extraction, generating volatile compounds responsible for sensory defects such as fusty, musty, or winey-vinegary. During the storage of unfiltered virgin olive oil, sediments are deposited that can also allow fermentation, generating volatile metabolites responsible for the sensory defect known as muddy sediment.

There are also other chemical mechanisms that produce undesirable volatiles. The main one is auto-oxidation of fatty acids. This process is generated spontaneously by the action of atmospheric oxygen, producing a series of chain reactions by a free-radical mechanism. The products of this oxidative change are responsible for rancidity, as well as significant deterioration in nutritional quality.

When the intensity of these sensory defects is high, the oils are classified as "lampante" according to current regulations (EC 2001), require further refining, and are often rejected by the consumer.

The extraction conditions of virgin olive oil have a great influence on its sensory quality. During the centrifugation process, temperature and time of malaxing can be altered to potentially affect quality. Volatile compounds, produced through the lipoxygenase pathway (hexanal, Z-3-hexenal, E-2-hexenal, hexyl acetate, Z-3-hexenyl acetate, hexan-1-ol, E-3-hexen-1-ol, Z-3-hexen-1-ol, and E-2-hexen-1-ol), have been analyzed by dynamic headspace gas chromatography, gas chromatography–mass spectrometry, and gas chromatography–olfactometry (Morales and Aparicio 1999) as a function of different malaxing times and temperatures in an experimental oil mill. The results demonstrate that each volatile responds differently depending on the variables such as time and temperature of malaxing. Nevertheless, the indices proposed in relation to best extraction conditions on the basis of volatile are a temperature of 25°C and a malaxing time of between 30 and 45 min. Higher temperature (T greater than or equal to 35°C) with minimum values of time ($t < 30$ min) could also be useful as an alternative way to obtain pleasant green virgin olive oils.

Nevertheless, it seems that something of controversy exists as far as the conclusions of investigations carried out on the influence of processing on olive oil characteristics. Recently, Tura and others (2004), characterizing the volatile compounds of 40 Australian virgin olive oils, concluded that, except for the effect of malaxing time on the hexanal content, they do not appear significantly different. In this study, an increase in the time of malaxing induces a reduction in the hexanal formation (comparing 15 and 60 min of malaxing). These results agree with results previously reported by Ranalli and others (2001).

The effect of the solid–liquid separation system on the volatile fraction has been studied. Aparicio and Luna (2002) verified that the concentration of almost all the volatile compounds, mostly C_6 and C_5 alcohol, was superior in oils obtained by press than those of three phases. Nevertheless, as commented previously, because of problems of residual water, the three-phases system has evolved to the horizontal centrifuge or decanter of two phases, verifying that this implies a greater content in E-2-hexenal and total aromatic substances (Aparicio and Luna 2002).

33.3.2 Phenolic Compounds

The hydrophilic phenolic compounds constitute a group of secondary metabolites in the plant that present peculiar sensorial as well as beneficial health properties. The principal polyphenols of olive oil are tyrosol and hydroxytyrosol, both derived from hydrolysis of oleuropein.

Also found are a smaller proportion of caffeic, vanillic, siringic, *p*-coumaric, *o*-coumaric, protocatechic, synapic, *p*-hydroxybenzoic, *p*-hydroxyphenylacetic, and homovanillic acids.

The presence of hydrophilic phenolic compounds in virgin olive oil is strictly related to activities of several endogenous enzymes of the fruit. This explains why its concentration in the oil is strongly affected by the conditions of extraction. In fact, some of the secoiridoid aglycons presents in the virgin olive oil originate during crushing of the fruit (Servilli and others 2004). This is the reason for studying the effect of different variables during the extraction process based on phenolic compounds content in the olive oil.

Thus, it is known that the increase in the time and temperature of processing originates a reduction in the concentration of secoiridoid aglycons (3,4-DHPEA-EDA and 3,4-DHPEA-EA) and phenolic alcohol (Angerosa and others 2001; Di Giovacchino and others 2002). The time of exhibition of pastes to contact with air (TEOPAC) is a parameter that modifies the content of phenolic compounds in the oil (García and others 2001; Servili and others 2003). It seems that when the oxygen levels in the paste are reduced, polyphenoloxidase and peroxidase are inhibited, improving the hydrophilic phenolic compounds in the virgin olive oil (Bianco and others 2002).

In the same way, it has been discovered that oils obtained from pastes with de-stoned olives have superior levels of phenolic compounds if we compare them with the traditional pastes that include stones of the olive in the paste prior to separation of solid–liquid. The hypothesis is that the peroxidase enzyme that degrades hydrophilic phenolic compounds during olive oil processing is highly concentrated in the stones (Montedoro and others 2001).

Aids such as enzymatic preparations during the extraction process also favor the increase in phenolic compounds in the corresponding oils (Vierhuis and others 2001).

Finally, the effect of the selected extraction system on polyphenol content of the corresponding oils has been studied. Years ago, it was reported that oil obtained by pressure, which does not require addition of water to the paste of olives, shows greater levels of polyphenols in comparison with the traditional centrifuged oil (Montedoro and Servili 1992). More recently, the works have been focused in comparing the two-phase and three-phase systems. The three-phase system is much more positive from the point of view of phenols than the decanter producing two phases (García and others 2001; Gimeno and others 2002).

The amount of mass (by time unit) that is introduced into the horizontal centrifuge decanter (DCH), in relation to the theoretical capacity, constitutes a parameter of control and regulation. This is closely related to effectiveness of the DCH, and is of great importance in obtaining a good centrifugal separation, and therefore good yields of elaboration. Maintaining constant the geometric characteristics of the DCH, the variations of the injected volume affect the mass residence time in the interior of the decanter, so that an increase of rate leads to a faster separation using the centrifugal separator. An increase in injection rate probably produces a significant increase in polyphenol content (Jiménez-Márquez and others 1995), because the increase in mass volume implies a reduction of malaxing time of the paste in the thermomixing.

The separated oil in the DCH is not completely clean, but includes suspended mass particles, and water that has not been removed. That elimination is necessary to avoid alterations in the oil, such as an increase in acidity, oxidation of the oil, and so on, taking place during storage. This elimination takes place in vertical plate centrifuges diluting the oil with water to carry out the separation. The more elevated water : oil relation (1.5:1) produces a more intense washing of the oil, resulting in oils with minor polyphenol content. Similarly, in comparing processing at different temperatures (30, 40, and 50°C), a diminution in the polyphenol content occurs when higher temperatures are used (Jiménez-Márquez and others 1995).

33.3.3 Tocopherols

Gimeno and others (2002) have studied the effect that centrifuge systems having: two and three phases have in the content of α-tocopherol. In comparing 60 virgin olive oils of the Arbequina variety, coming from two different harvesting periods and in two different states of maturity, there is definitely no difference in the total content of α-tocopherol. This is in agreement with the earlier works of Ranalli and Angerosa (1996).

Nevertheless, the content of α-tocopherol is affected if it is produced with fruits de-stoned prior to the extraction of virgin olive oil. Recently, Lavelli and Bondesan (2005) have confirmed that using de-stoned fruits (instead of stoned fruits) diminishes the content of α-tocopherols of the corresponding virgin olive oil, which is in agreement with previous works (Frega and others 1997). Although it is important to emphasize the content of tocopherols in virgin olive oil, the effect of the technology is minimal in comparison with genetic factors or degree of maturity.

33.3.4 Chlorophylls and Carotenoids

One could expect that, given their lypophylic nature, all the chlorophylls and carotenoids present in the olive fruit will be transferred to the olive oil. However, it has been demonstrated (Gallardo-Guerrero and others 2002) that the extraction process affects

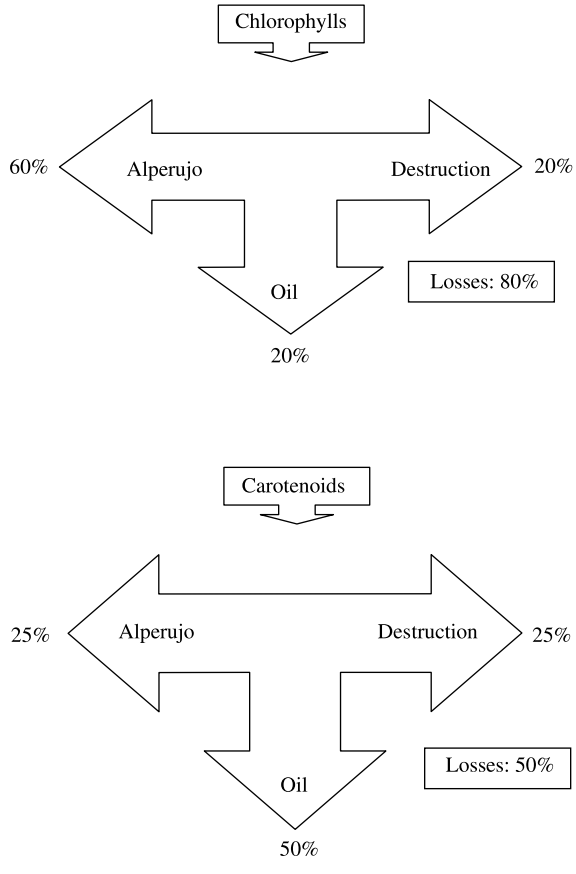

Figure 33.2 *Percentage of transferred, occluded and destroyed pigments during olive oil extraction.*

chlorophylls and carotenoids in different ways (Fig. 33.2). Only 20% of the chlorophylls are transferred to the oil, with 60% of the same fraction occluded in the alperujo and 20% destroyed during the extraction process. On the other hand, 50% of the carotenoids present in the fruit are transferred to the olive oil, 25% of the fraction occluded, and the other 25% destroyed during proccesing.

In general terms, chlorophylls tend to experience chemical and physical modifications as a result of processing and storage of green vegetables. Chlorophyll pigments are particularly affected by acid conditions and heating (Schwartz and others 1981; Mínguez-Mosquera and others 1991; Chen and Chen 1993). Therefore, chlorophylls and their derivatives can be used as treatment and quality markers in processed foods (Gandul-Rojas and others 2000). In the chl (chlorophyll) molecule, the ester of the methoxycarbonyl group in C-13^2 is exceptionally stable towards acids and remains virtually intact during short treatments at room temperatures. At higher temperatures, however, acid conditions lead to hydrolysis of the ester followed by decarboxylation, producing chl pyroderivatives (Hynninen 1991). Although pyrophys are also found in fermented foods such as wild rice or table olives (Schwartz and Lorenzo 1990; Mínguez-Mosquera and Gallardo-Guerrero 1995), the presence of chl pyroderivatives is largely related to the thermal treatment of vegetables, making pyrophys the main pigment in sterilized products (Schwartz and Lorenzo 1991). Teng and Chen (1999) have recently investigated the degradation of chlorophylls and formation of pyrochlorophylls and their derivatives during baking, blanching, steaming, and microwaving of spinach leaves. In olive oil submitted to physical refining by deodorization with nitrogen, pyrophys have also been detected (Gandul-Rojas and others 1999). This fact converts pyrophys into authentic traceability markers of the thermal process and by so much of great interest into the sector of the olive oil to guarantee the smooth thermal conditions in which virgin olive oil should be extracted.

Recently, investigations have been carried out on the effect that the addition of some enzymatic preparations, natural extracts obtained from genetically unmodified organisms, can exert to a greater advantage for the paste and an oil with better qualities as an end result. These preparations are usually a celulolytic, hemicelulolytic, and pectolytic enzyme mixture. Ranalli and others (2005) have studied the effect that some of these preparations have exerted on some chemical compounds in the oil, specifically on the pigments. In fact, the study was carried out with two different varieties of olives, and concluded that the addition of this enzymatic processing aid increases significantly the chlorophyllic and carotenoid fractions in the oils in comparison with control oils.

The increase in malaxing temperature between 20 and 30°C increases the chlorophyll and carotenoid contents. Nevertheless, temperatures greater than 30°C do not imply an increase in the green and yellow chromatic fractions of oils (Ranalli and others 2005). There are only limited investigations into the effect of extraction systems (two or three phases) on oil coloration. Work by Gimeno and others (2002) indicates that the extraction system chosen does not affect the β-carotene content of oils.

33.4 QUALITY MARKERS OF OLIVE OIL

According to the International Olive Oil Council, olive oil is "the oil obtained solely from the fruit of the olive tree (*Olea europaea sativa* Hoffm. Link) to the exclusion of oils

obtained using solvents or by re-esterification processes and of any mixture with oils of another kinds". This oil can be produced commercially under different denominations. Virgin olive oil is "the oil obtained from the fruit of the olive tree solely by mechanical or other physical means under conditions particularly thermal that do not lead to alteration in the oil and which has not undergone any treatment other than washing, decantation, centrifugation and filtration".

To define the quality of olive oil, like any other food product, is a difficult task influenced by a multitude of variables. Generically, it can be defined as the property or set of inherent properties to a thing, that allow to appreciate it like equal, better or worse "than the rest of its type" (Uceda and others 2004).

There are different conceptions of quality according to the use of the olive oil. Established first is that quality is not unique and that it can be different, depending on the point of view: from the regulated viewpoint, which is defined by the established norms, through the nutritional, commercial, sensorial angles.

33.4.1 Regulated

The regulated quality is the easiest to define as it is clearly defined by EC Regulation 2568/91, modified by CE n°. 1989/2003 (6 November), and is shown in Table 33.1. Currently, two rules exist that regulate the denominations of olive oils and olive-pomace oil (EC 2001; IOOC 2001). In both regulations there are parameters, known as quality parameters, to evaluate the quality of the oils and these are free acidity, peroxide index, K_{232}, K_{270}, ΔK, and organoleptic characteristics.

The degree of free acidity measures the percentage of free fatty acids, expressed as oleic acid. It is the index of changes experienced by the fruit during fermentation in the production and storage process.

The peroxide index evaluates the state of primary oil oxidation. The most important causes of a high value of this index are the history of the fruit (soil, frosts) and exposure to factors that cause oxidation (high temperatures, aeration, and the presence of trace metals) during production and storage. It is expressed in miliequivalents of active oxygen by kg of fat.

The K_{232} is a spectrophotometric measure of conjugated dienes, which is used along with the peroxide index to evaluate the primary oxidation of the oil. This parameter only is included in the EC regulation.

TABLE 33.1 Quality Olive Oil Indexes Established by CE n° 1989/2003 (6 November 2003).

	Acidity (%)	Peroxide Index	K_{270}	ΔK	K_{232}	Median Value of Fruity Aroma	Median Value of Defects
Extra virgin olive oil	≤0.8	≤20	≤0.22	≤0.01	≤2.50	>0	0
Virgin olive oil	≤2.0	≤20	≤0.25	≤0.01	≤2.60	>0	≤2.5
Lampante virgin olive oil	>2.0	–	–	–	–	>2.5	–
Refined olive oil	≤0.3	≤5	≤1.10	≤0.16	–	–	–
Olive oil	≤1.0	≤15	≤0.90	≤0.15	–	–	–
Crude olive–pomace oil	–	–	–	–	–	–	–
Refined olive–pomace oil	≤0.3	≤5	≤2.0	≤0.20	–	–	–
Olive–pomaceoil	≤1.0	≤15	≤1.70	0.18	–	–	–

Shading indicates commerical categories.

The K_{270} is used to evaluate, spectrophotometrically, the conjugated trienes and indicate the state of secondary oxidation of the oil. The resulting products of this oxidation (aldehydes and ketones) also absorb at wavelengths of 262, 268, and 274 nm. The ΔK coefficient takes into account these absorbencies and is defined as

$$\Delta K = K_{268} - [(K_{262} + K_{274})/2].$$

Besides physico-chemical parameters, virgin olive oils are also classified by their organoleptic characteristics determined by a group of trained tasters, according to the rules of sensory analysis (Albi and Gutierrez 1991; IOOC 2001). When no defects exist in the flavor (visual together with olfactory–taste–tactile), the tasters evaluate the presence and intensity of positive attributes. The sensory attribute "fruity" is responsible for a mixture of olfactory–taste sensations attributed to fresh and healthy fruit at an optimal degree of ripeness. This attribute is essential in the sensory evaluation because the absence of this attribute excludes the oil from the virgin grade. However, increased intensity of fruity attribute is often accompanied by a perception of high intensities of bitterness and spiciness, which makes the oil unacceptable for direct consumption, requiring mixing with other virgin oils of less intense flavor. On the new sensory evaluation form, proposed in 1996 by IOOC and adopted by the EC in May 2002, the most frequent negative attributes are scored "fusty, musty, muddy sediment and winey-vinegary". Also included in the "Others" section are all other well-defined negative attributes such as "earthy, esparto, pungent, cucumber, grubby, etc". Only fruity, bitter, and pungent are considered positive attributes. Depending on the median value of the defect perceived with greater intensity and the median value of the fruity attribute, the virgin olive oil is classified into distinct categories. A median organoleptic evaluation of the defect (Md) and the fruity attribute (Mf) is made, valuing from 0 to 5:

0 = Total absence;
1 = Almost imperceptible;
2 = Light;
3 = Medium;
4 = Big;
5 = Extreme.

Besides these quality criteria, the Commission regulation (CE) n° 1989/2003 also described purity criteria that include limits for the following parameters: 3,5, estigmastadiene (mg/kg), % *trans* isomers of fatty acids, fatty acid content, ΔECN42, sterols composition and total sterols, erythrodiol plus uvaol (%), waxes (mg/kg), saturated acids in the 2-position of the triglycerides (mg/kg) and sum of translinoleic and translinolenic isomers (%). All the quality and purity criteria should be fulfilled for a specific category of olive oil.

Color is another organoleptic quality characteristic fundamental to virgin olive oil as it is one of the attributes that affects the consumer most at the time of purchase. The first evaluations of color were based on the visual comparison of oil with standard solutions of bromothymol blue (BTB), using an adaptation of methods developed for seed oils (AOCS 1977, 1988; Gutierrez and others 1986). Photometric evaluations at two wavelengths have been proposed for olive oil (Papaseit and others 1986), and also numerical correlation between the chromatic coordinates and the chlorophyll and carotenoid

content (Mínguez-Mosquera and others 1991), as well as with the BTB indices (Moyano and others 1999). Despite the importance of this quality attribute, none of the current regulations includes color.

33.4.2 Chlorophylls and Carotenoids

In recently extracted virgin olive oil, the chlorophylls and carotenoids of the olive must be present, plus those transformed during the oil extraction process. The modifications these pigments experienced during crushing and malaxing of the paste are derived from the release of cytoplasmic components that come into contact with different enzymes and substrates isolated under normal conditions. To a large extent, pigment modification is influenced by the release of acid compounds. For the chlorophyllic fraction, the generalized reaction is the pheophytinization, and for the carotenoids, the isomerization of xanthophylls with epoxides groups like violaxanthin, neoxanthin, and anteraxanthin, which are transformed into their corresponding derivatives 5,8 furanoids, auroxanthin, luteoxanthin, neochrome, and mutatoxanthin, respectively (Mínguez-Mosquera and others 1990). Also, traces of intermediaries of the chlorophyll catabolism, such as 13^2-OH-pheophytin and 15^1-OH-lactone pheophytin are among the oxidation metabolites and chlorophyllides and pheophorbides as intermediaries in the deesterification initiated by chlorophyllase (Gandul-Rojas and Mínguez-Mosquera 1996; Gandul-Rojas and others 2000).

33.5 TRACEABILITY MARKERS OF OLIVE OIL PROCESSING

33.5.1 Phenols and Volatiles

In addition to the studies made on the effect of processing conditions on olive oil exerted on the chemical composition of the same, statistical studies have been made considering as much the fraction of volatiles as the fraction of phenols. Such studies allow discrimination of oils according to extraction method.

In this sense, Angerosa and others (2000) could classify correctly 54 virgin olive oil samples corresponding to three harvesting periods based on the type of extraction: laboratory-scale, industrial two phases, and three phases. By means of principal component analysis (PCA) the variables were selected between volatile and phenol fractions. This allowed the conduction of a linear discriminante analysis (LDA) capable of classifying correctly the samples, based exclusively on the methodology of extraction used.

A similar approach was employed by Servilli and others (2003) to classify (PCA) oils of two Italian varieties obtained with differents time and temperature of malaxing, on the basis of phenolic and volatile composition. Additionally, applying a partial least-squares analysis (PLS) allows the development of a response surface model (RSM), which, besides the explanation of between 89% and 95% of the variance of the two varieties, allows the selection of best conditions (based on volatile and phenolic composition) of malaxing. Thus, for the Frantoio variety a temperature of 22°C and 30 min of TEOPAC consitutes the theoretical optimal conditions, whereas for the Moraiolo variety these conditions are 26°C and 0 min of TEOPAC. Besides confirming that the variety is a fundamental factor in the volatile and phenolic composition of virgin olive oil, the authors

demonstrated the production of a virgin olive oil of high quality. It would be interesting to fit processing parameters to each variety.

33.5.2 Chlorophyll and Carotenoid Indexes

As commented in a previous section, in recently extracted virgin olive oil, only the pigments of the olive must be present, plus those transformed during the process of extraction of the oil. Nevertheless, the small but always important differences found in the carotenoid and chlorophyll metabolism during the ripening of the fruit according to variety, influenced by endogenous enzymatic activities, are going to be reflected in the pigment composition of the corresponding oils. Consequently, the chlorophylls and carotenoids of virgin olive oil become parameters of quality and authenticity for this product. The presence of chlorophylls and carotenoids that are pigments different from those just described, or the detection of a greater degree of transformation is indicative of incorrect or fraudulent practices in processing (Gandul and others 1999).

A study of the chlorophylls and carotenoids in 50 monovarietal virgin olive oils of Spanish origin, besides defining the inherent pigment profile of the virgin olive oil, has allowed the establishment of two parameters of quality that must be fulfilled by these oils (Gandul-Rojas and others 2000). On the one hand, it has been shown that between both pigment fractions exists a constant relation, around the unit, independently of the variety and the state of ripening of the fruit. This relation is maintained within narrow margins, oscillating between 0.5, when the oils come from mature fruits, up to 1.4 when, the oils are obtained from unripe fruits. On the other hand, the carotenoid fraction has a constant relation between lutein, which is the main component of this fraction, and the rest of the minority carotenoids. In all virgin olive oils, the relation of minoritary carotenoids/lutein is located around 0.5 or exceptionally superior to 1 in the oils obtained from olives of the Arbequina variety, and this parameter, in addition to authenticating the quality "virgin olive oils", allows differentiation of varietal origin. In the same way as the relation of chlorophylls/carotenoids in oils obtained from very mature fruits, the relation between minoritary carotenoids and lutein diminish up to values of 0.2 in oils obtained from very mature fruits.

Later studies have allowed the verification of such parameters of quality and authenticity of virgin olive oil, in general, to stay stable after 12 months of storage of the oil at 15°C and in the dark. These are conditions generally used in the industry to keep the oils that are not commercialized immediately after their production (Roca and others 2003).

Although the relation between the fractions of pigments or presence of certain carotenoids stays constant in oils during a year of storage, it has been verified that, during that period, the chlorophyll molecule experiences specific changes that imply modification of the pigments profile associated with the recently extracted virgin olive oil. From the quantitative point of view, losses of pigments do not take place. However, there is a generalized advance of the reactions catalyzed by acids and initiated during oil extraction: the pheophytinization reaction of chlorophylls and the isomerization of the groups 5,6-epoxides of minoriarty xantophylls. Possibly, the greater or smaller content of substances of acid character that are transferred from the fruit to the oil is going to modulate the advance of these reactions (Gallardo-Guerrero and others 2005).

A slight increase of hydroxylation of the C-13^2 of pheophytin *a* takes place, as well as small formation of pyropheophytin *a*, the pigment absent in the freshly extracted oil. It has

been verify that the maximum presence of pyropheophytin in oil stored at 15°C and in the dark for one year is around 3% of the total chlorophyll compounds and that the relation between pheophytin *a* and pyropheophytin *a* must always be superior to 20. In this sense, these small structural pigment transformations, which are not inherent to the extraction process and therefore undesirable, are going to be indications that the oil has been stored. Inadequate conditions of storage such as high temperatures and/or illumination cause increases in the content of these compounds (Gallardo-Guerrero and others 2005).

A combined SPE and HPLC method has been developed, which can be considered as a modification of a previous one (Mínguez-Mosquera and others 1992) in two ways. First, it assures a total recovery of pheophytin *a* and pyropheophytin *a* during SPE sample extraction, and, secondly, it improves selectivity of detection and sensitivity of quantification by using fluorescence detection in tandem with UV–visible spectroscopic detection (Hornero-Méndez and others 2005). This method has allowed the control of "undesired" formation of pyropheophytin in oils obtained with temperatures higher than the recommended ones for virgin olive oil extraction and comparison with the presence or absence in a statistically significant number of oils cataloged as virgin olive oil. Thus, an index of quality of the extra virgin olive oil has been proposed: the calculation of the percentage of pyropheophytin, %Pyrophy = 100*Pyrophy/(Phy + Pyrophy). In the case of reaching values higher than 10%, it would indicate that the oil has been stored at inappropriate temperatures or has been obtained under heat treatments (Gandul-Rojas and others 2005).

34.1 INTRODUCTION

Apple (*Mauls domestica Borkh*) a pome (*Pomoideae* subfamily of *Rosaceae*) fruit is among the top five fruits produced in the world (Table 34.1). Studies support a positive association between fruits and vegetables consumption and good health. Phytochemicals present in fruits and vegetables may protect biological molecules (lipids, proteins, and DNA in our body) from oxidative damage. It is believed that a diet rich in fruits and vegetables can enhance our endogenous antioxidant defenses against chronic degenerative diseases. Apples make a greater contribution than berries to phytochemicals in western diets, because the intake is relatively higher. This chapter describes supply, demand, storage, processing, physico-chemical, antioxidant, and nutritional values of apples.

34.2 SUPPLY AND DEMAND

34.2.1 Supply

Apple is an important commercial tree crop in many countries. The world apple production in 2005 was estimated to be about 63.5 million metric tons. Five countries, China (39.4% of world total), United States (6.8%), Turkey (4.0%), Iran (3.8%), and France (3.3%) accounted for 57% of world apple production in 2005 (Table 34.2). China is a major exporter of fresh eating apples (approximately 0.8 million metric tons in 2004) and apple juice concentrate (0.5 million metric tons) to Europe, North America, Asia, and Africa (Anon 2005).

Apples were the second most valuable fruit crop next to grapes in the United States with estimated farm gate value of $1.78 billion, or 11.5% of all fruit and tree cash receipts of $15.5 billion (USDA 2005). Nearly 100 varieties are grown, however, 15 varieties account for over 90% of the U.S. apple production (Perez and others 2001).

34.2.2 Organic Apples

The EU and the United States together accounted for 95% of the $25 billion in world retail sales of organic food products in 2003 (Dimitri and Oberholtzer 2006). The growth in organic market is due to our rising concern for health and environment. In order for a farm to produce organic apples, the land must be free of any harmful pesticides and fertilizers for a minimum of three years prior to organic production. For a product to be labeled "organic", it must contain over 95% organic materials. A "made with organic" product must contain over 70%.

TABLE 34.1 Leading Fruits and Producing Countries, 2005.

Leading Fruit	World Production (Metric ton, Mt)	Leading Country
1. Banana	72,464,562	India (16,820,000)
2. Grapes	66,533,393	Italy (9,256,814)
3. Apples	63,488,907	China (25,583,934)
4. Oranges	59,858,474	Brazil (17,804,600)
5. Mangoes	27,966,749	India (10,800,000)

Source: FAO (2005).

TABLE 34.2 Apple Production (Mt) in Leading Countries and World.

Country	Average (2000–2005)	2005
1. China	21,583,934	25,583,934
2. United States	4,315,744	4,354,290
3. Turkey	2,383,333	2,550,000
4. Iran	2,338,169	2,400,000
5. France	2,175,184	2,213,000
6. Italy	2,061,605	2,194,875
7. Poland	2,195,917	2,050,000
8. Russia	1,865,333	2,050,600
9. Germany	1,859,483	1,600,000
10. India	1,308,333	1,470,000
World (total)	59,690,201	63,488,907

Source: FAO (2006).

In the United States, organic apple acreage increased from 12,770 acres in 2000 to 17,272 acres in 2001. Washington (6540 acres) California (4529 acres), Arizona (2800 acres) and Colorado (1535 acres) were leading U.S. states in organic apple production. Outside the United States, Europe (8675 acres in 2000), New Zealand (2873 acres), South America (1385 acres), Canada (800 acres) and Turkey are expanding organic apple acreage. Two other factors, premium price to growers for organic apples and organic production as a way to prepare for the loss of production tools such as pesticides are cited for the growth of organic farming (Granatstein and Kirby 2002).

34.2.3 Demand

Apple products from across the globe are available in the United States. About 37% of apples produced in the United States are utilized as fresh (Table 34.3). The remaining 63% is processed as, juice and cider (49%, or 75% of all processed), canned apples (mostly applesauce, 10%), frozen and dried (2% each), and jam, jelly, apple butter, etc. (about 1%). Next to oranges (83.5 lb), apples (50.4 lb) were the second most utilized fruit in the United States during 2004 (Table 34.4).

TABLE 34.3 Per Capita Consumption of Apple and Apple Products in United States[a].

34.3 HARVEST AND STORAGE

34.3.1 Harvest

Apples are harvested at maturity. Farmers use "days after full bloom (DAFB)" to predict harvest maturity. Gala and Fuji apples have "DAFB" of 110–120 days and 170–185 days, respectively. In the United States early season apples are ready for harvest in August. However, peak apple harvest is from September to October. The date of first harvest in New Zealand is February to March (McGhie and others 2005). A low-chilling requirement apple "Anna" in Israel is harvested in June (Lurie and others 2002). In India where apples are grown only in the three mountainous states (Jammu & Kashmir, Himachal Pradesh, and Uttranchal Pradesh) harvesting can be as early as June, or as late as November (Deodhar and others 2006).

Among objective tests for harvest maturity, firmness of apple flesh measured by a pressure tester is considered reliable. Apples for storage and processing typically have pressures above 15 lb, while a pressure in the 13 lb range is suitable for fresh use fruits (Anon 2004). Sensory and other objective measurements such as skin color and appearance, fruit size, soluble solids (Brix) and acidity (% malic acid), starch and internal ethylene concentration (especially for apples to be stored in CA storage) are also taken into account to determine harvest maturity.

Premature harvesting of apples affects flavor, color, size, and storability (susceptibility to bitter pit: dark, dry spots, or pits near or below the fruit surface; and storage scald: brown patches on the fruit surface). Late harvesting causes softer fruits and a shorter storage life.

Preharvest foliar spray of calcium is shown to maintain fruit firmness and decrease physiological disorders such as water core, bitter pit, and internal breakdown. Application of bioregulators such as ethephon may also improve fruit quality and storability (Drake and others 2002).

Apples are picked by hand to minimize bruising. Fresh market apple should be free of bruises, blemishes, and other defects. Bruising during harvest, transport, grading, storage, and packing affect returns to growers, and bruised fruits are generally used for processing into juice and other products.

34.3.2 Post Harvest Handling and Storage

Post harvest treatments of apples involve, washing, sorting, grading, waxing, packing, and cooling. Apples are stored at 0° to -1°C with 92–95% humidity in regular cold storage for a short period. Prompt cooling prevents softness in apples. Under controlled atmosphere (CA) storage, apples can be stored for one year without any appreciable loss of quality.

The CA storage requires airtight refrigerated rooms that are sealed after apples are stocked up inside (and must not be opened for at least 90 days after the seal is affixed). In CA storage, oxygen (O_2) is reduced from atmospheric 21% to 1–3%, and carbon dioxide (CO_2) is increased from atmospheric 0.25% to 1–3%. Relative humidity in the CA storage is maintained at 92–95%.

Storage disorders (loss of firmness, browning, bitter pit, superficial scald, water core, chilling injury, etc.) are not uncommon and result from inconsistent storage protocols and questionable fruit quality going into long-term storage (Anon 2004).

As expected, apples from normal cold (NC) storage are softer than those stored in CA storage (Lopez and others 2000). Lavilla and others (1999) reported improvement in sensory qualities of apples when the CA atmosphere had a low (1.8–2% O_2/1.8–2% CO_2) and ultra-low (0.8–1% O_2/0.8–1% CO_2) as compared to standard oxygen (2.8–3.0% O_2/2.8–3% CO_2).

Use of coatings (carnauba-shellac mixture and candelilla having intermediate gas resistance; shellac and shellac-protein with highest gas resistance) can extend shelf life of apples (Saftner 1999). Coatings can create elevated CO_2 and reduced internal O_2 concentrations similar to CA storage and modified atmosphere (MA) packaging. However, use of coatings can also affect flavor by regulating their synthesis and minimizing loss by evaporation from the fruit surfaces. In Braeburn and Granny Smith apples, gas resistance coatings produced anaerobic fermentation and ethanol. A wax coating with intermediate gas resistance gave increased fruit-like and apple-like volatiles (Bai and others 2002).

As a post harvest treatment, Golden Delicious, Ida Red and McIntosh apples were dipped in sucrose polyester solutions and stored at 5°C with 90–95% RH for four months (Chai and others 1991). Ripening was delayed as evidenced from little loss of tissue firmness and color in Golden Delicious and McIntosh apples.

Use of ethylene action inhibitors such as 1-methylcyclopropane (MCP) has been investigated to study changes in apple quality. A delay in softening, retention of green color and reduction in acid degradation were observed in MCP treated apples (Defilippi and others 2004).

34.4 APPLE VARIETIES

Size, shape, color, flavor, crisp-juicy texture, post harvest storability, etc., are important varietal characteristics. Varieties are grouped as, fresh market, juice and cider, baking, processing, and all-purpose apples. During planting trials apples are screened for, disease resistance such as, susceptibility to bitter-pit, soft scald, sunburn, bruising, fire blight, etc., fruit quality (firmness, size, appearance, juiciness, sweetness, tartness, aroma, and flavor), yield, and storability. Growers receive higher returns for apples going into the fresh market than processing (Table 34.5). There are several all-purpose apples suitable for fresh consumption and processing (Table 34.6).

TABLE 34.5 Season-Average Grower Price (cent/lb) of Apples in the United States.

	2000	2001	2002	2003	2004
1. Fresh	20.0	18.0	24.0	26.0	28.0

TABLE 34.6 Characteristics of Selected Commercial Apple Varieties.

Variety	Characteristics	Use
1. Braeburn	Developed in New Zealand in 1952; harvest – September to October; color – typical greenish-gold with red sections; sweet-tart, spicy flavor; yellow flesh; texture is crisp and juicy.	For fresh eating and processing as sauce, pies, baking and freezing, juice, and cider.
2. Empire	A cross between McIntosh and Red Delicious; harvest – late September to early October; dark red appearance; mild tart; crisp; flesh is creamy white.	A good apple for fresh eating and for salad, can be used in other applications as well.
3. Fuji	Developed in Japan in 1962; parentage- Ralls Janet and Red Delicious; harvest – September to late October (in some regions late October to mid-November); appearance – golden hued to red; round shape; sweet and aromatic; crisp texture; flesh is whitish yellow; a good storage apple.	A good apple for fresh eating, salad, sauce, pies, baking, and freezing.
4. Gala	Developed in New Zealand in 1965; harvest – mid to late August; appearance – creamy yellow with red/orange stripes; mild sweet flavor; flesh is yellow, firm, and juicy; a right size apple for snacking.	For fresh eating and salads, it is also a good apple for applesauce and baking.
5. Golden Delicious	Introduced in 1914; Origin, West Virginia, United States; a chance seedling, believed to be due to Golden Reinette and Grimes Golden; harvest – mid-September to early October; pale greenish-yellow appearance; sweet apple with excellent flavor; juicy yellow flesh.	An all-purpose apple; skin is soft and thin for fresh eating; used in salads, applesauce, baking, and fresh apple cider.
6. Granny Smith	Credited to an Australian grand mother Maria Ann Smith; a long season fruit, may not ripen before frost, harvest – October to early November; appearance – signature green; size – large; a slightly tart apple with a crisp texture and white flesh.	Has good eating and cooking qualities, excellent for applesauce, salad, and apple juice.
7. Ida Red	Developed from Jonathan and Wagener; harvest – mid to late October; large apple; appearance, bright red; tart flavor, flesh is white, firm and juicy.	Used as fresh, frozen, canned, sauces, and pies.
8. Jonagold	A "Jonathan × Golden Delicious" cross; harvest – mid October; size – medium large; appearance is orange red; well-flavored greenish white flesh; good taste; crisp and juicy.	Excellent fresh eating and cooking (pie and baked) apple.
9. Jonathan	Discovered as a chance seedling in 1820s on a farm in Woodstock, New York; named after the man who promoted it; harvest – mid-September to mid-October; crimson color with touches of green; flavorful with small to medium slices; flesh is off-white, sweet and juicy; blends well with other varieties in sauces and cider; stays firm during cooking.	All purpose apple suitable both for fresh eating and for applesauce, and pie.
10. McIntosh	An important commercial variety; harvest – early to mid-September; appearance red, striped; white juicy flesh, tender skin, medium large fruit; good aroma.	Mainstay of fresh cider; for eating out of hand and sauce making.

(*Continued*)

TABLE 34.6 *Continued.*

Variety	Characteristics	Use
11. Mutsu (Crispin)	Origin, Japan; a cross between Golden delicious and Japanese variety Indo; one of the later variety apple with mid-October harvest; Light green to yellow; large fruit; moderately sweet; creamy flesh.	Preferred use: fresh, pies, and baked.
12. Northern Spy	Harvest – mid October; large size; yellow–green skin and creamy white flesh; crisp and juicy; spicy, aromatic flavor.	Can be used in various processing, including, slices, sauces, and pie.
13. Pink Lady	Origin, Australia; introduced in 1985; a cross between Golden Delicious and Lady Williams; harvested – late October; appearance bright pink and thus the name; firm, crisp flesh and sweet-tart flavor.	Excellent apple for fresh, salad and sauce use; good for baking and freezing.
14. Red Delicious	Believed to be the most popular variety in the world and in the United States; discovered as a chance seedling on a farm (of a non-apple region) in central Iowa; glossy red with a distinctive "typey" five-pointed elongated shape. Sweet and flavorful; harvested late August; can generally be found in market in Fall and early winter; good aroma apple.	For fresh eating and salads.
15. Rome	Origin, Rome township, Ohio; harvest – mid to late October; size – large; bright red skin; sweet, juicy, white flesh; low acidity.	Good processing apple for pies, sauce, and as baked.

34.5 PHYSICO-CHEMICAL CHARACTERISTICS

Apples contain about: 85% water, 14% carbohydrate, 2.4% dietary fiber, 0.3% protein, 0.20% lipids, and 0.0% cholesterol (Table 34.7). Some variation in these components is expected due to variety, maturity, growing location, agronomical, and environmental conditions.

Approximately 75% of carbohydrates in apples are sugars, fructose (about 6%), glucose (2.4%), and sucrose (2.0%). Sugar alcohol, sorbitol (0.2%) is also present (Gorsel and others 1992). Malic acid is the predominant organic acid (0.3–1.0%). Variety, maturity, and environmental conditions during growth and storage influence acidity of apples (Ackermann and others 1992).

Table 34.8 shows physico-chemical qualities of apple slices stored for 12 days at 2°C. Firmness of Empire apples held better (only 8% loss) than Golden Delicious and Rome (both lost 32% of their original firmness). The flesh colors of Empire and Golden Delicious were better than Rome.

34.5.1 Apple Flavor

Various esters, alcohols, aldehydes, ketones, and terpenoids formed due to biochemical and metabolic reactions during growth, ripening and storage impart characteristic flavor and aroma to fruits. A majority of flavor compounds in apples are volatile esters (Lopez and others 2000). Compounds such as ethyl propionate and butyl acetate give

TABLE 34.7 Approximate Composition of Apples (Raw, with Peel).

Component	100 g	154 g/one Serving

the characteristics "apple" flavor. Hexyl acetate, imparts "sweet-fruity" note, and 1-butanol, a sweet sensation. Cunningham and others (1986) showed β-damascenone (flower like aroma), butyl isomyl and hexyl hexanoates, along with ethyl, propyl, and hexyl butanoates, important to apple flavor. Other apple flavor compounds are, propyl acetate, butyl butyrate, t-butyl propionate, 2-methylpropyl acetate, butyl acetate, ethyl butyrate, ethyl 3-methylbutyrate, and hexyl butyrate.

The apple flavors are maintained during CA storage (Lavilla and others 1999; Table 34.9).

Compounds responsible for undesirable flavors such as acetaldehyde (piquancy), trans-2-hexanal and butyl propionate (bitter), 3-methylbutylbutyrate and butyl 3-methylbutarate (rotten) were not found in apples analyzed by Lopez and others (1998).

34.5.2 Phenolic Compounds and Antioxidant Capacity

Apples are rich in phenolics compounds (Sun and others 2002), which are secondary plant metabolites having antioxidant properties. Apples differ in their concentration of phenolic compounds (Sluis and Others 2001). The popular Red Delicious apples contain about 240 mg total phenolics per apple (Table 34.10; McGhie and others 2005). Flavonols are present more in peels than in flesh, while hydroxycinnamics such as chlorogenic acid is present more in flesh than in peel (Tsao and Others 2003; Table 34.11). Wolfe and others (2003) reported apple peels to more effectively inhibit the growth of $HepG_2$ human liver cancer cells than other apple components.

Brands of apples juice differ in their phenolic content, and fresh apples juice has more phenolics than stored juice (Table 34.12).

Total antioxidant capacity (TAC) of selected apples was reported as, 3578–5900 μmole of Trolox Equivalent (TE)/serving of an apple (Wu and others 2004; Table 34.13). As expected, apples with peel had higher TAC values than without peel. Red Delicious apples had more TAC (5900 μmole) than Granny Smith (5381 μmole), Gala (3903 μmole), Golden Delicious (3685 μmole) and Fuji (3578 μmole).

34.5.3 Nutritional Quality

Apples are a natural source of sugars and dietary fiber (80% of which are soluble fibers) various minerals and vitamins (Table 34.7). Fresh eating apples have little fat and cholesterol, and contribute less than 100 calorie per serving size. Table 34.14 shows nutrient profile of various apple products.

TABLE 34.13 Total Antioxidant Capacity and Total Phenolics in Selected Apples.

34.6 PROCESSED APPLE PRODUCTS

Processed apples such as apple juice, cider, applesauce, jam, and jelly are well-known products. Frozen diced and sliced apples are used in pies and other baked applications. Minimally processed apple slices are retailed as snack items. Intermediate moisture and infused dried apples are used as ingredients in bakery, dairy products, cereals, snack

bars, confection, etc. Infused processed frozen and stabilized apples are used in dairy and bakery products. This section describes processing of selected apple products.

34.6.1 Apple Juice and Cider

In the United States apple juice is the most dominant of all processed apple products (Perez and others 2001). Apple juice-making has traditionally been a mechanical process involving milling/mashing of apples into smaller pieces and pressing with a hydraulic press to express juice. Thus, apple juice and cider are extracted liquids containing soluble solids primarily fruit sugars and acids. Cider is cloudy and amber brown because suspended solids are not removed by filtration. Unpasteurized ciders are a great safety concern. Unlike a "hard cider," which contains a little alcohol, regular ciders are not fermented. The characteristic cider flavor varies from region to region and is based on types of apples used in the manufacturing process.

Apples used in juice-making are generally culled from fresh packing lines. In traditional milling-pressing operations, the yields are 70–80% (w/w), and even lower (~65%) for stored apples (Cliff and others 1991). However, through use of enzyme liquefaction and membrane filtration, the apple juice yields can be as high as 98%.

Process for apple juice would vary among processors. However, basic juice-making involves (Fig. 34.1): Fruit receiving: air cleaning, washing, inspection-grading (to remove rotten and moldy fruits), quality checks (weigh, Brix, acidity, etc.) → milling/slicing (to crush/mash/ using bars/knives) → pressing/extraction → enzyme treatments or use of fining steps, or both (to remove suspended solids) → clarification/membrane filtration → pasteurization → packaging (hermetically sealed in cans or bottles), or asceptically processing and packaging.

Usually a blend of several apples is used to provide flavorful apple juice and cider. A batch hydraulic press (a traditional rack and frame press where milled apples are placed in thick fabrics separated by wooden racks and hydraulic pressure is applied from the top of the rack to release the juice) and various types of continuous pressing equipments can be used. The latter are often employed in commercial operations because of efficiencies in yield, quality, and process controls. It also allows low residual moisture in the pressed cake or pomace.

Commercial juice press designs include a belt press where milled apple pulp is held between belts and juice is released through pressure from rollers, and a screw press made up of tapered screws to convey and squeeze juice against close fitting screens. Juice extraction can also be done using a centrifuge. In a counter current extraction process, juice is extracted using liquids such as water to remove juice solids. This extracted water is then depectinized and passed through membrane separation systems to generate about 10–14 Brix juice, which can be further concentrated.

Presence of colloidal pectic substances such as starch, cellulose, hemicelluloses, pectins, etc., cause haze, cloudiness, and sedimentation in apple juice. Therefore, after extraction, apple juice is treated with enzymes, fining agents, or both, to remove suspended solids and clarified using membrane filtration.

Two pectinase enzymes are usually employed in juice making operations. (1) Polygalacturonase (endo-form: EC 3.2.1.15; and two exo-forms: EC 3.2.1.67 and EC 3.2.1.82), which act on glycosidic linkage and are responsible for fruit ripening. These enzymes can be used as a press aid. (2) Pectin lyase (EC 4.2.2.10) it degrades the pectin chain by acting on glycosidic linkage through β-elimination. A combination of endo- and exo-lyases can be used to degrade pectin as a clarification and membrane

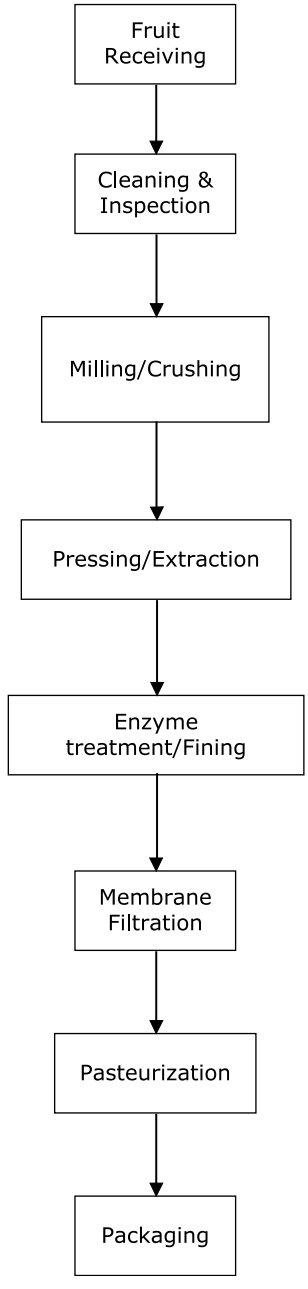

Figure 34.1 *Process for apple juice.*

filtration aid. The enzyme doses, time, and temperature would depend upon specific enzymes; the clarification time is inversely proportional to the enzyme concentration used.

Membrane filtration such as ultrafiltration capable of retaining particles of about 0.005 micron (molecular weight >1000 Dalton) or larger (components such as plant gum, proteins, enzymes, gelatin, etc., operating pressure of 70–200 PSI) but allowing low

molecular weight particles such as sugars, salts, and acids to pass through has become the industry standard to remove haze-forming particles following an enzyme treatment or use of various adsorbents or fining agents (diatomaceous earth, gelatin, etc.).

Presence of amino acid proline has been linked with haze formation. A protein-polyphenol haze is due to interactions between a protein fraction capable of binding polyphenols (haze active protein) and a polyphenol fraction (haze active polyphenol) that can form a bridge between two protein molecules. Stabilization steps for manufacturing a clear apple juice are designed to reduce the levels of either protein or polyphenol or both (Siebert and Lynn 1997, 2000).

Following the enzymic treatment and membrane separation the juice is pasteurized ($\sim 88^{\circ}C/1$ min) and packaged. A large part of apple juice is sold as frozen concentrate as well.

In 2001, the FDA promulgated rules requiring juice processors to use HACCP principles and sanitary standard operating procedures (SSOPs) because of the risk of food-borne illness from consumption of unpasteurized juice products. Under the federal Juice HACCP rule, juice processors must comply with: (1) HACCP principles and systems; and (2) reduce a theoretical population of "pertinent" microorganisms in the juice by five-log cycles. The "pertinent" microorganism is defined as the most resistant microorganism of public health concern that is likely to occur in juice. *E. coli* 0157:H7 and *Cryptosporidium parvum* are regarded as "pertinent" organisms for apple juice.

In 1996, *E. coli* 0157:H7 contamination of apple juice was responsible for over 70 illnesses and one death in the northwest. This organism due to its acid tolerance and low infectious dose (10–2000 cfu/g) is of concern in unpasteurized juices and ciders. Chikthimmah and others (2003) reported a five-log cycle reduction in *E. coli* 0157:H7 in cider by adding fumaric acid (0.15% w/v) and sodium benzoate (0.05% w/v) to the product. The use of these preservatives lowered the natural pH of cider (i.e., 3.40–3.87) to pH 3.19–3.41 and inactivated any *E. coli* organisms in the product.

Patulin a mycotoxin (one of the microbial hazards to be controlled under HAACP regulation) produced by certain species of *Penicillium*, *Aspergillus*, and *Byssochylamys* molds that may grow on harvested apple is a regulatory concern. The regulations typically limit patulin content in apple juice to no more than 50 μg/kg (Kryger 2001).

34.6.2 Apple Slices

A number of different techniques are used to maintain flesh color, flavor, and crisp texture of apple slices. The softening of apple tissue due to loss of cell fluids and enzymatic browning are subject of many investigations including modified atmosphere packaging, low temperature storage, and addition of preservatives (Soliva-Fortuny and others 2001).

Polyphenol oxidase (PPO) catalyzed oxidation of phenolic compounds present (enzymatic browning) in apples into o-quinines, which polymerize to produce dark brown color when apple slices are exposed to air. The role of oxygen in enzymatic browning and cellular damage was evident from lower firmness values and greater amount of cell fluid's loss in apples packed in a 2.5% O_2 and 7% CO_2 atmosphere package than in 100% N_2 atmosphere package (Soliva-Fortuny and others 2003). Commonly used effective inhibitors of PPO are sodium metabisulfite and ascorbic acid. However, Sulfites have been linked to allergic reaction, especially in asthmatic individuals. The FDA regulates the use of sulfites in foods and sulfite content ≥ 10 ppm is required to be shown on the labels. The alternatives to sulfites are based on ascorbic acid, citric acid and calcium salts. Santerre and others (1988) reported ascorbic acid or D-araboascorbic acid/citric acid and calcium chloride combinations effective in preserving color of frozen apple slices.

Calcium ascorbate or calcium erythorbate and ascorbic acid applications and storage at −7–20°C have been claimed to extend shelf life of fresh cut fruits including apples (Chen and others 1999; U.S. patent 5,939,117). Powrie and Hui 1999 (U.S. patent 5,922,382) described a method of preserving fresh apple by immersing apple pieces in an acid solution containing 5–15% ascorbic acid and erythorbic acid (pH 2.2–2.7) for up to 3 min, followed by removal of excess solution from fruit surfaces, quick chilling and storing at 0–10°C.

34.6.3 Applesauce

Applesauce contains apple, sugar, and other sweeteners, honey, acidulants, salt, flavorings, spices, preservatives, etc. The desired characteristics of applesauce are golden creamy color, a balance of sweetness and tartness, glossy texture, which is not soft and mushy. The Brix of unsweetened applesauce is about 9.0. However, the Brix of sweetened applesauce is about 16.0. Applesauce has a pH of approximately 3.4–4.0. The basic processing steps involved are: dice/chop washed apples (a blend of several apple cultivars, in peeled or unpeeled forms can be used) → heat process apple pieces (similar to blanching, this step is critical for consistency and texture of the finished product) → pass through a pulper/finisher (screen size: 0.16–0.32 cm; for coarse grainy sauce: 0.25–0.32 cm) to remove seeds, peels, etc. → fill and seal in containers (the fill weight is 90% of the container's capacity and allow for a head space of about 0.6 cm upon cooling) → heat process (if the fill temp is ≤88°C, heat containers in boiling water for 10–15 min in an open container to insure microbiological safety; a high-pressure processing ensures product safety and longer shelf life by destroying spoilage organisms) → invert containers and cool.

34.6.4 Processed Frozen Apples

Apple can be infused and pasteurized for use in frozen desserts such as ice cream, frozen yogurt, etc., or for addition into baked goods. The water content of apple is stabilized by infusion with sweeteners or by incorporating stabilizer (pectins, carrageenan, gums, and starches). The fruits thus processed are not icy when frozen. The products are pasteurized and are a ready to use ingredients in frozen desserts which cannot use IQF or frozen fruits. The process maintains fruit piece identity, natural color, texture, and flavor (Sinha 1998).

34.6.5 Dried Apples

The drying of apples at a given temperature would depend on raw material (fresh or frozen, with or without skin), composition, size and geometry (sliced, diced, etc.), and drying load. In general, drying rate follows three phases (1) a initial phase of rapid water evaporation, because the fruit contains relatively large amounts of unbound moisture; (2) a steady evaporation phase thereafter; and (3) a falling and slow rate of evaporation towards the end because the water is more tightly bound to the fruit constituents and is difficult to dislodge.

The rate and completion of drying can be monitored by measuring changes in water activity (a_w). The cut-off a_w of shelf stable dried fruits should be below 0.65; above which mold can grow (Beuchat 1981), unless antimycotic agents are used.

Consumers like the dried apples to be as close as possible in eating quality to a fresh apple. Thus the texture, color, and taste of dried apples are important. The aim of infusion drying as discussed below is precisely to achieve this. Most dried foods with reduced moisture are partly or completely amorphous. According to the glass transition (T_g)

theory, a glass (amorphous material) is changed into a super-cooled melt or liquid during heating, or to reverse during cooling. Mobility of water is high in glassy food systems. Following completion of drying, the apples should be equilibrated at cooler temperatures to enable a free-flowable texture.

In dried fruits, plasticization (T_g decreases) is mainly due to water, but other solutes such as glycerin may also act as plasticizers to enable soft textured dried products (Le Meste and others 2002). The T_g of freeze-dried apples has been reported to be $33.8 \pm 3.4^{\circ}C$. The T_g is shown to increase with the temperature of drying. The T_g represents the thermal limit between a state where the molecular mobility is rather low (no reaction) and a state of increased molecular mobility, which favors diffusion and other reactions. Thus a freeze-dried strawberry with a T_g of $45.4 \pm 2.2^{\circ}C$ would be less

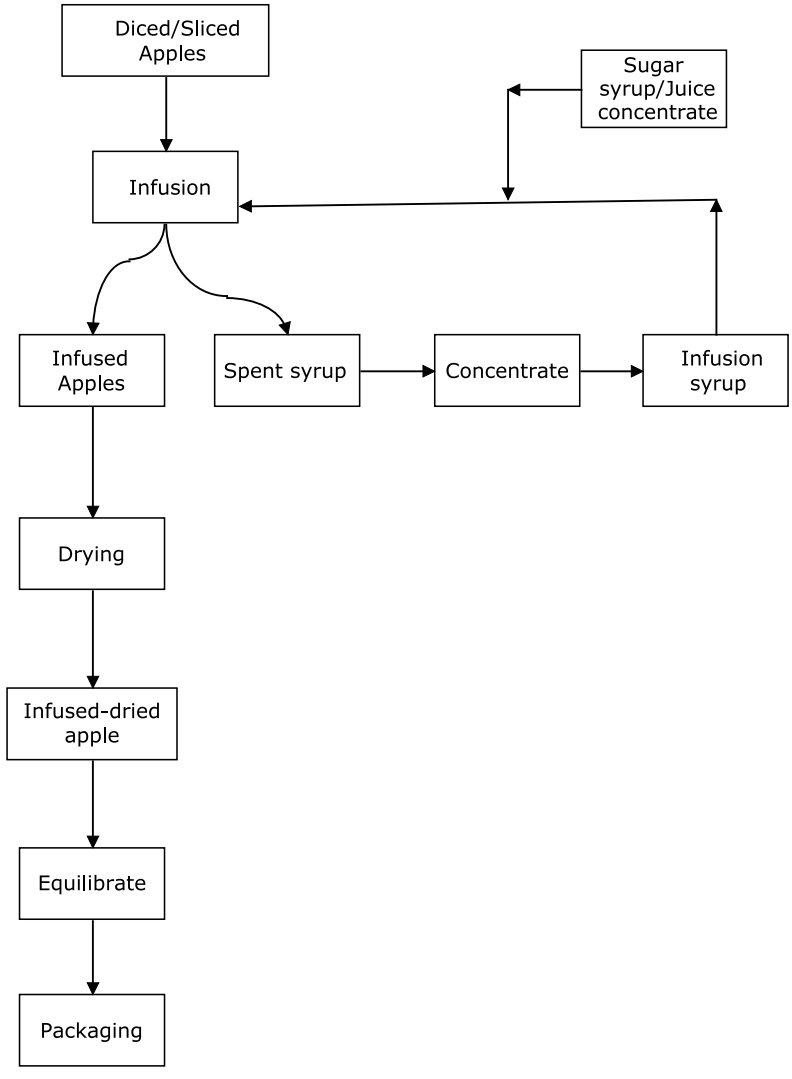

Figure 34.2 *Process for infused-dried apples.*

susceptible to color changes than freeze dried apples (T_g of 33.8 $\pm$ 3.4°C) or pear (T_g of 24 $\pm$ 2.6°C). However, other factors (besides T_g) such as, internal fruit structure, porosity, thermal conductivity, matrix elasticity, temperature within the product, and rate of heat transfers during drying can affect fruit quality (Khalloufi and Ratti 2003).

The hygroscopic properties of dried apple chips are due to their composition of sugars and pectins, in combination with their porous structure. At a_w below 0.12 apple chips demonstrated excellent crispness (Konopacka and others 2002).

During air-drying of apple rings, nonuniform moisture and/or temperature distribution can cause varying degree of shrinkage. Apples dried at 60–65°C showed higher cellular collapse than those dried at 40–45°C and 20–25°C (Bai and others 2002).

Infused dried apples retain their shape and texture much better than those, which are traditionally dried. A range of texture from chewy to crisp can be achieved by controlling the water activity of infused dried apples. The infusion drying process (Fig. 34.2) consists of infusing diced or sliced apples in a sweetener or juice solution to a desired Brix range, separating it from the infusion solution and drying to generally about 0.40–0.60 water activity (about 8–14% moisture). The spent syrup is concentrated and recycled.

Infused-dried apple is a value-added ingredient in various foods or snacks. Unlike other dried apples, infused-dried apples can be diced for application into foods. With infusion-drying use of sulfites is not warranted (Sinha 1998). On the basis of about 40 g serving size, the infused dried apples are not high in calories (Table 34.14), besides noncaloric sweeteners can be used for infusion. Infusion process can allow incorporation of desirable vitamins, minerals, flavors, and colors as well.

35.1 STRAWBERRIES

35.1.1 Introduction

The strawberry (Fragaria x ananassa Dutch) is prized for its typical red color, heart-like shape, and fresh eating qualities (small size, soft skin, and fresh fruit flavor). Strawberries used in products such as ice-cream, yogurt, bakery products, ready-to-eat cereals, breakfast bars, and so on, enhance consumer value in these products. However, strawberries are one of the few important commercial fruits to be grown close to the soil, which leads to harvesting and microbial challenges. Development of disease-resistant strawberry varieties, soil fumigation, hill plasticulture, and drip irrigation have positively impacted the strawberry industry. Further, recent investigations into the beneficial effects of bioactive phenolic compounds in berries are likely to boost demand for strawberries. This chapter provides an overview of supply and demand, physico-chemical, phytonutrients, nutritional, and processing aspects of strawberries.

35.1.2 Supply and Demand

35.1.2.1 Supply. The average production of strawberries in the world during the period 2001–2005 was about 3.4 million metric tons (Table 35.1). The top ten producing countries accounted for 65% of harvested acreages, and 75% of world production. The United States is the leading producer (27% of world production), and more than 80% of these strawberries are grown in the state of California. The farm gate value of strawberries ($1.47 billion) in the United States was close to oranges ($1.57 billion) in 2004 (USDA 2005). Poland and Russia have the largest areas under strawberry cultivation, but the per acre yield is low. In China strawberries are cultivated in greenhouses, plastic sheds, and open fields. China is emerging as a major producer and exporter of strawberries to other countries, including the United States and Japan.

TABLE 35.1 Strawberry Production in Leading Countries: Average for 2001–2005.

Countries	Average Production (2001–2005; Metric Ton)	Average Area Harvested (2001–2005; Hectare)
1. United States	912,070	19,705
2. Spain	290,771	8,605
3. S. Korea	204,166	7,443
4. Japan	204,040	7,326
5. Russia	202,400	33,520
6. Poland	191,707	50,747
7. Italy	162,458	6,368
8. Turkey	145,400	10,200
9. Mexico	144,743	5,558
10. Germany	112,401	10,839
World	3,364,760	243,725

Source: FAO (2006); available at http://faostat.fao.org/faostat

35.1.2.2 Demand. In the United States strawberry is the leading berry, with annual per capita consumption of over 3.0 kg (USDA 2005). About 75% of strawberries produced in the United States are utilized as fresh, and the remaining 25% are frozen and processed into other products. Demand for strawberry is also strong in Japan and many European countries.

35.1.3 Strawberry Varieties and Postharvest Handling

35.1.3.1 Strawberry Variety. Based on flower and fruit-bearing properties, strawberries are grouped as:

1. Short-day or June-bearers, which flower in fall when the days are relatively shorter and bear fruits in the following spring – these strawberries produce a single crop each year;
2. Everbearers, which initiate flowers and fruits during the long days of summer; and
3. Day-neutrals, which initiate flowers under any day length.

In selecting a variety, considerations are given to disease resistance, yield, and end-use requirements. For example, firmness and drip loss are important for strawberries to be used in processing. Table 35.2 gives characteristics of selected strawberry varieties.

35.1.3.2 Postharvest Handling. Strawberries are picked by hand and harvesting is carried out several times during the season because the berries do not ripen simultaneously. Strawberries are very perishable (the market life of fresh strawberries is only 1–2 weeks from harvest) and prompt cooling is important for maintaining fruit quality. Carbon dioxide gas is injected into strawberry crates before shipment to slow respiration, and transportation with refrigerated carriers helps in extending fruit quality. Because strawberries are grown close to the ground, simply washing with water does not ensure food safety. A hepatitis A (a viral liver disease) outbreak occurred in some parts of the United States in 1997 after consumption of sliced

TABLE 35.2 Characteristics of Selected Strawberry Varieties.

Variety	Characteristics
Allstar	A mid-season maturity strawberry of large size; produces high yield; light red exterior and light pink to white interior color; sweet; medium firmness; a good dessert-quality strawberry
Annapolis	Early to mid-season large fruit; light red; soft texture; mild flavor; a good strawberry for fresh consumption and freezing
Aromas	A day-neutral strawberry developed in California with good yield potential; firm with good flavor and red color; suitable for fresh market and processing
Camarosa	An important short-day variety in southern California; long wedge shape, good firmness; uniform red color; fruits vary in sweetness; high acidity; suitable for fresh market and freezing
Cavendish	A good quality and juicy strawberry similar to Annapolis; dark red and glossy
Chandler	A short-day variety; large and firm; suitable for fresh market and processing
Diamante	A day-neutral variety; more vigorous than Selva; requires less chilling to maintain excellent fruit quality; larger fruit than Aromas, lighter in color especially on interior fruit; suitable for fresh market and processing
Senga Sengana	A popular variety of Poland; medium size; good for freezing
Sweet Charlie	A strawberry from the Florida region; distinct sweet flavor; size similar to Selva; external fruit color is orange red, and internal color is orange streaked with white
Totem	A major short-day variety of Pacific northwest; attractive red color; uniform medium shape; firm texture; suitable for fresh market and processing
Ventana	A short-day strawberry from California; bright light red fruit of good quality; production pattern similar to Camarosa

Sources: http://www.msue.msu.edu/vanburen/e-839.htm; http://wwwcalstrawberry.com; http://www.oregon-strawberries.org; http://strawberry.ifas.ufl.edu/breeding/varieties.htm; http://www.gov.on.ca/OMAFRA/english /crop/facts/strawvar.htm

frozen strawberries. However, washing strawberries with chlorinated water was reported to significantly reduce microbial population, hepatitis A, and other viruses (Williamson 1998).

35.1.4 Physico-chemical, Phytonutrients, and Nutritional Qualities

35.1.4.1 Sugars, Organic Acids. Sugars are present naturally in strawberries primarily as, fructose, glucose, and sucrose. However, arabinose, xylose, and inositol have also been reported (Castro and others 2002; Macias-Rodriguez and others 2002). During ripening, as the strawberries turn from half red to dark red, an increase in sugars (sucrose: 1.4% to 1.7%; glucose: 2.2% to 2.9%; fructose: 2.4% to 3.1%) and

TABLE 35.3 Physico-chemical and Sensory Qualities of Selected Strawberries.

				Sensory scores[a]				
Variety	Soluble Solids	Titrable Acidity (% as Citric)	pH	Color	Sweet	Sour	Texture	Overall
Rainier	7.6	1.07	3.32	6.1	4.1	5.0	4.6	4.4
Redcrest	9.7	1.04	3.18	6.5	2.6	3.8	6.6	3.1
Selva	7.8	0.92	3.49	5.2	4.0	3.8	6.1	4.5
Sumas	7.7	0.91	3.24	6.9	4.7	4.4	6.9	4.8
Totem	8.4	1.07	3.35	8.2	4.2	5.0	5.5	4.6

Source: Shamaila and others (1992).
[a]Sensory scores based on a 10-cm scale.

malic acid (0.3% to 0.4%), but a decrease in citric acid (0.7% to 0.5%) have been reported (Menager and others 2004). Strawberries vary in level and types of acids they contain. For example, a study of "Camarosa" and "Selva" strawberries showed citric acid, malic acid, and ascorbic acid contents as: 0.76%, 0.13%, 0.04% and 0.5%, 0.0%, 0.04%, respectively (Castro and others 2002).

Table 35.3 presents physico-chemical and sensory data of selected strawberries. Strawberry varieties analyzed had a Brix range of 7.6–9.7. The overall consumer ratings of these strawberries were dependent on sweetness and odor. Variety Redcrest was sour (lowest pH) and scored least on the overall fruit quality rating. The Totem strawberries scored highest for color by the judges. Azodanlou and others (2003) reported a significant positive correlation ($r = 0.94$, $p \leq 0.05$) between strawberries' °Brix and overall consumer acceptance.

Effect of Growing Conditions on Sugars. Wang and others (2002) reported effects of growing conditions, matted-row (MR, without plastic mulch) vs. hill plasticulture (HC, beds covered with black polyethylene mulch) on sugars and other quality characteristics. The average fructose, glucose, and sucrose contents of 14 strawberry varieties grown on MR and HC were 2.13% and 2.39%, 1.83% and 2.22%, and 0.73% and 0.73%, respectively.

35.1.4.2 Pectins and Cell Wall Enzymes. Lefever and others (2004) reported that soft strawberries have more water-soluble pectin, and higher pectin methylesterase (PME) and polygalacturonase (PG) activities than firm strawberries. PME and PG are considered primary cell wall hydrolases involved in fruit softening. Darsanga strawberries, which had lower levels of water-soluble pectins and hydrolases, were firmer and had 50% less drip loss than Senga Sengana. Postharvest dipping of strawberries in 1% calcium chloride followed by storage at 1°C for 1 day was shown to improve firmness of strawberries (Garcia and others 1996).

35.1.4.3 Strawberry Flavor. Naturally present sugars in strawberries are important nonvolatile flavor components. An increase in sugars in strawberries during maturity and ripening produces strawberry aromas (Bood and Zabetakis 2002). The typical strawberry flavor is due to esters, alcohols, and carbonyl compounds. Table 35.4 lists important aroma compounds in strawberries. The presence of esters such as acetates, butanoates, and

TABLE 35.4 Important Flavor Compounds of Strawberries.

Compounds	Flavor Notes
Methyl butanoate	Fruity (fresh strawberry)
Ethyl butanoate	Fruity
Methyl hexanoate	Fruity, pineapple
Hexyl acetate	Banana, apple, pear
Hexanal	Green, sour, cut grass
Trans-2-hexenol	Green leaves
Linalool	Lemon peel, flower
2,5-Dimethyl-4-methoxy-3(2H)-furanone	Caramel-like, burnt
2,5-Dimethyl-4-hydroxy-3(2H)-furanone	Caramel-like, sweet
1-octanol	Chemical

Sources: Azodanlou and others (2003), Perez and Sanz (2001), Schieberle and Hofmann (1997).

hexanoates give fresh, fruity, strawberry aromas. Hexanal and trans-2-hexenol give green cut grass notes. Furaneol: 2,5-dimethyl-4-hydroxy-3 (2H)-furanone (DHF), and mesifuran: 2,5-dimethyl-4-methoxy-3 (2H)-furanone (DMF) together with other flavor compounds contribute to the overall strawberry flavor. Until strawberries turn about half red, furanones and esters are not detected; at full maturity more furaneol and mesifurane than other flavor compounds are analyzed (Menager and others 2004). Both DMF and DHF were shown to correlate with fresh strawberry flavor (Golaszewski and others 1998).

35.1.4.4 Phytonutrients

Anthocyanins. The typical red strawberry color is due to anthocyanins, pelargonidin 3-glucoside (P 3-G; orange color), cyaniding 3-glucoside (C 3-G; red color), pelargonidin 3-rutinoside and pelargonidin 3-glucoside succinate (Garzon and Wrolstad 2002; Wang and others 2002; Kosar and others 2004). Differences in anthocyanin concentration (and thus the strawberry color) can occur as a result of cultivation practices, harvest maturity, variety, geographical location, storage, and processing. For example, strawberries grown on hill plasticulture (HC) and flat matted row (MR) had average P 3-G levels of 55.4 mg and 51.5 mg per 100 g fresh weight, and average C 3-G levels of 3.6 mg and 2.8 mg per 100 g fresh weight, respectively (Wang and others 2002). Aaby and others (2005) reported that although the major anthocyanin in the strawberry flesh was P 3-G, achenes (seeds) attached to the strawberry surface consisted of equal amounts of C 3-G and P 3-G.

Freezing strawberries causes minimal loss of anthocyanins (Zabetakis and others 2000). Often, sugar is added (Wrolstad and others 1990) to strawberries before freezing to minimize color loss, and sugar-pack frozen strawberries are softer and easier to handle.

Storage of strawberries in various CO_2 atmospheres has little effect on the anthocyanin content of the exterior tissues, but causes anthocyanin loss in the interior tissues (Gil and others 1997).

Maintaining strawberry color during storage and processing is difficult. Exposures to light, oxygen, high pH, and high temperature have negative effects on anthocyanins. For example, during concentration about 22% loss of anthocyanin occurred and the anthocyanins content of strawberry juice (8 Brix) and concentrate (68 Brix) were 26.8 mg to 29.0 mg, and 21.0 mg to 22.7 mg per 100 mL, respectively (Garzon and Wrolstad 2002).

A study by Wesche-ebeling and Montgomery (1990) of the effect of strawberry polyphenol oxidase (PPO) on D-catechin alone or in combination with pelargonin or cyanin showed formation of brown pigment. However, little PPO activity was observed with pelargonin and cyanin as substrates. The PPO's effect on D-catechin was responsible for 50–60% loss of the anthocyanins after 24 h at room temperature. Rwabahizi and Wrolstad (1988) have suggested that a thermal loss of anthocyanins and not enzymatic oxidation causes browning of strawberry juice.

Addition of ascorbic acid (which inactivates PPO) had negative effect on color of strawberry syrup (Skrede and others 1992). It is likely that the hydrogen peroxide formed as a result of ascorbic acid degradation affects anthocyanins.

Phenolic Compounds. Strawberry contains many phenolic compounds with potential health benefits. The concentration of total phenolics in 14 strawberries has been reported to be 70.5 mg to 80.3 mg/100 g fresh weight. Important phenolic compounds (based on 100 g fresh weight) in strawberries are ellagic acid (0.81–0.96 mg), ellagic acid glucoside (0.96–1.24 mg), quercetin 3-glucoside and quercetin 3-glucuronide (1.65–2.12 mg), and kaempferol 3-glucoside (0.31–0.36 mg) (Wang and others 2002).

Antioxidant Capacity. Anthocyanins, phenolic acids, and flavonoids are sources of natural antioxidants in our diet. On a dry weight basis, strawberries (147.7 μmol TE/g) had slightly more oxygen radical absorbance capacity (ORAC) than black raspberries (136.2 μmol TE/g), blackberries (133.3 μmol TE/g), and red raspberries (104.3 μmol TE/g) (Wang and Lin 2000). In a more recent study, water-soluble and lipid-soluble antioxidant capacities in market samples of strawberries were shown to be 35.41 μmol TE/g and 0.36 μmol TE/g (as is basis; % moisture = 91.1), respectively (Wu and others 2004).

Antiproliferative Properties. The phytochemicals in strawberry extracts have been shown to inhibit proliferation of $HepG_2$ human liver cancer cell (Meyers and others 2003). However, the antiproliferative activities did not correlate with their antioxidant activities ($r = 0.41$, $p > 0.05$) or total phenolics ($r = 0.37$, $p > 0.05$). It is likely that a specific phenolic compound or classes of phenolics in fruits are responsible for antiproliferative activities (Sun and others 2002).

TABLE 35.5 Nutrients in Strawberries.

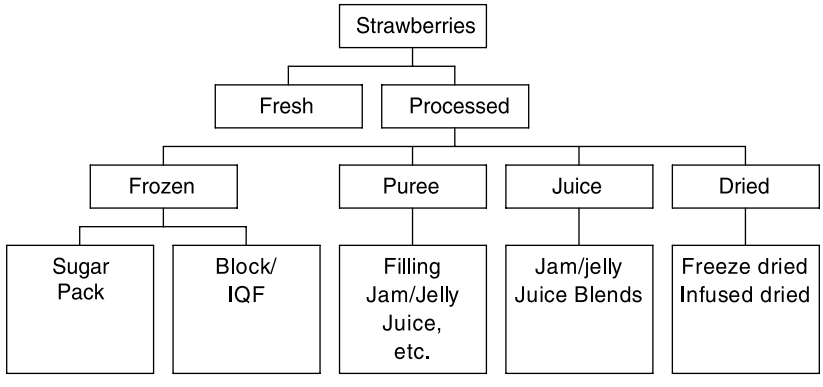

Figure 35.1 *Utilization of strawberries as products.*

35.1.4.5 Nutritional Quality. Fresh strawberries are a source of fiber, potassium, and vitamin C. The sugar infused-dried strawberries, which are used as snacks and ingredients in various foods, have <100 calories per 28 g serving size. These products are also a good source of dietary fiber (Table 35.5).

35.1.5 Strawberry Products

Figure 35.1 shows utilization of strawberries as products. Strawberry is frozen or made into a puree. The processing steps for strawberry products are similar to other fruits. However, specific value-added products have been developed, for example, a light crispy freeze-dried strawberry for use in ready-to-eat cereals and strawberry fruit preparations for ice-creams and yogurts. This section highlights processing of selected strawberry products.

35.1.5.1 Frozen Strawberries.

IQF and Block Frozen Strawberries. Frozen strawberries can be used as such or as raw materials for a variety of products. For example, individual quick frozen (IQF) strawberries are used for freeze-drying and infusion drying. The IQF strawberries can also be sliced or diced for use in ice-creams, jelly, and jam. It is important to select uniform red color and good quality fruits for freezing. The process consists of:

Fruit reception $\longrightarrow$ precooling ($\sim 0-2^{\circ}$C) to remove field heat $\longrightarrow$ removal of stems and caps $\longrightarrow$ air classification to remove extraneous matter $\longrightarrow$ inspection and grading $\longrightarrow$ washing with chlorinated (20–35 ppm) cold water $\longrightarrow$ individually quick freezing the fruit (about -40°C) in a blast air freeze tunnel $\longrightarrow$ metal detection $\longrightarrow$ packaging and storage under frozen temperatures (-18°C).

Quick freezing reduces formation of large ice crystals, which cause drip losses upon thawing. The IQF strawberries have free-flowing texture and hold their color and shape better than block frozen or sugar-pack strawberries. Frozen strawberries were shown to contain higher ascorbic acid and total phenolics than dried strawberries (Asami and others 2003). Often, freezer burn (off-flavor and discoloration) due to moisture loss or ice crystal evaporation from fruit surface is encountered in improperly packaged strawberries held in freezers for an extended period. Packaging in heavyweight, moisture-resistant, and airtight packages is helpful in minimizing this problem.

Sugar Pack Frozen Strawberries. In this process, sugar is added on top of the strawberries, and the product is frozen below -18°C. In the industry, $4+1$ (80% fruit $+20\%$ sugar) and $7+3$ (70% fruit plus 30% sugar) pack strawberries are common. These products are used in fillings, baking, dairy, and other applications.

35.1.5.2 Strawberry Puree. Fruits, not sold as fresh or frozen, can be made into puree or pulp. It is critical that moldy and rotten fruits are not used for processing into puree. The fruit preparation steps (cleaning, sorting, and washing with chlorine) are as previously described. However, it is not necessary to remove the berry cap. Figure 35.2 shows the basic steps involved in making strawberry puree. A pulper with screens (0.5–10 mm) mashes the fruit into a smooth pulp or puree and also removes, skins, seeds, and so on. Depending on the size of the screens used, the resulting puree would be either seedless or contain some seeds. Often the puree is passed through a vacuum system to maintain flavor and color and pasteurized (88°C for ~ 2 min and cooled to about 15°C). The finished

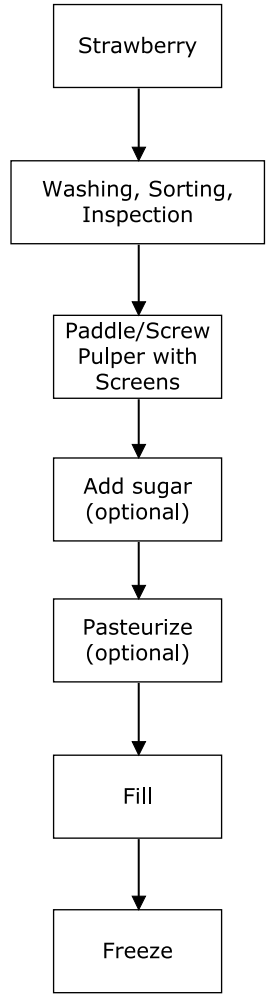

Figure 35.2 *Basic steps in making strawberry puree.*

product is metal-detected and stored frozen. A single strength strawberry puree will have the same °Brix as the starting raw fruit. However, concentrated strawberry purees of about 28°Brix are also available. The puree may be treated with enzymes and filtered before concentration to provide better quality puree for use in jams, juices, and so on. Sweeteners such as sucrose can also be added to the puree to adjust the °Brix depending on the end use.

35.1.5.3 Strawberry Juice. Strawberry juice is mostly used in fruit juice blends. Figure 35.3 describes the steps involved in strawberry juice manufacture. Following pressing/centrifugation to obtain the juice, pectinase enzymes (e.g., Rapidase® Super BE @ 3 mL/kg; 50°C for 2 h) can be used for clarification. Subsequently, a clear juice is obtained through use of membrane separation processes. A single strength pasteurized (88°C for 1 min followed by cooling to 2°C) or concentrated (to higher °Brix) juice can be made.

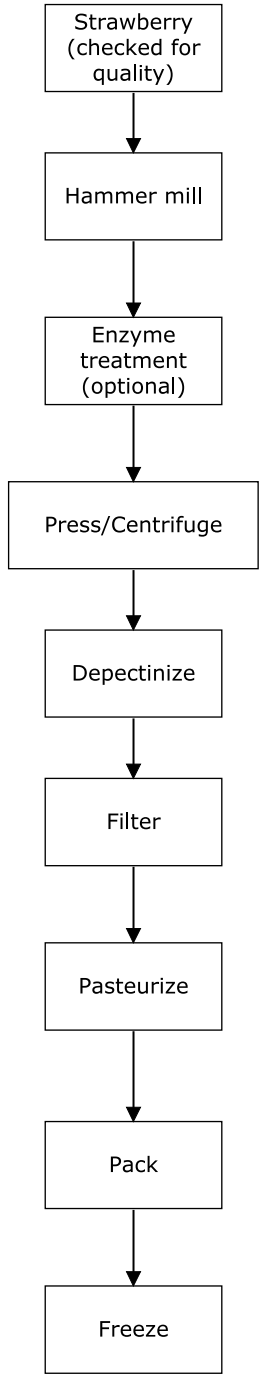

Figure 35.3 *Steps in making strawberry juice.*

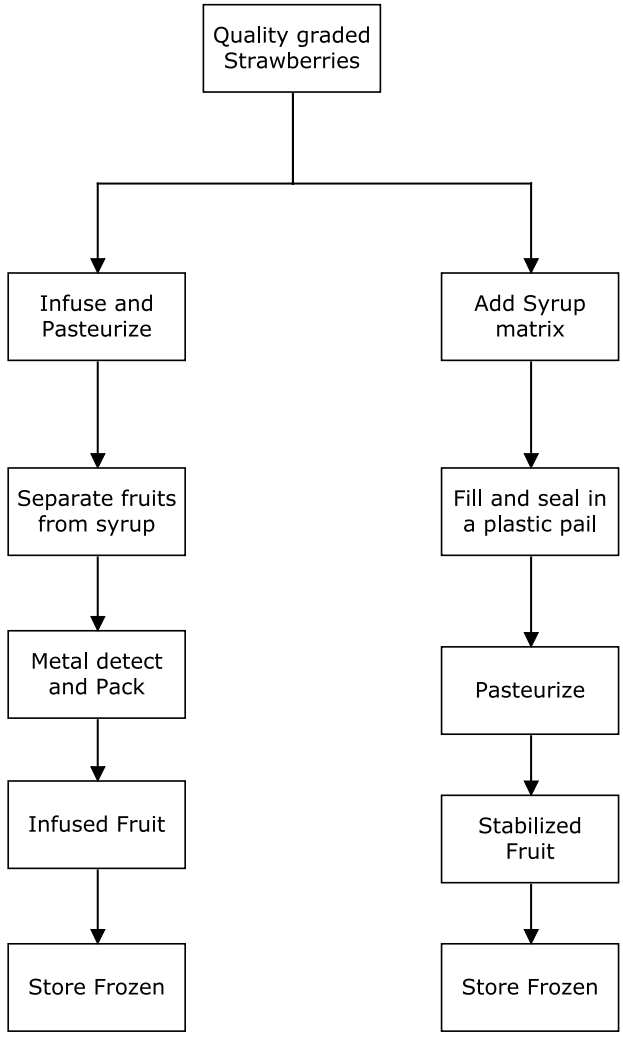

Figure 35.4 *Process for making infused and stabilized frozen strawberries.*

35.1.5.4 Infused and Stabilized Frozen Strawberries. Figure 35.4 shows the process for infused and stabilized frozen strawberries. The process for infused strawberry consists of infusing whole or sliced strawberries in sugar solution or corn syrup or fruit juice to about 25–45°Brix depending on application, processing (heating at least to 65°C with 5 min hold and cooling to about 24°C), separating the processed strawberries from the infusion solution, metal detecting, packaging, labeling, and storing at −18°C. The process for stabilized frozen whole or sliced strawberries consists of combining about 50–70% fruits with a syrup matrix (30–50%), which contains sweeteners (sugar, corn syrup, fruit juice), stabilizers (pectins, starch, carrageenan, gums), acidulants (citric acid, malic acid, ascorbic acid), and flavorings, in-pail processing (preferable in a retort) with agitation at 80–82°C with 5 min hold time, and cooling to 20–24°C. The stabilized strawberries are stored frozen (−18°C) until used. Both infused and stabilized

strawberries are soft (unlike IQF and block frozen strawberries) even when frozen; the fruit piece identity, natural, color, and flavor of the fruit can be retained without use of a preservative such as potassium metabisulfite (Sinha 1998). These products have excellent microbial quality and can be used directly without further processing in ice cream, sorbets, yogurts, frozen bakery products, and so on.

35.1.5.5 Dried Strawberries

Freeze Dried Strawberry. Dried strawberries are used in ready-to-eat cereals, dry bake mixes, breakfast or other food bars, as snacks, and so on. Although traditional atmospheric drying provides a higher drying rate than freeze-drying or vacuum drying, the quality of dried strawberries is not very appealing. There is a loss of the red strawberry color and the texture is hard. Freeze-drying provides perhaps the best retention of natural red strawberry color and shape. Further, it has a positive effect on retention of ascorbic acid and phenolics (Asami and others 2003). However, freeze-drying is expensive and time-consuming (about 1 day or more compared with a few hours for atmospheric drying).

IQF whole or sliced strawberries work well as raw materials for freeze-drying that takes place under vacuum. The pressure in the drying chamber is typically (boiling point of water is $\leq 10^{\circ}$C), where water is transformed from the ice state to water vapor and removed through sublimation. The sublimation temperature for strawberries is -15°C (Khalloufi and Ratti 2003). As a majority of water is removed at a very low temperature, color and shape are maintained. Subsequently, to complete drying and reduce the moisture of the strawberries to about 2%, the temperature of the heating plates can be raised from 20°C to 50°C, while maintaining a low vacuum pressure. Crushing strawberries before drying and low drying temperatures ($<40^{\circ}$C) has a positive effect on strawberry flavor. However, off-flavor was detected when the temperature of the heating plates was raised to 60°C (Paakkonen and Mattila 1991).

Freeze-dried strawberries have a light, crisp, porous texture and their low bulk density (about 0.1 g/cc) and water activity (about 0.2) makes them ideal for use in ready-to-eat cereals. However, freeze-dried strawberries require special laminated packaging to maintain a crisp texture.

Infused-Dried Strawberries. In this process the strawberries are infused in a sugar or juice solution to increase the initial Brix content by three-fold or more and simultaneously decrease its moisture. This moisture loss from the fruit takes place at a relatively lower temperature than in the drying process. The fruit surface serves as a semipermeable membrane for exchange of sugars and water to and from the infusion medium. A number of variables beginning with fruit itself (fresh or frozen, initial Brix, size, whole, sliced, or diced), infusion syrup's Brix, fruit to syrup ratio, infusion temperature, infusion time, agitation, and type of infusion vessel influence infusion process. After infusion, the initial moisture of the fruit can be reduced by 30–40%. The infused strawberries are separated from the infusion syrup and dried using traditional dryers. The moisture of the infused-dried strawberry can range from 8% to 14% (water activity, <0.60). These product are soft and can be diced into julienne pieces for use in other foods (Sinha 1998). The flavor of infused-dried strawberry is good (Escriche and others 2000). However, there can be some loss of strawberry color, especially if the drying temperature is too high. The product is shelf stable for one year or more.

35.2 BLUEBERRIES

35.2.1 Introduction

Blueberries (family, Ericaceae; genus, Vaccinium) are indigenous to North America. The Vaccinium genus consists of many species, which have edible fruits. Like bilberry (V. myrtillus), cranberry (V. macrocarpon), lingonberry (V. oxycoccus), and huckleberry (V. ovatum and V. vaccillans), blueberries are valued fruits. Native Americans enjoyed fresh blueberries and also dried them for use with other foods. They are believed to use blueberry roots and leaves as medicine. A tea made from blueberry leaves was considered good for blood and blueberry juice was used to treat coughs (Anon 2004). These early insights and experiences about the health benefits of blueberries are now being corroborated. Ehlenfeldt and Prior (2001) showed that blueberry leaves have higher phenolics and antioxidant values than the fruit tissues. In laboratory studies, dried extract of blueberries having high antioxidants reversed signs of aging (Joseph and others 1999). Other studies (Schmidt and others 2004; Kraft and others 2005) have shown that specific wild blueberry extracts may have antiadhesion (against *E. coli*, which causes urinary tract infection) and chemopreventive properties. Thus, blueberries are emerging as a functional fruit for improving health and quality of life. This section provides an overview of supply, demand, physico-chemical, phytonutrient, nutritional, and processing aspects of blueberries.

35.2.2 Supply and Demand

35.2.2.1 Supply. The production of blueberries is currently concentrated in North America. The United States and Canada produce more than 80% of the blueberries harvested throughout the world and also lead in advancing the blueberry as a commercial fruit. Outside North America, Poland is the largest producer, with about 10% of the world total (Table 35.6). Argentina and Chile have also begun commercial production of blueberries and import to the United States. The types of blueberries commercially harvested in the United States and Canada are:

1. Northern highbush or cultivated blueberries (V. corymbosum);
2. Southern highbush blueberry (V. virgatum);
3. Rabbiteye blueberries (V. ashei);
4. Lowbush or wild blueberries (V. angustifolium).

TABLE 35.6 Leading Blueberry Producers in the World.

Countries	Average Production (2001–2005; metric Ton)	Average Area Harvested (2001–2005; Hectare)
United States	121,415	17,028
Canada	74,448	25,057
Poland	21,080	3,900
Ukraine	4,180	680
Netherlands	3,960	980
Romania	3,700	580
Lithuania	2,280	580
New Zealand	1,700	370
Italy	1,568	195
World	237,199	49,880

Source: FAO (2006).

TABLE 35.7 Characteristics of Selected Blueberry Varieties.

	Characteristics
	I. Northern Highbush (Cultivated Blueberries)
Bluecrop	Leading commercial variety in North America; ripens mid-season; very productive; bears fruit over one-month harvest season; large, light blue; small scar; firm; mild tart flavor; good for fresh market and processing
Duke	An early variety; frost-tolerant; medium size firm fruit; medium blue color with a small scar; good flavor; suitable for IQF and fresh shipping
Elliott	A late season berry; light blue; medium size; firm; small scar; mild tart flavor; suitable for fresh market and processing
Jersey	One of the earliest (1928) released late season variety; small firm fruit with medium scar; light blue; suitable for processing
Nelson	A late season berry; large, light blue, firm; good quality fruit for fresh use and processing
	II. Southern Highbush
O'Neal Reveille	A very low chill requirement variety; large size berry; mild sweet flavor
	III. Rabbiteye
Brightwell	An early season fruit; medium size; blue color, gritty texture and tough skin
Premier	An early season fruit; large fruit with good flavor
Tifblue	A benchmark for rabbiteye; mid season variety; large fruit
Powderblue	Similar to Tifblue but slightly smaller; blue color with slight white powdery coat, thus the name; resist cracking from rain
	IV. Lowbush (Wild Blueberries)
Cumberland	High in soluble solids and dry matter; not as firm
Fundy	Low dry matter and soluble solids content; high in acidity and anthocyanins

Sources: Blueberry Production Summary—Cornell Cooperative Extension 2002, available at http://www.cce.cornell.edu; Jim Hancock 2001: Blueberry varieties evaluated, available at http://mtvernon.wsu.edu/frt_hort/blueberry.htm; Kalt and McDonald (1996); Blueberry Information from Michigan State University Extension, Available at http://www.msue.msu.edu/fruit/bbvarbul.htm; Blueberry Information from University of California Cooperative Extension, available at http://www.mastergardeners.org/picks/bluvar.html

The first three types of blueberries commercially cultivated and harvested are termed "cultivated" blueberries. The lowbush or "wild" blueberries are managed "wild" stands of blueberry. Table 35.7 lists selected blueberry varieties and their characteristics.

The northern highbush blueberries (woody shrubs that can grow to exceed 10 ft but plants are kept pruned to 5–6 ft in height) are commercially planted in cooler regions of Michigan, New Jersey, New York, Washington, Oregon, British Columbia (Canada), and so on. These berries generally require 160 frost-free days; severe winter temperatures (about -20°C or below) will injure most highbush varieties. Southern highbush blueberries with low chill tolerance are grown in southern states. Some traits like bloom date and ripening period of these berries are similar to the northern highbush blueberries (USDA 2003).

Rabbiteye blueberries (Fig. 35.5) are grown in the warmer regions of the southeastern United States. These berries (comparable to highbush) are not winter-hardy, but are generally drought-resistant. They have a somewhat fibrous mouthfeel.

Figure 35.5 *Blueberry Plant (Courtesy of Tim Kelly, Solo Foods, North Carolina).*

Wild blueberry plants (about 1–2 ft tall) are not commercially planted, but natural wild blueberry clones are maintained (pruned, sprayed, and harvested) as a commercial crop in the northeastern United States (primarily Maine) and eastern Canada (Prince Edward Island, New Brunswick, Quebec). The wild blueberry fruits are distinctly smaller than the cultivated blueberries.

In the United States, Michigan leads in cultivated blueberry production, followed by New Jersey, North Carolina, Oregon, Georgia, and Washington. Maine is the largest producer of wild blueberries. The blueberry production in the United States, which was valued at a little over $100 million in 1993 increased to over $325 million in 2004 (USDA 2005).

Blueberries are a perennial crop that can produce for more than 20 years. The berries do not ripen at the same time, therefore harvesting is done several times during the season (USDA 2003). Generally, plant shakers are used for harvesting cultivated blueberries. The harvested berries are kept in plastic crates and stored in cold rooms (at about 2°C) to maintain quality.

35.2.2.2 Demand. The demand for blueberries in the United States and many parts of the world, especially in Japan and Europe, is continuing to grow. In the United States, the consumption of both fresh and frozen blueberries, which was about 0.2 lb each during the 1980s, has almost doubled. A little over 40% of the cultivated blueberries are consumed fresh and the remaining are processed into products. However, in North Carolina and New Jersey, more than 70% of blueberries are sold for fresh consumption. In contrast to

TABLE 35.8 Quality Profile of Blueberries.

Component	Highbush	Lowbush	Rabbiteye

cultivated blueberries, most of the wild blueberries produced are processed (USDA 2003). Blueberries are utilized as jam/jellies, juice/concentrates, infused, dried, and so on.

35.2.3 Physico-chemical, Phytonutrients, and Nutritional Qualities

35.2.3.1 Physicochemical Quality. Blueberries have waxy skin, and unlike some other berries (strawberry, raspberry, and cranberry), they are mildly sweet. Table 35.8 shows typical quality profiles of blueberries. Variations in these quality attributes can occur due to variety, maturity, time of harvest, geographic locations, season, storage, and processing. In general, wild blueberries have lower Brix (10–12°) and titrable acidity (0.4–0.7% as citric) than cultivated (11–14°; 0.5–1.3%) blueberries. Wild blueberries contain citric acid, malic acid, and quinic acid, and both wild and cultivated blueberries contain slightly more fructose than glucose (Sapers and others 1984; Kalt and McDonald 1996). The blue color of blueberries is easily denoted by the "–b" value on the Hunter color scale (Simon and others 1996).

35.2.3.2 Flavor Compounds in Blueberries. Blueberries emit a low level of aromatic note relative to other fruits. In the manufacture of concentrated blueberry juice, volatile blueberry essence is recovered and blended back to provide the desired blueberry flavor note. The twelve major volatile constituents analyzed in blueberries are E-hept-3-enal; 2,3,5-trimethylheptane; 1,8-cineole; 2,4-dimethyl-5-ethyl-hept-2-ene; nonanal; camphor; menthone; 2,6-dimethoxyphenol; decanoic acid; α-cubebene; valencene; and hexadec-4-en-6-yne (Simon and others 1996).

35.2.3.3 Phytonutrient Quality

Anthocyanins, Total Phenolics, and Antioxidant Capacity. The typical blue color of blueberries is due to anthocyanin pigments. In highbush blueberry, anthocyanins were analyzed as malvidin (purple color), delphinidin (blue-violet), cyanidin (red), and petunidin (blue-purple) (Zheng and others 2003). Blueberries contain about 2 mg/g fresh weight anthocyanins, and 7 mg/g fresh weight of total phenolics. The total antioxidant capacity ranges from 62 to 110 μmol Trolox equivalent/g fresh weight (Table 35.9).

In an early work (Prior and others 1998), anthocyanins (as cyanidin 3-glucoside/g fresh weight) in northern highbush, southern highbush, rabbiteye, and wild blueberries were quantified as 1.29 mg, 0.93 mg, 1.24 mg, and 0.95 mg, phenolics (as gallic acid equivalent/g fresh weight) as 2.61 mg, 2.27 mg, 3.40 mg, and 2.91 mg, and antioxidant capacity

TABLE 35.9 Anthocyanins, Total Phenolics and Antioxidant Capacity of Blueberries.

Component	Highbush	Lowbush	Rabbiteye	References
Anthocyanins as cyanidin 3-glucoside (mg/g as is basis)	2.08 ± 0.78	2.08 ± 0.04	2.42 ± 0.06*	*Variety Bluegem; Moyer and others (2002)
Total phenolics as gallic acid (mg/g as is basis)	5.31 ± 0.96	7.95	7.17 ± 0.016*	Wu and others (2004); *Rabbiteye variety Bluegem from Moyer and others (2002)
Total antioxidant capacity (μmol TE/g as is basis)	62.20	92.60	110.8*	Wu and others (2004); *Rabbiteye variety Bluegem from Moyer and others (2002)

(oxygen radical absorbance capacity or ORAC measured as Trolox equivalent/g fresh weight) as 24.0 μmol, 16.8 μmol, 25.0 μmol, and 25.9 μmol, respectively. These researchers showed a higher linear relationship between total phenolics and ORAC value ($r_{xy} = 0.85$) than anthocyanins and ORAC value ($r_{xy} = 0.77$). Kalt and others (2001) reported more anthocyanins and phenolics in wild blueberries (1.63 mg/g and 3.76 mg/g on a fresh weight basis, respectively) than highbush (1.18 mg/g and 1.91 mg/g) blueberries. Their analysis also showed higher antioxidant values (ORAC) in wild blueberries (69.8 μmol/g fresh weight) compared to the highbush (45.2 μmol) blueberries. Other studies (Moyer and others 2002; Wu and others 2004) have also shown higher phytonutrients (especially, phenolics and antioxidants) in rabbiteye and wild blueberries than the cultivated blueberries (Table 35.9).

Effect of Processing on Phytonutrient Quality. Skrede and others (2000) analyzed anthocyanin concentration in pasteurized (single-strength highbush blueberry juice of 15.0 Brix) and concentrated (Brix 73.5) juice as 0.38 mg/g and 1.78 mg/g, respectively. The recoveries for anthocyanins, flavonol, procyanidins, and chlorogenic acid in the single-strength juice were 32%, 35%, 43%, and 53%, respectively. The press-cake

TABLE 35.10 Effect of Processing on ORAC Values.

	ORAC values (mmol)
Fresh (82.3% moisture)	52.9
IQF (84.5–87.8% moisture)	31.2–39.3
Puree (87.2% moisture)	42.0
Canned fruit (74.6% moisture)	18.7
Pie filling (63.4% moisture)	6.49
Jam (72.7% moisture)	10.6
Juice concentrate (50.5% moisture)	29.4
Dried (33.8% moisture)	25.5
Dried (16.8% moisture)	15.1
Sugar infused-dried (28.2% moisture)	28.2
Dried fruit for cereal (7.8% moisture)	2.97

contained 1% chlorogenic acid and 18% anthocyanins. The anthocyanin pigment malvidin was more stable than delphinidin, and the losses in anthocyanins and phenolics during milling and depectinization were believed to be due to native polyphenol oxidase in blueberries. Lee and others (2002) showed that blanching blueberries (95°C for 2 min) or treatment with 50 ppm potassium metabisulfite before juice processing minimized anthocyanin loss in blueberry juice.

Kalt and others (2000) reported the effect of various processing steps on ORAC (mmol Trolox equivalent/100 g dry weight) values of wild blueberries as in Table 35.10. Dried fruit for cereal had the lowest ORAC value, followed by pie filling and jam.

Chemopreventive and Anti-Adhesion Properties of Wild Blueberry. Wild blueberry fractions containing 4–8-linked oligomeric proanthocyanidins with average degrees of polymerization (DPn) of 3.25 and 5.65 were shown to inhibit adhesion of *E. coli*, which is responsible for urinary tract infections. The fraction with a DPn of 5.65 showed antiproliferation activity against human prostate and mouse liver cancer cell lines (Schmidt and others 2004).

Kraft and others (2005) showed that a wild blueberry extract containing phytosterols was active against initiation (quinone reductase assay) of carcinogenesis; fractions containing flavan-3-ols and anthocyanins, phenolic acids, flavan-3-ols, and some proanthocyanidin dimers demonstrated activity against the promotion stage (cyclooxygenase and ornithine decarboxylase assays), and a proanthocyanidin-rich fraction had antiproliferation (progression stage) activity.

Schmidt and Others (2005) showed that in both cultivated and wild blueberries, fresh and IQF blueberries had more total phenolics, antioxidant activities, and antiproliferative activity than processed products. Further, except for freeze-dried wild blueberry (freeze-dried cultivated was not analyzed), all other heat-treated blueberries lacked or had

diminished antiproliferative activity. However, appreciable antioxidant capacity and phenolic compounds were retained even in intensively processed products like jam and pie filling.

35.2.3.4 Nutritional Quality. Table 35.11 shows nutritional values of blueberry and its products. Besides the bioactive phytochemicals for which the blueberries have become best known, these berries are also a good source of fiber, natural sugars, vitamins, and minerals.

35.2.4 Blueberry Products

Similar to strawberries, blueberries are processed into traditional products such as jam and jelly, juice, puree, canned, and dried. Premium value-added products such as infused-frozen, infused-dried, freeze- and vacuum-dried blueberries have been developed for specific uses. An overview of blueberry products is described in the following.

35.2.4.1 IQF Blueberries. Following cleaning and sanitation (with 20–35 ppm chlorine water spray) steps, the berries are conveyed through a freezing tunnel (with high-velocity cold air at -40°C) for about 10 min. The IQF berries are destemmed, color sorted, visually inspected, metal detected, packed, and stored frozen at $<-18^{\circ}$C. The berries, that do not meet IQF quality grades, are culled and used for processing into juice, puree, and so on.

35.2.4.2 Blueberry Puree. Similar steps as described for strawberry puree are followed for making blueberry puree and puree concentrates. Berries are cut/crushed, passed through a pulper/finisher, pasteurized or concentrated, and filled into containers.

35.2.4.3 Blueberry Juice and Concentrate. Blueberry juice is generally marketed as a blend with other juices. The basic juice-making steps are similar to strawberries. Single-strength blueberry juice is about 8–12° Brix. Frozen blueberry juice concentrates of 45–65°Brix are made by concentrating single-strength blueberry juice and freezing to less than -18°C. The blueberry essence is captured from the concentration process and blended back into the concentrate and also sold separately.

35.2.4.4 Infused and Stabilized Frozen Blueberries. These products are specifically made for use in bakery and dairy products. They are infused with sugar, corn syrup, or fruit juices to about 25–45° Brix and heat processed. The processing is similar to infused and stabilized strawberries. The berries thus processed are soft and do not undergo syneresis (release water) like IQF berries when thawed.

35.2.4.5 Infused-Dried Blueberries. Infused-dried blueberries have a moisture content of about 10–15% and a water activity of 0.40–0.60. The berries thus dried have a fresh-like texture, color, and flavor, and are shelf stable. They rehydrate well and can be used as ingredients in many food applications. The process is similar to infused dried strawberries and apples.

35.2.4.6 Freeze-Dried and Vacuum Dried Blueberries. As indicated for strawberries, freeze-drying is a long (almost 24 h) process, and the cost of the freeze-dried

products is about 3–5 times higher than products dried by other methods. However, as the freeze-dried blueberries are light, crispy, porous, and hold shape better, they are desirable in ready-to-eat cereals. A published patent application (Bauman and others 2006) describes the process for vacuum puffed and expanded fruits including blueberries. In this process, the berries are lightly infused and then processed under specific vacuum and heating conditions to expand/puff and dry the blueberries. The product is claimed to have crispy and light texture, low water activity, and low buoyant density.

36.1 INTRODUCTION

Tropical fruits, by definition, are products of warm climates and equatorial regions of the world. Major commercial tropical fruits such as banana, mango, and pineapple are sources of important nutrients in our diet. For example, banana is an excellent source of potassium and slow digesting starch, mango is a rich source of vitamin A, and pineapple is one of the lowest caloric fruits and a source of vitamin C. Recognizing the diet–health relationship, the USDA's new "MyPyramid" and the 2005 U.S. Dietary Guidelines emphasized fruit and vegetable consumption. Tropical fruits, as a part of the fruit basket with special flavor and taste appeal, can help in meeting our dietary goals for fruits and vegetables. Recent growth of tropical fruits in the United States can be attributed to an ethnically (particularly, Hispanics and Asians) diverse population. This market is also creating new tropical-fruit-based products (mango salsa, tropical fruit beverage blends, and so on). Further, a continuing influence of ethnic cuisine, for example, Nuevo Latino cuisine, in the food service and food industry provides a venue for the utilization of tropical fruits. This chapter provides an overview of the horticulture, supply, demand, physico-chemical, nutritional, and processing aspects of three major commercial tropical fruits: banana, mango, and pineapple.

36.2 BANANA

36.2.1 Introduction

36.2.1.1 Historical Brief. The origin of bananas (*Musa* sp.; banana from Arabic for "finger") is located in Southeast Asia. The first Europeans to come across bananas were the army of Alexander the Great during their invasion of India in 327 B.C. However, Portuguese and Spanish explorers brought bananas to the New World. The international trade in bananas started towards the end of the nineteenth century as a result of developments in railroads and refrigerated maritime transport. The early processed banana products imported into the United States came from Brazil, Honduras, and Mexico, and included dried and evaporated bananas (Von Loesecke 1949). At present, major exporters of processed banana products to the United States are Latin American and Asian countries.

36.2.1.2 Classification. Bananas are members of the genus *Musa* (family *Musaceae*) and include dessert bananas (fresh eating quality, soft and sweet: *Musa acuminata*) and plantains (starchy, less sweet, cooking or processing bananas: *Musa balbisiana*). Among important banana cultivars for fresh consumption are "dwarf" and "giant" Cavendish, and Gros Michel. The subgroup of "giant" Cavendish, *Grand Nain* (has thick skin and can withstand bruising) and is the most common cultivar imported into the United States, where consumers prefer bananas with unblemished skins. Subtropical Baby Bananas (*Lady Finger*, *Oritos*, *Manzanos*, or *Apple*) have thin skin with a yellow-pinkish cast and are very sweet. Other sweeter and thin-skinned cultivars (*Senorita*, *Lacatan*, and *Sucrier*) are small and easily brown.

36.2.1.3 Cultivation. Bananas are herbaceous giant perennial plants grown from corms, rhizomes, or suckers. They can normally be found in the field as a cluster of plants with the most mature one known as the leader surrounded by a couple of growing suckers (Fig. 36.1). Modified leaves compactly cluster around each other as the plant height increases, each of which ultimately unfurls to the familiar banana "leaves". At the center of these modified leaves will emerge a modified growing point in the shape of a "heart", which houses the plant's inflorescence. The inflorescence is covered by a flap structure arranged in layers. The floral cluster in between two flaps consisting of a row of 15 to 30 individual flowers will ultimately develop into a "hand" of the banana bunch, with each "finger" of the "hand" representing the individual flowers. As each hand increase in size, it forces the flap to open up wider. The next lower flap will follow the same series of steps. When a banana bunch is fully grown it will be composed of 7–10 hands spiraling around the fruit axis. The leader will eventually die off and the next mature sucker will take its place.

The banana plant thrives in tropical climates (temperatures around 80°F, annual rainfall of 79–98 in., moist soil with good drainage), and generally grown within 30° North and South latitude. Growth ceases when temperatures drop below 56°F, causing chilling injury to the banana fruit. Minimal hurricane winds can uproot plants bearing heavy fruit stalks, and bring damage to an entire plantation.

Tissue cultured plantlets are now used to start new plantations. Micropropagated banana plants provide pest-free propagation materials for starting new plantings, but require more investment, including a nursery.

Figure 36.1 *Growth of Bananas A-corm; B-Rhizome; C-Tightly-packed unopened leaves; D-Sucker (single); E-Stool (group of suckers); F-Inflorescence (unopened); G-Bunch growing with the inflorescence; H-Bunch of "hands" and "fingers".*

36.2.2 Supply and Demand

36.2.2.1 Supply. About 20% of bananas are exported from the developing to developed countries, an example of unidirectional, South–North trade. The world production of bananas in 2005 was 72,464,562 metric tons, grown over 4,349,485 hectares (Table 36.1). Asia and Latin America contributed about 64% and 33%, respectively, of world banana production in 2005. India ranks number one in banana production. However, its internal demand and consumption is relatively high and, as a result, not much enters into the export market. The Philippines, which ranks fifth in world production of fresh bananas, is a leading exporter of banana chips to the U.S. market. Ecuador is the top exporter of banana flakes.

TABLE 36.1 Leading Countries and World Aggregate in Banana Production (2001–2005).

Country	Production (Mt)		Area Harvested (Ha)	
	Average (2001–2005)	2005	Average (2001–2005)	2005
1. India	16,298,000	16,820,000	638,000	680,000
2. Brazil	6,542,080	6,702,760	501,518	494,462
3. China	6,004,626	6,390,000	263,974	274,200
4. Ecuador	5,880,729	5,877,830	215,760	209,027
5. Philippines	5,428,529	5,800,000	407,946	430,000
6. Indonesia	4,427,973	4,503,467	290,740	315,000
7. Costa Rica	2,129,600	2,220,000	43,960	45,700
8. Mexico	1,998,727	2,026,610	70,381	72,645
9. Thailand	1,890,000	2,000,000	145,200	153,000
10. Colombia	1,547,822	1,600,000	57,569	62,000
World	70,133,020	72,464,562	4,322,081	4,349,485

Source: FAO (2006).

Plantain yields are lower than the dessert banana. They serve as a major staple food in many countries. In 2005 world plantain production (33,407,921 Mt) was dominated by the African countries Uganda (30%), Rwanda (8%), Ghana (7%), Nigeria (6%), Cameroon (4%), Cote d'Ivoire (4%), and Congo (1%); Latin American countries were led by Colombia (10%).

36.2.2.2 Demand. Banana is perhaps the most consumed fruit in the world. One reason is that it is relatively inexpensive, and it is also easily digestible by the very young and old alike. Bananas are not domestically grown in the United States, yet it ranks top among fresh fruit consumption, with average per capita consumption of over 28 lb. Most U.S. imports of bananas are from Costa Rica, Honduras, and Guatemala. Bananas are also liked in Europe and the per capita consumption in Sweden, for example, is 35 lb. The EU considers banana a fair trade commodity from certain Pacific, Asian, and African countries.

36.2.3 Harvest, Postharvest Handling, Ripening, and Storage

The interval between inflorescence/flowering and harvest of bananas is about 8–10 months, and there is year-round production. Bananas are harvested from the plants when light green in color and about 75% mature. Entire bunches (Fig. 36.1) are cut by hand from pseudostems. For local consumption, the hands are left on the stalks and sold to vendors who cut hands/fingers according to customer specifications. In large-scale operations, the banana bunches are carried to a nearby tramline or cableway for transport to the packinghouse. Banana bunches hanging on tramways are pulled by tractors to minimize handling and bruising of the fruits. Bananas for export are treated by floating in water or dilute sodium hypochlorite solution to remove latex, which causes black peel staining. Hands are cut into units of 4–10 fingers, graded for both length and width, and carefully placed in poly-lined 40 lb boxes for export.

Fruits are shipped when they are green, and ripened by exposure to ethylene ($\sim$1000 ppm for $\sim$24 h) in sealed "banana ripening rooms". Palmer (1971) discussed in detail respiratory and compositional changes during ripening of bananas. Bananas

should be protected from light after harvesting to delay softening and onset of ripening. Bananas are susceptible to chilling injury; storage temperature should not be lower than 55°F. Gibberellins, reduced temperatures, and modified atmospheres have all been reported to delay the onset of banana ripening (Kapoor and Turner 1976; Taylor 2001). A seven-point color index scale (1 = all green; 2 = with trace of yellow; 3 = more green than yellow; 4 = more yellow than green; 5 = green tips and necks; 6 = all yellow; 7 = yellow with brown flecks) describes various stages in ripening of bananas (Nakasone and Paull 1998). A computer vision system using Hunter color L^*, a^*, b^* bands and brown area percentage has been used to predict the seven ripening stages of banana (Mendoza and Aguilera 2004).

36.2.4 Physico-Chemical, Nutritional, and Phytonutrient Quality

The edible portion of banana contains about 5% starch and 12% sugars. It is one of the few low-acid fruits (pH of about 5.0). Ripened banana has a pleasant flavor and creamy yellow color. Isoamyl acetate is responsible for overripe sweet banana flavor. Table 36.2 summarizes the nutritional composition of banana and its products. Bananas contain more digestible carbohydrates and a relatively higher starch content than any other fruit. One fresh banana has about 15% vitamin C, 20% vitamin B_6, 11% potassium, and 16% dietary fiber needed as per the Recommended Daily Allowance. The American Heart Association has certified Chiquita® bananas as meeting their food criteria for saturated fat and cholesterol for healthy people over two years of age.

36.2.4.1 Phenolic Compounds and Antioxidant Capacity. A strong water-soluble antioxidant, dopamine, has been identified in the popular commercial banana *Musa cavendishii*. The peel and pulp of ripened banana were shown to contain 80–560 mg and 2.5–10 mg dopamine respectively, per 100 g (Kanazawa and Sakakibara 2000). Dopamine (through its condensation product salsolinol), however, is implicated in

the appearance of black spots in overripe bananas (Palmer 1971; Riggin and others 1976). Table 36.3 shows antioxidant capacity and total phenolic content of banana fruit. Because we consume banana so extensively, it is an excellent contributor of natural antioxidants to our diet.

36.2.5 Banana Products and Processing

The "cooking" banana or plantains are preferred for processing (especially for making banana chips, and so on) over the "dessert" or table bananas due to their higher starch content. They are also less susceptible to enzymatic browning due to polyphenol oxidase (PPO), and to discoloration as a result of the reaction between metal ions and the vascular bundles loosely attached to the banana skin ("peel rag") (Occeña-Po 2006). Figure 36.2 presents the utilization and processing of banana, and the use of some commercially processed banana products is shown in Table 36.4.

36.2.5.1 Banana Puree. Banana puree (with or without seeds) is the most important and the highest volume processed banana product (Sole 2005). It is available either in canned or frozen forms. It is incorporated into the preparation of many retail products (Figs 36.2 and 36.3, Table 36.4), even catsup.

Figure 36.3 summarizes the processing steps involved in the manufacture of aseptic banana puree (and banana essence). Both cold and evaporator-recovered essence can be

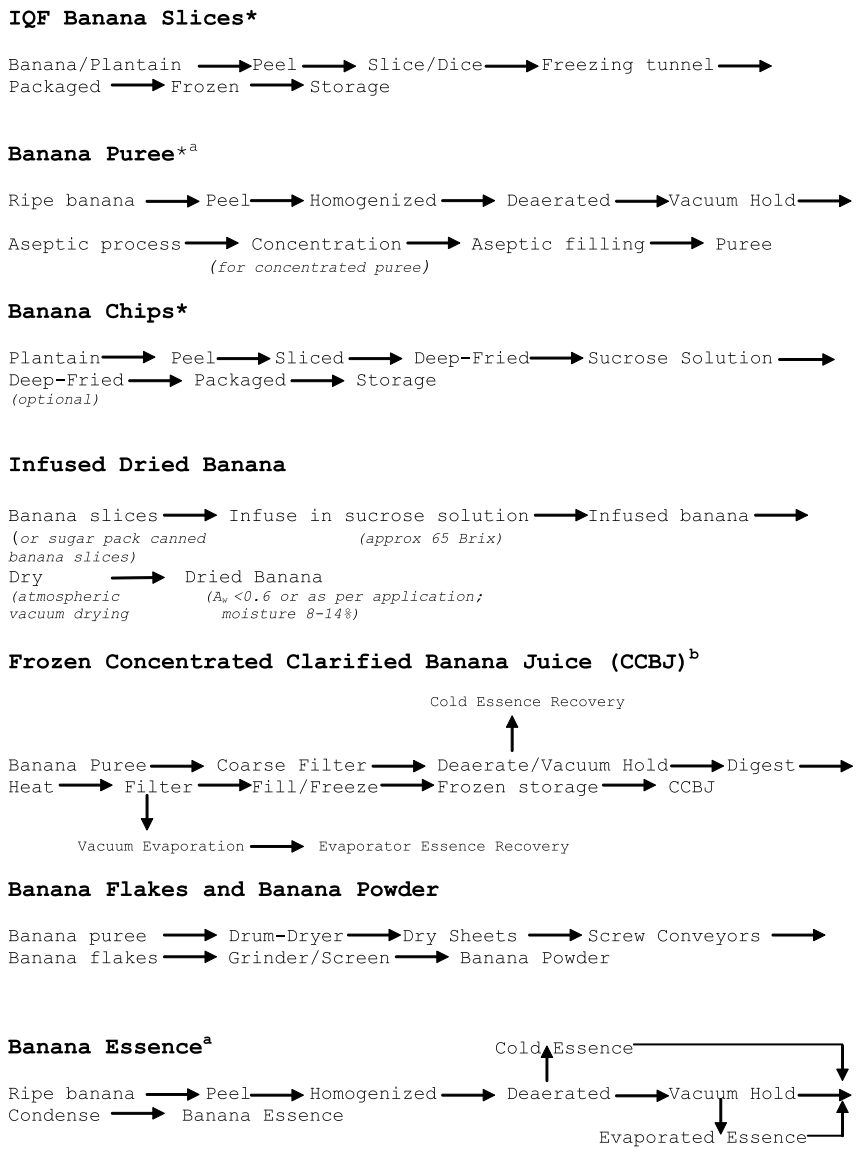

Figure 36.3 *Processing of selected banana products.*

added back to the banana puree to enhance flavor profile. Banana puree is mixed with other fruit purees (e.g., in formulation of baby foods) to provide various fruit flavor characteristics.

An acidification (use of ascorbic acid and citric acid to prevent browning) step is often followed in making banana puree. Johnson and Harter (1981) used an extrusion process: heating up to 249.8°F and cooling to 35–37°F, filling, and blast freezing (−4°F) to produce banana puree. Others (Palou and others 1999; Premakumar and Khurdiya 2002) have investigated the use of high hydrostatic pressure, microwave (3 min), and

water bath (212°F; 8 min) blanching of bananas to retard enzymatic browning. Banana puree can also be prepared without freezing or sterilization, using citric acid (to lower the pH to 4.1–4.2) and potassium sorbate (200–250 ppm) (Downing 1996).

Banana catsup (ketchup) is a popular substitute for tomato catsup in the Philippines, and is usually prepared from fresh banana pulp or puree mixed with vinegar, salt, sugar, onion powder, and spices. The product is mainly exported to the United States, the UK, mostly for people of Philippine descent (Sole 2005; Occeña-Po 2006).

36.2.5.2 Banana Chips. In the Philippines, Green *Saba* (plantain), a cooking banana, is utilized for making banana chips. Figure 36.3 summarizes the main steps involved. After osmotic dehydration (soaking in sugar solution) and deep-frying (~375°F for 1 min) in coconut or other oils, banana chips can be air-dried at room temperature (~81°F), or cabinet dried (~140°F) to allow for moisture equilibration. For making natural banana chips, the osmotic dehydration step is skipped. The light-colored banana chips are exported in bulk and repacked in moisture-resistant laminated plastic pouches (Fig. 36.4*a*). They can be used as snacks or incorporated in fruit trail mixes or ready-to-eat breakfast cereals (Sole 2005; Occeña-Po 2006).

To improve the quality and color of banana chips, studies have looked at

1. Browning inhibitors, osmotic dehydration, microwave, sulfiting agents, water- or steam-blanching prior to deep-fat frying, and freeze-drying (Woodroof 1975; Krokida and others 2000; Waliszewski and others 2000; Krokida and others 2001);
2. Combination of air and vacuum-microwave drying (Mui and others 2002); and
3. Effects of packaging during storage on the color of banana chips (Ammawath and others 2002).

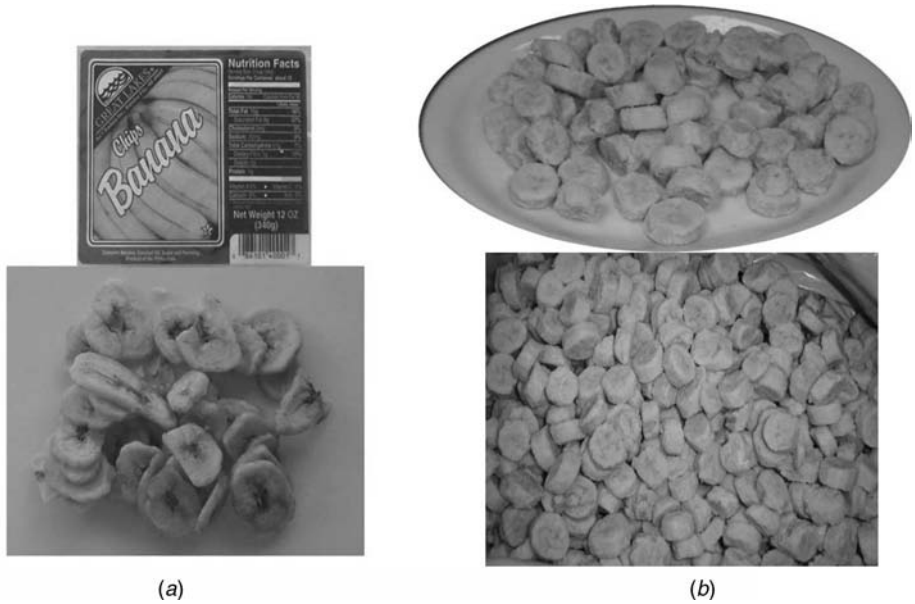

Figure 36.4 *(a) Dried banana chips and (b) Individually Quick Frozen (IQF) baby banana samples.*

36.2.5.3 Other Processed Banana Products. Figure 36.3 and Table 36.4 provide the processing and product descriptions, respectively, of commercial banana products. Figure 36.4*b* is a photograph of Individually Quick Frozen (IQF) plantain banana slices, prepared as summarized in Figure 36.3. IQF bananas are utilized in many product applications.

36.3 MANGO

36.3.1 Introduction

36.3.1.1 Historical Brief. The cultivated mango (*Mangifera indica* L.) originated in southeastern Asia, and was brought to England during the colonization of India in the 1800s. Mangoes were introduced in Brazil and the West Indies during the 1700s, and to Florida in the late 1800s. Portuguese and Spanish traders brought the mangoes to East Africa, the Philippines, and western Mexico.

36.3.1.2 Classification. Mangoes are large fleshy drupe fruits in which the hard stone (endocarp) containing a single seed is covered with an edible juicy pulp. There are two classes of mango:

1. The "Indochinese" cultivars characterized by kidney-shaped, elongated and flattened fruit with light green or yellow skin (Fig. 36.5*a*); and
2. The "Indian" cultivars described as rounded and plump, having a bright red blush to the skin (Fig. 36.5*b*). Indian cultivars are monoembryonic (e.g., *Alphonso*, *Malda*, *Totapuri*, *Kent*, *Tommy Atkins*), so they are mostly grafted on seedling rootstocks and bear fruit much earlier than do seedling trees, which is the case for polyembryonic Indochinese mangoes (e.g., *Carabao*, *Cambodian*, *Kaewsaard*) (Rieger 2005). Knight (1997) has provided a review of the important mango cultivars in the world.

36.3.1.3 Cultivation. Mangoes grow best in seasonally wet/dry climates of the lowland tropics, or frost-free subtropical areas. Mangoes can grow in many soil types

(*a*) (*b*)

Figure 36.5 *(a) Typical appearance of the Indian cultivar and (b) typical appearance of the Indochina cultivar.*

provided they are adequately drained and mildly acidic, although they are grown on limestone gravel in Florida. Commercial growers maintain the mango trees in cultivated orchards. However, in many mango-producing countries, it is not uncommon to find them as backyard trees or along the roadside. In India, the mango tree is considered auspicious and mango leaves are used during worship and other important ceremonies.

36.3.2 Harvest, Postharvest, Ripening, and Storage

Mango is a climacteric fruit, which is best harvested in a mature but unripe stage about $2\frac{1}{2}$ months to $4\frac{1}{2}$ months from blooming. Fruits are essentially hand-picked and pickers use poles to reach fruits high up in the tree. Other devices such as ladders and hydraulic lifts can also be used. Mangoes are usually transported in the firm, green preclimacteric stage. Following harvesting, mangoes should be dipped in hot water (122–127°F; 15 min) as a postharvest control of mango anthracnose – a destructive pest. Additionally, this postharvest dip helps in the removal of the latex sap that can cause darkening.

Among other factors, the ripening of mango depends on variety, degree of maturity at harvest, storage temperature, and humidity. For the purpose of ripening, about one week of storage at 72–75°F (relative humidity of about 85–90%) enables development of mango flavor. Ethylene can also be used to effect ripening. The shelf-life of mango will vary depending on the initial quality of the fruit and storage temperatures (2–3 weeks storage life at 41–50°F is not uncommon). However, mangoes are susceptible to chilling injury (pulp having brown/dark spots, and discoloration of skins) when stored at temperatures near freezing.

36.3.3 Supply and Demand

36.3.3.1 Supply. The export market has been led by India (Table 36.5), and so by the Indian cultivars (several are of Florida origin), initially by *Haden*, but now by other cultivars similar in appearance, including *Tommy Atkins*, *Keitt*, *Kent*, *Palmer*, and *Irwin*. The United States imports most of its mangoes from Mexico. A total of 27,966,749 metric tons of mangoes were produced in 2005, up by only 4% over the average production of the last

TABLE 36.5 Leading Countries and World Aggregate in Mango Production (2001–2005).

	Production (Mt)		Area Harvested (Ha)	
Country	Average (2001–2005)	2005	Average (2001–2005)	2005
1. India	10,616,000	10,800,000	1,580,000	1,600,000
2. China	3,522,353	3,673,000	408,716	433,600
3. Thailand	1,720,000	1,800,000	273,000	285,000
4. Mexico	1,521,928	1,503,010	169,143	173,837
5. Indonesia	1,353,709	1,478,204	214,687	273,440
6. Pakistan	1,158,281	1,673,900	110,673	151,500
7. Philippines	952,290	950,000	152,315	160,000
8. Brazil	849,935	850,000	67,608	68,000
9. Nigeria	730,000	730,000	125,000	125,000
10. Vietnam	269,140	320,000	55,660	53,000
World	26,727,864	27,966,749	3,686,316	3,870,200

Source: FAO (2006).

five years. These figures may not actually account for all mangoes produced, especially those in family backyards and in small farms.

36.3.3.2 Demand. Fresh mangoes used to be sold only in ethnic stores/markets in the United States, but some varieties can now be easily spotted in the produce section of many supermarkets. Imported mangoes are mostly processed into puree and juice. The per capita consumption of processed mango products in the United States is higher than the consumption of fresh mangoes.

36.3.4 Physico-Chemical, Nutritional, and Phytonutrient Quality

36.3.4.1 Physico-Chemical. The chemical composition of ripe mangoes varies with the cultivar. Moisture content ranges from 72% to 86%; soluble solids from 14 to 23°Brix; pH from 3.8 to 5.6, and acidity (as citric acid) from 0.11 to 0.48%. Major organic acids include citric, tartaric, oxalic, malic, and glycolic. Ripe mangoes have a relatively higher sucrose content compared to reducing sugars (3–10%), and total sugars can ranges from 9% to 21% (Hulme 1971; Nanjundaswamy 1997).

36.3.4.2 Mango Flavor. The major volatiles found in mango are monoterpene hydrocarbons. In canned mango puree, the volatiles identified included butyrolactone, gamma-octalactone, furfural, and 5-methyl furfural methoxy furanone (Hunter and others 1974). A commercial water-soluble distillate (Treattarome 9830) derived from ripe mango contains high levels of fruity esters, lactones, spicy terpenes, and sugary/caramel-like furanones.

36.3.4.3 Nutritional Content. The nutritive value of mango products varies with cultivar, cultural and climatic conditions, ripeness, postharvest storage, and processing. Table 36.6 shows that mangoes are excellent source of vitamin A. It is also a source of

TABLE 36.6 Nutrients in Mango and Mango Products.

Nutrients/100 g	Fruit[a]	Infused-Dried Fruit[b]	Slices[c]
Calories (kcal)	65.0	331	70
Total fat (g)	0.27	0.78	0

vitamin C. The vitamin B complex content is relatively low, except for niacin (Wu and others 1993).

Little loss of carotenoid pigment occurs during freezing of mango slices, although there is some decline with storage. The loss of β-carotene during candied mango processing has been shown to be 17–18%, which increases to 30–40% during storage (Chavasit and others 2002). Ascorbic acid retention in mangoes frozen by liquid nitrogen is 90% compared to 72% by slow tray freezing (Pruthi 1999).

36.3.4.4 Phenolic Content. Phenolic content (31–75 mg tannic acid equivalent/100 g flesh) of ripe mango is influenced by variety and size (Hulme 1971; Narain and others 1998). Table 36.3 gives total phenolic content and total antioxidant capacity of the mango fruit.

36.3.5 Mango Processing

Figure 36.6 shows utilization of mango and processed mango products. With the exception of mango chutneys and pickled mango products, which utilize immature or green mangoes, fully ripened mangoes with well-developed flavor, color, and texture are preferred for processing into mango products. Some mango cultivars, which are too fibrous or soft for fresh consumption, can be used for juice making. This section describes major processed mango products.

36.3.5.1 Mango Puree. Mango puree is processed either as a canned or frozen product. It serves as the starting raw material for mango beverages, jams, and dehydrated products, and is also incorporated into infant foods, bakery, dairy, and probiotic products. Various mango cultivars, which differ in their sensory attributes, can be blended and made into mango puree. Whole (for cultivars with thin and yellow color peels) or peeled mangoes can be utilized. Figure 36.7 shows the basic steps involved in manufacturing canned and frozen mango puree, and Table 36.7 provides Brix ranges and packaging

Clarified concentrate[c]	Brix: 70°	55 gal drums	Storage below 0°F	
Flakes[a]	Moisture $\leq$3.0%	22.1 lb bag-in-box; 24.5 lb per box; polyethylene bag;	18 months (70°F)	Dry fruit preparations; substitute for fresh mango puree (6 : 1 reconstitution); beverages; bakery products; frozen desserts, and soft food diets
Powder[a]	Moisture $\leq$3.0%	39.6 lb bag-in-box 41.8 lb polyethylene bag	18 months (70°F)	Dry fruit preparations; beverages; bakery products; substitute for mango puree(6 : 1 reconstitution); fruit preparations; dairy products; soft food diets;frozen desserts
Infused dried diced[d]	Moisture 12% $\pm$ 3%; Oil <1%	25 lbs 10 lbs	Store in a cool(preferably 40–50°F), dry location. Shelf-life : 1 year	Cereals; trail mixes; bakery products; snacks
Essence[c]		40 lb pail		Applications in water-based system to impart mango flavor

Sources: [a]Trobana® Products, Confoco, http://www.confoco.com/confoco/ingles/mango.htm; [b]Del Monte http://www.delmonte.com/Products/FruitItem.asp?id=46; [c]iTi Tropicals, http://www.ititropicals.com/ProductList.pdf; [d]GracelandFruit, http://www.gracelandfruit.com/dried_fruit.php

information of commercial mango puree. Frozen mango puree is usually vacuumed to remove air (Wu and others 2005). Mango pulp in trays has been frozen using air-blast freezers or plate freezers (−34.9°F to −40°F) and stored at −0.4°F to −4.0°F prior to consumption or export. Prior to a quick freezing process, mangoes are subjected to a "steaming" tunnel, cooled, peeled and passed through a combined pulper/destoner unit. The resulting puree is homogenized, sterilized, placed in an aseptic buffer tank, cold sterilized, and filled into bags-in-drums (Pruthi 1999).

36.3.5.2 Mango Juice Concentrate. Mango concentrates are utilized in the preparation of juice and energy drinks (Fig. 36.7; Table 36.7). Enzymatic liquefaction has been employed to improve the quality of higher °Brix concentrates (Wu and others 2005).

36.3.5.3 Mango Juice. Figure 36.7 outlines the processing steps for mango juice production. Studies have been conducted showing the use of enzymes to facilitate juice extraction, control cloud stabilization and viscosity, and increase the free flow and yield extraction of juice (Occeña-Po 2006).

Mango juice can also be aseptically packaged in a bag-in-box and stored at ambient temperature, although storing at low temperature preserves it better (Wu and others 2005).

Mango juice can be made into mango nectar or squash, and processed by any of the following methods:

1. Spin-cooker;
2. Flash pasteurization; or
3. Pasteurization and aseptic packing in plastic-lined cartons (Wu and others 1993, 2005). When a preservative (350 ppm SO_2 or 0.1% sodium benzoate) is utilized, the product is referred to as mango squash.

36.3.5.4 Mango Slices and/or Scoops. Figure 36.7 summarizes the process for canning mango slices/scoops. Mango slices can also be packed in polythene or pliofilm bags and stored at −0.4°F for 12–18 months. Calcium pretreatment (2%) helps keep the texture firm. The advantages of quick freezing of mango slices by immersion in liquid nitrogen are reduced weight loss and lower loss in textural properties (Pruthi 1999).

36.3.5.5 Mango Leather and Mango Bar. Mango leather is a promising source of vitamin A (provitamin A content of 600–650 retinol equivalents). The industrial preparation of mango leather is summarized in Figure 36.7. Highly acceptable mango bars have been prepared using 25°Brix pulp with 0.5% sodium alginate and drying at 140°F (Singh and others 2004). The drying rate for mango leather was reported to have been lowered by the addition of soy protein concentrate (Gujral and Khanna 2002).

Sulfiting is a common practice in developing countries to retain the yellow-orange color of dehydrated mango products, but has been under critical consideration with respect to allergen labeling of foods. The process for preparing infused-dried mango fruit (Fig. 36.7) retains the natural color without the use of sulfites (Sinha 1988).

36.3.5.6 Other Mango Products. Figure 36.7 outlines the manufacture of other mango products. Table 36.7 summarizes the characteristics and applications of commercial mango products.

36.4 PINEAPPLE

36.4.1 Introduction

36.4.1.1 Historical Brief. It is believed that the pineapple originated in southern Brazil and Paraguay, and was spread by the Indians to other parts of South and Central America. The pineapple was brought to Europe by Columbus in 1493, and distributed to the Pacific Islands, India, Philippines, and Africa by the Spanish and Portuguese explorers.

Hawaii used to produce most of the world's pineapple with the establishment of the first commercial plantation on Oahu in 1885. However, since 1960, Hawaii's pineapple industry has been on the decline. Pineapple was first canned in Malaysia and canned fruits were exported from Singapore around 1900 (Rieger 2005).

36.4.1.2 Classification. The pineapple fruit is a multiple fruit covered with a waxy, leathery rind made up of hexagonal "eyes" arranged spirally, denoting the position of individual flowers. The predominant cultivar is *Smooth Cayenne*, chosen for worldwide dissemination for its desirable characteristics. Table 36.8 summarizes the characteristics of pineapple cultivars used for canning. The Del Monte Gold® Extra Sweet, reportedly the world's sweetest pineapple, claims to be twice as sweet as the traditional variety, and contains up to four times the vitamin C.

36.4.1.3 Cultivation. Pineapples can take up to 18 months to grow. They are grown in climates with high rainfall and grow best in well-drained sandy loams with pH 4.5–6.5, and temperatures of 75–90°F.

36.4.2 Harvest, Postharvest, and Storage

Pineapple is categorized as a nonclimacteric fruit, not capable of continuing its ripening once removed from the plant. The most common method of determining maturity of the pineapple fruit is by the change in color from green to yellow, the flat eyes, and the large, well-formed crown. However, a minimum Brix of 12 measured by a refractometer can signal harvest maturity. Pineapples for canning are allowed to reach a more advanced stage (about $\frac{1}{2}$ to $\frac{3}{4}$ yellow) prior to harvest. An application of ethephon during ripening of the pineapples forces synchronization of maturity and eliminates multiple pickings.

Fruits for export are almost completely green when harvested for trans-oceanic shipment, but pineapples that are too ripe and yellow are hand-harvested for the fresh market. In big plantations, mechanical harvesting is utilized, with two conveyors, one on top of the other, breaking off the pineapples and carrying the fruits to the lower conveyor where they are de-crowned (Fig. 36.8). Fresh pineapples are washed and waxed prior to packing in boxes.

Pineapples can be stored for up to 4 weeks at temperatures $\geq$45°F. The recommended storage for pineapple is 45–54°F, and 90–95% relative humidity. (Paull and Chen 2003).

TABLE 36.8 Commercial Pineapple Varieties.

Group	Varieties	Country	Flesh Color	Sugar (Brix)	Acid (%TA)	Descriptor
Cayenne	Smooth Cayenne, Hilo, Kew, Champaka, Sarawak	Thailand, Philippines, Indonesia, Australia	Pale yellow	12–16	0.5–0.9	Most important group; more than 70% of pineapple grown in the world; ave. wt. 2.5 kg; for fresh fruit consumption and canning
Queen	Moris, Mauritius, MacGregor, Ripley Queen, Alexandra	India, South Africa, Australia, South East Asia	Deep yellow	14–18		Ave. wt. 0.8–1.5 kg; fresh fruit
Spanish	Singapore Spanish, Ruby, Red Spanish, Masmerah, Gandul, Hybrid 36, Selangor Green, Nangka, Betik	Malaysia	Deep golden yellow	10–12	0.3–0.6	Ave. wt. 1–2 kg; poorer cannery recovery; fibrous flesh
Pernambuco and Mordilona	Perolera	Brazil, Ecuador, Peru, Colombia	White	Mild flavor	Low acid	Less economic importance, restricted to South America; Perolera has high vitamin C content and is used in hybridization programs for improving Smooth Cayenne cultivars

Source: Shukor and others (1998).

36.4.3 Supply and Demand

36.4.3.1 Supply. Table 36.9 summarizes the average world production of pineapple over the last five years (2001–2005). World production in 2005 was 15,886,647 metric tons over 857,771 hectares. The top 10 leading producers contributed about 75% of world production. Pineapple production and marketing in the Philippines (and Costa Rica, Honduras, and Ecuador) is conducted exclusively by multinational corporations,

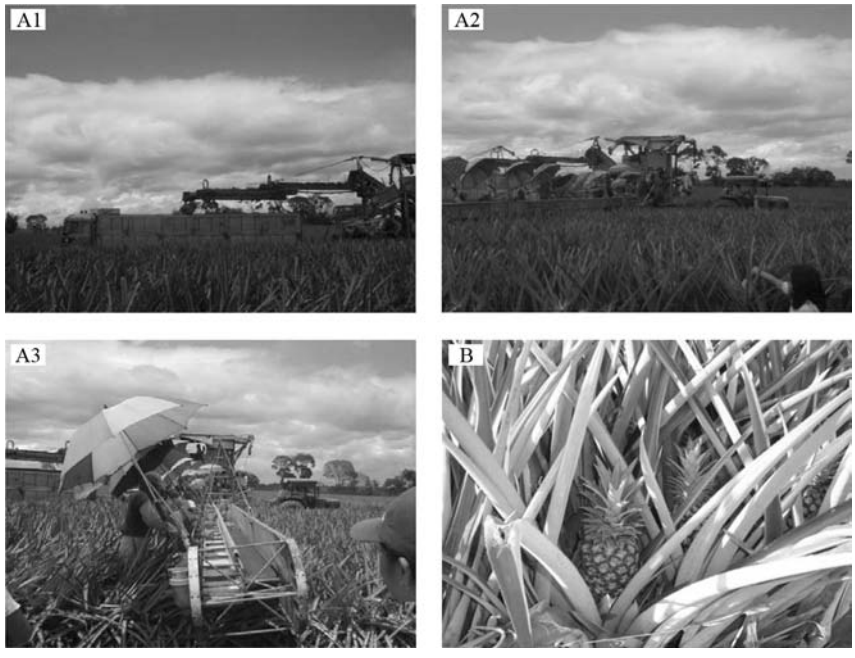

Figure 36.8 *(A1–3) Plantation harvesting, sorting, and decrowning, (B) Pineapple fruit plant.*

TABLE 36.9 The Ten Leading Countries and World Aggregate in Pineapple Production (2001–2005).

	Production (Mt)		Area Harvested (Ha)	
Country	Average (2001–2005)	2005	Average (2001–2005)	2005
1. Thailand	1,952,709	2,050,000	86,209	90,000
2. Philippines	1,702,863	1,800,000	46,785	49,000
3. China	1,326,900	1,460,000	68,564	75,400
4. Brazil	1,431,468	1,418,420	57,896	53,116
5. India	1,262,000	1,300,000	86,000	90,000
6. Nigeria	887,400	889,000	115,800	116,000
7. Costa Rica	898,570	725,224	15,956	17,400
8. Mexico	689,695	720,900	16,624	17,906
9. Indonesia	622,126	673,065	67,400	80,000
10. Kenya	566,242	600,000	13,212	13,500
World	15,442,696	15,886,647	827,983	857,771

Source: FAO (2006).

on large plantation systems with mechanized operations. In contrast, pineapple production in Thailand is through thousands of small farms.

The top three suppliers of fresh and frozen pineapple to the United States are Costa Rica, Honduras, and Ecuador. Although the Philippines is the largest supplier of processed canned pineapple products and juice, it has exhibited a slight decline in shipments in recent years.

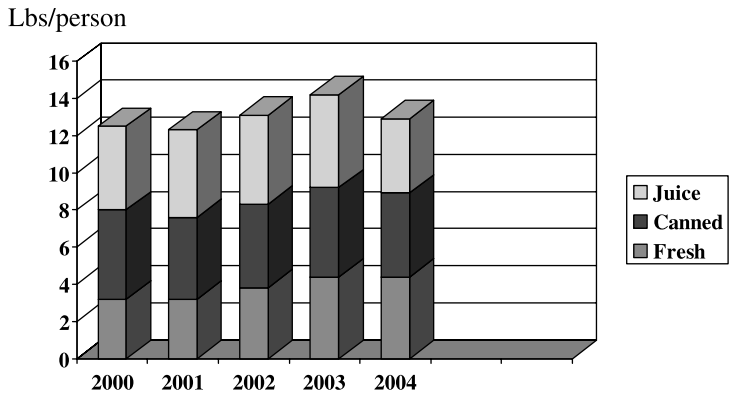

Figure 36.9 *U.S. per capita consumption of pineapple 2002–2004.*

36.4.3.2 Demand. Figure 36.9 summarizes U.S. per capita consumption of fresh and processed pineapple products for the period 2002–2004. Like other tropical fruits, total pineapple consumption in the United States declined (4.33 lb per person) slightly in 2005.

36.4.4 Physico-Chemical, Nutritional, and Phytochemical Quality

36.4.4.1 Physico-Chemical Quality. Ripe mature pineapple flesh contains about 85% moisture, its pH, % citric acid, and Brix are, 3.4, 0.70, and 14.0, respectively. It contains about 7% sucrose and 3% each of glucose and fructose. Citric acid is the predominant organic acid followed by malic, oxalic, and phosphoric acid.

36.4.4.2 Flavor Components in Pineapple. The characteristic pineapple flavor is due to two thioesters, methyl 3-(methylthio) propanoate and ethyl 3-(methylthio) propanoate (Brat and others 2004). In addition to these compounds, Elss and others (2005) also reported methyl 2-methylbutanoate, methyl butanoate, methyl hexanoate, ethyl hexanoate, 2,5-dimethyl-4-methoxy-3(2H)-furanone(mesifurane) and 2,5-dimethyl-4-hydroxy-3(2H)-furanone (furaneol) as major constituents (Table 36.11).

36.4.4.3 Nutritional Composition. Table 36.3 shows the nutritional composition of fresh pineapple and processed pineapple products. Pineapple is a low-calorie fruit. It contains little sodium and fat. It is a good source of potassium and vitamin C. It also contains vitamin A.

36.4.4.4 Phenolic Content and Antioxidant Compounds. Phenolics in pineapple have been identified as *p*-coumaric acid and ferulic acid (33–73 and 20–76 μg/g fresh weight, respectively) (Dull 1971). Wu and others (2004) reported total phenolics and total antioxidant capacity of 1.74 mg GAE/g and 7.93 μmol TE/g, respectively, in pineapple (Table 36.3). Huang and others (2004) reported total phenolic content in pineapple core to be 74.42 ± 3.31 μg of gallic acid equivalents/g fresh weight, and antioxidant activity (73.05 ± 3.95 μmol of ascorbic acid/g fresh weight). The alkaloid 6-hydroxy-1-methyl-1,2,3,4-tetrahydro-*â*-carboline, acting as antioxidant, was reported by Herraiz and Galisteo (2003) in pineapple (0.62 μg/g ± 1.02) and its juice (1.69 μg/g ± 1.40).

TABLE 36.10 Nutritional Value of Pineapple and Pineapple Products.

Nutrients/100 g	Raw[a] Pineapple, (All Varieties)	Pineapple Juice[b], Canned with Ascorbic Acid	Pineapple Canned Juice Pack[c], Solids and Liquids	Pineapple Frozen, Chunks[d], Sweetened	Pineapple Juice, Frozen Concentrate[e], Unsweetened, Undiluted	Infused-Dried[f] Pineapple

36.4.5 Pineapple Processing

Pineapples harvested from the field are mechanically graded for size, automatically peeled, cored, and trimmed using a machine referred to as *Ginaca*. The resulting pineapple cylinder is further divided into sections including slices, chunks, and tidbits, and canned. Figure 36.10 represents the primary pineapple products and byproducts. For every 100 lb of pineapple fruit, only about 27% goes into the processing of primary pineapple products, of which 59% are processed as pineapple chunks, slices, and tidbits; 41% goes into the processing of crushed pineapple and/or utilized as juice material. About 35% of the pineapple fruits are utilized as juice material, 91% of which is made into pineapple juice, and 9% is the remaining pomace after extraction. About 38% of the pineapple fruits become byproducts, including pomace (32%) and mill juice (68%). Figure 36.11 shows photographs of various commercial processed pineapple products derived from fresh pineapple. Figure 36.12 provides flow diagrams for the processing of frozen and dehydrated pineapple products. Table 36.12 summarizes high-sugar pineapple products including jams, marmalades, and conserves, which are increasingly popular food toppings.

36.4.5.1 Selected Pineapple Products

Pineapple Slices. The USDA/FDA Standards for grades and identity, quality, and container fill weight provide guidelines for canned pineapple products. Pineapple fruits

TABLE 36.11 Aroma Profile of Pineapple Fruit and Pineapple Products.

Aroma Compound	Juice from Fresh-Cut Pineapple (μg/L)	Single-Strength Juices (μg/L)	Concentrates (μg/kg)	Juice from Concentrates (μg/L)	Water Phases/ Recovery (mg/L)

Source: Elss and others (2005).

are sized and trimmed mechanically to fit corresponding can sizes. Slicers equipped with single or multiple blades cut slice packs out of trimmed pineapple cylinders. Slices or rings of $\frac{1}{2}$ in. are designated for No. $2\frac{1}{2}$ cans, and 25/64 in. slices for No. 2 cans. Pineapple slices are visually graded to meet specifications, and manually or automatically packed in cans. Slices are graded as *fancy* (geometrically perfect, excellent, uniform color, whole), *choice cut* (not as perfect with less color), or *standard*. The cans go to an exhaust or vacuuming chamber, or directly to the syruping step. The syrup concentration depends on the quality

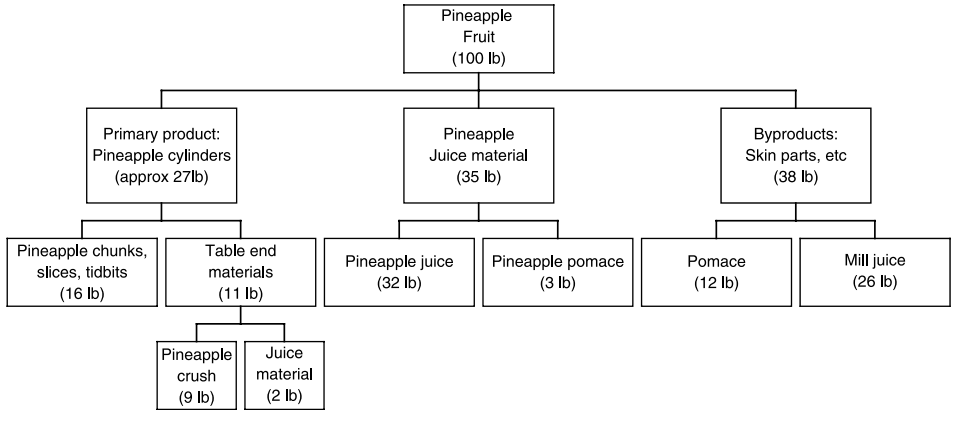

Figure 36.10 *Primary pineapple products and by products. (Adapted from Mumaw 1996).*

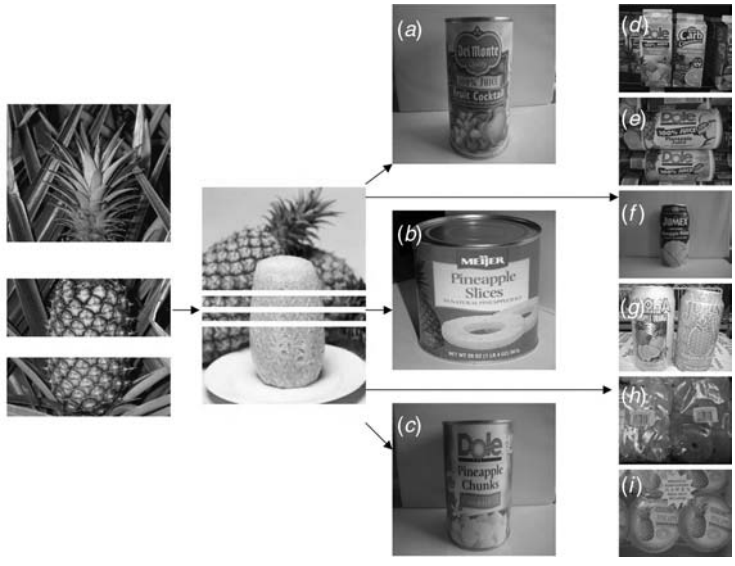

Figure 36.11 *Pineapple products processed from fresh pineapple (a)-fruit cocktail; (b)-slices; (c)-chunks; (d)-juice blends; (e)-concentrate; (f)-Nectar; (g)-Juice Drinks; (h)-Dehydrated Slices; (i)-Custard.*

of the pineapple product: the Hawaiian No. 1 grade is packed with 24°Brix cut-out syrup, and No. 2 and 3 grades with 20°Brix syrup. Atmospheric closure is used for hot filling (190.4°F). With a prevacuuming syruper, either a mechanical vacuum or steam-flow closure is utilized. Processing is carried out by either a continuous rotary pressure sterilizer (215.6–219.2°F) or by an ordinary retort operating at atmospheric pressure (212°F for 12–18 min for No. $2\frac{1}{2}$ cans). Cans from a rotating cooker go to a rotating cooler (Pruthie 1999; Hepton and Hodgson 2003).

Pineapple Chunks and Tidbits. Pineapple slices may be further cut into tidbits, cubes, and chips, and thicker slices are cut into chunks or pieces. For pineapple tidbits, fresh pineapple is cut into segments (1.27 cm × 1.37 cm), in symmetrical segments or cubes (Woodroof and Luh 1975).

Pineapple Juice. The extraction of juice is often combined with the production of canned fruit packs to utilize any pineapple pieces discarded from other product lines, including slices that have been cut too thick or too thin, and broken pieces. These are all crushed to extract juice. Other solid components utilized for juice consist of

1. Pineapple cores;
2. *Eradicator meat* (thin layer of flesh between the shell and fruit cylinder removed using *Ginaca*);
3. Trimmings.

Whole fruits not required for solid packs, or fruits too small for canning are peeled and pressed for juice, or simply crushed and pressed. The juice is homogenized to stabilize

the slightly cloudy appearance, and heated to coagulate solids. The thin slurry passes through a continuous centrifuge, removing suspended solids, including fibers and coarse pieces (Woodroof and Luh 1975; Hepton and Hodgson 2003). "Processing beverage juice" (juice from fruit, cores and skin waste) is distinguished from "skin juice", utilized

TABLE 36.12 High-Sugar Pineapple Products.

Products	Ingredients	Procedure	Comments
Pineapple jam	Pineapple puree or pulp; sugar	1. Boil the pineapple pulp or puree with sufficient quantity of sugar until it reaches a thick consistency. 2. Pack in jars. 3. Process at 100°C for 15 min. 4. Cool immediately.	It can be prepared from a single fruit or using a combination of different fruits, e.g., pineapple–papaya (30 : 70); mango–pineapple.
Pineapple conserve[a]	Crushed pineapple; orange or lemon juice; sugar; raisins; nuts	1. Mix crushed or chopped pineapple with orange or lemon juice. 2. Heat until the mixture becomes thick. 3. Pack in jars. 4. Process at 100°C for 15 min. 5. Cool immediately.	Nuts are optional; can mix with other fruits like mango.
Pineapple marmalade	Crushed pineapple; lemon zest; sugar	1. Mix crushed or chopped pineapple with sugar. Add the lemon zest. 2. Heat until the mixture becomes thick. 3. Pack in jars. 4. Process at 100°C for 15 min. 5. Cool immediately.	In lieu of lemon zest, finely chopped orange rind.
Pineapple confectionery jelly[b]	Pineapple juice; granulated sugar; glucose syrup; citric acid	1. Mix pineapple juice and pulp with granulated sugar and glucose syrup (75%). 2. Citric acid is added to reduce the pH of the jellies to avoid pectin degradation, premature setting, and to reduce the rate of sucrose inversion. 3. Maintain temperature at not less than 90°C immediately after adding acid. 4. The product is packed in laminated oriented polypropylene/polyethylene package.

as a base for sweeteners. However, the use of other solid pineapple materials for juice production is not allowed in the United States (Shukor and others 1998; Hepton and Hodgson 2003).

Crushed Pineapple. Crushed pineapple is obtained from finely cut or shredded pieces of pineapple from other processing lines, from small, irregularly-shaped slices unsuited for regular canned pineapples, and eradicator meat. The crushed pineapple is pumped into steam-jacketed kettles and heated to 170.6–195.8°F, automatically packed into cans, sealed, and heat processed for 10 min. An alternative processing is to cold-fill, exhaust to 179.6°F, seal and process in boiling water for 30–40 min (Woodroof and Luh 1975; Pruthie 1999).

Minimally Processed Pineapple

"FRESH CUT" PINEAPPLES. The market for minimally processed pineapple has increased. "Fresh cut" pineapples are packaged as whole, slices, or chunks in sealed plastic tubs or cups, and chilled to optimum temperature levels until purchased by the consumer. The balance between sweetness and acidity is relevant in selecting the pineapple cultivar to use. Fresh-cut processing causes wounding, increases metabolic activities, and decompartmentalizes enzymes and substrates, causing possible browning and decay of the fresh fruit. Gonzalez-Aguilar and others (2004) reported that treatment of pineapple slices with anti-browning agents isoascorbic acid (IAA; 0.1 mol/L), ascorbic acid (AA; 0.05 mol/L), or acetyl cysteine (AC; 0.05 mol/L), prolonged the shelf-life of fresh-cut pineapples for up to 14 days at 50°F, with no observed off-flavors. Martinez-Ferrer and Harper (2005) reported the use of methyl jasmonate (MJ) emulsion (10^{-4} M) decreased microbial growth in diced pineapple by 3 logs after 12 days storage at 44.6°F, without affecting firmness or color.

HIGH PRESSURE PROCESSING (HPP). High hydrostatic pressure is a novel technology for minimal processing of pineapple products. Bacterial survival and total yeast and fungi counts decrease with increase in processing pressure in fresh-cut pineapple chunks packed in heat-sealed polyethylene pouches and treated under various ultra-high pressure, temperature, and time combinations (Hepton and Hodgson 2003). Water and solute of pressure-pretreated pineapple have been reported to demonstrate a significantly higher diffusion rate during osmotic dehydration (Ramaswamy and others 2005).

37.1 INTRODUCTION

Fruit juices represent a growing category in the United States beverage market. In 2000, juice consumption accounted for 44% of total fruit consumption, and this percentage is expected to increase in the future. Orange juice is the most popular of the juice products,

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

accounting for 60% of all juice consumed. Although orange, grapefruit, apple, and grape juices are considered to be the more traditional fruit juices, fruit juice blends of traditional and nontraditional fruits and fruit drinks contribute significantly to the fruit juice market and have received wide consumer acceptance (Thor and Savitry 2004).

The flavor of fruit juices is developed through enzymatic reactions during the maturation of the fruit and influenced by the processing the juice undergoes following extraction. The volatile compounds responsible for the characteristic flavor of fruits are dependent not only on the type of fruit, but also the cultivar. The flavor descriptions, based on gas chromatography-olfactometry, of volatile compounds identified in fruit juices are compiled in Table 37.1. The data presented in this table reflect the significant amount of research conducted on the flavor characteristics of citrus juices. However, it is also interesting to note that many volatile flavor compounds are present in several different fruit juices. Esters are major contributors to the floral, fruity aromas of many juices.

TABLE 37.1 Flavor Characteristics of Volatile Flavor Compounds in Fruit Juices.

Volatile Compound	Flavor Characteristic	Source[a]
	Esters	
Ethyl acetate	Fruity, orange	Orange juice (G, I), grapefruit juice (D), muscadine grape juice (A)
Isobutyl acetate	Solvent-like	Apple juice (B)
Octyl acetate	Unpleasant, dusty, green	Orange juice (I)
p-menth-1-en-9-yl acetate	Citrusy, fruity, floral	Orange juice (I)
Ethyl propanoate	Fruity	Orange juice (G), grapefruit juice (D)
Methyl butanoate	Fruity	Orange juice (I)
Ethyl butanoate	Fruity, green, floral, orange	Orange juice, (C, G, I), grapefruit juice (D, F), apple juice (B), muscadine grape juice (A)
Propyl butanoate	Cooked apple-like, fruity, musty	Orange juice (C), apple juice (B)
Ethyl 2-methylpropanoate	Fruity, sweet	Orange juice (G), grapefruit juice (D, F, H)
Ethyl 2-methylbutanoate	Cooked apple-like, green apple, fruity	Orange juice (G), grapefruit juice (D, H), apple juice (B), muscadine grape juice (A)
Ethyl hexanoate	Fruity, green apple, orange	Orange juice (G, I), grapefruit juice (D, F), muscadine grape juice (A)
Methyl octanoate	Mint/citrus/moldy/musty/oil	Orange juice (C)
Ethyl decanoate	Roasted meat/cooked apple sauce	Orange juice (C)
Ethyl 3-hydroxybutanoate	Hay-like, burnt marshmallow, muscadine	Muscadine grape juice (A), grape musts (E)
Ethyl 3-hydroxyhexanoate	Sweet, fruity	Orange juice (G), grapefruit juice (D, F)

Terpenoid compounds have piney, floral characteristics, while alcohols and aldehydes have green, grassy aromas. In addition, nonvolatile flavor components, including sugars, acids, and bitter compounds are important contributors to the overall flavor quality of juices. Consumer acceptability of these juices is not only dependent on the presence of character-impact compounds, but also the appropriate balance of volatile and non-volatile flavor compounds (Jella and others 1998).

The major categories of juice products include frozen concentrated, pasteurized/refrigerated, refrigerated from concentrate, and aseptically packaged. The flavor of fruit juices is optimal immediately following extraction of the juice. Subsequent processing and storage contributes to alterations in the content and composition of the volatile flavor compounds and the overall flavor quality of the juice. This chapter will provide an overview of the volatile flavor compounds that contribute to the unique flavor of fruit juices and discuss the effects of processing, packaging, and storage on those flavor compounds that are important to the characteristic flavor of fruit juices.

37.2 PRODUCTION OF FLAVOR COMPOUNDS DURING FRUIT MATURATION

The synthesis of volatile and nonvolatile flavor compounds during maturation has a significant impact on the flavor quality of the juice. Enzymatic transamination and decarboxylation reactions of branched-chain amino acids are important in the biosynthesis of

esters, alcohols, aldehydes, and acids which are key contributors to the characteristic flavors of all ripening fruits. Terpenoid compounds, synthesized through the isoprenoid pathways, are important components of citrus flavor. These compounds exist as free and nonvolatile, bound terpenoid glycosides. During fruit maturation, endogenous β-glucosidases catalyze the release of volatile terpineols, including linalool, benzyl alcohol, and 2-phenylethanol, to enhance juice aroma (Gueguen and others 1996).

The degradation of starches to form sugars and the synthesis of acids through the metabolic pathways during ripening contributes to the sweet and tart taste characteristics associated with ripened fruits. Fructose, glucose, and sucrose are the primary sugars found in most fruits. The dominant organic acids present are characteristic of the specific fruit. The sugar to acid ratio, frequently reported as brix/acid ratio, is influenced by many factors, including fruit maturity. The brix/acid ratio has a significant impact on the perceived sweetness and tartness of the juices, quality, and consumer acceptability (Fellers and others 1988).

37.2.1 Citrus Fruit

Terpenes, esters, aldehydes, and alcohols are important constituents in the aroma of citrus juices (Fig. 37.1). The water-soluble compounds, including the esters and monoterpene alcohols, are associated predominantly with the sera of the juice and are extracted from the juice sacs. The monoterpene and sesquiterpene hydrocarbons and other oil-soluble compounds are extracted from the juice and from the peel and are associated predominantly with the pulp and cloud (Brat and others 2003; Moshonas and Shaw 1994).

Neral, geranial, valencene, linalool, β-sinenasal, β-myrcene, α-pinene, and ethyl butanoate are important contributors to orange aroma (Marin and others 1992; Bazemore and others 1999; Buettner and Schieberle 2001b; Rega and others 2003). Limonene, the most abundant compound in orange juice, has a very high odor threshold. Researchers disagree on the contribution of limonene to orange juice aroma. Marin and others (1992) concluded that limonene has a negligible impact on orange juice aroma, while Rega and others (2003) demonstrated that limonene does contribute to overall orange juice aroma. The contribution of specific volatile compounds to flavor depends on the cultivar. Compounds with fruity aroma characteristics, such as ethyl 2-methylbutanoate, ethyl

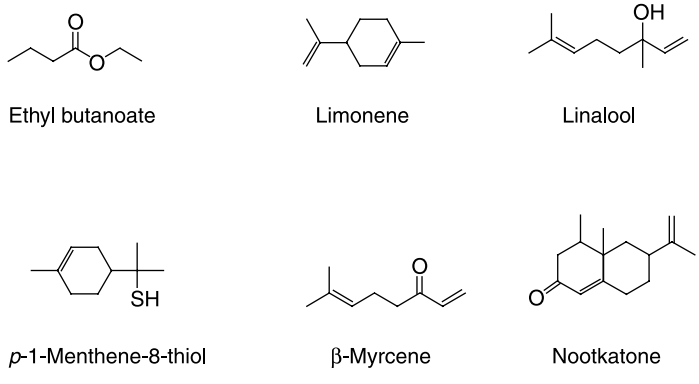

Figure 37.1 *Contributors to aroma of orange and grapefruit juices.*

butanoate, and *cis*-3-hexenal were the most important odor active compounds in Valencia orange juice, while *cis*-3-hexenal, ethyl 2-methylbutanoate, and acetaldehyde were most predominant in Navel orange juice (Buettner and Schieberle 2001b).

Nootkatone, *p*-1-menthene-8-thiol, and ethyl butanoate are character impact compounds of grapefruit (Rouseff and others 1994; Burgard 1995; Shaw and others 1995; Buettner and Scheiberle 1999; Cheetham 2002). Another thiol, 4-mercapto-4-methylpentan-2-one, present in trace amounts, has been shown to be an important contributor to grapefruit juice flavor because of its low threshold (Buettner and Schieberle 2001a). Although acetaldehyde and limonene are the most abundant volatile compounds present in grapefruit juice, these volatiles do not have a significant impact on overall grapefruit juice flavor (Buettner and Schieberle 2001a). Of the volatile flavor compounds identified in grapefruit juice, the contents of myrcene, β-caryophyllene, and linalool have a significant effect on acceptability. Grapefruit juice acceptability was positively correlated with the content of β-caryophyllene, and negatively correlated with the content of myrcene and linalool (Jella and others 1998).

The stereoisomers, geranyl acetate and neryl acetate, and citral, contribute to lemon flavor. Tangerine flavor is attributed to the presence of γ-terpinene, dimethylanthramilate, and α-sinenasal. In addition to these terpene compounds that contribute unique flavor characteristics to citrus juices, esters, aldehydes, and alcohols are also important contributors to the flavor of these citrus juices (Burgard 1995; Cheetham 2002; Rouseff and others 1994; Shaw and others 1995).

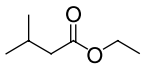
Sugar contents of citrus fruits range from 4% to 7%, depending on the specific fruit and cultivar. Sucrose is the predominant sugar in orange and grapefruit juices and fructose the predominant sugar in lemon juice (Braddock and others 1988). Citric acid, the key organic acid in citrus fruit, contributes sour flavor characteristics. Lemons and limes tend to be high-acid fruits, while oranges, tangerines, and grapefruit tend to be low-acid fruits (Matthews and others 1990; Rouseff and others 1994).

Bitterness in citrus fruits is attributed to limonin, a 22-carbon triterpenoid dilactone, and naringin, a 15-carbon glycosylated flavonoid. Bitterness from naringin is perceived immediately. However, bitterness from limonin is only perceived if the extracted juice is allowed to stand or is heated (Matthews and others 1990; Rouseff and others 1994).

In juices processed from Valencia oranges, early samples were characterized as having more bitter, sour, artificial, and cooked flavor characteristics, with low natural/fresh flavors than juices from more mature fruit. These sensory characteristics were attributed to high contents of peel oil (i.e., octanal, β-myrcene, α-pinene, and limonene) volatiles and moderate contents of essence (i.e., ethyl butanoate, ethyl hexanoate, hexanal, and acetaldehyde) and sesquiterpene (i.e., valencene) volatiles. As the fruit matured, increases in the contents of the essence and sesquiterpene volatiles and brix/acid ratio contributed to increases in sweetness and fresh/natural sensory characteristics and decreases in the bitter/sour and artificial/cooked sensory characteristics (Burgard 1995).

37.2.2 Apples and Pears

Esters are key contributors to the characteristic fruity aromas of apple and pear juices (Fig. 37.2). Ethyl 2-methylbutanoate, hexyl acetate, ethyl propionate, 2-methybutyl acetate, and butyl acetate are key contributors to apple flavor (Dimick and Hoskin 1983; Young and others 1996; Lopez and others 1998; Cheetham 2002). These esters are noted for their fruity, apple-like aroma (Lopez and others 1998). The composition



Ethyl 2-methylbutanoate

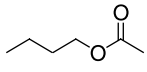
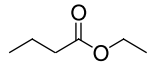
Ethyl *trans*-2-*cis*-4-decadienoate



Butyl acetate



Ethyl butanoate

Figure 37.2 *Contributors to aroma of apple and pear juices.*

and content of the individual volatile flavor compounds in apples has been shown to vary greatly between different cultivars (Poll 1981; Williams and others 1981; Young and others 1996; Lopez and others 1998). The major volatile compound present in pears is ethyl *trans*-2-*cis*-4-decadienoate. Other important volatile flavor compounds include ethyl-2-octenoate, hexyl acetate, ethyl-4-decenoate, butyl acetate, and ethyl butanoate (Cheetham 2002).

The initiation of the climacteric rise in apples and pears contributes to the color, texture, and flavor changes associated with ripening. The release of ethylene contributes to the development of the enzyme systems and volatile precursors necessary for flavor formation. The fatty acid content of the fruit also increases with maturity. Lipid hydrolases, lipoxygenase, and proteases contribute to the formation of the fatty acid and amino acid precursors of flavor formation. In the latter stages of ripening, β-oxidation of linoleic acid, lipoxygenase activity, and esterification of acids with alcohols contribute to ester formation. Since these enzyme systems and flavor precursors are not fully developed in the immature fruit, juice processed from immature fruit often lacks the esters and other volatile compounds that contribute desirable fruity flavor characteristics (Song and Bangerth 1994; Yahia and others 1990).

The storage time and environment of the apples prior to processing into juice also has a significant impact on the flavor of the juice. Apples are frequently held in controlled atmosphere storage to reduce fruit respiration, delay ripening, and extend storage. However, the reduced oxygen environment alters the production of volatile flavor compounds by the fruit resulting in decreases in the contents of butyl and hexyl esters, aldehydes, and ketones and increases in ethanol, acetaldehyde, and ethyl esters (Mattheis and others 1991; Boylston and others 1994; Plotto and others 1999).

In apples and pears, the predominant organic acid and sugar are malic acid and fructose, respectively. In the final stages of ripening, the accumulation of fructose and other sugars is accompanied by decreases in malic acid and starch contents (Blanco and others 1992). The ratio of sugars to acids, which has a major impact on the perceived sweetness and tartness of the juices, varies greatly depending on the specific apple and pear cultivars. Apple cultivars can be classified into four main types: bittersweets, bittersharps, sweets, and sharps. "Bitter" is associated with high polyphenol content, while "sharp" and "sweet" are associated with high and low acid contents, respectively (Dimick and Hoskin 1983).

37.2.3 Grapes

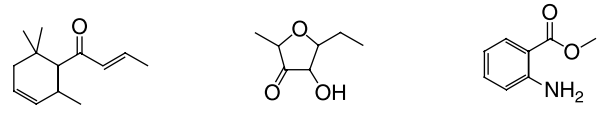
β-damascenone is an important contributor to the flavor of most grape cultivars (Shure and Acree 1994). Other important contributors to the characteristic flavor of grape juices are dependent on the specific grape cultivars. In Concord grapes, odor-active compounds include o-aminoacetophenone, methylfuraneol, and methyl anthranilate (Shure and Acree 1994). In muscadine grape juice, 2,5-dimethyl-4-hydroxy-3(2H)-furanone (furaneol) and o-aminoacetophenone contribute to the characteristic candy and foxy-like aroma characteristics (Baek and others 1997). *p*-1-Menthene-8-thiol and β-damascenone were shown to be important contributors of red fruit-like and grape aroma notes in musts from white grape hybrids (Serot and others 2001). Other contributors to the aroma profile of grape juices include aldehydes and alcohols with green and grass-like aromas, esters with fruity notes, and phenylacetaldehyde and other compounds with sweaty aromas (Baek and others 1997; Serot and others 2001). Significant increases in several important contributors to grape flavor, including o-aminoacetophenone, methylfuraneol, and methyl anthranilate (Fig. 37.3), occur at the onset of the final ripening (Shure and Acree 1994).

Tartaric and malic acids are the predominant organic acids present in grapes. Glucose and fructose are the predominant sugars and are present in relatively equal amounts. The content of the sugars and acids dependent on the grape cultivar and maturity (Buglione and Lozano 2002; Montgomery and others 1982).

37.3 PROCESSING OF FRUIT JUICE

Raw material selection is critical to the quality of the final product. The intensity of the aroma quality of the fruit prior to processing has a significant impact on the overall aroma and taste of the juice. Cultivars and maturity of the fruit have a significant impact on the quality of the final products. Other factors, such as ethylene and respiration rates, climate, soil, and fertilization can also contribute to variations in the volatile flavor compounds in the fruits (Lopez and others 1998). Extraction of the juice from the fruits though pressing is the initial step in juice processing. Depending on the nature of the final product, the extract juice may undergo pasteurization, concentration, and packaging treatments that have a significant impact on the flavor quality of the processed fruit juice.

In orange juice, descriptive sensory evaluation and multivariate statistical analyses showed that juice receiving similar processing treatments clustered into the same category. Fresh-squeezed orange juices were characterized as having raw/fresh and floral sensory notes. Canned juices had strong citrus/non-orange, pungent, sour, bitter, and metallic



β-Damascenone Methyl anthranilate Methyl furaneol

Figure 37.3 *Contributors to aroma of grape juice.*

notes. Frozen concentrated and refrigerated frozen concentrated orange juices were characterized as having orange and candy-like notes (Lotong and others 2003).

37.3.1 Juice Extraction

Juice production involves the pulverization of whole fruit into a puree, followed by pressing to extract the juice from the pomace. Several enzymatic reactions occur during the processing to alter the flavor profile in comparison to the raw materials. Enzymatic cleavage of esters, oxidation of fatty acids to alcohols and aldehydes, and synthesis of alcohols are among the reactions that occur during the processing of juices. Enzymatic oxidation of polyunsaturated fatty acids during the crushing of the fruit contributes to the formation of hexanal, 3-hexenal, 3-hexen-1-ol, and 1-octen-3-one and other oxidation products (Vidrih and Hribar 1999; Serot and others 2001; Williams and others 1981).

Volatile compounds from the peel oil account for 65–80% of the oil-soluble volatile compounds in citrus juices. The peel oil compounds include several terpenoid compounds recognized as important contributors to citrus flavor. The contents of these compounds are significantly higher in mechanically-extracted juice, as compared to hand-extracted juice (Moshonas and Shaw 1994). Separation of the pulp with low speed centrifugation following mechanical extraction results in significant losses of the monoterpene and sesquiterpene hydrocarbons due to their association with the pulp (Brat and others 2003).

37.3.2 Post-Extraction Juice Treatments

The use of styrene divinylbenzene resins for debittering citrus juices reduces limonin and naringin contents by more than 50%. However, the resin also binds the essential oils that contribute to desirable flavor characteristics. The addition of essential oils in commercial processing would compensate for the loss in these desirable flavor compounds (Ifuku and others 1988; Matthews and others 1990).

During apple juice processing, pectinase and other enzyme treatments and microfiltration are performed to increase juice clarity. To optimize these operations, the temperature of the juice is increased to 57°C. At these temperatures, the activity of the native enzymes, such as lipoxygenase, and the release of flavor compounds bound to cell membranes increase the content of several volatile flavor compounds, including isobutyl acetate, ethyl butanoate, ethyl-2-methyl butanoate, hexanal, propyl butanoate, and *trans*-2-hexenal (Su and Wiley 1998).

37.3.3 Thermal and Non-Thermal Processing Treatments

The association of food borne illnesses with the consumption of raw fruit juices has led to a Food and Drug Administration (FDA) ruling that requires juice processors to implement processing treatments that achieve a 5-$\log_{10}$ reduction in the numbers of the most resistant pathogen in the finished product compared to the untreated juice (CFR 2001). The specific processing method to cause a 5-log reduction is not specified by the FDA. Pasteurization, irradiation, and ultraviolet processing are among the treatments shown to be effective in achieving the required 5-$\log_{10}$ reduction. However, these treatments may adversely affect the flavor and other quality attributes of the juice.

Therefore, recent research has focused on the selection of processing treatments that effectively reduce the microbial load without adversely affecting the flavor and other quality attributes of the juice.

37.3.3.1 Pasteurization. As a result of the concerns regarding the safety of juices, 98% of the juice sold is pasteurized as an effective means to destroy all disease-causing pathogens and reduce the number of spoilage microorganisms (Kozempel and others 1998). However, the pasteurization results in significant losses in the natural fruity aromas and the development of cooked aromas due to the thermal degradation of the aroma compounds (Poll and Flink 1983; Poll 1985; Johnson and others 1996; Moshonas and Shaw 1997; Bettini and others 1998; Su and Wiley 1998; Bazemore and others 1999; Wang and others 2003).

Excessive heat treatment of orange juice resulted in the loss of compounds with buttery, fruity-floral, and terpene aroma characteristics and the formation of compounds with vinyl, rotten fruit, cooked grain, and piney aroma characteristics. The changes in aroma profile were associated with the increases in the contents of 4-vinylguaiacol, terpin-4-ol, *cis*-3-hexenal, *trans*-2-nonenal, decanal, and decreases in the contents of ethyl butanoate, propyl butanoate, octanal, methyl octanoate, linalool, and nonanal (Bazemore and others 1999).

In mandarin juices, dimethyl sulfide, furfural, linalool oxide, and 5-methylfurfural were formed during pasteurization. Degradation of S-methylmethionine sulfonium (MMS) during heat processing contributed to the formation of the off-flavor, dimethyl sulfide (DMS). Mandarin juices contain relatively high contents of MMS, although adsorption of MMS by ion-exchange resin effectively reduces the formation of DMS during heat processing and subsequent storage (Ifuku and others 1988).

37.3.3.2 Canning. The severe heat treatment during the canning of orange juice results in significant decreases in flavor quality. The processing results in large decreases in acetaldehyde, ethyl butanoate, and limonene and large increases in α-terpineol. The 10% orange juice drinks are characterized as having poor flavor quality, including the absence of important components for desirable orange juice flavor and high contents of linalool and α-terpineol (Nisperos-Carriedo and Shaw 1990).

37.3.3.3 Irradiation. As a result of concerns of the effects of thermal processing treatments on the flavor quality of juices, researchers have investigated the effects of irradiation treatments on the microbial and flavor quality of fruit juices. Although irradiation does effectively reduce the microbial load in these juices, the flavor quality of the irradiated juices is affected by the irradiation dose and juice environment.

Irradiation of orange juice at 3.5 and 4 kGy resulted in significant changes in the flavor characteristics of the juice. Sensory panelists described the juice as "plastic to decayed" with the increase in irradiation dose resulting in an increased intensity of the off-flavor. Although the irradiation treatment resulted in an increase in the content of total volatile compounds, the effect of irradiation on the characteristic orange juice volatiles and the specific compound responsible for the off-flavor was not determined (Foley and others 2002).

Potassium sorbate, an effective inhibitor of yeasts and molds, is frequently added during the processing of juices to control fermentation and extend the shelf-life

(Baroody and McLellan 1986; Wright and others 2000; Luedtke and Powell 2002). In irradiated apple cider, the presence of sorbate also decreased the rate of loss of esters and other volatile compounds which are important contributors to apple flavor during storage (Crook and Boylston 2004; Crook and others 2004). Sorbate can quench the free radicals that initiate oxidation reactions that form lipid oxidation products and degrade esters and other flavor compounds (Boylston and others 2003).

However, the degradation of sorbate during irradiation has also been shown to contribute to the development of undesirable off-flavors in irradiated juices. Irradiation of orange juice containing sorbic acid was shown to result in the formation of off-flavors at irradiation doses as low as 1.0 kGy (Thakur and Singh 1993). In model systems, descriptive sensory panelists detected a significantly higher intensity of musty off-flavors in irradiated water and apple cider containing sorbate than in either the water or apple cider containing sorbate or the irradiated water or apple cider (Yulianti and others 2005).

37.3.4 Juice Concentration

Concentration of juices, followed by freezing, provides an economical, year-round source for seasonal fruit juices. For these reasons, a large percentage of the juices on the market are reconstituted from juice concentrates. Vacuum concentration, which is often used to produce the concentrates, also results in the removal of volatile flavor compounds. Commercial evaporators use several stages of vacuum-assisted heating to heat the juices to higher temperatures, followed by rapid cooling. During the early stages of the evaporation process for processing juice concentrates, the volatile flavor compounds are vaporized with the water. These volatiles are recovered using an essence recovery system and added back to the frozen concentrates and other processed juice products to enhance the characteristic flavor of the juices (Johnson and others 1996; Sizer and others 1988; Lin and others 2002).

Fresh, pasteurized, and from-concentrate orange juices vary significantly in their flavor quality and consumer acceptability. Processing, either as pasteurization or reconstitution from concentrate, contributes to significant decreases in the contents of volatile compounds, such as ethyl butanoate, ethyl acetate, *cis*-3-hexenol, acetaldehyde, and ethanol and losses in fresh fruit and floral flavor notes in orange juice (Shaw and others 1995). The addition of peel oil to frozen concentrates and reconstituted single strength juices compensates for losses in flavor compounds during processing and results in significantly higher contents of linalool, citral, and limonene than in fresh juice (Nisperos-Carriedo and Shaw 1990).

A comparison of single-strength and reconstituted concentrate grapefruit juice showed that concentration results in more than a 90% loss in volatile compounds. However, not all volatile compounds are lost to the same degree. The fresh/citrusy and sulfur/grapefruit aroma characteristics of the grapefruit juice were almost completely lost during evaporation. This change in aroma profile was attributed to almost complete losses of the three major grapefruit volatile compounds, limonene, caryophyllene, nootkatone, and 30 other volatile flavor compounds. Thermal instability of the flavor compounds and physical evaporation contributed to the losses of these compounds. The aroma compounds with green/fatty/metallic and sweet/fruity characteristics were relatively stable to the effects of thermal evaporation. The contents of ethyl butanoate, 2-*trans*-hexenal, β-ocimene, and linalool oxide were relatively unchanged during processing. *p*-1-Menthene-8-thiol, identified as a key aroma impact compound in grapefruit juice was present only in the concentrated juice and is believed to be a reaction product of hydrogen sulfide with limonene or

α-pinene. Other sulfur-containing compounds, including methional, 2-methyl-3-furanthiol, and bis-(2-methyl-3-furyl)-disulfide, with cooked/meaty aroma characteristics, increased during concentration (Lin and others 2002).

37.4 PACKAGING OF FRUIT JUICES

Single-strength, "not from concentrate" fruit juices packed in glass containers provides the highest quality possible to consumers. However, the high container and shipping costs associated with these products have resulted in interest in application of lighter weight and less expensive packaging material for fruit juices. Plastic packaging is widely used as economic alternatives to glass bottles. The selection of packaging materials has a significant impact on the quality of processed juice during storage. Interactions between foods and packages have a significant effect on the flavor of the food due to adsorption of flavor compounds by the packaging materials, migration of components from the packaging material into the food, and permeation of small gas and water molecules through the packaging material to catalyze chemical degradation of flavor compounds (Sizer and others 1988; Moshonas and Shaw 1989; Letinski and Halek 1992; Marin and others 1992).

37.4.1 Characteristics of Plastic Packaging Materials

The absorption of volatile flavor compounds from juice products by plastic polymers is dependent on the polarity of the volatile compounds. For low-density polyethylene (LDPE), a polymer frequently used in plastic bottles, absorption was inversely related to polarity, with the hydrocarbons, ketones, and aldehydes adsorbed to the greatest degree and only trace amounts of alcohols and esters absorbed by the plastics (Mannheim and others 1987; Sadler and Braddock 1991; Charara and others 1992; Pieper and others 1992; Sadler and others 1995).

Limonene, a terpenoid hydrocarbon present in orange juice, has been shown to be rapidly absorbed by polyethylene packaging materials due to the similarities in the polarity of the volatile compound and packaging material (Mannheim and others 1987; Pieper and others 1992; Sadler and Braddock 1991). Although limonene has not been shown to be a major contributor to orange juice aroma (Marin and others 1992), studies have related losses in orange juice flavor packaged in plastic polymers to absorption of limonene (Kwapong and Hotchkiss 1987). The binding of volatile compounds by LDPE has been shown to increase the oxygen permeability of the packaging material, and thus, contribute to degradation of the volatile flavor compounds (Sadler and Braddock 1990, 1991).

The high absorption of the lipophilic terpene hydrocarbons by LDPE has been attributed to the large amorphous area and low crystallinity of the LDPE polymer. Absorption of volatiles by highly crystalline polymers, such as high-density polyethylene (HDPE), nylon, polyethylene terephthalate (PET), ethylene vinyl alcohol co-polymer (EVOH), and polypropylene (PP), is significantly less than the absorption of volatiles by LDPE (Imai and others 1990; Charara and others 1992; Letinski and Halek 1992; Sadler and others 1995).

A comparison of packaging materials for orange juice flavor showed the greatest losses in volatile flavor compounds occurring for the juices packaged in HDPE and LDPE in comparison to glass or PET. Decreases in the content of the hydrocarbons, limonene, myrcene, and α-pinene, were attributed to adsorption of the volatiles by the polyethylene

packaging material. Oxygen transmission through the polyethylene packages (HDPE and LDPE) contributed to chemical degradation of the aldehydes and esters (Ayhan and others 2001).

Results from sensory evaluation of orange juices packaged in different polymers indicated that the nylon, PET, and EVOH packaging materials did not alter the flavor in comparison to the control treatment. However, the orange juice in contact with LDPE was characterized as having fermented, musty, yeasty, and other spoilage off-flavors. Since D-limonene (or its oxidized or hydrolyzed derivatives) inhibits microbial growth, the reduced content of limonene in the orange juice through absorption by LDPE contributed to higher microbial counts in the orange juice in contact with LDPE in comparison to the other packaging treatments (Sadler and others 1995).

Similarly, sorption of volatile flavor compounds significantly affects the flavor profiles of apple juice. The content of four probe compounds, representative of key apple flavor compounds, was determined during storage in which the apple juice was in contact with LDPE, EVOH, or Co-PET (Co-polyester). The greatest sorption of the volatiles occurred with the LDPE film, in which significant decreases in the contents of ethyl-2-methyl butanoate, hexanal, and *trans*-2-hexenal, but not 1-hexanol, were noted. The EVOH and Co-PET films did not absorb significant amounts of hexanal, *trans*-2-hexenal, or 1-hexanol. Both films did absorb significant amounts of ethyl-2-methyl butanoate, but the level of absorption was lower than for the LDPE films (Konczal and others 1992).

Migration of off-flavor compounds from the plastic to the juice also contributes to losses in flavor quality of fruit juices (Marin and others 1992; Moshonas and Shaw 1989). The LDPE packaging material itself has also been reported to have an off-flavor. Sensory panelists, using a triangle test, were able to distinguish between water samples with and without LDPE strips (Mannheim and others 1987).

The oxygen permeability of the packaging material also has an impact on the flavor characteristics of the juice, especially during storage. Packaging materials with low oxygen permeability, such as Nylon and polystyrene, were more effective than LDPE in the retention of the esters and other volatile flavor compounds that contribute to apple flavor during the storage of apple cider (Crook and Boylston 2004).

37.4.2 Aseptic Packaging

The consumption of fruit juices and 10% fruit juice drinks packaged aseptically in 250 mL flexible, laminated cartons has increased significantly since the 1980s due to the shelf-stable nature of these products. The aseptic carton laminate includes aluminum foil as a barrier in the packaging material and LDPE as the food contact material. Flavor changes during storage of these juice products in laminated cartons limits their shelf-life from one to four months, which is about half that of juices packaged in glass (Mannheim and Havkin 1981; Mannheim and others 1987). The reduced shelf-life of orange and grapefruit juices packaged in laminated cartons was attributed to the absorption of limonene by polyethylene and transmission of oxygen through the packaging material (Mannheim and others 1987).

Deaeration of the juice is a critical step in aseptic processing to remove oxygen that can contribute to degradation of flavor compounds and formation of off-flavors, as well as color and vitamin C. Following pasteurization of the reconstituted juice and the addition

of sterile filtered flavor components the juice filled into the sterilized cartons and hermetically sealed (Sizer and others 1988).

A comparison of reconstituted frozen orange juice to aseptically packed orange juice resulted in the aseptically packed orange juice being significantly less acceptable. A cooked or "prune-like" flavor has been noted in aseptically packed orange juice by descriptive sensory panelists (Moshonas and Shaw 1989).

37.5 STORAGE OF FRUIT JUICES

The shelf-life and flavor quality characteristics of the fruit juices following processing are dependent on the processing and packaging the juice has undergone prior to processing. With the extended storage of juices, losses of volatile flavor compounds contribute to changes in the sensory flavor attributes. In Valencia orange juice, the loss of peel oil (i.e., octanal, β-myrcene, α-pinene, and limonene) and essence (i.e., ethyl butanoate, ethyl hexanoate, hexanal, and acetaldehyde) volatiles resulted in a decrease in the intensity of the fresh/natural flavor note, as evaluated by a sensory panel (Burgard 1995).

Decreased acceptability of aseptically packaged orange juice during a six-week storage period was attributed to decreases in recoverable oil and limonene contents and increases in the contents of the off-flavor compounds, ethyl acetate, and α-terpineol (Moshonas and Shaw 1989). Migration of ethyl acetate from the laminated multilayer carton to the juice contributes to the increase in the content of ethyl acetate (Passy 1983). α-Terpineol is a degradation product of limonene and also contributes to the stale or musty aroma in aged canned orange juice (Tatum and others 1975).

2-Methyl-3-furanthiol, methional, β-damascenone, 5-hydroxymethylfurfural (HMF), 4-hydroxy-2,5-dimethyl-3(2H)-furanone (DMHF), *p*-vinylguaiacol have been shown to increase significantly during pasteurization and storage of orange juice and contribute to storage off-flavors. 2-Methyl-3-furanthiol is formed through the acid-catalyzed degradation of thiamin and has a meaty aroma (Bezman and others 2001; Dreher and others 2003). β-Damascenone, formed through the acid-catalyzed degradation of terpene glycosides, is characterized as rose/tobacco (Bezman and others 2001). Methional, formed from methionine through the Strecker degradation reaction, has a cooked potato aroma (Bezman and others 2001). DMHF and HMF are products of Maillard and sugar degradation reactions (Haleva-Toledo and others 1997). DMHF, at a detection level of 0.1 ppm, has a pineapple-like flavor (Tatum and others 1975). At levels above 0.05 ppm, DMHF masks fresh orange juice aroma (Nagy and others 1989). Nonenzymatic decarboxylation of free ferulic acid results in the formation of *p*-vinylguaiacol, which has an undesirable old fruit or rotten flavor (Naim and others 1988; Tatum and others 1975). The addition of 0.5 mM L-cysteine inhibits the formation of DMHF (Naim and others 1993a) and *p*-vinylguaiacol (Naim and others 1993b) to preserve the fresh aroma of orange juice and minimize off-flavor formation.

During storage, slight changes in content of sugars in grape juice occur through the hydrolysis of sucrose and reaction of the reducing sugars in nonenzymatic browning reactions, with the formation of hydroxymethylfurfural (Cornwall and Wrolstad 1981; Toribio and Lozano 1984; Buglione and Lozano 2002). However, these changes

in sugar profiles most likely have a more significant impact on color and appearance than flavor. Acidity of grape juice is relatively stable during storage (Buglione and Lozano 2002).

37.6 CHALLENGES FOR THE FRUIT JUICE INDUSTRY

Consumption of fruit juices is expected to continue to be a major growth area. The use of juices as carriers of nutrients, making the juices "functional foods" will further contribute to the expansion of the fruit juice market. In addition, the development of juices and juice blends with nontraditional fruits will grow to meet consumers' demands for juices with unique flavor characteristics. With these changes on the horizon, significant opportunities exist for fruit juice processors, food scientists, and flavor chemists to develop processing and packaging technologies to maintain the desirable flavor characteristics of the fruit juices.

38.1 INTRODUCTION

Food drying is one of the oldest methods used to preserve food products for later use, being a good alternative to canning and freezing or even a way of complimenting these methods (Andress and Harrison 1999). Drying implies the removal of a significant part of the water from the food, and in low-water-activity conditions, the bacteria, yeasts, and molds cannot grow, and the enzymatic reactions are very slow.

Dried foods are lightweight, take up little space and do not require refrigeration, thus enabling low transportation and storage costs. The dried foods can be consumed (or

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

used) in the dry form, or after reconstitution by rehydration. In this operation, water is added back to the product, soaking until the desired volume is restored and the original shape is obtained. In the case of fruits, once reconstituted they are treated as fresh.

Bananas are quite perishable and highly sensible to heat; it is estimated that more than a quarter of the world's production is lost every year. For example, in Papua New Guinea and Ghana the production largely surpasses the needs, but the bad state of the roads does not allow its transportation. However, the banana is also very versatile, thus enabling its consumption in a wide range of products: canned or frozen purée, dried banana figs, banana powder, banana flour, flakes, chips (or crisps), canned slices, jams, and beverages (Dauty 1995). These products can be divided in two categories: those for direct consumption, such as figs, and those for incorporating into other food preparations in the food industry, like purées and powder. Effectively, the majority of the world's production is consumed either raw (in the ripe state) or cooked, and only a small part is processed to obtain a storable product. One of the most important and widespread banana products is the flour prepared by sun-drying of unripe banana and plantain (Dauty 1995).

In South Africa, in Mpumalanga, situated 400 km away from Johannesburg, for 30 years an enterprise has been transforming 10% of its production into dried bananas (in cubes, strips, or slices), which are consumed in the nearby schools. In Uganda, green bananas are sliced and dried to produce "mutere", which is used mainly as a reserve for when there is severe storage of food; it is not, however, a significant part of the local diet under normal conditions (Dauty 1995). Plantains are used in Gabon, dried in slices, for storing or for long journeys, and in Cameroon they are dried in pieces to produce flour, which is used to cook a local recipe known as "fufu". Flour is also produced from dried bananas in some parts of South and Central America and West Indies (Dauty 1995).

Dried bananas make a delicious and inexpensive snack, and, when dried correctly, their nutrients are almost completely preserved. Furthermore, they constitute a good way of increasing the incomes of some communities from a locally available product.

38.2 DRYING METHODS

Bananas, as many other food products, can be dried by conventional drying methods (in the sun, in dehydrators, in an oven, or in an industrial drying chamber) by using a combination of warm temperatures, low humidity, and an air stream to remove the evaporated water (Andress and Harrison 1999).

One of the most common and cheap drying methods, which is practiced in areas of suitable climate, is sun drying. However, ovens or fires are also used to dry bananas by traditional processing techniques. In West Africa, plantains are often soaked and sometimes parboiled before drying. The drying of unripe fruit slices is carried out on bamboo frameworks, cemented areas, mats, swept-bare patches of earth, roofs, or sometimes on stone outcrops or sheets of corrugated iron. In East Africa, peeled bananas are predried on a frame placed over a fire for 24 h, before drying in the sun. In Polynesia, ripe bananas are preserved by wrapping in leaves for storage, after oven drying (Dauty 1995).

Many banana products, such as banana figs or banana flour, are now produced on an industrial scale, using appropriate drying methods. The drying temperature should not exceed 60°C, in order to preserve the product's organoleptic characteristics, and minimize the loss of important nutrients. The drying rate should also be moderate, so as to prevent the product from drying in the outside, impeding the moisture from escaping from the

interior, originating a "case hardening" phenomena. The drying process is accelerated by higher flow rates (by increasing the heat and mass transfer coefficients) as well as by low humidity (by increasing the driving force for moisture transfer).

38.2.1 Sun and Solar Drying

The high carbohydrate content of fruits, and in particular bananas, allows their drying at direct open-air sun exposure. However, this is possible only if the atmospheric conditions are favorable, thus corresponding to sunny, hot, dry and, preferably, windy days. The relative humidity of the atmosphere should be below 60%, and the minimum temperature recommended is 30°C, although higher temperatures are preferable (Andress and Harrison 1999).

For sun drying, the fruits are placed on trays made of screen or wooden dowels. The best screens for a safe contact with the food are those made of stainless steel, teflon-coated with fiber glass or plastic. Screens made from galvanized metal cloth are coated with cadmium or zinc, and therefore must be avoided, because they are subject to oxidation and may leave harmful residues on the food. Also, copper and aluminum screens should be avoided, the first because it destroys vitamin C and increases oxidation, and the second because it tends to discolor and corrode. Most woods are adequate, but some (green wood, pine, cedar, oak, or redwood) are not recommended because they can warp, stain the food, or even cause undesirable flavors (Andress and Harrison 1999).

The trays should be placed on blocks to allow better aeration, and not over the ground because it is moist. If an aluminum sheet is placed under the trays, the temperature is increased by the reflection of the rays on the metal.

To minimize the effect of exposure to insects or birds, the trays can be covered with a cheesecloth, and to prevent rehydration from night moisture, they should be sheltered at night (Andress and Harrison 1999).

To sun dry bananas, firm but ripe fruits are used. After peeling, they are placed (whole or sliced) on the trays and covered with a thin net. The bananas should be turned two or three times a day, for a uniform drying, and the process takes from 3 to 6 days in the case of sliced pieces. The final product is brown, but not hard.

The solar drying methods also use the sun as an energy source, but the drying is not done at direct exposure. For instance, the use of solar dryers has been very promising in drying bananas in Thailand. In the natural convective dryers the products are protected from insects, dust, and rain, and the drying time is reduced when compared to natural sun exposure. However, they present some disadvantages such as relatively low holding capacity and risk of reverse air circulation, causing spoilage of the products. In the forced convection dryers these problems are overcome, but the investments are higher due to the glass-covered solar air heaters required (Schirmer and others 1996).

Schirmer and others (1996) describe a multipurpose solar tunnel dryer that has been developed using a new design concept and has many advantages over conventional solar dryer designs. The dryer comprises a plastic-sheet-covered flat plate collector that supplies energy to heat the air, which is sent to the tunnel by three fans powered by a 53 W solar cell module. This dryer can be used for up to 300 kg of bananas, spread in one layer over a plastic net in the drying tunnel to receive energy both from the incident solar radiation and from the hot air. The temperature of the air in the dryer varies from 40 to 65°C, and the drying time required is about 3–5 days, being approximately half of that required for natural sun drying (5–7 days). Furthermore, the bananas produced in

this dryer have been protected from rain, insects, and dust, and show a superior quality regarding flavor, color, and texture (Schirmer and others 1996).

38.2.2 Convective Air Drying

Brazil is a great banana producer, and the transformation of bananas by drying has been gaining importance over recent years. Dried bananas are produced from different varieties, but all have high sugar contents, are very aromatic, and are nonastringent if dried in the correct ripening state. The fruits are maturated in chambers at temperatures not exceeding 22°C, to prevent the pulp from suffering alterations in texture (being less consistent) or becoming darker and having less aroma, thus disabling their usage (Leite 2004). The maturation chambers should preferably have temperature and relative humidity control, and provide internal circulation and renewal of air. To activate a uniform maturation, different gases are used, such as ethylene or acetylene, the latter being more common because it is cheaper and does not present the risk of explosion in the concentrations used (Leite 2004).

The ripe bananas are washed with water with 50 ppm of chlorine, using a mechanical device, preferably in two stages: first by immersion and then with a water stream. To preserve the natural color of bananas, they are subject to a pretreatment with SO_2, obtained from two different processes. One consists in the burning of sulfur powder in a hermetic chamber, which is a simple and low-cost process, but is difficult to control. The residual value of sulfur in the bananas should be under 100 ppm or 0.01 g/100 g of product (wet basis). Another process is the immersion in an aqueous solution of sodium sulfate, more indicated for the pretreatment of sliced bananas. The 10-mm-thick slices are immersed in a sodium bisulfite solution at 0.4% for approximately 40 s (Leite 2004).

The drying is carried out in a convective air dryer, operated at a constant temperature of 70°C and with an air speed of 2.5 m/s. The trays are loaded at a rate of 14 kg/m^2 in the case of whole fruits or 4 kg/m^2 in the case of sliced bananas. The final moisture content is about 20%, and is reached in 24 h for the whole fruits and 5 h for the slices. In long drying tunnels the temperature can be set to 55°C at the beginning and to 70°C at the end. However, the temperature programs and the speed of the cars can be altered according to each situation (Leite 2004).

Also in Brazil (in Guaraqueçaba), bananas are dried in a convective dryer similar to a tunnel dryer. The fruits are ripened artificially in a chamber, by burning alcohol followed by chamber sealing for approximately 24 h. After this, the room is opened and ventilated for 24–48 h until full ripening of the bananas. When ripe they are selected, with rejection of the fruits not obeying quality standards, and then are peeled manually. The fruits are then placed uniformly over the trays and left in the dryer until they reach a final moisture content of around 25%. The dryer contains four cars with 20 trays of 0.80 × 0.90 m each. The air is heated by six infrared burners, providing a power of 23,012 kJ/h each, and the energy source used is liquid petroleum gas (LPG). The air circulation is provided by an electrical ventilator of 0.6 m diameter, with a motor of 1.47 kW, capable of inducing an air speed of 1.5 m/s. This system allows an important reduction in the drying time, and obtains a final product with clearer color and a more pronounced aroma (Bittencourt and others 2004).

38.2.3 Microwave Drying

Conventional drying methods have a major disadvantage, in the low energy efficiency arising from a constantly decreasing drying rate, which leads to long drying processes.

This is a result of the low conductivity of the foods, which reduces heat transfer inside the product. Therefore, the use of microwaves to process foods, and in particular to dry them, has increased in recent years. This method allows the speeding up of the process, while maintaining the nutritional, medicinal, and sensory properties of the product (Sousa and others 2004a).

The use of microwaves accelerates moisture removal because heat is not transferred from outside the food, but is generated internally by friction of the molecules. Microwave drying equipment also allows a reduction of the physical space required to only 20–35% of that needed for conventional drying (Maskan 2000).

Microwave drying, if not properly applied, may lead to products of poor quality (Yongsawatdigul and Gunasekaran 1996). However, if adequately used, it can produce foods of high quality, with a better aroma and color, with much less energy requirement and processing time when compared to conventional drying (Maskan 2000).

Some research has been done on the microwave drying of bananas (Drouzas and Schubert 1996; Garcia and others 1988; Nijhuis and others 1998; Maskan 2000; Sousa and others 2004a; Sousa and Marsaioli 2004b). The resulting products show an excellent quality and good consumer acceptance, with color, texture, and sweetness close to the accepted ideal (Drouzas and Schubert 1996; Sousa and Marsaioli 2004b). Other authors recommend the combination of conventional convective air drying with microwaves (Prabhanjan and others 1995; Feng and Tang 1998).

38.2.4 Osmotic Dehydration

Osmotic dehydration allows the partial removal of water from fruits by immersion in a hypertonic solution (syrup). The drying force for water removal is due to the difference in the osmotic pressure in the food and in the surrounding solution. The complex cellular structure of the product acts as a semipermeable membrane, allowing the transfer of water from the product into the osmotic solution. The factors that influence the rate of diffusion are the temperature, the osmotic solution concentration, the size and geometry of the product, the mass ratio material/solution, and the level of agitation of the solution (Fernandes and others 2006).

Osmotic dehydration removes water until a certain level is reached, which is still high for preservation purposes, and therefore must be complemented with another drying method, usually by contact with a hot air stream. Fernandes and others (2006) studied the drying of bananas by a combination of osmotic dehydration with convective air drying, and optimized the process by selecting the most appropriate operating conditions that would reduce the total processing time.

Chua and others (2004) used a combination of intermittent infrared and continuous convection heating to dry different samples of banana, which had been osmotically pretreated in sucrose solutions at 15%, 25%, and 35%, to investigate the effects on drying rates and color. They observed that an appropriate control of the intermittences and heat flux intensity regulation, as well as the use of osmotic pretreatments, enables the production of premium quality products while maintaining high drying rates.

38.2.5 Freeze-Drying

Freeze-dried foods are characterized by high-quality characteristics, like superior taste and aroma retention, low bulk density and high porosity, as well as better rehydration

properties, when compared to other drying processes such as air, vacuum, microwave, and osmotic drying (Krokida and others 1998).

Freeze-drying is a dehydration process involving two phases: a first in which the product is frozen, followed by a second in which the water is removed by sublimation. The final product quality depends on the temperature at which the frozen product was kept during the sublimation of ice, and that must be below a critical temperature (the collapse temperature). During freeze-drying, the sublimation of the ice originates pores that may shrink due to surface forces of gravity, thus influencing the porosity of the products. Krokida and others (1998) studied the effect of freeze drying on shrinkage and porosity of some products, and in particular banana, and concluded that for temperatures above the glass transition temperature ($T'_g = -45^\circ C$), the freeze-dried materials shrank, and that an increase in temperature increased bulk density and decreased the final porosity.

38.3 PROCESSING OF SOME DRIED BANANA PRODUCTS

In general, good quality products are obtained from ripe bananas that have, preferably, been harvested green and ripened artificially under controlled conditions at the processing factory.

The primary criteria for accessing maturity is the total sugar content of the fruits, which should be about 19.5%. However, other criteria have been suggested, such as the β-carotene and reducing sugar contents (both of which increase with increasing maturity), as well as pH (which decreases as the fruit ripens). For fruits in the right stage of maturity the β-carotene content should be about 2000 μg/100 g, the reducing sugar content should be less than 1.5%, and the pH should be 5.8 or above. Browning was found to occur if the reducing sugar content was higher than 1.5% (Dauty 1995).

It is important to remove all impurities prior to processing of products, and this is done by washing to remove dirt and spray residues and control on the processing line so that substandard fruit can be removed (Dauty 1995).

After washing, the ripe bananas are peeled, most commonly by hand using stainless-steel knives. However, a mechanical peeler for ripe bananas can also be used, being capable of peeling 450 kg of fruit per hour. For the peeling of unripe bananas and plantains, the fruits are immersed in hot water. For example, immersion for 5 min in water at 70–75°C has been suggested as an aid for peeling green bananas for flour production (Dauty 1995).

38.3.1 Banana Figs

Banana figs, or fingers as they are also known, are usually whole, peeled fruits, carefully dried so as to retain their shape. However, there are some banana figs produced from sliced or halved fruits, which facilitates drying (Dauty 1995).

For the production of banana figs the fruits should be fully ripe, with a minimum sugar content of 19.5% and fully yellow but still firm. The state of maturity of the fruits is very important, because, on the one hand, if they are not mature enough the final product is liable to be tough and lacking in flavor; on the other hand, if overripe fruits are used, the figs tend to be sticky and dark in color (Dauty 1995).

The fruits are peeled and treated with sulfurous acid, and then dried as soon as possible. Various drying systems have been described, where drying takes from 10 to 24 h using temperatures between 50 and 82°C, to obtain products with a moisture content ranging from 8 to 18%. The yield of dried figs is 12–17% of the fresh banana on the stem (Dauty 1995). One factory in Australia uses a solar heat collector on the roof to augment the heat used for drying bananas.

Banana figs can also be obtained by osmotic dehydration, using a technique that involves drawing water from $\frac{1}{4}$ in. thick banana, by placing them in a sugar solution (of 67–70° Brix) for 8–10 h, followed by vacuum-drying (at 65–70°C and a vacuum of 10 mmHg) for 5 h. The moisture content of the final products is 2.5% or less, much lower than that achieved by other methods (Dauty 1995).

38.3.2 Banana Powder

Banana powder is used chiefly in the baking industry for the preparation of fillings for cakes and biscuits and is also used for food preparations for invalids and babies.

In the manufacture of banana powder, fully ripe banana pulp is converted into a paste by passing through a chopper followed by a colloid mill. A 1 or 2% sodium metabisulfite solution is added to improve the color of the final product. Both spray- or drum-drying may be used; however, the latter is more favorable as it allows the recovery of all solids. A typical spray-dryer can produce 70 kg of powder per hour, giving yields of 8–11% of the fresh fruit, but drum-drying gives a final yield of about 13% of the fresh fruit. In the latter method the moisture content is reduced to 8–12% and then further decreased to 2% by drying in a tunnel or cabinet dryer at 60°C (Dauty 1995). Banana powder seems to be able to support storage for up to a year.

38.3.3 Banana Flour

Banana flour is said to be highly digestible and is used in foods for babies and invalids, but can also be used in the preparation of bread and beverages. For the preparation of banana flour, unripe bananas are used. The fruits are harvested at three-quarters the full-ripe stage and are processed within 24 h prior to the onset of ripening. If less mature fruits are used, the flour may taste slightly astringent and bitter due to the tannin content (Dauty 1995).

The production of flour has been carried out by peeling and slicing green fruits, followed by exposure to sulfur dioxide gas. The bananas are then dried in a countercurrent tunnel dryer for 7–8 h, with an inlet temperature of 75°C and outlet temperature of 45°C. After drying, carried out until the bananas reach a final moisture content of 8%, they are milled (Dauty 1995).

38.4 PROPERTIES AND NUTRITIONAL COMPOSITION

The nutritional value of fresh bananas is 92 kcal/100 g of edible portion (Senser and others 1999), and the detailed composition as well as the amounts of vitamins and minerals are listed in Tables 38.1 and 38.2. Bananas have long been recommended as dietary supplements for individuals suffering from digestive disorders due to their anti-ulcerogenic properties. The anti-ulcerogenic agents in banana are various

TABLE 38.1 Nutritional Composition of Bananas.

Component	Composition (g/100 g of Edible Part)[a]
Water	73.9
Protein	1.2
Fat	0.2
Carbohydrates	20.8
Organic acids	0.6
Fiber	2.0
Minerals	0.8

[a] In bananas the edible part is 59% of the fruit (Ferreira and Graça 1977).

flavonoids, and the major components of this group of polyphenolic compounds are the flavan-3,4-diols (also known as leucoanthocyanidins). However, the anti-ulcerogenic activity is lost if the bananas are submitted to temperatures higher than 50°C (Lewis and others 1999).

The different steps in the processing of bananas, such as preparation, pretreatments, and drying, have an important impact on the final properties of the resulting products.

TABLE 38.2 Amounts of Vitamins and Minerals Present in Bananas.

Component	Composition (per 100 g of Edible Part)
Vitamins	
Carotenes	230 μg
Vitamin B_1 (thiamine)	45 μg
Vitamin B_2 (riboflavin)	55 μg
Vitamin B_5 (pantothenic acid)	230 μg
Vitamin B_6 (pyridoxine, pyridoxal phosphate)	370 μg
Vitamin B_9 (folic acid)	20 μg
Vitamin C (ascorbic acid)	12 mg
Vitamin E (α-tocopherol)	270 μg
Vitamin H (biotin)	6 μg
Vitamin PP (nicotinamide)	650 μg
Minerals	
Calcium	9 mg
Chlorine	110 mg
Copper	130 μg
Fluorine	20 μg
Iodine	3 μg
Iron	550 μg
Magnesium	35 mg
Manganese	530 μg
Phosphorus	30 mg
Potassium	395 mg
Selenium	4 μg
Sodium	1 mg
Zinc	220 μg

Therefore, the study of changes induced by processing operations assumes an increasing importance for obtaining high-quality products.

The influence of drying temperature on the characterization, sensorial evaluation, and microbial quality of bananas was studied by Leite and others (2006) for bananas obtained in a forced-air drying chamber, under a constant air flow rate of 30 m^3/h at 60 and 70°C. They concluded that the resulting products were in good sanitary conditions, and their chemical composition was not affected by drying. Moreover, the sensorial analysis performed revealed that the products obtained with lower drying temperatures were better accepted.

Boudhrioua and others (2003) have evaluated the changes in aromatic components of banana during ripening and air drying at temperatures of 40, 60, and 80°C. Their results indicated that the changes in aromatic components were dependent on the moisture content of the pulp and on the temperature of the drying air. Furthermore, some components such as the isoamyls strongly decreased during drying, whereas others were partly retained, with elemicine being the most thermal-resistant.

The effect of stepwise change in drying air temperature on the color of dried bananas was studied by Chua and others (2001). They observed that by employing stepwise-varying drying air temperature with appropriate starting temperature and cycle time it was possible to reduce significantly the drying time necessary to reach a desired moisture content, with substantial color improvements.

Demirel and Turhan (2003) investigated the effects of pretreatments and temperature on the final color of dried bananas. The study covered untreated bananas, as well as bananas treated with sodium bisulfite and ascorbic/citric acid, which were dried at temperatures between 40 and 70°C. It was observed that pretreatments and increasing temperature reduced the browning, and that the color change in the untreated bananas was fairly acceptable.

The effect of sugar and NaCl soaking treatments on the quality of dried banana figs was evaluated by Ehabe and others (2006). They concluded that soaking in plain water before drying improved brightness and that the use of a solution of sugar (at 10%, w/v), or NaCl (also at 10%), or even sugar plus NaCl (at 5% each), improved water-binding. Although soaking enhanced the diffusion of solutes into the bananas, their sensory attributes were not significantly altered. However, the use of the composite solution (NaCl + sugar) had some benefits, such as improvement in the sensory qualities as well as in storage capability, by retarding mold development and inhibiting mold growth at the surface.

Sousa and others (2003b) investigated the drying kinetics as well as color and texture changes in bananas that have been processed by osmotic dehydration followed by air-drying. The fruits were submitted for 2 h to sucrose solutions of 45, 55, and 65° Brix and 1 : 2 fruit/syrup ratio at 65°C. Following this pretreatment, the bananas were dried in an oven with air circulation at 65°C. Their conclusions indicated that an increase in the syrup concentration increased browning and texture.

Boudhrioua and others (2002) characterized how the rheological properties and the texture of bananas changed during hot air drying with changes in temperature, as well as the influence of their state of ripeness. The results showed that a radical change occurred after different periods of time (according to the state of ripeness) for drying at a temperature of 80°C. These changes consisted of loss of deformability (becoming brittle) and were due to the product being below the glass transition temperature (T_g) when cooled after drying.

38.5 PACKAGING AND STORING

Banana products are very hydroscopic and highly susceptible to flavor deterioration and discoloration, and, although modern production techniques have developed in this area, the organoleptic characteristics of processed products are still far from those of the fresh fruits. However, this can be overcome to some extent by storing in moisture-proof containers and sulfiting the fruit before drying to inactivate the oxidases (Dauty 1995).

Dried products are also liable to attack by insects and molds if not stored in dry conditions. The sun- or solar-dried fruits can undergo a pasteurization operation prior to conditioning and storage, to kill any insects or eggs that they might contain. In the freezer method, the fruits are sealed in plastic bags appropriate for freezing, which are then placed for 48 h in a freezer at a temperature of $-18^{\circ}C$ or below. In the oven method, the product is placed over trays that are left for 30 min in a preheated oven at around $70^{\circ}C$ (Andress and Harrison 1999). Alternatively, after drying, the products may be disinfested by heating for 1 h to $80^{\circ}C$ or fumigated with methyl bromide or ethylene oxide (Dauty 1995; Leite 2004).

Sousa and others (2003a) studied the stability of two banana products obtained by osmotic dehydration, one at atmospheric pressure and the other under vacuum, complemented by convective air-drying. The bananas were evaluated over 120 days in terms of their sensory, microbiological, and physico-chemical properties. The products were packed in transparent polyethylene terephthalate (PET) containers with a capacity of 200 g, and were stored at room temperature (between 23 and $34^{\circ}C$) and at a relative humidity in the range 33–81%. They concluded that both products were relatively stable in terms of microbial growth and maintained their chemical, physico-chemical, and sensory characteristics. However, the color suffered some significant variation, indicating an increasing tendency for darkening for longer storage periods, due to enzymatic and nonenzymatic browning. This may be explained by the high quantities of sugars present and by the absence of additives for the preservation of color. Finally, they concluded that in terms of acceptance, bananas treated with vacuum were preferable.

The conditioning of bananas can be performed under hermetic conditions, in polyethylene bags of 25 μm thickness containing 10 kg of product. These bags are then placed inside wooden or card boxes and stored in a cool and dry place, protected against external factors such as moisture, insects, and shocks. At this stage no moisture condensation should occur at the surface of the fruit, and the moisture distribution inside the fruit should be uniform. The occurrence of moisture condensation at the surface indicates a moisture content above 23%, making the product unsuitable for commercialization (Leite 2004).

For the commercialization of smaller quantities (200, 250, or 300 g), the fruits are packed manually. The extremities are cut, because they are darker and lower the quality of the product, and then the fruits are weighted and pressed, in a special manual press. Finally, the block obtained is packed inside two layers of plastic film, type PT, the external one being yellow to protect against light. Vacuum packaging is not recommended for fruits like bananas, because the diminution of the pressure inside the package may alter the equilibrium of the water vapor at the surface of the fruit, thus altering its surface moisture, making it sticky and more vulnerable to microbial growth (Leite 2004).

39.1 INTRODUCTION

Fresh-cut fruits and vegetables are among the fastest growing businesses of the fresh produce industry. Fresh-cut commodities are usually offered to the consumer in a state that allows for direct and immediate consumption without need for previous preparation or transformation. Hence, fresh-cut commodities meet the consumers' desire for convenience, without losing fruit freshness and other highly desired quality attributes. However, fresh-cut fruits have lagged in sales behind vegetables because they are more problematic

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

in their higher water content and increased physiological activity. Fresh-cut fruit processing is, therefore, still in need of innovative technologies of preservation that allow maintenance of the cut-fruit quality while ensuring safety until consumption.

The term "fresh-cut" refers to any type of processing that physically affects the fruit's original state (trimming, peeling, washing, and/or cutting), but maintains it in a fresh state, near to that of a nonprocessed vegetable tissue. Fresh-cut produce is usually packaged in sealed bags to maintain an adequate environment and is kept at refrigeration temperatures to delay senescence by decreasing physiological respiration, microbial growth, and some quality-related degrading reactions. When fruits are wounded in any way their tissue respiration undergoes a steep rise, causing accelerated consumption of sugars, lipids, and organic acids, and increasing ethylene production, which induces ripening and causes senescence (Kays 1991). In addition, physical damage also triggers a series of decay processes, including oxidative browning, tissue softening, loss of water and nutritive substances, and production of undesirable flavors and odors.

Each fruit may have a different response to fresh-cut processing. This response depends on the extent to which the deteriorative processes occur in a product, which is in turn influenced by several factors such as variety and cultivar, handling during harvest, postharvest, and distribution, and the nature of the processing treatments.

39.2 REGULATORY ISSUES TO BE APPLIED TO FRESH-CUT FRUITS

Specific legislation for fresh-cut products is currently being developed. Most of the existing regulations in both the United States and the EU countries refer only to safety and microbiological quality of the produce. Microbial load limits should be commodity-specific and cut-specific, but, up to now, limits for pathogenic microorganisms in different products have not been established. The French regulations (Ministère de l'Economie des Finances et du Budget 1988) were the first to appear in the EU and are regarded as a reference legislation for many countries. It fixes a maximum contamination value of 5×10^7 cfu/g at the expiration date and bans the presence of pathogenic microorganisms such as Salmonella, whereas *Escherichia coli* or *Listeria monocytogenes* counts are severely restricted.

Improper handling of fresh-cut products may have severe safety risks associated with foodborne illnesses. Implementation of HACCP specific plans for the fresh-cut product industry is not mandatory but strongly advised. The Codex Alimentarius Commission issued a document entitled "Code of Hygienic Practice for Fresh Fruits and Vegetables" (FAO 2003) with an annex for "Ready-to-eat Fresh Pre-cut Fruits and Vegetables" and with the purpose of assisting in the implementation of Good Manufacturing Practices (GMPs), which help to control the microbiological, physical, and chemical hazards associated with the processing of fresh-cut fruits and vegetables. The Annex refers extensively to the Code for fresh fruits and vegetables and to the General Principles of Food Hygiene (FAO 2003) but with special emphasis on some key aspects such as control of food hazards through appropriate facilities, personnel training programs, and adequate documentation and records of the processing and storage stages. A similar document was issued by the U.S. Food and Drug Administration (FDA), "Analysis and Evaluation of Preventive Control Measures for the Control and Reduction/Elimination of Microbial Hazards on Fresh and Fresh-Cut Produce" (FDA 2001), identifying the potential

hazards and reviewing comprehensively the methods of intervention to reduce microbial risks in fresh-cut produce (FDA 2001). A new EU regulation on microbiological criteria for foodstuffs (Official Journal of the European Union 2005) sets a limit of 1×10^2 cfu/g for *E. coli* as indicative of the acceptability of a process. This criterion is set to be applied without prejudice to specific rules affecting other microorganisms, but it is intended to serve as a tool for manufacturers to decide whether a product is ready to be commercialized.

As outlined, information about proper handling of fresh-cut produce is being provided to manufacturers, but efforts should still be strengthened in order to reach consumers and mold their habits with respects to product handling.

The safety of chemicals involved in processing treatments must be carefully considered. Inclusion within the FDA list of GRAS (generally recognized as safe) additives and the Codex Alimentarius list of additives guarantees, in principle, the innocuousness of the treatments applied.

39.3 CONSIDERATIONS ABOUT RAW MATERIALS AND THEIR RESPONSE TO PROCESSING

The state of raw fruits at the moment of processing greatly affects the quality and shelf-life of fresh-cut products. Intrinsic factors such as fruit variety, firmness, size, and ripeness, as well as preharvest, harvest, and postharvest handling are determinants for obtaining high-quality fresh-cut products. Fruit cultivar selection and the ripeness state have a capital importance in most fruits. Different fruit varieties may present different phenolic compositions and amounts of oxidase enzymes, which determine their susceptibility to browning. The stage of maturity may affect both firmness and browning sensitivity. In some fruits, advanced maturity accounts for texture loss and the subsequent solubilization of polyphenol oxidases, leading to an increase in browning sensitivity (Soliva-Fortuny and others 2002b). Ethylene stress response is closely related to fruit maturity. In general, overripe climacteric fruits produce less ethylene but are more sensitive to mechanical damage and microbial alteration (Kader 2002). Ethylene response of partially-ripe fresh-cut apples and pears is double that of ripe fresh-cut fruits (Soliva-Fortuny and others 2002a, 2004a).

Fruit ripeness, together with postharvest handling, also conditions the microbiological quality of the raw produce. Storage under adequate temperature/RH conditions must be conducted in a very few hours after harvest. Sanitation treatments just before processing are advised, especially in fruits with high microbiological risk or in those that have been stored for prolonged periods. Chlorine is extensively used to sanitize whole fruits. Concentrations of up to 1000 ppm have been suggested to sanitize melon and watermelon (Qi and others 1999; Portela and Cantwell 2001). However, chlorine is highly reactive with organic matter, thus losing efficiency and resulting in the formation of potentially harmful substances.

Other sanitizers such as H_2O_2, chlorine dioxide, and organic acids have been used to reduce microbial loads in whole fruits. A treatment with H_2O_2 on whole melon was found to extend the shelf-life of the fresh-cut product by 4–5 days in comparison with chlorine treatment (Sapers and Simmons 1998). The treatment was also effective in decontaminating prunes and table grapes (Sapers 1996) and inactivated *E. coli* in combination with commercial sanitizing agents (Sapers and others 1999). Ukuku and others (2005) achieved total

inactivation of *L. monocytogenes* and at least 4 log cfu/mL reductions of *E. coli* in melon rind rinsed with a washing solution containing 1% H_2O_2 + 25 μg/mL nisin + 1% sodium lactate + 0.5% citric acid. On the other hand, Wisniewsky and others (2000) reported that chlorine dioxide, applied at 16-fold recommended concentrations of 80 μg/mL, could only reduce *E. coli* O157:H7 counts by 2.5 log cfu/mL. Wright and others (2000) found that a 2 min dip in 5% acetic acid was the most effective treatment for inactivating populations of *E. coli* O157:H7 on apple surfaces, achieving three decimal reductions.

Other treatments on whole fruits may be used not only to reduce the microbial loads but also to improve sensory quality maintenance of the processed product. Some studies have assessed the effect that mild heat pretreatments applied to whole fruits have on the quality of the fresh-cut products. Abreu and others (2003) and Steiner and others (2006) reported good results in firmness and color retention of fresh-cut pears and peaches obtained from heat pretreated fruits. UV light can also be used as a pretreatment to improve fresh-cut fruit quality and safety. The microbiocidal effect of UV light is based on its incidence on microbial DNA and to its ability to stimulate resistance mechanisms against pathogens in plant tissues. Yaun and others (2004) achieved a 3.3 log cfu/g reduction of *E. coli* O157:H7 inoculated on whole apples with a UV-C treatment of 24 mW/cm^2. Bai and others (2004) studied the effects of different ethanol vapor, heat, and methylcyclopropene (1-MCP) pretreatments on the quality of fresh-cut apples. Ethanol vapors applied to whole Gala apples at a concentration of 5 mL/kg for 24 h at 25°C and heat treatments of 38°C over 4 d at >98% RH were found to be effective in reducing respiration and wounding ethylene response and prolonging the visual quality of fresh-cut apples at the expense of aroma quality, whereas 1-MCP promoted decay development on the cut surface.

39.4 PROCESSING CONDITIONS

Fresh-cut fruit processing requires the observance of strict handling conditions not only to ensure that microbiological hazards are effectively controlled but also to reduce physiological disorders that are directly related to quality preservation in fresh-cut commodities. Working areas and treatment solutions need to be maintained refrigerated throughout processing in order to reduce the proliferation of microorganisms, the activity of enzymes released due to cutting operations, and the respiratory response of the fruit tissues to mechanical injuries. Microbiological risks in fresh-cut fruits include contamination with human pathogens (FDA 2001). Chilly temperatures do not suffice to stop microbial proliferation. Some foodborne pathogens such as *L. monocytogenes* can even grow under refrigeration (Zagory 1999). Therefore, the implementation of Hazard Analysis Critical Control Points (HACCP) is critical to detect possible risks of contamination. Furthermore, GMPs should be applied to the process to regulate hygiene aspects related to workers' protective clothing (smocks, gloves, caps, and footwear), product handling at the different processing steps, and the cleaning and maintenance operations before, during, and after plant production. Personnel training programs should be designed insisting on the importance of hygiene on quality and safety.

39.4.1 Cutting Operations

Physical damage accounts for most of the detrimental changes that occur in fresh-cut tissues. Cutting and peeling fruits boosts respiration rates and also increases their

susceptibility to microbial spoilage. The removal of the natural protective epidermal barrier and the increase in moisture and dissolved nutrients on the surfaces provide ideal conditions for the colonization and multiplication of microorganisms (Nguyen-The and Carlin 1994). Juice leakage from bruised tissues, containing sugars and organic acids, among other nutritious substances, may allow some fermentative yeasts such as *S. cerevisiae* and *S. exiguous* to grow on fresh-cut produce (Heard 2002). In addition, if sanitation of the whole fruits has not been carried out properly, the risk of cross-contamination with pathogenic microorganisms can be dangerously increased, especially when processing wounded fruits with signs of rot initiation (Garg and others 1990). Hygienization of the whole unprocessed fruits is therefore advised before peeling in order to reduce the initial microbial loads. Furthermore, peeling equipment should allow conscientious cleaning of those components that can be in contact with the product, with special attention to cutting blades. Blades should also be sharpened periodically to maintain cutting performance.

Mechanical damage can be detrimental not only to microbiological stability but also to the appearance and sensory attributes of fresh-cut fruits, which are directly related to consumer acceptability. Tissue browning occurs when the phenolic compounds released from damaged cells are exposed to oxygen and oxidizing enzymes, leading to the formation of dark compounds (Osuga and Whitaker 1995). Phenolic substrates are oxidized to reactive o-quinones that in turn may react with other quinones, phenolic substrates, amino groups of peptides, amino acids or proteins, and other compounds including thiol-containing groups, aromatic amines, or ascorbic acid (Whitaker and Lee 1995). Although browning is mostly influenced by phenolic composition and the amounts of native oxidases, the decompartmentalization and solubilization of these compounds is dependent on mechanical injuries during processing that account for chloroplast breakdown (Rocha and others 1998; Garcia and Barrett 2002).

A common response of fruits to fresh-cut processing includes enhanced respiration and ethylene production and water vapor migration. The increase in respiration rates and water loss promoted by cutting operations affect the structure of cell wall, middle lamella, and cellular membrane, promoting loss of cohesion among cells and resulting in softer and weaker structures. As widely reported for leafy vegetables, turgor pressure has been found to exert a clear effect on the texture of some fresh-cut fruits (Luna-Guzmán and Barrett 2000; Rojas and others 2001). Cell degradation also results in electrolyte leakage and a decay in tissue calcium levels. Therefore, texture loss is strongly determined, among other factors, by the tissue morphology, cellular structure, and composition as well as by the content and delocalization of pectinolytic and proteolytic enzymes (Harker and others 1997). Occurrence of these phenomena may be reduced through the addition of calcium salts. The firmness retention properties of calcium have been attributed to cross linkage of the divalent cation with deesterfied regions of pectins and with cell membranes, imparting improved membrane and cell wall integrity, cell adhesion, and cell turgor (Poovaiah 1988; Picchioni and others 1998). Firmness retention of fresh-cut fruits in response to calcium treatments has been reported on apples and pears (Rosen and Kader 1989; Soliva-Fortuny and others 2002a, 2004), cantaloupe melon (Luna-Guzmán and Barrett 2000), tomatoes (Floros and others 1992), watermelon (Mao and others 2006), and kiwifruit (Agar and others 1999).

The role of ethylene in fresh-cut fruit softening is not yet very well known, but its production in response to wounding does not seem to be inconsequential. Even fruits producing very low levels of ethylene such as melon or watermelon are very sensitive to

ethylene, exhibiting tissue water soaking and overall softening, promoting a loss in soluble solids and some nutritious compounds such as lycopene in watermelon (Mao and others 2006). Other responses induced by ethylene may include enhanced activity of hydrolytic enzymes targeting both cell walls and membranes such as lipoxigenases, polygalacturonases, and phospholipases (Karakurt and Huber 2003), as well as phospholipid catabolism (Mao and others 2004). Some fruit tissues, such as placental tissue in tomato, melon, and watermelon, or core tissue in pome fruits exhibit a significant ethylene production burst in response to fresh-cut processing and therefore should be carefully handled during cutting operations or even removed if necessary.

It is now known that 1-MCP, a potent antagonist to ethylene action, may help to extend the shelf-life of fresh-cut fruits, providing evidence for the role of ethylene in at least some texture deteriorative changes. The action of 1-MCP, generally applied as a pretreatment for the whole nonprocessed fruits, seems to be linked to its ability to bind to the cell membrane of fruits, thus blocking the ethylene binding sites (Laurie 2005). Some research studies have reported promising results in fresh-cut fruits such as apple (Jiang and Joyce 2002; Bai and others 2004; Calderón-López and others 2005), tomato (Jeong and others 2004), pineapple (Budu and Joyce 2003), or watermelon (Mao and others 2006). In general, the beneficial effects of 1-MCP include reduction of weight loss and water soaking, and prolonged firmness. Other reported positive effects in some fruits are a high retention of nutritious compounds such as ascorbic acid and lycopene (Budu and Joyce 2003; Mao and others 2006) or a reduction in the microbial spoilage when combined with calcium dips (Mao and others 2006).

39.4.2 Preserving Techniques for Cut Fruits

39.4.2.1 Treatments to Improve Safety. The naturally occurring microorganisms of most fruits are composed of molds and yeasts, which are in turn responsible for the production of many enzymes participating in the degradative processes that curb their shelf-life. Fungi such as *Botrytis cinerea* and *Aspergillus niger* and yeasts such as *Canidia*, *Cryptococcus*, *Fabospora*, *Kluyveromyces*, *Pichia*, *Saccharomyces*, and *Zygosaccharomyces* have been found to be naturally present on cut fruit surfaces (Chen 2002). Lactic acid bacteria have the ability to grow at low pH and their colonization may happen when low O_2 concentrations are reached in the package headspace just a few days after processing. Lamikanra and others (2000) associated the decay of fresh-cut melon and the accumulation of lactic acid in the product with the proliferation of *acidophilus* bacteria. Most fruits have a low pH that protects them against the growth of pathogenic microorganisms. However, the presence of *Cyclospora cayetanensis*, *Salmonella* spp., and *Shigella* spp. has been reported by Heard (2002) in raspberries, watermelon, and fruit salads, respectively. Dingman (2000) reported the ability of *E. coli* O157:H7 to grow on the moderate pH of wounded apple tissues, which would allow this microorganism to grow on fresh-cut fruits of moderate pH. Kärenlampi and Hänninen (2004) demonstrated that *Campylobacter jejuni* can survive on diced melon and strawberries, whereas *Shigella* spp. has been shown to grow on fresh-cut watermelon and papaya (Fernández-Escartín and others 1989). To reduce the risk of contamination with foodborne pathogens, several antimicrobial treatments can be applied either to transportation and treatment waters, in order to reduce microbial loads through the process, or directly to the product. Washing is one of the first processing operations to which a fruit is subjected. Wash water chlorinated up to 200 ppm is routinely applied to

reduce microbial contamination in produce processing lines. However, the use of chlorine is of concern due to the potential formation of harmful byproducts (Richardson and others 1998).

The use of hydrogen peroxide on fresh-cut fruits has been investigated in recent years. The antimicrobial effect of H_2O_2 lies in its properties as an oxidant. However, the treatment may lead to color changes, depending on the commodity, and residual levels may be variable as a function of the amount of peroxidase in the food system. Park and Beuchat (1999) achieved only <1 log cfu/g reduction in cantaloupe melon treated with a 2% H_2O_2 solution over 2 min. A more intense dipping treatment of 5% H_2O_2 bleached the product surface and had to be discarded. Consistently, Sapers and Simmons (1998) reported reduction of microbial populations on fresh-cut cantaloupe and honeydew melons without modification of their sensory characteristics. Treatment on pome fruits was not advised because problems with H_2O_2 residuals could occur. In addition, the treatment caused anthocyanin-bleaching in red fruits.

Alternative methods for the disinfection of cut surfaces are currently being investigated, some of them based on physical antimicrobial treatments. Ozone has excellent ability to penetrate and does not leave residue. Although it is reactive and may cause physiological injury to the produce, it may be useful for the treatment of process water (Parish and others 2003). Exposure of cut surfaces to UV/visible light can also be a way of reducing microbial loads with minimal effects on the fruit physiology and quality. Lamikanra and Richard (2004) found that UV treatments, applied at desired intensity, induced the formation of copaene, a sesquiterpene phytoalexin with antimicrobial effect that contributed to the fruit response to wounding. In a previous work, UV light also induced formation of phytoalexins in fresh-cut melon, thus improving the fruit defense against microbial spoilage (Lamikanra and others 2002).

Consumer perception of the addition of antimicrobial compounds to minimally processed food is usually negative and it is necessary to explain to them the importance and advantages for certain products. Nevertheless, the demand for products with extended shelf-life still persists. Antimicrobials may tarnish the image that consumers have of fresh-cut fruits and, therefore, the use of compounds obtained from natural sources, such as organic acids, essential oils, or several carbonyl compounds, could be a way of extending the shelf-life of fresh-cut fruits, thus improving the attitude of consumers towards those products containing additives.

Organic acids such as citric are used to preserve fresh-cut fruits not only because they are effective against microorganisms by lowering the pH of the cut surfaces, but also because of the inhibition of some browning reactions. The use of organic acids such as acetic, benzoic, citric, malic, sorbic, succinic, and tartaric, naturally present in plants and plant products, are currently being studied. Treatments with citric acid in the form of lemon juice have been shown to reduce the viability of populations of *S. typhi* and *C. jejuni* inoculated onto cubes of papaya and watermelon, respectively (Fernández-Escartín and others 1989; Castillo and Escartín 1994), with a more pronounced effect on papaya than on watermelon. Carbonyl compounds such as 2-nonanone, a nine-carbon ketone, have been applied in fresh-cut apples to inhibit the growth of *Penicillium expansum* with promising results (Leepipattanawit and others 1997). Some of the natural aroma compounds of fruits and vegetables such as hexanal, hexanol, 2-(E)-hexenal, and 3-(Z)-hexenol, are compounds formed through the lipoxygenase pathway. This enzyme catalyses the oxygenation of unsaturated fatty acids to fatty acid hydroperoxides that are metabolizable to compounds having important roles in plant

defense against microbial growth in wounded tissues (Lanciotti and others 2004). Hexanal can interact with the volatile phase of fruits to form compounds such as hexanol and hexyl acetate, which also act as inhibitors of enzymatic oxidative reactions. Lanciotti and others (1999) observed a strong inhibition of both mesophilic and psychrotrophic microorganisms in apple slices stored under an atmosphere containing 0.15 mmol hexanal/100 g. Consistently, treatments with 150 ppm hexanal or 2-(E)-hexenal and 20 ppm hexyl acetate were lethal on *L. monocytogenes* and prolonged the lag phase period of *E. coli* and *S. enteriditis* (Lanciotti and others 2003).

Some phenolic substances naturally present in fruit tissues such as flavonols and hydroxycinnamic acids have exhibited antioxidant potential and antimicrobial properties (Lule and Xia 2005). Treatments of kiwifruit wedges with low concentrations (1 mM) of cinnamic acid and carvacrol, a major component of the essential oils from oregano and thyme, prevented the appearance of visible spoilage and inhibited growth of the microbial flora for 5 d at 4°C and 8°C (Roller and Seedhar 2002). This treatment prolonged the lag phase period of the microbial flora from less than 1 d in the untreated controls to 3 d at 8°C and 5 d at 4°C. Higher concentrations of the antimicrobials inhibited the onset of microbial spoilage for 21 days, but imparted a pungent and unpleasant aroma to the fruit.

Some plant essential oils may be used to control microbial spoilage in fresh-cut fruits. However, widespread application of these compounds, which are constituted mainly of terpenoids, as natural preservatives is not always possible due to the strong flavors associated with them. Lanciotti and others (2004) reported that citrus, mandarin, cider, lemon and lime essential oils, added at levels compatible with the sensory properties in atmospheres of a fresh sliced fruit mixture of apple, pear, grape, peach and kiwifruit, were able to inhibit the proliferation of naturally occurring microbial populations, to reduce the growth rates of a *Saccharomyces cerevisiae* strain inoculated at levels of 10^2 cfu/g and to increase the death rate of *E. coli* inoculated at levels of 10^6 cfu/mL.

Methyl jasmonate is a plant volatile that acts as an important cellular regulator mediating diverse developmental processes and defense responses. Martínez-Ferrer and Harper (2005) treated diced pineapple with a methyl jasmonate emulsion at a concentration of 10^{-4} M for 5 min. The treatment reduced microbiological loads by 3 log after 12 d storage at 7°C compared with the control pineapple, and did not affect the fruit sensory attributes.

Some microorganisms or their products can also be used as biocontrol agents to limit the growth of pathogenic microorganisms. Leverenz and others (2003) reported that a mixture of lytic bacteriophages in combination with nisin, a broad-spectrum, pore-forming bacteriocin, was capable of reducing *L. monocytogenes* populations by 5.7 log units on melon slices and by 2.3 log units on apple slices.

39.4.2.2 Treatments to Maintain Sensory Quality. Cutting operations, although conducted under controlled conditions, often result into browning, softening, and changes in aroma during storage. To minimize these changes, dips in aqueous solutions containing antibrowning compounds, firming agents, and/or other additives with different purposes can be used. Ascorbic acid (AA) is used in many fruits because of its potential to prevent browning caused by polyphenol oxidase (PPO) enzymes, mostly by reducing quinones to phenolic compounds before they are oxidized to form brown-colored compounds. The AA can also act directly on the enzyme by reducing the cuprous ions of its active site (Osuga and Whitaker 1995). Thiol antioxidants such as glutathione, cysteine, and their derivatives have a great antioxidant potential towards polyphenol oxidases and peroxidases. Three mechanisms have been proposed to explain the

inhibition of enzymatic browning by thiol antioxidants: reduction of quinones back to dihydroxyphenols, direct inhibition by acting on the active site of the enzyme, and formation of a colorless cys-quinone adduct (Gorny and others 2000). Nevertheless, the use of cysteine and thiol antioxidants has some limitations. When cysteine is used as an inhibitor of enzymatic browning on fresh-cut fruits, pinkish-red colored compounds are formed due to phenol regeneration, and the product flavor can be undesirably modified (Richard-Forget and others 1992). Some phenolic compounds that can be naturally found in fruits may also be used to delay browning. 4-Hexylresorcinol is a monophenolic molecule with specific effect on PPO. Organic acids such as citric acid have also been shown to reduce browning in fresh-cut surfaces, in particular combination with a chemical reductant (Sapers 1993).

Combinations of these compounds and their derivatives have been extensively used in the literature to prevent fresh-cut fruit browning (Table 39.1). Most antioxidants may act synergistically in combination with others, in particular when actuating at different levels to stop browning reactions. Some other substances have been found to improve the effect of antioxidants on cut fruit surfaces. Pilizota and Sapers (2004) suppressed core browning of apple wedges treated with an acidic AA + citric acid antibrowning formulation for at least three week storage when using sodium hexametaphosphate as an additive with preservative effect. The addition of calcium chloride may also be effective in delaying browning, probably because calcium has a firming effect on cell membranes that may account for a reduction of the leakage of enzymes and substrates (Sapers and Miller 1992).

The addition of calcium salts to the antioxidant dips may help to improve the texture of fresh-cut fruits during their commercial shelf-life. Calcium cross-links the pectic acid layer found in the cell wall middle lamella (Perera and Baldwin 2001). Several researchers have reported the positive effects of $CaCl_2$ dips to prevent softening in fresh-cut fruits. Luna-Guzmán and others (1999) found that a concentration of 2.5% $CaCl_2$ was optimal

TABLE 39.1 Antioxidant Treatments Recommended to Improve the Visual Appearance of Fresh-Cut Fruits.

Fruit	Dipping Treatment	Reference
Apple	1% AA + 0.5% $CaCl_2$	Soliva-Fortuny and others (2001)
	0.001 M 4-HR + 0.5 M IAA	Buta and others (1999)
	0.75% AA + 0.75% $CaCl_2$	Rocha and others (1998)
	0.01% 4-HR + 0.5% AA	Luo and Barbosa-Cánovas (1997)
	1% AA + 0.2% CA or 0.5% NaCl	Pizzocaro and others (1993)
Pear	2% AA + 1% CaL + 0.5% Cys	Gorny and others (2002)
	1% AA + 0.5% $CaCl_2$	Soliva-Fortuny and others (2002b)
	0.01% 4-HR + 0.5% AA	Dong and others (2000)
	4% NaE + 0.2% $CaCl_2$ + 100 ppm 4-HR	Sapers and Miller (1998)
Peach/nectarine	2% AA + 1% CaL	Gorny and others (1999)
Banana	0.5 M CA + 0.05 M N-Acys	Moline and others (1999)
Melon	2.5% CaL	Luna-Guzmán and Barrett (2000)
Watermelon	2% $CaCl_2$	Mao and others (2005)
Mango	0.001 M 4-HR + 0.5 M IAA	González-Aguilar and others (2000)
Kiwifruit	1% $CaCl_2$ or 2% CaL	Agar and others (1999)
Avocado	1% AA + 0.2% Cys	Dorantes and others (1998)

AA = ascorbic acid, 4-HR = 4-hexylresorcinol, IAA = isoascorbic acid, CA = citric acid, CaL = calcium lactate, Cys = cysteine, NaE = sodium erythorbate, N-ACys = N-Acetylcysteine.

to preserve the texture of fresh-cut melon. However, the use of calcium chloride at such amounts has been reported to impart off-flavors to the cut product, which did not occur in treatments with calcium lactate (Luna-Guzmán and Barrett 2000). Consistently, Manganaris and others (2005) suggested calcium lactate as a potential calcium source for the peach fresh-cut and canning industries. Treatments with calcium lactate improved firmness and visual appearance of fresh-cut peaches without modifying their characteristic flavor and aroma.

39.4.3 Packaging Strategies

39.4.3.1 Modified Atmosphere Packaging (MAP). Modified atmospheres can effectively control the growth of microorganisms on the surface of fresh-cut fruits. Low oxygen atmospheres are especially effective in inhibiting Gram-negative bacteria, but alone are not able to limit the proliferation of Gram-positive microaerophilic species such as *Lactobacillus* (Al-Ati and Hotchkiss 2002). However, some safety concerns have arisen regarding the effects that MAP may have on the naturally occurring microbiota of fresh-cut fruits. Restrictive O_2-atmospheres may inhibit the growth of spoiling microflora, benefiting the proliferation of anaerobic psychrotrophic pathogenic microorganisms such as *L. monocytogenes* (Conway and others 2000; Corbo and others 2005), *E. coli* (Gunes and Hotchkiss 2002), or *Clostridium botulinum* (Larson and Johnson 1999). An appropriate combination of gas composition and package dimensions and permeability adapted to the respiration of the product are critical to reach a sustainable equilibrium of gas concentrations, thus ensuring that O_2 levels inside the packages are high enough to avoid the triggering of anaerobic fermentative processes. Some researchers have studied the effects of superatmospheric levels of O_2 on the microbiological growth on fresh-cut fruits to face the microbiological risk that low O_2 concentrations may pose for consumers. Thus, concentrations ranging from 30 to 100 kPa O_2 have been shown to inhibit the growth of some microorganisms and some oxidative reactions (Kader and Ben-Yehoshua 2000) although levels above 80 kPa seem to be phytotoxic for some vegetable tissues. Results about the effect of high-oxygen atmospheres are, however, often controversial. Van der Steen and others (2003) reported that high-oxygen atmospheres (70 kPa) slightly reduced the maximum specific growth of Gram-negative bacteria but did not affect or stimulated the growth of *L. monocytogenes* and *Aeromonas caviae* (HG4) isolated from fresh-cut produce. These authors also reported that high O_2 concentrations generally inhibited the growth of yeasts, although some particular strains were not affected or even stimulated, which proves that the inhibitory effect is not true for every individual strain.

On the other hand, high CO_2 concentrations are generally effective in controlling the growth of most aerobic microorganisms, especially bacteria and molds, but fail to inhibit most yeasts. In addition, lactic acid bacteria can grow under moderate CO_2 environments (Al-Ati and Hotchkiss 2002). Nevertheless, high CO_2 concentrations may be detrimental to the fruit physiology and, therefore, the package permeability should be enough to evacuate the excess of CO_2 generated by the increase in respiration that occurs after processing.

The effect of high CO_2 levels on respiration and ethylene production appears to be synergistic with low O_2 concentrations. Under these conditions, ethylene wounding response can be severely reduced or almost suppressed, which is an important limiting factor of a great number of physiological reactions in the fruit tissue. Generally, although

CO_2 in small amounts (1%) is necessary for ethylene synthesis, high CO_2 atmospheres have been found to slow down ethylene production. The biosynthetic pathway of ethylene in fruits has been studied for many decades, but the molecular mechanism of how ethylene synthesis is regulated is still not clear. So, the mode of action of CO_2 on this pathway is not yet fully understood, although recent research suggests it has a double effect as, on the one hand, a competitor of ethylene binding and, on the other hand, by reducing the efficiency of the conversion of 1-amino-cyclopropane-1-carboxylic acid (ACC) to ethylene by ACC oxidase. In a similar way, O_2 has been found to be indispensable for the conversion of ACC to ethylene (Yang 1981), which would explain the inhibitory effect of low O_2 concentrations. Most studies on fresh-cut fruits coincide in suggesting storage atmospheres of 1–4 kPa O_2 + 10–20 kPa O_2 for diverse fruits such as melon (Qi and others 1999; Bai and others 2001), watermelon (Cartaxo and others 1997), pear (Gorny and others 2002), or mango (González-Aguilar and others 2000; Poubol and Izumi 2005).

MAP is also used to delay the loss of fresh fruit qualities. However, most MAP conditions alone do not suffice to maintain the visual quality of fresh-cut fruits and their effect on texture is minimal. Packages should be designed to reduce water loss, which may result in texture changes, translucency, and/or surface dehydration, but without facilitating the formation inside the package of water condensates that may favor microbiological proliferation. Passive MAP systems in combination with antioxidant treatments have been suggested to delay browning of fresh-cut apples (Soliva-Fortuny and others 2002a), pears (Senesi and others 1999; Soliva-Fortuny and others 2004a) and mangoes (González- Aguilar and others 2000). Low oxygen concentrations (0.25–5%) in combination with moderate levels of CO_2 (10–20%) have been used to maintain the visual appearance of several fresh-cut fruits such as peach (Palmer-Wright and Kader 1997; Gorny and others 1999), kiwifruit (Agar and others 1999), mango (Rattanapanone and others 2001), and melon (Qi and others 1999; Bai and others 2001). Some studies have assessed alternative MAP concentrations that improve the color retention of fresh-cut fruits. Atmospheres containing 65 kPa N_2O + 25 kPa Ar + 5 kPa O_2 + 5 kPa CO_2 and 90 kPa N_2O + 5 kPa O_2 + 5 kPa CO_2 were shown to be effective in preserving the color of kiwifruit and apple, respectively (Rocculi and others 2004, 2005). Storage under super atmospheric O_2 concentrations has been reported to be effective in inhibiting enzymatic browning in some fresh-cut commodities (Kader and Ben-Yehoshua 2000; Farber and others 2003). Nonetheless, this claim should be corroborated in depth for different fruits.

Research on the effect of MAP on the nutritional composition and bioactive compounds of fresh-cut fruits is still incipient and needs further development. The availability of O_2 in the package headspace as well as high CO_2 levels stimulate the oxidation of ascorbic acid and inhibit the reduction of dehydroascorbic acid (Agar and others 1999; Soliva-Fortuny and others 2003, 2004b). No changes have been reported in the sugar, organic acids, and phenolic contents of fruits as a consequence of MAP (Gil and others 1998; Lamikanra and others 2000; González-Aguilar and others 2000). On the contrary, the aroma profile of fresh-cut fruits can be completely modified by some MAP systems. Gil and others (2002) reported the best overall flavor quality for tomato slices preserved under 2 kPa O_2 + 20 kPa CO_2. Bett and others (2001) reported an increase of the compounds that conform to the flavor of fresh-cut apples a few hours after processing, followed by a dramatic decline that accounted for a loss in product marketability.

39.4.3.2 Edible Coatings. The use of edible materials as a coating has multiple potential applications. Specifically, for fresh-cut fruits, the creation of a modified atmosphere in the fruit and the reduction of water and aroma loss are of special interest. Edible coatings can reduce the gas exchange rates between the fruit product and its environment, thus producing a modified atmosphere. Lee and others (2003) reduced the respiration rate of apple slices with a whey protein concentrate based coating. Wong and others (1994) also reduced respiration and ethylene production of apple slices with a polysaccharide/ lipid bilayer coating. Edible bilayer coatings cast from proteic, lipidic or polysaccharide ingredients are more likely to have improved barrier properties. Polysaccharide and protein polymers are generally of a hydrophilic nature whereas lipidic coatings have better water vapor barrier properties. Le Tien and others (2001) found that a whey protein/ carboxymethyl cellulose coating prevented oxidative browning on apple slices by acting as an oxygen barrier. The addition of a lipid to coating formulations for fresh-cut apples, based on apple purée and pectin, remarkably diminished the gas permeation through the edible matrix (McHugh and Senesi 2000).

TABLE 39.2 Edible Coatings Used on Fresh-Cut Fruits.

Fruit	Coating	Results	Reference
Apple	Chitosan	Delayed microbial growth	Assis and Pessoa (2004)
	Carrageenan/WPC + CMC	Reduced gas transmission; improved sensory properties	Lee and others (2003)
	Beeswax + WPI	Reduced gas transmission browning, and moisture loss	Pérez-Gago and others (2003) McHugh and Senesi (2000)
	Apple purée + pectin + lipid (beeswax, vegetable oils)	Prevented browning due to better gas barrier	Le Tien and others (2001)
	Maltodextrin + MC	Lessened tissue respiration but resulted in surface discoloration	Brancoli and Barbosa-Cánovas (2000)
	Casein + Alginate + AMG	Reduced moisture loss	Pavlath and others (1993)
Pear	MC + Stearic acid	Delayed browning and water loss; high aroma retention	Olivas and others (2003)
Mango	CMC	Prevented discoloration	Nísperos-Carriedo (1994)
Strawberry	Amilose	Gas barrier: improved color and firmness	García and others (1998)
Papaya	Casein + Carnauba wax	Improved gas and moisture barrier properties	Guilbert (1988)
Citrus	Carrageenan + locust bean gum	Reduced water loss	Rouse and Moore (1972)
	Locust bean gum + pectin + grapefruit juice	Reduced water loss and improved overall quality	Bryan (1972)

WPC = whey protein concentrate, CMC = carboxymethyl cellulose, WPI = whey protein isolate, WPC = whey protein concentrate, MC = methylcellulose, AMG = acetylated monoglyceride.

Edible coatings may be used to maintain the aroma and flavor of fresh-cut fruits. Olivas and others (2003) enhanced the aroma retention of pear wedges coated with methylcellulose films with the addition of stearic acid, showing higher production of hexyl acetate and butyl acetate during storage than the uncoated controls. Fatty acids may be used in fruit coating formulations to be incorporated by the fruit into their metabolism as precursors of volatile compounds (Olivas and Barbosa-Cánovas 2005).

Coatings can also act as carriers of antioxidants, antimicrobials, and/or other food additives that may help to control reactions that are detrimental to fruit quality (Baldwin and others 1995). A list of edible films found in the literature to coat fresh-cut fruits is presented in Table 39.2. Baldwin and others (1996) reported that ascorbic acid applied as a component of a coating matrix was more effective in preventing apple browning than when applied by direct immersion of the fruit into an aqueous solution of the antioxidant. The addition of antimicrobial compounds from natural sources to coating formulations has great future prospects in improving the control of microbial growth on the cut fruit surfaces. Chitosan, a polysaccharide produced from chitin found in the exoskeletons of arthropods, has been shown to limit fungal growth in sliced apples (Assis and Pessoa 2004), fresh strawberries (El-Ghaouth and others 1991; Han and others 2005), banana, and mango (Kittur and others 2001).

39.5 GUIDELINES FOR COMMERCIAL DISTRIBUTION AND STORAGE

The commercial shelf-life of fresh-cut fruits can be seriously reduced due to improper handling during storage, distribution, or merchandising. During these stages, temperature is the most important factor to be controlled. Headspace modified atmospheres have multiple benefits for the quality of fresh-cut products but make it very difficult to cool the fresh-cut product once it is packed. Therefore, the product should be cooled before packaging and temperature oscillations should be minimized to avoid condensation phenomena on the cut surfaces and plastic layers. High storage temperatures have a direct impact on quality and safety. Corbo and others (2005) reported inoculated *L. monocytogenes* growing on fresh-cut cactus-pear fruit at any temperature ranging from 4 to 20°C. However, at temperatures greater than 4°C, this proliferation could lead to a significant health risk. *E. coli* O157:H7 was reported to grow in samples stored at 4 and 8°C. Bagamboula and others (2002) found that the growth of *Shigella* spp. on the surface of strawberry and apple fresh fruit salads was also temperature-dependent, claiming that acid products, especially those kept at refrigeration temperatures, may support the survival and growth of *Shigella* spp., causing food poisoning. Low temperatures may also influence the fruit response to deteriorative agents. In fresh-cut melon, low temperatures and reduced oxidative and microbial stress during storage appeared to favor production of cyclic and acyclic phytoalexin terpenoid compounds β-ionone, geranylacetone, and terpinyl acetate, which were effective in inhibiting microbial growth in the fruit (Lamikanra and Richard 2002). On the other hand, Gorny and others (1998b) observed that an increase in the storage temperature from 0 to 10°C reduced by one-half the shelf-life of fresh-cut peach and nectarines due to a rise in respiration and ethylene production. Mass transfer phenomena such as water vapor transfer are also boosted at elevated temperatures. Rivera-López and others (2005) reported weight loss in papaya slices below 5% during 15 days storage at 5°C, whereas this loss was almost trebled at 10°C. Furthermore, storage temperature is the most influential factor affecting the aroma and

composition of fresh-cut fruits. Lamikanra and others (2000, 2002) reported storage temperature as the unique factor influencing the organic acid content in fresh-cut melon and the most significant affecting its volatile profile.

The temperature and return air flow of storage chambers, refrigerated transports, and storage display cases should be adequately controlled and registered in order to ensure maintenance of the cold chain throughout distribution. Most fresh-cut fruits, except for chilling-injury-sensitive commodities like bananas, can safely tolerate storage temperatures of 0°C. The traditional bed of ice used by some retailers to display fresh-cut produce can even be counterproductive. Studies have shown that the food surfaces not touching the ice become warm because of exposure to room temperature. Ice used in refrigeration units may actually act as an insulating layer, hindering product cooling and allowing internal temperatures to increase (IFPA 2006). Information about proper storage and handling conditions should be included in the product labeling so that both retailers and consumers are warned about the impact of high temperatures on quality and the potential safety risks of fresh-cut produce.

39.6 FUTURE PROSPECTS

The fresh-cut fruit industry has a great potential to grow during the next few years, but more research is still needed to find new treatments and to improve those already existing. Innovation in the next years should focus on the following issues:

- To develop new fresh-cut products, obtained from new varieties, by mixing different fruits or with the use of new processing techniques, that are more appealing to consumers;
- To study the effects of different antimicrobial treatments, especially those using compounds obtained from natural sources, on the naturally occurring microflora and foodborne pathogen microorganisms;
- To evaluate the effect of new MAP conditions and edible coatings on the microbiological and physiological stability of fresh-cut fruits;
- To investigate the effects of processing and storage conditions on the nutritional value and health-related compounds of fresh-cut fruits;
- To design specific equipment for the fresh-cut industry that meets hygiene standards, thus allowing processors to control health hazards without affecting the fresh quality of fruits.

40.1 INTRODUCTION

The terms "functional foods" and "functional food ingredients/nutraceuticals" are applied broadly to foods and food constituents, respectively, that provide specific health or medical benefits, including the prevention and treatment of diseases, as well as nutritional value (the term nutraceuticals is synonymously used for functional food ingredients in several countries). The practice of using certain foods or plants for the prevention or treatment of diseases by human societies must have started far back in time, as hunters and gatherers, and even primates (the closest living relatives of *Homo sapiens*), are known to use medicinal herbs. Hippocrates proclaimed nearly 2500 years ago, "*Let food be thy*

medicine and medicine be thy food." Our ancestors did not know why those plants produced the observed effects, and the discovery of medicinal properties of specific plants and foods was probably accidental or the result of trial and error. It is conceivable that certain edible plants and other foods (but not necessarily the ones that were consumed on a regular basis) were helpful in alleviating sickness, which led to the knowledge of the medicinal properties of such foods. Repeated trial and error could have led to the categorization of specific foods for treating particular diseases or other medical conditions. The use of specific decoctions containing phytochemicals was scientifically practiced in Ayurvedic, Greek, and Oriental systems of medicine, although the precise mechanism of the observed effects of the ingredients was not completely understood.

In modern society, there has been a widespread upsurge of interest in functional foods and functional food ingredients since the mid-1980s. Thus, there has been considerable popular demand for the health-enhancing, physiologically active components of functional foods, as consumers have become increasingly aware of the important link between diet and health and the vital role that diet plays in combating chronic diseases such as cancer and heart diseases.

Functional foods and nutraceuticals include food additives, vitamin and mineral supplements, herbs, phytochemicals, and probiotics. Nutraceuticals can be derived from plant, animal, and microbial sources, including those from the aquatic environment. Phytochemicals are chemical compounds produced by plants such as alkaloids, polyphenols, uncommon amino acids, and so on. Several of these compounds are non-nutritive, but effective in preventing or combating diseases. More than 900 different phytochemicals have been identified as components of different plants. The disease-preventing and disease-combating properties of phytochemicals have been investigated intensively, but further research is needed to enable mankind to benefit from the medicinal properties of as yet unknown plants.

The identification of phytochemicals, together with clinical trials to test their efficacy in the treatment of certain diseases, is essential. It is also necessary to investigate thoroughly the characteristics and biological activity of functional foods and nutraceuticals, such as their therapeutic or disease-preventing efficacy, proper dosage, and possible adverse effects (e.g., interaction with prescription drugs or with other functional foods and nutraceuticals), and so on. At the same time, standardized national and international regulation (e.g., by the United States Food and Drug Administration (FDA), Health Canada, and public health authorities of the European Union) is needed to provide guidelines to ensure the safety and quality of the functional food and nutraceutical products. Important areas of future research in this field include the following:

1. Identification and quantification of promising bioactive components in functional foods;
2. Standardization of bioactive components;
3. Clinical and population studies to assess effects of functional foods and nutraceuticals on human health;
4. Development of standardised analytical methods to enhance and ensure the levels of selected phytochemicals and other biologically active compounds in raw and processed foods;
5. Establishment of proper dosage and delivery systems;
6. Investigation of bioavailability and metabolism of functional foods and nutraceuticals;
7. The study of technical and safety issues that have a bearing on FDA regulation and health claim evaluation (University of Illinois 2000);

8. Examination of regulatory issues;
9. Research on effects of processing on the functional food and nutraceutical products;
10. Stability of the products; and
11. Interaction of functional foods and nutraceuticals with prescription and nonprescription drugs and with other functional foods and nutraceuticals.

40.2 DEFINITION OF FUNCTIONAL FOODS AND NUTRACEUTICALS

40.2.1 Functional Foods

There is, as yet, no universal definition of "functional food". This term was introduced in Japan in the mid-1980s and refers to processed foods containing ingredients that aid specific bodily functions in addition to being nutritious. So far, Japan is the only country that has a specific regulatory approval process for functional foods, which, if approved for public consumption, bear a seal of approval marked "*Foods for Specified Health Use* (FOSHU)" from the Japanese Ministry of Health and Welfare (Arai 1996; Hasler 1998). In the United States and Canada, functional foods are not legally recognized at present; however, many organizations and individuals concerned with the link between foods and health have proposed definitions of this emerging and expanding category of foods. Some examples of such definitions are as follows:

1. "Foods that, by virtue of physiologically active components, provide health benefits beyond basic nutrition" (International Life Sciences Institute);
2. "Any food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains" (Institute of Medicine's Food and Nutrition Board) (IOM/NAS 1994); and
3. "A food, either natural or formulated, which will enhance physiological performance or prevent or treat diseases and disorders" (Wildman 2000).

Some examples of functional foods and their physiological effects are listed in Table 40.1.

40.2.2 Nutraceuticals

Nutraceuticals, as defined by Wildman (2000), are naturally occurring substances in foods that have been found to be effective in the prevention or treatment of one or more diseases, or the improvement of physiological performance, thereby enhancing human health. The term functional food ingredients has also been synonymously used for nutraceuticals. Essential nutrients can be considered as nutraceuticals required by the human body. Examples include vitamins C and E, which function as antioxidants.

Health-conscious "baby boomers" have made functional foods a leading trend in the U.S. food industry. In the United States the market value of functional foods is estimated to have been $28.9 billion in 1998 (Waltham 1998) and is expected to be as high as $37.7 billion by 2007. Moreover, the great potential ability of functional foods to mitigate and prevent diseases and promote health and well-being could bring about a significant reduction in overall national health-care costs. The most prominent nutraceuticals in the Western world have included plant fibers, β-carotene, omega-3 (n-3 or ω-3), and polyunsaturated fatty acids, polyphenols, and so on, and the number of known nutraceuticals has been increasing

TABLE 40.1 Examples of Functional Foods.

Functional Foods	Bioactive Components (Known)	Health Benefit or Physiological Effects	Other Sources
Berries (especially blueberry)	Anthocyanins and anthocyanidins	• Neutralize free radicals • May reduce risk of cancer, heart diseases and age-related diseases	Blackberry, raspberry, brightly colored vegetables, eggplant skin, red cabbage
	Catechins	• Neutralize free radicals • May reduce risk of cancer	Tea, grapes
Cantaloupe	β-Carotene	• Fighting cancer	Carrots, pumpkins
Celery	Flavones: apigenin	• Neutralize free radicals • May reduce risk of cancer	Parsley
Citrus fruits	Flavanones, hesperidin, silybin, xanthohumol, limonoids	• Neutralize free radicals • May reduce risk of cancer	Citrus, milk thistle, hops
Fish oil	• Omega-3 fatty acids (necessary for properly maintaining human and animal health)	• May play a role into reducing risk of CVD • Improve mental function (e.g., attention deficit disorder and Alzheimer's disease) • Improve visual function, anti-inflammatory effect	Cold-water fish (e.g., tuna, salmon, trout, halibut, and mackerel) are rich in omega-3 fatty acids because they eat other fish, algae & zooplankton, which are high in DHA. Breast milk (contains DHA).
	• DHA (docosahexaenoic acid)	• A major component of brain and eye tissue	Canola oil, soybean oil, flax seed and some nuts.
	• EPA (eicosapentaenoic acid) ALA (α-linolenic acid)	• Anti-inflammatory properties • Prevent blood clotting (cause of fatal heart attacks) and lowers LDL and total cholesterol	Omega-enriched eggs.
	Conjugated linolenic acid (CLA)	• May improve body immune system • May decrease risk of certain cancers	Cheese, meats

(*Continued*)

TABLE 40.1 *Continued.*

Functional Foods	Bioactive Components (Known)	Health Benefit or Physiological Effects	Other Sources
Flax seed	Phytoestrogens, lignans	• Phytoestrogen, antioxidant properties	Flax seeds, sesame seeds, rye, grain products, vegetables and berries
	Omega-3 fatty acids, phenolic acids, flavonoids, tocopherols	• May reduce risk of hormone-related cancer (breast cancer) by competing with estrogen receptors in cells and against prostate and colon cancers	
	Soluble and insoluble fibre	• Lowers LDL, total cholesterol and triglycerides by blocking uptake of cholesterol and increased excretion of it from body	
Ginkgo	Ginkgo flavone glycosides	• Improve memory and blood flow to brain • May help cure Alzheimer's disease	
Green tea	Epicatechin (EC) Epicatechin gallate (ECG) Epigallocatechin gallate (EGCG)	• Neutralize free radicals • May reduce risk of cancer	
Grapefruit	Flavonols, quercetin, rutin,	• Anticancer and antioxidant	Grapefruits, gingko, grapes, onions
Oats (FDA approved 1st food specific health claim, January 1997)	Insoluble fiber	• May reduce risk of breast or colon cancers	Wheat bran, grain, many vegetables
	Soluble fiber (β-glucan)	• Cholesterol lowering effect (reduces risk of CVD)	Oats, apples, many fruits and vegetables
Olive oil (*Olea europaea*, Oleaceae)	Oleic acid, palmitic acid, linoleic acid, stearic acid	• Increase HDL, anticancer, antioxidant	*Olea europea* (olive)
Onions (yellow and red)	Quercetin	• May reduce heart disease	Tea, apples, cherries, and red wine

Rosemary (*Rosmarinus officinalis*, *Lamiaceae*	Camosol, α-pinene, camphor, cineole	• Antioxidant; • May prevent cholesterol oxidation • Prevent cancer and Alzheimer's disease	Rosemary
Sage (*Salvia officinalis*)	Anti-acetylcholinesterase (AchE), camphor, α-caryophyllene, cineole, limonene	• Antioxidant, estrogenic, and anti-inflammatory properties • Enhance memory (potential treatment for Alzheimer's disease)	Lamiaceae members
Shallots	Fructo-oligosaccharides	• May improve gastrointestinal health	Shallots, onions
Soybean (*Glycine max*. L.) and Sunflower seed (*Helianthus annus*)	Isoflavones: daidzein, genistein, glycitein and their glycosides	• May protect against heart diseases and some cancer • May lower LDL and cholesterol	Soybean product, kudzu root (pueraria lobata ohwi), red clover
	Protein	• 25g/day may reduce heart disease (Health Claim approved by FDA, 1999)	Soybeans, soy protein concentrate, soy protein isolate, soy-containing food
	Soyasaponins A & B	• May help control blood cholesterol, triglycerides and blood sugar. • Contain anticancer enzymes	Soybeans, legumes
	Carotenoids, α-tocopherol (common form of vitamin E), γ-tocopherol (primary source of vitamin E in diet), fatty acids (linoleic and oleic acids)	• Act as antioxidants, protecting fats, blood and other body fluids from free-radical damage	Tomato, orange, spinach
Spinach	Flavonoids ($>$1500 different types), lutein	• Active against age-related macular degeneration	Leafy vegetables, corn, egg yolk

(*Continued*)

TABLE 40.1 *Continued.*

Functional Foods	Bioactive Components (Known)	Health Benefit or Physiological Effects	Other Sources
Sunflower seed *Helianthus annuus* (Compositae)	Vitamins B_1, B_2, B_3, E, Ca, Mg, Mn, P, K, Cu, Re, Se, Zn, complex carbohydrates, fiber, omega-6 fatty acid, protein, unsaturated fat	• Immune-boosting benefits • Antioxidant • Improve skin health • Regulate blood-fat levels • Aid in tissue repair (e.g., treating eczema)	Tomato, guava, rose hip, watermelon, pink grapefruit
Tomato	Lycopene	• Antiprostate cancer • Antioxidant	
Wine, grapes, pomace	Phenolic (e.g. flavonoids, anthocyanins), resveratrol, ellagic acids	• Antioxidant action, blocks cholesterol oxidation (lower LDL, prevent risk of CVD) • Bind to and prevent the absorption of cholesterol	
Yogurt	*Lactobacillus* sp	• Probiotics	Yogurt

progressively. Currently, the number of recognized nutraceutical substances has increased to more than 100, the more popular ones including isoflavones, tocotrienols, organo-sulfur compounds, conjugated linoleic acid (CLA), carotenoids, and flavonoids. Some examples of nutraceuticals and their sources are listed in Table 40.2.

TABLE 40.2 Examples of Vitamins and Functional Food Ingredients (Nutraceuticals) by Food Sources.

	Food Sources	Effects of Health Benefits
	Plants	
Allicin	Garlic, onions, chives, leek	• Antibacterial • Reduce risk of cancer and CVD, thinning blood
Ascorbic acid	Rose hip, fruits, peppers	• Antioxidant (e.g., regenerate oxidized vitamin E) • Reduce risk of cataracts • Reduce cold symptoms (note: not recommended if one has kidney stones or hemochromatosis)
β-Carotene	Carrots, tomato, yellow squash, broccoli, citrus fruits, cantaloupe, pumpkin, sweet potatoes, tomato, paprika, green vegetables	• Antioxidant (not recommended to smokers – incidence of increased lung cancer when administered alone)
Capsaicin	Pepper fruit	• Anti-inflammatory
Catechin	Teas, berries	• Antioxidant
Cellulose (insoluble fiber)	Most of plants (cell wall), whole grain, bran, cabbage family, peas, beans apples, root vegetables	• Holds water, reduces colonic pressure, reduced transit time of digestion • Lowers cholesterol level and CVD
Coenzyme Q-10 (ubiquinone)	Meat, seafoods	• Antioxidant
Cyanidin	Grapes, raspberries, strawberries	• Antioxidant
Flavonoids and anthocyanins	Fruits, many plants, red wine	• Lowering of cholesterol levels, anti-osteoporosis, anti-carcinogenic, antioxidant
Folic acid (vitamin B_9)	Citrus fruits, vegetables, tomato, grains	• Reduce blood level of homocysteine • Decrease CVD
β-Glucan	Brans of oats, barley, wheat	• Lowering blood lipid
Indoles	Cabbage, broccoli, cauliflower, kale, Brussel sprouts	• Antioxidant, anticancer agents
Isoflavones (daidzein, genistein, and glycitein)	Soybeans, other legumes, red clover	• Anti-osteoporosis, anti-cancer, • Reduce stroke, heart disease, and hot flush
Isothiocyanates	Cruciferous vegetables	• Anticancer
Lecithins	Soybeans	• Lower LDL
δ-Limonoide	Citrus fruits	• Anticancer
Lignin	Plants	• Improve vision
Lutein	Spinach, banana, egg yolk, green vegetables	• Antioxidant • Improve vision
Lycopene	Tomato and its products	• Antioxidant • Antiprostate

(*Continued*)

TABLE 40.2 *Continued.*

	Food Sources	Effects of Health Benefits
Resveratrol	Grapes (skins), red wine	• Decrease LDL and increase HDL • Antioxidant
Quercetin	Red grapes, citrus fruit, onion, apple skin, berries, tea, broccoli	• Lowering blood lipid • Anti-inflammatory • Antioxidant
Selenium	Grains, Brazil nuts, seeds, meat, eggs	• Antioxidant
Soy protein	Soybeans	• Lower the LDL
Tocopherols	Soybean oil, olive oil, corn oil, nuts, seeds, wheat germs, peppers	• Anticancer • Antioxidant • Lowering blood lipid (protects cell membrane, prevents lipid oxidation) (note: high doses may interfere with blood clotting)
	Animals	
Calcium	Milk, meat	• Bone protection
Choline	Meat, fenugreek leaves, fava beans	• Possibly to prevent and treat Alzheimer's disease
Conjugated linoleic acid (CLA)	Meat, milk	• Bone protection
Decosahexaenoic acid (DHA) and eico-sapentaenoic acid (EPA)	Fish oil	• Anti-inflammatory • Reduce CVD
Sphingolipids	Most membrane of animal cells	• Building-block components of lipid in tissues
Ubiquinone (coenzyme-Q_{10})	Almost all organisms	• Electron carriers for the electron transport chain in mitochondria
Zinc	Meat, milk, seafood, liver, eggs	• Requires Zn as part of many prosthetic groups of over 80 enzymes
	Microbials (Naidu 2000)	
L. acidophilus (NCFB 1748)	Yogurt, fermented milk	• Probiotics, gastrointestinal health
Bifidobacterium bifidum	Yogurt, sour milk	• Probiotics, disease prevention from harmful bacteria
Bifidobacterium infantis *Bifidobacterium longum*		• Produce both acetic and lactic acid, which reduces intestinal pH, restrict the production of phenols, ammonia, steroid metabolites, bacterial toxin and vasoconstriction-causing amines.
Streptococcus sailvarius sp. (*Thermophilus*)	Yogurt, soured milk	• Probiotics, beneficial role in the ecosystem of the human gastrointestinal tract

40.3 EFFECTS OF FUNCTIONAL FOODS AND NUTRACEUTICALS ON MAJOR CHRONIC DISEASES IN MODERN POPULATIONS

40.3.1 Cardiovascular Diseases (CVD)

Mortality from CVD in the world as a whole is about 51%, which could perhaps be lowered considerably if we had a better understanding of the causes and processes of pathogenesis. Inflammation of the artery lining is the initiating cause for plaque formation in arteries. Recent results of biochemical, epidemiological, and cell culture research suggest that one of the major risk factors for CVD is inadequate intake of foods containing antioxidant micronutrients such as vitamins E and C, β-carotene, and ubiquinone (coenzyme Q10). Increasing intake of fruits and vegetables containing antioxidants is recommended as a protective measure against cardiovascular diseases (Duthie and Brown 1994). Moreover, eating fish at least twice a week can significantly reduce the risk of suffering heart attack or stroke (Brody 2003).

Omega-3 fatty acids are thought to play a particularly important physiological role in the prevention of CVD (Simopoulos 1997; Dewailly and others 2001; Holub 2002; Hu and others 2002;). Decosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) in fish oil are considered essential fatty acids, but they can be formed in the body from another omega-3 fatty acid, α-linolenic acid (ALA). ALA is found in various foods, such as flax seed, spinach, and marine animals that eat organisms containing ALA. ALA is included as an ingredient in several foods.

40.3.2 Cancer

Cancer, which is responsible for the second highest mortality rate after CVD in "developed" countries, correlates with environmental factors and dietary habits (Milner 1994). Epidemiological and clinical observations have provided convincing evidence that a good diet can significantly lower the risk of developing cancer. Many phytochemicals and other substances in foods appear to afford protection against cancer (Delaquis and Mazza 1998; Oomah and Mazza 1998; Bruno and Wildman 2000; DiSilvestro 2000; Guthrie and Kurowska 2000). These include fibers, vitamins A, D, and C, vitamins of the B complex, organo-sulfur compounds found in *Allium* plants (i.e., garlic and onions), ellagic acid and other phenols, flavonoids found in fruits and vegetables, and glucosinolates in cruciferous vegetables such as broccoli (components that, on hydrolysis, yield the biologically active derivatives indole-3-carbinol and isothiocyanates) (Jeffery and Jarrell 2000). These multifarious essential and nonessential nutrients apparently modify the carcinogenic process at specific sites, interfering with carcinogenesis. Diet is not the only factor that determines cancer development, but it provides an easy and potentially effective means of lowering the risk. In-depth research is needed to elucidate the processes by which components of the human diet affect the initiation and growth of cancer cells. One of the objectives of future research should be to reveal in which ways nutritional intervention would be appropriate and effective, providing a basis for realistic recommendations regarding dietary regimes (Milner 1994; Arnot 1998).

40.3.3 Obesity

In recent years obesity has been showing an alarming increase in the developed and developing countries among people of all ages (World Health Organization 2000; The House of Commons 2004). This phenomenon can be attributed to a number of causes, notably

1. The change from "traditional foods" (a well-balanced diet) to "fast foods" containing higher concentrations of undesirable ingredients (e.g., trans and saturated fatty acids, and large amounts of sugar);
2. The hectic pace of modern life, which often prompts busy people to eat more convenient but less wholesome foods; and
3. A lack of exercise and a largely sedentary life-style that commonly involves excessive computer usage and TV watching (often accompanied by the munching of fattening snacks).

Obesity increases the incidence of ailments such as heart disease, diabetes, and cancer. The number of people who are classified as obese (i.e., people whose body mass index exceeds 30) has increased by about 2% both in men and women within the last 20 years. Dietary factors of potential importance for energy balance and fat distribution in humans include

- Macronutrients (e.g., carbohydrate, protein, and fat);
- Micronutrients (e.g., thiamin and Zn); and
- Non-nutrients (e.g., dietary fiber, caffeine, capsaicin, and phytoestrogens).

It is important to understand the relationship (whether biochemical or physicochemical) between energy intake, energy expenditure, and the deposition of fat at various anatomical sites. Furthermore, there are great opportunities for research designed to identify or develop functional foods that may help to ameliorate the growing problem of obesity in modern society (Wahlqvist 1994).

40.3.4 Alzheimer's Disease

Consumption of fish containing the omega-3 fatty acid docosahexaenoic acid (DHA) twice a week has been found to reduce the risk of Alzheimer's disease (AD) by 60% (Morris and others 2003). Morris and others (2003) concluded that DHA "had the strongest protective effect against AD" compared to other omega-3 fatty acids. In contrast, eicosapentaenoic acid (EPA), another omega-3 fatty acid, appeared to have no protective effect, and α-linolenic acid (ALA), which is also an omega-3 fatty acid, protected only people with a specific genotype. In short, DHA may play an important part in the prevention of AD.

40.4 SOURCES AND BIOLOGICAL EFFECTS OF FUNCTIONAL FOODS AND NUTRACEUTICALS IN NATURE

Evidence yielded by several epidemiological studies has shown that people consuming diets rich in vegetables and fruits had, on average, a 50% lower incidence of cancer than those who consumed lesser amounts (Block and others 1992; Potter 1992; Hasler 1998; Jeffrey and Jarrell 2000). It appears that the plant-based diets, besides providing basic nutrients, are sources of phytochemicals that reduce the incidence of chronic diseases such as cancer. Many classes of the biologically active phytochemicals had been identified in the mid-1980s (Steinmetz and Potter 1991a,b), and many more of them are still being identified and isolated. Phytochemicals in fruits and vegetables have important

beneficial effects on human health, including disease prevention, the mechanisms of which are gradually coming to be better understood. It must also be borne in mind, however, that health-enhancing products from plants are not necessarily safe for all individuals (see Section 40.6). In addition, the Nutrition Labeling and Education Act of 1990 (NLEA), which requires nutrition labeling for most foods and allows health-beneficial information on food labels, is helping to heighten awareness of functional foods and optimize their benefits (ADA 1995; Howard and Kritchevsky 1997). Examples of functional foods and nutraceuticals and their respective health benefits are listed in Tables 40.1 and 40.2, respectively, and selected ones are discussed in more detail below.

40.4.1 Flaxseed (*Linum usitatissimum*)

Among the major seed oils, flaxseed oil contains the highest level of the omega-3 fatty acid α-linolenic acid (ALA) (57%) (Oomah and Mazza 1998), but research on flaxseed has mainly focused on lignans, a class of phytoestrogens. Flaxseed contains many important functional components, including high concentrations of protein and dietary fiber, lignin, and other phytochemicals with antioxidant activities, such as flavonoids, phenolic acid, and tocopherols (Oomah and Mazza 1998). The two primary mammalian lignans, enterodiol and enterolactone, are formed in the intestinal tract by bacterial action on plant lignan precursors (Setchell and others 1987; Setchell 1995). Flaxseed is the richest source of mammalian lignan precursors (Thompson and others 1991). Owing to the structural similarity of enterodiol and enterolactone to naturally occurring and synthetic estrogens, some scientists have claimed that these compounds exert both weak estrogenic and antiestrogenic effects. Moreover, they may play a role in the prevention of estrogen-dependent cancers such as breast cancer. In experiments on rodents, flaxseed has been shown to decrease tumors of the colon, mammary glands (Thompson 1995), and lungs (Yan and others 1998). Only a few studies have been conducted to evaluate the possible cancer-reducing potential of flaxseed consumption among humans. They have shown that ingestion of 10 g of flaxseed per day may cause several hormonal changes associated with reduced breast cancer risk (Phillips and others 1993). Aldercreutz (1995) found that urinary lignan excretion was significantly lower in postmenopausal breast cancer patients than in controls eating a normal mixed or lacto-vegetarian diet. Flaxseed is also known to reduce total and LDL cholesterol levels as well as platelet aggregation (Bierenbaum and others 1993; Cunnane and others 1993). Flaxseed, however, cannot be digested unless it is powdered. When it is powdered and consumed, α-linolenic acid (ALA) is released, and this essential fatty acid may help to prevent blood clotting, which can cause fatal heart attacks. Because the whole flaxseed contains both soluble and insoluble fiber, it can reduce constipation and diseases of the diverticula.

40.4.2 Phytoestrogens

Phytoestrogenic compounds (e.g., isoflavones, coumestans, and lignans), which are weak estrogens found in plant food, may have anti-estrogenic effects. Some phytoestrogenic compounds, at the levels consumed in the typical U.S. diet, impart a reduced risk of developing endometrial cancer. A recent investigation revealed an inverse correlation between dietary intake of food containing three classes of phytoestrogens (isoflavones, coumestans, and lignans) and the risk of endometrial cancer development (Horn-Ross and others 2003). The relationships were slightly stronger in postmenopausal women than in premenopausal women.

40.4.3 Tomatoes

Tomatoes have been in the spotlight since the mid-1990s because they contain the health-benefiting compound lycopene, a primary carotenoid. Consumption of products containing lycopene has been linked to a reduced risk of cancer development (Giovannucci and others 1995; Goodman and others 1998; Krinsky 1998; Bruno and Wildman 2000), especially cancers of the prostate, breast, digestive tract, cervix, bladder, and skin, and possibly the lung (Clinton 1998). A study of more than 47,000 men revealed that those who consumed tomato products 10 or more times per week had less than half the risk of developing advanced prostate cancer than controls (Giovannucci and others 1995). The mechanism for prevention of cancer by lycopene may be related to the compound's role as an antioxidant. Lycopene is known to be the most efficient quencher of singlet oxygen in biological systems (Di Mascio and others 1989). This antioxidant function of lycopene may also explain the results of a multicenter European study that demonstrated that levels of carotenoids in adipose tissue were inversely related to the risk of myocardial infarction (Kohlmeier and others 1997).

40.4.4 Garlic (*Allium sativum*)

Garlic is one of the most widely used traditional culinary herbs in the world, and it has long been noted for its medicinal virtues. Indeed, it has been called "Russian penicillin" owing to its antibacterial activity. Many medicinal functions of garlic have been documented in the literature (Alder and Holub 1997; Nagpurkar and others 2000). These include antihypertensive, cholesterol-lowering, cancer-chemopreventive, and antibiotic effects (Srivastava and others 1982). The characteristic aroma and taste of garlic is due to an abundance of oil- and water-soluble organosulfur compounds (e.g., allicin), which are probably responsible for the various medicinal effects of garlic. The intact garlic bulb contains an amino acid called alliin, which is converted to allicin by an enzyme called allinase when garlic bulbs are cut or crushed (Block and others 1992; Koch and Lawson 1996). The allicin spontaneously decomposes to numerous sulfur-containing compounds, some of which have been shown to inhibit tumorigenesis in experiments and to reduce cancer risk in humans (You and others 1988; Dorant and others 1993). Indeed, they apparently reduce the incidence of colon cancer by 50% in postmenopausal women (Steinmetz and others 1994). *Allium* vegetables in general, including onions, are believed to offer protection against cancer of the gastrointestinal tract. However, not all epidemiological studies have shown garlic to be effective against carcinogensis (Steinmetz and Potter 1991a,b). This contradiction may reflect differences in the types and quantities of organosulfur compounds present in fresh garlic and garlic products (Lawson and others 1991).

Garlic has also been shown to reduce the incidence of CVD and hypertension and to lower cholesterol levels (Warshafsky and others 1993; Silagy and Neil 1994a,b; Ernst 1997; Isaacsohn and others 1998). It is not clear, at present, which compound or group of compounds in garlic is responsible for the cholesterol-lowering effect.

40.4.5 Cruciferous Vegetables

Cruciferous vegetables include broccoli, cabbage, cauliflower, Brussels sprouts, collard, kale, kohlrabi, turnip, mustards, horseradish, and watercress. The consumption of cruciferous vegetables has been shown to reduce the risk of developing several kinds of cancer (Verhoeven and others 1996). The cruciferous vegetables have high concentrations of

glucosinolates (a group of glycosides), which have been linked to the anticarcinogenic properties of cruciferous vegetables (Verhoeven and others 1997; Delaquis and Mazza 1998). All cruciferous vegetables store glucosinolates in their vacuoles. They are hydrolyzed by the enzyme myrosinase, which is found in plant cells, to a variety of products such as isothiocyanates and indoles. These hydrolysis products appear to have anticancerous effects, which are under investigation. Although natural and synthetic isothiocyanates as a whole have been shown to prevent cancer in animals (Hecht 1995), attention is currently being directed mainly to a particular class of isothiocynates known as sulforaphanes, which can be isolated from broccoli. Sulforaphanes induce enzymes (e.g., quinone reductases) involved in carcinogen detoxification in the human body (Fahey and others 1997). Three-day-old broccoli sprouts contain concentrations of glucuraphanin (the glucosinolate of sulforaphane) that are 10–100 times greater than those of mature plants (Nestle 1998), and hence may be more beneficial.

40.4.6 Citrus Fruits

Citrus fruits include oranges (*citrus sinensis*), tangerines (*citrus reticulata*), lemons (*citrus limon*), and grapefruit (*citrus paradisi*). There are many physiologically active components in citrus fruits, among them citrus flavonoids and limonoids, which comprise two major classes of compounds that have been extensively investigated. A large number of components in citrus products are pharmacologically active, and they have shown to be capable of preventing or alleviating diseases and promoting health, for example because of their anticancer effects (Tillotson and others 1993; Middleton and Kandaswami 1994; Rouseff and Nagy 1994; Girard and Mazza 1998). Some of the principal nutrients in citrus fruits, such as vitamins C and E, folic acid, dietary fiber, and carotenoids, are thought to play a role in preventing or delaying the onset of major degenerative diseases (e.g., cancer, cardiovascular disease, and cataracts) by counteracting oxidative processes. Several "non-nutrients", including limonoids and flavonoids, appear to block and suppress carcinogens (Hasegawa and Miyake 1996) and may be effective against a variety of spontaneous and chemically induced rodent tumors (Crowell 1997; Gould 1997; Ripple and others 1998).

40.4.7 Cranberries

Cranberry juice has been used to treat urinary tract infections, its effectiveness being attributable to the fact that it is rich in benzoic acid, which acidifies the urine (Blatherwick 1914). In addition to benzoic acid, this juice also contains two other phytochemicals, fructose and a nondialysable polymeric compound, which have the ability to inhibit adherence of *Escherichia coli* to uro-epithelial cells (Schmidt and Sobota 1988). The polymer compound was eventually isolated from cranberry and blueberry juices and was found to inhibit adhesins present on the pili of the surfaces of certain pathogenic *E. coli* cells (Ofek and others 1991). A clinical trial in which 150 subjects were allowed to consume 300 mL of juice per day for 6 months showed significant (58%) reduction in urinary tract infection compared to the control group (Avorn and others 1994). Cranberries evidently help to combat not only urinary infection but also several forms of cancer and heart disease.

Furthermore, there is evidence that cranberries also have the potential to protect animals against brain cell damage resulting from strokes, and that cranberry juice has a statistically significant tendency to diminish the occurrence of brain cell death. Stroke

is the third leading cause of death in the United States and the most common cause of disability in adults (Neto 2003). The specific phytochemicals responsible for these protective effects have not yet been characterized but may include anthocyanins, which are strong antioxidants.

40.4.8 Tea

Next to water, tea is one of the most commonly consumed beverages in the world. Tea, especially green tea, is a potent anticancer agent owing to its high concentrations of polyphenolic compounds (AHF 1992; Dreosil and others 1997; Harbowy and Balentine 1997; Mueller–Klieser and others 2002). The polyphenol content of tea leaves can amount to as much as 30% of their total dry weight. Catechins are the principal polyphenols in tea and the most significant ones from the standpoint of medicinal effects (Graham 1992). In green tea there are four major catechins, that is, epicatechin, epicatechin-3-gallate, epigallocatechin (EGC), and epigallocatechin-3-gallate (EGCG), which are similar to flavonoids. EGC and EGCG in particular are known to be effective in preventing cancer (Yamamoto and others 1997). Although the occurrence of such effects in humans is inconclusive, it has been found that consumption of large quantities (5–6 cups per day) of green tea is associated with decreased incidence of breast cancer in Japanese women (Kohlmeier and others 1997; Nakashi and others 1998). The tea polyphenols appear, moreover, to block the formation of nonmelanoma skin tumors. Unlike sunblock, which prevents the skin from absorbing harmful ultraviolet (UV) light, tea polyphenols function metabolically after the skin is exposed to excessive sunlight. The compounds found in both green and black teas inhibit a newly discovered chemical pathway involving an enzyme called JNK-2 that appears to play a key role in the development of tumors (Dong 2003). JNK-2 levels increase after the skin is exposed to sunlight, and remain elevated in the skin area exposed to sunlight, increasing the probability that skin cancers will develop. Dong (2003) believes that tea is effective only if large quantities of it are consumed, suggesting that a topical "cream" containing tea polyphenols is likely to be more effective.

Tea appears to be effective against CVD as well as cancer. A study of elderly men in Netherlands (Hertog and others 1993) who consumed tea as the major source of flavonoids (e.g., quercetin, kaempferol, myricetin, apigenin, and luteolin) in their diet showed reduced mortality from CVD in this population. There are other studies demonstrating a link between consumption of tea and reduction in the incidence of CVD, although the evidence is not yet conclusive (Tijburg and others 1997).

40.4.9 Wine and Grapes

Mounting evidence indicates that wine, especially red wine, reduces the incidence of CVD. St. Leger and others (1979) found a strong inverse correlation between wine intake and death from ischemic heart disease in both men and women from 18 countries. In France, in particular, there is a relatively low incidence of CVD despite the prevalence of a diet rich in dairy fat (Renaud and de Lorgeril 1992). This "French paradox" has been explained, in part, by the ability of red wine to increase HDL cholesterol (Das and others 1999). The beneficial effects of red wine are thought to result from high concentrations of polyphenols, which are extracted from grape skins during fermentation and act as antioxidants. The concentrations of phenolic compounds in red grapes were found to range from 260 to 920 mg/kg, and red wines contained 1800 (Cabernet Sauvignon) to 3200 mg/L

(Petite Sirah) of polyphenols (Kanner and others 1994). The tendency of red wine to prevent CVD could be explained by the ability of phenolic compounds to prevent the oxidation of LDL, a critical factor in the process of atherogenesis (Frankel and others 1993a,b). Moreover, moderate consumption of red wine is associated with a decreased risk of age-related macular degeneration (Obisesan and others 1998). Red wine is also a good source of trans-resveratrol, a phytoalexin found in grape skins (Creasy and Coffee 1988). Resveratrol has been shown to have estrogenic properties (Gehm and others 1997), which may help to explain the observed cardiovascular benefits of drinking wine (Jang and others 1997).

Despite the evidence for effectiveness of wine against CVD, a study of over 100,000 adults in North California demonstrated that consumption of red wine involved no significant reduction of coronary risk (Klatsky and others 1997). It should also be pointed out that excessive consumption of alcoholic beverages has been linked to the development of several types of cancer, such as breast cancer (Bowlin and others 1997), as well as cirrhosis of the liver. Those who wish to enjoy the health benefits of wine without undue risk may consider alcohol-free wine, which has been shown to increase total plasma antioxidant capacity, or grape juice, which is effective in inhibiting the oxidation of LDL (Stein and others 1999).

40.4.10 Chocolate

Chocolate contains flavonoids such as (−) epicatechin, which may promote cardiovascular health as a result of direct antioxidant effects or through antithrombotic mechanisms. Dark chocolate brings about an increase in both the total antioxidant capacity and the (−) epicatechin content of blood plasma, but these effects are considerably reduced when milk chocolate is consumed instead, or when dark chocolate is consumed with milk (Serafini and others 2003). This finding indicates that milk may interfere with the absorption of antioxidants from chocolate *in vivo* and may reduce the potential health benefits conferred by consumption of moderate amounts of dark chocolate (Geleijinse and others 1999; Serafini and others 2003).

40.4.11 Fish

Omega-3 (ω-3 or n-3) fatty acids (e.g., DHA, EPA, and ALA) comprise a class of essential polyunsaturated fatty acids obtained primarily from fish oils. DHA and EPA can be formed in the body from another omega-3 fatty acid, ALA, besides being consumed directly with fish oil. ALA is found in plants, such as flaxseed and spinach, as well as fish and other marine animals that eat organisms containing ALA. DHA is one of most important omega-3 fatty acids and is a major component of brain and eye tissues. The omega-3 fatty acids may play an important role in reducing the incidence of CVD, cancer, mental disorders (e.g., attention deficit disorder, bipolar disease, depression, and Alzheimer's disease), and alcoholism (Hibbeln 2003). In addition, omega-3 fatty acids perform many biological functions that can benefit the heart and blood vessels. They can inhibit the synthesis of substances that promote inflammation, reduce the tendency of the blood to form clots, stabilize the electrical activity of heart, lower triglyceride levels, reduce blood pressure moderately, and improve the functioning of artery linings (www.nytimes.com/2003/0729/health/nutrition/29BROD.html). In October 2000, these findings prompted the American Heart Association to recommend the consumption of at least

two servings of fish per week, especially fatty fish such as salmon, sardines, mackerel, herring, lake trout, tuna, halibut, and anchovies. Besides, the results of a study undertaken to investigate possible effects of fish consumption and the intake of DHA and other types of omega-3 fatty acids on Alzheimer's Disease indicate that weekly fish and DHA consumption reduces the risk of Alzheimer's Disease by 60% (Martek Biosciences Corp. 2003). Finally, note that although fish is an important part of the inuit (Eskimo) diet (Krumhout and others 1985; Harris and others 1990; Harris 1997), which contains high levels of fats, this does not increase the incidence of CVD among these people (Bang and Dyerberg 1972).

40.4.12 Dairy Products

Dairy products, such as milk, cheese, and yogurt, are among the best sources of several important vitamins (e.g., vitamin D and riboflavin) and minerals (e.g., calcium and phosphorus) (Jelen and Lutz 1998). Calcium is an essential nutrient, which prevents osteoporosis and possibly colon cancer. The fermented dairy products, such as yogurt, kefir, and sour milk, are categorized as "probiotics", which are defined as "live microbial food supplements, which beneficially affect the host animal by improving its intestinal microbial balance" (Fuller 1994; Jelen and Lutz 1998; Farnworth 2000). Probiotics have attracted considerable attention, primarily because they display anticarcinogenic, hypocholesterolemic, and antagonistic action against intestinal pathogens (Mital and Gang 1995).

Microorganisms have been used traditionally in the fermentation of milk, lactic acid bacteria being of particular interest. In studies of Masai tribesmen in Africa, hypocholesterolemic effects of fermented milk have been discovered (Mann and Spoerry 1974; Mann 1978). The Masai have low levels of serum cholesterol and a low incidence of CHD, in spite of the high proportion of meat in their diet. It was found that they consume large quantities of fermented whole milk daily. Mital and Gang (1995) performed studies pointing to a role of probiotics in the prevention of colon cancer. It may be due to the presence of lactic acid bacteria, which alter the activity of fecal enzymes (e.g., β-glucuronidase, azoreductase, and nitroreductase) that are thought to play a role in the development of colon cancer.

40.4.13 Carbohydrates

Fermentable carbohydrates that serve as nutrient substrates for the good microflora of the gut make up a class of "prebiotics", which have been defined as "nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon and thus improve host health" (Gibson and Robertfroid 1995; Farnworth 2000). These include dietary fibers, nonabsorbable sugars, sugar alcohols, and fruit oligosaccharides (Tomomatsu 1994; Gibson and others 1996). Oligosaccharides consist of short-chain polysaccharides made up of 3–10 simple sugars linked together. They are found in many fruits and vegetables (e.g., bananas, garlic, onions, milk, honey, artichokes, and chicory). The category of prebiotics has been extended to include "symbiotics", which are mixtures of probiotics and prebiotics (Gibson and Robertfroid 1995). Many symbiotic products are available in the European market.

40.4.14 Beef

A conjugated linoleic acid (CLA) known as an "anticarcinogenic fatty acid" was first isolated from grilled beef (Ha and others 1987). This CLA is an isomer of linoleic acid (18 : 2, n-6), in which the double bonds are conjugated instead of being in the typical methylene-interrupted configuration. Reportedly, there are nine different isomers of CLA that occur naturally in foods. They have been shown to be effective in suppressing stomach tumors in mice and mammary carcinogenesis in rats (Ip and Scimeca 1997). It has even been suggested that they play a role in reducing weight (Park and others 1997).

The highest concentrations of CLAs are found in the fatty fractions of foods obtained from ruminants, for instance, beef, dairy products, and lamb. Beef fat contains 3.1–8.5 mg CLA/g, the 9-cis and 11-trans isomers contributing 57–85% of total CLAs (Decker 1995). A significant increase in the CLA content of meat may result from cooking or processing; yet the obvious advantage of this from the standpoint of cancer prevention is likely to be at least partially offset by the fact that the concentrations of many mutagens and carcinogens increase as well.

40.4.15 Vitamins

Vitamins are defined as biochemical compounds required by the body in small amounts. There are two types of vitamins, water-soluble and fat-soluble. Fat-soluble vitamins, which include vitamins A, D, E, and K, are found mainly in fatty foods such as animal fats (including butter and lard), vegetable oils, dairy foods, liver, and oily fish. They are essential for proper functioning of the body. Excess amounts of vitamins derived from the foods are stored in the liver and fatty tissues for future use, but consumption of an excess can be very harmful. Water-soluble vitamins, which include vitamins B_6, B_{12}, and C, biotin, folic acid, niacin, pantothenic acid, riboflavin, and thiamin (Padh 1994), are found in fruits, vegetables, and grains. As they are not stored in the body, these vitamins must be constantly supplied from dietary sources. In contrast to the fat-soluble vitamins, consumption of larger than essential quantities of water-soluble vitamins is generally not harmful, as the excess amounts are excreted in urine. As a rule, they are unstable when exposed to heat or air. When food is boiled in water, any water-soluble vitamins can be leached into the water and lost. Foods containing water-soluble vitamins are best cooked by steaming or heating in a microwave oven to ensure retention of vitamins.

40.4.16 Minerals

Minerals are essential inorganic nutrients that the human body needs in small quantities and that are often absorbed from food. Minerals are present in varying concentrations in a variety of foods, such as meat, cereals, fish, milk and dairy foods, vegetables, fruits (including dried fruits), and nuts. Minerals such as calcium and phosphorous are necessary for building strong bones and teeth, and sodium and potassium control the level of water inside and outside cells. Many minerals, including magnesium, iron, phosphorus, potassium, sodium, and sulfur, are enzyme co-factors and control the rate of enzyme reactions and energy production within the body (Anderson and Allen 1994).

"Trace elements", such as boron, cobalt, copper, chromium, fluoride, iodine, manganese, molybdenum, selenium, silicon, and zinc, are essential minerals that are needed in minute quantities compared with other minerals (Anderson and Allen 1994). They are found in a variety of foods such as meat, fish, cereal, milk and dairy foods, vegetables, and nuts.

40.5 FUNCTIONAL FOODS AND NUTRACEUTICALS: HEALTH CLAIMS AND BENEFITS

40.5.1 Health Claims

40.5.1.1 Oats. There is evidence that oat β-glucan, like many other polysaccharides, may reduce total and low-density lipoprotein (LDL) cholesterol, thereby reducing the risk of coronary heart disease (CHD) (Wood and Beer 1998). Oats contain β-glucan, which is one of the dietary sources of cholesterol-lowering soluble fiber and has been studied extensively. In support of a petition of health claim, the Quaker Oats company (Chicago, Illinois) conducted clinical trials on the effects of oat consumption by humans between 1980 and 1995. This study revealed that a statistically significant reduction in total cholesterol and LDL cholesterol was achieved in hypercholesterolemic subjects by daily consumption of 34–123 g of oat bran or oatmeal. It also showed that 3 g of β-glucan is required to obtain a 5% reduction of serum cholesterol, meaning that approximately 60 g of oatmeal or 40 g of oat bran had to be consumed. In order to qualify for a health claim, an oat product must contain 13 g of oat bran or 20 g of oatmeal, and provide at least 1.0 g of β-glucan per serving without any fortification (Hasler 1998). On the basis of these studies, the Food and Drug Administration (FDA) awarded the first food-specific health claim in January 1997 (DHHS/FDA 1997) for oats and oat products.

40.5.1.2 Psyllium. FDA extended the soluble fiber health claim to psyllium fiber in February 1998. Psyllium husk, which is marketed as Metamucil and used as an additive in several other products, such as cereals, supplements soluble fiber in the diet. It confers several health benefits, notably alleviation of constipation and a moderate decrease in blood pressure.

40.5.1.3 Soybeans. Besides being a source of high-quality protein, soybean lowers cholesterol levels and reduces the risk of CVD. Soybeans and soy foods contain many phytochemicals that are considered to be effective in preventing and ameliorating many chronic diseases such as cancer, CVD, and osteoporosis, and it alleviates menopausal symptoms (Messina and others 1997). The phytochemicals in soybeans include phytoestrogens (e.g., genistein, daidzein and glycitein, and their glucosides), phytosterols, tocophenols, saponins, phenolic acids, lecithins, protease inhibitors, and phytic acid. The cholesterol-lowering effect of soybean has been well documented. A meta-analysis (1995) of 38 separate studies involving 743 subjects revealed that consumption of soy protein (25 g/day) resulted in a significant reduction in total cholesterol (9.3%), LDL cholesterol (12.9%), and triglycerides (10.5%), with a small increase in high-density lipoprotein (HDL) cholesterol (2.4%) (Anderson and others 1995). However, isoflavones in soy protein did not seem to have any cholesterol-lowering effect (Nestle and others 1997; Hodgson and others 1998). The exact mechanism by which soy protein exerts its

hypocholesterolemic effect has not yet been fully elucidated. Recently, a meta-analysis of the relationship between soy isoflavones and LDL- and HDL-cholesterol concentrations in humans showed decreased LDL cholesterol and increased HDL cholesterol during isoflavone consumption (Weggemans and Trautwein 2003). However, there was no dose–response relation between soy isoflavones and changes in LDL or HDL cholesterol levels, even though the study was carried out by feeding the subjects 36 g of soy protein per day together with 52 mg of soy isoflavones on average. In November 1999, FDA approved a health claim for soy protein on the grounds that daily consumption of at least 25 g of soy protein tends to reduce the risk of CVD.

Among the soybean phytochemicals that have anticarcinogenic effects, isoflavones (phytoestrogens) are the most noteworthy, because soybeans are the only known dietary source of significant amounts of these compounds (Messina and Barnes 1991; Hendrick and Murphy 2000). There are 12 forms of isoflavonoid components. These include three aglycones (daidzin, genistin, and glycitin), three glucosides of aglycones (daidzin, genistin, and glycitin), three acetyl ester glucosides (acetyl-daidzin, acetyl-genistin, and acetyl-glycitin), and three malonyl ester glucosides (malonyl-daidzin, malonyl-genistin, and malonyl glycitin) (Jackson and others 2002). Isoflavones are heterocyclic flavonoid components structurally similar to estrogenic steroids. Owing to their weak estrogenic activity, isoflavones may act as anti-estrogens by competing with the more potent, naturally occurring endogenous estrogens (e.g., 17β-estradiol) for the estrogen receptor. This might be the reason why populations that consume large quantities of soy products daily (e.g., inhabitants of Far Eastern countries) generally have a reduced risk of estrogen-dependent cancers (Messina and others 1997).

Soybean and soy foods may also benefit bone health (Anderson and Garner 1998; Messina and others 2000). A clinical study of 66 postmenopausal women conducted at the University of Illinois (Erdman and Potter 1997) demonstrated that consumption of 40 g of isolated soy protein (ISP) containing 90 mg total isoflavones per day increased both bone mineral content and density in the lumbar spine by ~2% over a period of 6 months. Furthermore, Far Eastern women are reported to have significantly lower incidence of postmenopausal hot flushes and night sweating compared to Western women, probably because soy food is an important part of their diet (Albertazzi and others 1998). Yet the suggestion that soy food consumption may substitute for hormone replacement therapy (HRT) may require further study. Recent research has shown that not only soybean seeds, but also soybean leaf powder and ethanol extracts of soybean leaf, exert cardio-protective effects by modulating serum lipid profiles (Ho and others 2003). These findings are very interesting, but, again, more research is needed.

40.5.1.4 Phytosterols. FDA expanded the scope of a phytosterol heart-health claim in February 2003. The agency allowed a broader range of food products and dietary supplements to bear the heart health claim in labeling when they are formulated with 0.65 g of phytosterol ester or 0.4 g of free phytosterol per serving (www.cfsan.fda.gov/~dms/ds-ltr30.html).

40.5.1.5 Fiber. FDA adopted a final rule to a regulation authorizing a health claim for the role of β-glucan from whole oat sources in reducing the risk of coronary heart disease (CHD) in July 2003 (FDA, Federal Register of July 28, 2003 [68FR 44207–44209]).

40.5.1.6 D-tagatose. FDA authorized a dental health claim for D-tagatose in July 28, 2003 (FDA, Federal Register of 3 July, 2003 [68 FR 44207–44209]).

40.5.2 Qualified Health Claims

In July 2003 FDA began allowing qualified health claims for food in an effort to make it easier for food manufacturers to make health benefit claims for their products. Even if the scientific evidences in support of the claims are not conclusive, FDA has been helping consumers to obtain accurate, up-to-date science-based information about the health effects of these products. Qualified health claims have been approved for a number of foods, and conditions for their use have been specified (www.cfsan.fda.gov/~dms/hclmgui3.html, www.cfsan.fda.gov/~dms/qhc-sum.html). These foods and their nutraceutical components, and diseases against which they appear to be effective, are itemized in the following sections.

40.5.2.1 Selenium and Cancer. Selenium may help to prevent certain kinds of cancer. However, FDA has determined that the evidence for this is limited and inconclusive. Eligible foods are dietary supplements containing selenium.

40.5.2.2 Antioxidant Vitamins and Cancer. Some scientific evidence suggests that consumption of antioxidant vitamins may reduce the risk of developing certain kinds of cancer. However, the evidence is limited and is not conclusive. Eligible foods are dietary supplements containing vitamin E and/or vitamin C.

40.5.2.3 Nuts and Heart Disease. Scientific evidence suggests, but does not prove, that eating about 46.51 g (1.5 oz.) per day of most nuts as part of a diet low in saturated fat and cholesterol may reduce the risk of heart disease. Eligible foods are whole or chopped almonds, hazelnuts, peanuts, pecans, pine nuts, pistachio, Brazil nuts, and walnuts, or foods containing one or more of these nuts.

40.5.2.4 Omega-3 Fatty Acids and Coronary Heart Disease. Consumption of omega-3 fatty acids may reduce the risk of coronary heart disease. FDA evaluated the data and determined that, although there is scientific evidence supporting the claim, the evidence is not conclusive. Eligible foods are dietary supplements containing the omega-3 long-chain polyunsaturated fatty acids EPA and/or DHA.

40.5.2.5 Phosphatidylserine and Cognitive Dysfunction and Dementia. Consumption of phosphatidylserine may reduce the risk of dementia in the elderly. However, FDA concludes that there is little scientific evidence in support of this claim. Eligible foods are dietary supplements containing phosphatidylserine.

40.5.2.6 Folic Acid and Neural Tube Birth Defects. A level of 0.8 mg folic acid in a dietary supplement is more effective in reducing the risk of neural tube defects than lower amounts present naturally in foods. FDA does not endorse this claim yet. Eligible foods are dietary supplements containing folic acid.

40.6 FUNCTIONAL FOODS AND NUTRACEUTICALS: SAFETY ISSUES

As functional foods and nutraceuticals are being marketed in ever-increasing quantities for human consumption, it is absolutely essential to ensure that they are safe, and that they

meet high standards of quality. The biologically active components have to be identified and quantified, and the manufacturers must strive for consistency of product quality and levels of active components in the products. Above all, clinical studies must verify the safety and efficacy of the products, and must establish the proper effective dosage for the treatment of particular diseases and conditions. The optimal dosage has to be defined, as the dosage must be high enough to be effective, yet not so high that it is hazardous or causes adverse side effects or interacts in undesirable ways with other functional foods or nutraceuticals, or with prescription or nonprescription drugs.

It is highly advisable to consult a physician before planning to take any nutraceuticals or herbal supplements, especially if one has certain medical conditions, such as high blood pressure, thyroid dysfunction, psychiatric disorders, Parkinson's disease, blood clotting problems, diabetes, heart disease, epilepsy, glaucoma, or a history of stroke. Furthermore, consumers should not assume that functional foods and nutraceuticals are safe merely because they are labeled "natural". It is important to recognize the fact that

1. Functional foods and nutraceuticals may have harmful side effects in at least some individual cases, and
2. These products may tend to cancel or amplify the function of a prescription drug or over-the-counter drug, causing adverse health effects (American Academy of Family Physicians 2003; Mayo Clinic 2003).

Unfortunately, testing is not, at present, required for herbal health products, as these products are not subject to government regulations pertaining to product safety and standardization of quality and concentrations of active components.

Some examples of the problems that may arise through consumption of functional foods or nutraceuticals along with drugs are given in the following (American Academy of Family Physicians 2003; Mayo Clinic 2003):

40.6.1 Echinacea

Taking echinacea with anabolic steroids or medicines for treatment of irregular heartbeat, rheumatoid arthritis, or fungal infections should be avoided. Echinacea should not be combined with certain other drugs, as it may

1. Cause liver damage;
2. Stimulate the immune system and interfere with effects of immunosuppressants,
3. Raise the levels of HIV protease inhibitors and calcium channel blockers; or
4. Produce undesirable side effects when combined with anti-anxiety drugs.

40.6.2 Ephedra

(Also called "ma huang", "herbal ecstasy", or "mahuanggen.") Taking Ephedra products with caffeine, decongestants, stimulants, heart drugs, antidepressants, or asthma inhalers should be avoided. They can cause high blood pressure or uneven heartbeat, nervousness, or headache, and can lead to potentially fatal heart attacks or strokes.

40.6.3 Feverfew

Feverfew should not be taken with aspirin or other medicines that interfere with the clotting of blood. Feverfew may enhance this effect, causing spontaneous and excessive bleeding.

40.6.4 Garlic

Garlic should not be taken with aspirin or other medicines that interfere with the clotting of blood, or with immunosuppressants or HIV protease inhibitors. Combining garlic and anticoagulant medication may cause spontaneous and excessive bleeding. Besides, garlic may decrease the effectiveness of immunosuppressants and HIV protease inhibitors.

40.6.5 Ginger

Ginger should not be taken with aspirin or other medicines that interfere with the clotting of blood or with H2 blockers or acid-blocking medication. Ginger may increase the effect of anticoagulants and also increase the production of stomach acid, which would counteract the effect of anti-acid medications. On the other hand, ginger may lower the blood pressure or blood sugar levels, which may reduce the need for blood-pressure-lowering medicines or insulin.

40.6.6 *Gingko Biloba*

Gingko biloba should not be taken with aspirin or other medicines that interfere with the clotting of blood or with antidepressant or antipsychotic medicines, or insulin. It may increase the anticoagulant effect of these drugs and can cause bleeding as a side effect. *Gingko biloba* can also increase the levels of antidepressant drugs in the blood. When combined with antipsychotic drugs, it may cause seizures. In addition, it may affect insulin levels.

40.6.7 Ginseng

Ginseng should not be taken with aspirin or other medicines that interfere with the clotting of blood or with antidepressants, heart medication, insulin, or oral antidiabetic medicines. Ginseng combined with warfarin (coumadin) can increase the risk of excessive spontaneous bleeding. It can also interfere with digoxin's pharmacologic action. Moreover, it can reduce blood sugar levels in people with type-2 diabetes (requiring especially careful glucose-level monitoring).

40.6.8 Kava Kava Products

Kava kava products should not be taken with sedatives, sleeping pills, antipsychotic drugs, alcohol, or drugs for anxiety or Parkinson's disease. When combined with any of these drugs, kava kava can induce deep sedation and, in some cases, even coma. Liver damage resulting from the use of kava kava was reported in Europe in late 2001. FDA subsequently undertook an investigation of the product's safety.

40.6.9 St. John's Wort

St. John's wort should not be taken with alcohol or with any prescription medicines such as antidepressants, digoxin, asthma medication, oral contraceptives, blood-thinning medication, Tamoxifen, drugs for controlling blood pressure, or medicines for heart disease. St. John's wort affects the body's metabolism of these substances.

In conclusion, the benefits and risks of consuming physiologically active functional foods and nutraceuticals have to be balanced carefully, because

1. Biological responses may differ widely among different individuals;
2. Adverse effects are possible in some cases, and

3. These substances may interfere with the effects of prescription or nonprescription drugs or other functional foods and nutraceuticals.

Systematic regulation and quality control of functional foods and nutraceuticals marketed for human consumption are essential to public health and well-being.

40.7 REGULATION OF FUNCTIONAL FOODS AND NUTRACEUTICALS

There has been growing recognition of the key role of diet in disease prevention and treatment. Thus, the production and consumption of functional foods and nutraceuticals, the popular demand for them, and realization of their importance in promoting good health, have increased greatly in recent years. Accordingly, for manufacturers and consumers alike, there must be well-defined, science-based standards and regulations to ensure that these products have consistently high quality, that their components are identified and accurately quantified, and that they are safe (Stephen 1998). Product labels must list not only the components and their concentrations, but also warnings about possible adverse effects and interactions or interference with other substances, such as drugs and food supplements. In addition, stringent clinical trials must be performed to investigate the beneficial effects, efficacy, and adverse effects of the products, to establish the proper dosage for the treatment or prevention of specific medical conditions, to determine the range of doses that are safe, and to study the consequences of combining them with drugs and other substances.

Regulatory policies for functional foods and nutraceuticals are not well established in most countries of the world, except for Japan (see later), as there are so many different types of products with different health benefits. Moreover, there is considerable confusion about "what these products should be called, how they should be regulated, whether or not they raise safety concerns, and whether or not health claims should be permitted and so on" (Stephen 1998). In brief, the different national policies regarding functional foods and nutraceuticals in Canada, the European Union, Japan, the United States, Australia and New Zealand, are described in the following.

In its Food and Drug Act, Canada has, thus far, recognized no separate category for functional foods or nutraceuticals. Some "biological role claims", however, have been approved for certain foods through the Food Directorate. To gain official recognition of an effect of such a product on a specific disorder or disease (whether the product is eaten as food or prepared as a concentrate), an application for approval as a drug must be submitted under the Therapeutic Products Programme of the Health Protection Branch of Health Canada (Scott and others 1996; Smith and others 1996; Stephen 1998). However, advertising the supposed effects of functional foods and nutraceuticals on selected diseases and disorders specified in a list called "Schedule A" (e.g., hypertension, diabetes, arteriosclerosis, cancer, arthritis, and obesity) is prohibited. For instance, the manufacturer of a functional food or nutraceutical that tends to lower cholesterol levels is not allowed to publicize this effect (Smith and others 1996). The current system in Canada offers manufacturers the option of licensing and selling such products as "drugs" in accordance with the definition of drugs in the Food and Drug Act. This process is very expensive and imposes severe restrictions on marketing. Apart from that, most functional foods and nutraceuticals in Canada are marketed without regulation. Nevertheless, this situation has changed as Health Canada issued a revised Nature Health Product Policy in July 2003 and its regulation came into effect as of 1 January, 2004 (updated 20 October, 2006).

In contrast, the regulatory system of Japan has been supportive of the development and marketing of functional foods. The Ministries of Agriculture and Health and Welfare joined forces to develop a comprehensive policy to promote the manufacture of food components that confer potential health benefits. This policy is rooted in traditional Oriental lore, which holds that many foods and food constituents are effective in the prevention and treatment of disease. Accordingly, in 1991 the government established a system called "Foods for Specified Health Use" (FOSHU) for the purpose of licensing such substances (Stephen 1998). Their objective, above all, was to maximize the health of the growing numbers of elderly people in the population (Lapsley 1996). It has evolved through close collaboration among food industries, government, academics, and research organizations. Thus, accredited food industry organizations work closely with government agencies and food companies, and play a direct role in the regulation of functional food products under the regulations of FOSHU. The licensing process is clearly defined and is managed jointly by government and industry. As a result, a functional food is evaluated, and food manufacturers may make health claims for it. On being licensed and receiving an official FOSHU seal of approval, these foods may then be sold on the domestic market, and consumers have confidence in them. Currently there are over 150 FOSHU-approved products available in Japan.

In the 15 nations of the European Union, there are a number of initiatives concerning functional foods, but they appear to concentrate mainly on relevant scientific issues (Smith and others 1996; Stephen 1998). Currently, regulation of functional foods, food supplements, and/or nutraceuticals is voluntary and is therefore left to the discretion of each member country. There are no universal standards, regulations, or policies pertaining to such products. Therefore, the systems of regulation vary widely from one member nation to another, and many countries consider these products simply as foods. Claims relating to a disease are generally not permitted. If such claims are made, however, the products come under the regulations for drugs and other medicinal substances.

In the United States, there is no separate category or set of regulations for functional foods and nutraceuticals. These products fall under the regulations for conventional foods. They must be safe to be marketed as foods, and the ingredients must be "generally recognized as safe" (GRAS) or approved as food additives. Nevertheless, there is a distinction between dietary supplements and foods. For a new ingredient to be approved for use as a dietary supplement, it is submitted to the FDA 75 days before the supplement is to be put on the market. FDA then evaluates it and either accepts or rejects it on the basis of safety data provided by the producer. Where foods are concerned, however, if an ingredient is not already GRAS, it takes a long time to be declared GRAS. There are no definite rules to guide this process, and no clear standards for judging the data provided by companies. Having functional foods approved as GRAS is not a simple task.

Regarding botanicals used as food ingredients, the fundamental issues are the identity of the plant and identification and quantification of the phytochemicals in the plants. To settle the first issue, harvesting the correct genus of the plant is essential.

In Australia, the Parliamentary Secretary to the Minister for Health and Ageing Consumers recently released a policy statement called Food Standards Australia–New Zealand (FSANZ) – Food Labeling Issues, after a survey of consumers in Australia and New Zealand. The key findings of the survey were that the most commonly examined specifications on the labels were the "by" or "best before" dates, lists of ingredients, and information about health claims, allergens, GMOs, and novel or irradiated food declarations. The research also revealed that consumers want further information to help them to understand the basics of healthy eating and to make healthy choices of foods by

following the guidelines provided by food labels. As a result, FSANZ has undertaken to work with food industry, health professionals and educators to ensure that this information is available. This survey was very timely, as it was conducted just before December 2002, when the New Food Standards Code came into full force (www.foodstandards.gov.au).

40.8 PUBLIC EDUCATION AND DIETARY GUIDANCE

As a party to the Consumer Health Information for Better Nutrition Initiative of the U.S. Government, FDA is seeking ways to promote inclusion of dietary guidance statements on food labels. The agency is encouraging good nutrition among consumers in a variety of ways, including food manufacturers' dietary guidance statements, which are available from Federal government agencies. The National Cancer Institute (NCI), in a collaborative effort with FDA, recently issued an important dietary guidance message for consumers: "Diets rich in fruits and vegetables may reduce the risk of some types of cancer and other chronic diseases." Food manufacturers may also use this statement on food labels along with the new "5-to-9-Day" logo. FDA has pointed out that this statement about fruits and vegetables is only a "dietary guidance statement" and not a "health claim", emphasizing, however, that dietary guidance statements must be truthful and not misleading. FDA works cooperatively with Federal agencies on an ongoing basis to encourage the development and use of dietary guidance messages (FDA 2003). An example is FDA's small entity compliance guide (SECG) for a final rule on food labeling published in the Federal Register of July 11, 2003, entitled "Trans Fatty acids in Nutrient Content Claims, and Health Claims". Alternatively, this SECG is called "Food Labeling – Trans Fatty Acids in Nutrition Labeling, Nutrient Content Claims and Health Claims" (FDA, Federal Register, 68 (161), 50155–50156).

The average American eats over 4 g of salt a day. In order to reduce possible harmful effects of hidden salt in food, the National Institute of Health (NIH) advises healthy people to have no more than 2.4 g of salt (as sodium chloride) a day and 1.5 g for those with high blood pressure. Salt is concealed in common foods, especially restaurant foods and processed foods. Too much sodium increases the blood pressure, and high blood pressure has adverse effects on the heart, brain, and kidneys. The American Public Health Association, backed by many other health-care and medical groups, urge the processed food industries and restaurants to lower the amounts of salt in their foods (NIH 2003).

Another example of hidden food components that may be harmful is gluten, a protein found in wheat and related cereal grains. About 10–15% of the American population cannot tolerate gluten; indeed, gluten is actually toxic to some individuals. Today's consumers must check food labels to detect hidden gluten. They must be more cautious than ever nowadays, as gluten is found in more than 40,000 supermarket products, compared with 7000 products in the 1960s (www.glutenfree101.com).

A survey carried out jointly by the Food Marketing Institute (FMI) and Prevention magazine revealed that the choice of food purchases made by families with children depends mainly on convenience. However, most consumers would like to have more information to help them to eat more healthful foods and have a balanced diet (http://www.ift.org/ and http://www.fmi.org/mediatext.cfm?id = 565). In the United States, nearly 65% of adults and 15% of young people aged 6 to 19 are overweight, and 31% of the adults are classified as obese according to the National Center for Health Statistics of the Centers for Disease Control and Prevention. An even more alarming fact is that the estimated number

of overweight children and adolescents has nearly tripled in the past two decades according to the U.S. Surgeon General. The new survey showed that 74% of households with children and 63% with no children admit that their diets could be healthier. The survey results revealed the following primary reasons that the subjects did not have healthier diets:

1. They were "too busy" to eat healthy foods, they had no time to cook at home, and a third of the women worked outside the home.
2. "Healthy fast foods are hard to find." One third of shoppers would like to see a greater variety of healthy foods on the menus of fast-food restaurants.
3. "Healthy foods cost too much."
4. Friends and family members "do not care" about healthy eating habits, educating friends and family members about nutrition and the necessity of eating balanced meals to maintain good health is important.
5. There is "confusion about health claims"; consumers are confused about what qualifies as a healthy food product and what they should eat to have healthy and balanced diet (http://www.fmi.org/mediatext.cfm?id=565).

40.9 CONCLUSIONS

In recent years there has been enormous progress in the study of functional foods and nutraceuticals and their importance to the health of humans and animals, but there is a need for further research in many areas of this ancient, yet modern, field. To begin with, there is ample scope for more basic research that will lead to a better understanding of the mechanisms by which functional foods and nutraceuticals exert their beneficial (and, in certain cases, harmful) effects. This, in turn, should lead to advances in the applied aspects of the field. Thus the biologically active components must be identified and quantified using rigorous, standardized, internationally accepted methods. Concomitantly, clinical and epidemiological investigations are required to assess the effects of functional foods and nutraceuticals on human health, with attention not only to their efficacy but also to issues such as proper dosage, delivery methods, bioavailability, and safety (for instance, possible adverse effects arising from allergies or interference with prescription or over-the-counter pharmaceuticals or with other functional foods and nutraceuticals). Another important research area is exploration for the purpose of discovering as yet unknown medicinally beneficial substances in plants and other organisms (e.g., marine algae and animals). It is essential, however, that the discovery and subsequent exploitation of new sources of functional foods and nutraceuticals in nature be accomplished without damaging the environment or depleting populations of wild species.

Furthermore, the field of functional foods and nutraceuticals has political, legal, and administrative dimensions. Thus, laws and government policies, regulations, and guidelines must be established to authorize the marketing, labeling, and advertising of specific products on the basis of scientifically sound criteria for evaluating their efficacy, safety, and quality. The field is economically important as well. The production, processing, and marketing of functional foods are a thriving, multifaceted business. The sale of such products has expanded greatly in the recent past to meet rising public demand for such products as a consequence of increasing awareness of their beneficial effects on human health. A less direct but equally significant economic issue is the reduction in the cost of health-care that may be expected if public health is benefited by improvements in eating habits.

Finally, public education about functional foods and nutraceuticals is another vitally important aspect of this field. A healthful diet helps to prevent and ameliorate the chronic diseases that are so prevalent in modern society. Yet, poor eating habits and their inevitable harmful consequences constitute a serious, widespread problem. The more thoughtful members of the general public have become increasingly concerned about dietary issues, increasingly aware of the crucial importance of a balanced, healthful diet, and increasingly knowledgeable about the good health and improved quality of life that may result from regular consumption of functional foods and nutraceuticals.

41.1 INTRODUCTION

In the late 1980s, consumers began to recognize that certain foods and food supplements could have an impact on health. The first phase of this "health and wellness revolution" belongs to dietary supplements, where, through the passage of the Dietary Supplement Health and Education Act (DSHEA) in the United States in 1994, market dynamics changed significantly – initially to the positive and then to the negative (United States Food and Drug Administration 2004).

For the food industry, it has been a somewhat different story, which has yet to play itself out fully. The United States responded to industry pressure in 1990 by enacting the Nutrition Labeling and Education Act (NLEA) to allow manufacturers to promote the benefits of their food products (United States Food and Drug Administration 2003). This regulatory framework catalyzed the functional foods revolution in the North American marketplace, which welcomed new food product introductions, and a revival of science and consumer interest.

The global market for functional foods and ingredients is comprised of companies that see the industry as a growth opportunity and the ability to make higher margins. It has attracted players the size of BASF, DSM, Nestle, Cargill, Bayer, and Danone, as well many small but growing small- and medium-sized enterprises.

41.1.1 Functional Foods

In many respects, comparing the industry across regions is challenging due to the various definitions, and thus scope, of functional foods, dietary supplements and natural health products throughout the world. "Functional foods" is essentially a marketers' or analysts' term and globally is not recognized in law or defined in the dictionary. For the purposes of this chapter, the definition of functional foods as proposed by Health Canada will be used. In 1998, it was proposed that a functional food was "... similar in appearance to a conventional food, consumed as part of the usual diet, with demonstrated physiological benefits, and/or to reduce the risk of chronic disease beyond basic nutritional functions" (Health Canada 2000).

As a category, functional foods include:

- Conventional foods containing naturally occurring bioactive substances (such as dietary fiber in wheat bran to promote digestive regularity, or β-glucan in oat bran to lower blood cholesterol);
- Foods that have been modified, by enrichment or other means, in terms of the amount, type, or nature of their bioactive substances. An example is margarine that contains added phytosterol, an extract from plant sources that is known to interfere with cholesterol absorption, thereby lowering serum cholesterol levels; and
- Synthesized food ingredients, such as some specialized carbohydrates intended to feed microorganisms in the gut.

41.1.1.1 United States. The most commonly referenced definition for a functional food in the United States is that used by California-based Nutrition Business Journal (NBJ) (Anon 2003). NBJ defines a functional food as fortified with added or concentrated ingredients and/or marketed to emphasize "functionality" to improve health or performance. Unlike Health Canada's definition, NBJ includes "substantially fortified", "inherently functional", and "performance" foods within their definition.

41.1.1.2 Japan. Japan is the only country with a regulatory framework for functional foods. Foods for Specified Health Uses (FOSHU) are defined as those to which a functional ingredient has been added for a specific health effect, designed to promote or maintain good health. Under FOSHU such foods include those that contain functional substances that affect the physiological function and biological activities of the body; those that claim if used in the daily diet, one can hope for a specified health benefit. Under the legislation, such foods must be evaluated individually and approved by the government. FOSHU can also be used for dietary supplements (Japan Health Food and Nutrition Food Association 2004).

41.1.1.3 Europe. As in North America, several definitions of functional foods are used throughout the 15 countries of the European Union. The most widely accepted is "Foods that by virtue of physiologically active food components provide health benefits beyond basic nutrition" (Fielding and Frayn 1998).

41.1.2 Dietary Supplements

41.1.2.1 United States. In 1994, the Dietary Supplement Health and Education Act (DSHEA) was passed in the United States as an amendment to the Federal Food Drug and Cosmetic Act (United States Food and Drug Administration 2004). DSHEA regulates dietary supplements, which are defined as "a product, other than tobacco, intended to supplement the diet that contains at least one or more of the following ingredients: a vitamin, a mineral, a herb or other botanical, an amino acid, or a dietary substance for use to supplement the diet by increasing the total dietary intake; or a concentrate, metabolite, constituent, or extract or combination of any of the previously mentioned ingredients".

41.1.2.2 Canada. Canada is the only global jurisdiction that has legislation related to "natural health products (NHP)". These regulations became effective on January 1, 2004 (Government of Canada 2003). The new regulations apply to all NHPs, including homeopathic preparations, substances used in traditional medicine, a mineral or trace element, a vitamin, an amino acid, an essential fatty acid or other botanical, animal or microorganism-derived substance. These products are generally sold in a medicinal or "dosage" form. Until publication of these regulations, the working definition for a nutraceutical in Canada has been "a product that has been isolated or purified from foods and generally sold in medicinal forms not usually associated with food. Nutraceuticals have been shown to exhibit a physiological benefit or provide protection against chronic disease". Health Canada decided that the product category of nutraceuticals would be encompassed within NHP regulations.

However, like functional foods, although the nutraceutical category is not recognized in law, it is used extensively as a marketing term for plant and animal based bioactives and ingredients that are sold in a medicinal form.

41.1.2.3 Europe. In the EU, dietary supplements are referred to as "food supplements", the purpose of which are to supplement the normal diet and which are concentrated sources of nutrients or other substances with a nutritional or physiological effect, alone or in combination, marketed in dose form (European Parliament 2002). Such dosages are capsules, pastilles, tablets, pills and other similar forms, sachets of powder, ampoules of liquids, drop dispensing bottles, and other similar forms of liquids and powders designed to be taken in measured small unit quantities.

The EU adopted Directive 2002/46/EC on June 10, 2002, with the requirement that it be passed into national laws by all member states by July 31, 2003 (Hanssen 2004). It deals with laws relating to food supplements. The nutrients that are included are restricted to vitamins and minerals. Additional nutrients such as amino acids, essential fatty acids and fiber may be added later. For countries where products currently exist that included ingredients not yet on the EU Directive List, these will be able to continue to be marketed, but not permitted for EU-wide use. Until January 31, 2009, the authorities of the European Union Member States may provide derogations for vitamins and minerals and their forms not included in the Food Supplements Directive, as long as the following conditions are fulfilled:

- The substance in question was used in food supplements marketed in the Community prior to July 12, 2002;
- The European Food Safety Authority has not given an unfavorable opinion in respect of the use of the substance (European Commission 2006).

41.1.2.4 Japan. Since 2001, 13 vitamins, 13 minerals, and 101 herbal supplements have been regulated within the food category, rather than as drugs. In April 2001, Japan implemented new regulations allowing dietary supplement labels to provide health and efficacy information for the first time. Dietary supplements may now carry claims that are regulated under FOSHU or Nutrient content claims. Herbals that carry health claims are considered within the more stringent FOSHU regulations. Currently, 12 vitamins and 2 minerals have been placed with the nutrient content category. This area represents 20% of the nutritional supplements market, and the remaining 80% is classified as either FOSHU (requiring individual approvals for health claims) or "other food" for which no health or efficacy claims are allowed.

With regard to market segregation, functional foods and dietary supplements lie between the health-care continuum of foods and drugs as indicated in Figure 41.1 (Anon 2003).

41.2 THE GLOBAL MARKET

For 2004, the Nutrition Business Journal (NBJ) estimated current world consumption of dietary supplements and functional foods to be approximately US $182 billion. The

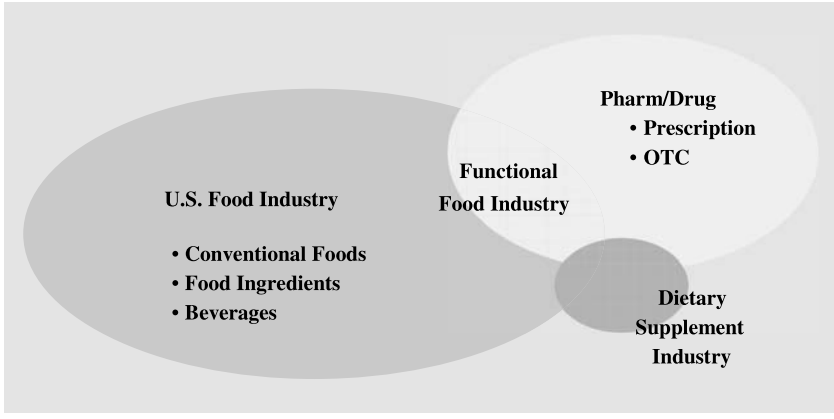

Figure 41.1 *Context for functional foods and dietary supplements.*

primary markets for supplements and functional foods are the United States, Europe, Japan, and Asia (Ferrier 2004). These regions are, for the most part, characterized by greater levels of economic development and more sophisticated economies. In the case of Asia, historical consumption patterns play a role.

The 2004 global functional food market is valued at over $70 billion. The United States, Europe, and Japan are the major markets for functional foods, capturing approximately 30% each, similar to the overall market capture for total sales in all nutrition categories. The United States is the most dynamic market for functional foods, with a growth rate of more than triple that of conventional foods at $\sim$9–12% per annum. It is anticipated that, based upon past data, the industry will witness steady and continuous growth to 2008, when projections of sales for functional foods globally near $95 billion (Ferrier 2005).

41.3 MACRO TRENDS AFFECTING THE FUNCTIONAL FOOD INDUSTRY

Several macro trends are driving the growth of the global functional foods industry.

41.3.1 The Rising Cost of Health-Care Related to Chronic Disease

The World Health Organization's 2003 report on diet, nutrition and the prevention of chronic disease noted that, "the burden of chronic disease is rapidly increasing worldwide" (WHO 2003). In 2001, chronic diseases contributed approximately 60% of all deaths worldwide and 46% of the total burden of disease. Almost half of these deaths are from cardiovascular diseases, obesity and diabetes. Increasingly, these diseases are also becoming more prevalent in developing countries. The WHO estimates that chronic disease will account for 70% of all deaths worldwide by 2020.

An increase in disease incidence leads to overall increases in the cost of health-care. In most developed countries these costs average between 9 and 14% of the gross national product (GNP). The United States, in particular, is facing steep increases in the cost of

delivering health-care. Along with the United States, Canada is among the top three of the G7 countries in terms of the cost of health-care per capita.

In the United States, health-care costs were $1.6 trillion in 2003 and are projected to reach $3.1 trillion by 2012 – or 17.7% of GNP. Spending by private health insurance has increased 10-fold since 1987. Costs increased from $3.6 billion in 1987 to $36.5 billion on obesity-linked illnesses in 2002. Total health-care spending on obesity in 1987 was 2% compared to 11.6% in 2002. The rise in treated disease prevalence, rather than the rise in spending per treated case, was the most important determinant of spending growth (Thorpe and others 2005).

According to Health Canada, in 2003 Canada spent approximately $121 billion on health-care (averaging $3839 per person) (Public Health Agency of Canada, Economic Burden of Illness in Canada, 2004). It is estimated that Canada's health-care system will cost $1.4 trillion by 2015 (Lussier 2005). Chronic disease accounts for a significant portion of that burden. Cardiovascular diseases, diabetes, and cancer, combined, cost the Canadian economy more than $55 billion annually (Public Health Agency of Canada 2002). As a specific example, Canada's health-care burden is expected to increase as a result of obesity in Canada. The direct cost of obesity to Canada's health-care system is estimated to be $1.8 billion (Heart and Stroke Canada 2006).

In part, the increase in health-care costs is related to an aging population. During the twentieth century, the number of Americans aged 65 years and above increased 1100%. By the year 2035, it is estimated that 70 million people will be in this age bracket (U.S. Census Bureau 2005). By 2010, the number of people over 50 years old will increase by 48%; in contrast, the group aged 13–24 years will increase by only 16%.

Currently, more than 75% of those over 65 years old suffer at least one chronic disease, whereas 50% have at least two, a situation that imposes a tremendous burden on the health-care system.

Dietary intervention is one pillar within a successful health-care mandate. Any effective dietary intervention policy must begin in early life and stress the importance of a life-style approach. Governments are attempting to develop measurements to benchmark the dietary practices of the population to identify areas for improvements and to track changes in disease incidence as a result of health policy initiatives. The Japanese government has been very successful in implementing polices that capture these elements.

The World Health Organization has created new guidelines for governments in an attempt to reduce global chronic diseases (WHO 2005). The guidelines are featured in a comprehensive survey, "Preventing Chronic Diseases: a vital investment", which charts the rise of preventable deaths from heart disease, stroke, cancer, and diabetes in nine EU countries. In the report, 80%, or 36 million, deaths from heart disease, stroke, cancer, and adult-onset diabetes could be prevented through life-style modifications, over the next 10 years.

The report calls for a series of measures to be introduced to reach the target of cutting deaths by 2% per year by 2015. These include limiting the availability of high-fat, high-salt, and high-sugar foods, while other milestones are intended to encourage governments to implement food-labeling legislation and increase regulation of food marketing aimed at children.

Although the strategy is not enforceable, the surrounding debate generated by this and other reports on rising obesity in the world continues to put pressure on the food industry to offer healthier foods.

41.3.2 The Role of Food in Prevention Strategies

There is limited information regarding the impact of nutritional strategies in disease prevention and health-care cost reduction. Some case studies, however, are available that support the use of functional foods to improve the health of populations.

According to Unilever, a reduction of LDL cholesterol by 14% through the consumption of a cholesterol-lowering margarine, if sustained over a five-year period, could result in a decrease in coronary risk in the UK population of around 25% (Unilever UK 2001). If this risk reduction were achieved in practice, this would reduce UK heart disease patient numbers by 250,000 and save the UK health-care system £433 million.

One of the principal examples is the introduction of margarine spreads fortified with plant sterols in the United Kingdom. The UK National Health Service estimated that these products have the potential to lower health-care costs for cardiovascular disease by £100 million per year. An added benefit to this cost savings is that fact that this reduction can be delivered at an annual cost of only £70 per patient per annum, which is borne at the expense of the patient and not the government (UK National Health Service 2000).

In Canada, Holub (2002) suggests that there is a potential for the Canadian government to save an approximate $19 billion in health-care costs per annum with the introduction of several functional foods and nutraceutical ingredients, including citrus pectins, guar gum, plant sterols, long-chain omega-3 polyunsaturated fatty acids, cholestin (red rice yeast) and policosanol into the diet.

41.3.3 Safety and Toxicology Aspects Related to Functional Foods and Nutraceuticals

Functional ingredients, although intended to produce a physiological effect to reduce chronic disease risk or otherwise optimize health, may also produce adverse effects under certain circumstances due to the fact that they encompass elements of drugs, nutrients, and food additives (Kruger and Mann 2003). Thus, assurance of safety for such ingredients is critical, particularly because the general population consumes them in an unsupervised manner (i.e., without medical oversight). When evaluating the safety of functional ingredients, clinical substantiation of safety is critical and, in particular, whether current or historical human exposure is associated with an adverse health outcome.

In the United States, health ingredients can be marketed as dietary supplements, food additives, or as generally recognized as safe (GRAS) ingredients. The regulatory requirements to determine safety are different for each of these categories. In 1997, the Food and Drug Administration (FDA) proposed replacing the current GRAS affirmation process with a notification procedure by which any person may notify FDA of a determination that a particular use of a substance is GRAS. Under the proposed notification procedure, the FDA evaluates whether the submitted notice provides a sufficient basis for a GRAS determination and whether information in the notice or otherwise available to FDA raises issues that lead the agency to question whether use of the substance is GRAS. Notification is not mandatory if the sponsor chooses to inform the FDA of its GRAS determination. The FDA does not make its own determination of the GRAS status of an ingredient. A substance is GRAS if its use in food has a proven track record of safety based either on a history of use before 1958 or on published scientific evidence (Kruger and Mann 2003).

Under DSHEA, no requirement for pre-market approval is required for dietary supplements, which include "vitamins, minerals, herbs or other botanicals, amino acids, or

other dietary substance[s] for use by man to supplement the diet . . . including concentrate, metabolites, constituents, extracts, or any combination . . . ". Such ingredients must not present "a significant or unreasonable risk of illness or injury" a standard that has been criticized by some experts as reducing the criteria of safety compared with food additives or GRAS ingredients (Burdock 2000).

There are several issues critical to the evaluation of the safety of a functional ingredient (Kruger and Mann 2003). First, due to the fact that these ingredients are physiologically active, mechanisms of action for pharmacologic activity are essential to determine consequences of exposure at varying doses. Secondly, functional ingredients can be single compounds, complex mixtures, or products derived from novel sources/processes – each of which presents unique safety issues, which must be assessed on a case-by-case basis. Thirdly, potential exposure from a functional ingredient must be compared to its determined safe level of intake. Finally, potential adverse drug–food interactions must be assessed.

Although a functional ingredient is intended to produce optimized consumer health, because there is potential for lifetime exposure and consumption is unsupervised, the assurance of safety is critical. The primary measure of safety must be derived from well-controlled randomized, double-blind human clinical intervention trials. Safety must encompass an understanding of the physiologic activity of the functional component, not only as it relates to a potential health benefit, but any potential toxicological effect that may result.

41.3.4 Globalization of the Food Industry

For global survival, more companies are experiencing corporate mergers and acquisitions. As companies seek to gain market share, the functional food market has become increasingly attractive, with larger margins than the conventional food industry and in some regions triple the growth rate. Many large multinational companies see the functional food industry as a way to escape their product being considered a commodity, as the profit margins in functional foods can be between 5 and 6% and sometimes higher, whereas in conventional food products the margins can be as low as 1–2%.

The globalization trend is very evident in Europe, where currently 30 of the largest food companies control 70% of the market compared with 51% of the market in 1992. M + M Planet Retail market research predicts that Europe's top 30 companies could dominate 80–90% of the grocery trade in a few years. This is in part due to the fact that Europe is a contained market where companies from global regions have difficulty in competing as successfully as European companies (AROQ 2003).

The European model for the consolidation of food companies is not unique. Table 41.1 provides a list of the top ten food companies, the location of their headquarters, 2002 sales, growth compared to 2001 sales and the type of food products marketed (Prepared Foods 2002).

Like the traditional food industry, the functional food industry is also consolidating. Figure 41.2 depicts the market consolidation that is present in the North American functional food industry, with five companies controlling nearly 40% of the market. The top 50 control nearly 80% of the market (Anon 2003).

At first glance, it would appear that the companies listed in the top ten of North American functional food companies (Table 41.2) are conventional food companies. However, the many factors in play in the global food market are forcing such companies

TABLE 41.1 Global Top Ten Food Companies.

Company	Headquarters	Food Sales Billions $	% Change vs Prior	Food Type
Nestle	Switzerland	$46.2	+20	Diversified
Kraft Foods	Northfield, IL	$38.1	+12	Diversified
ConAgra	Omaha, NB	$27.6	+2	Diversified
PepsiCo	Purchase, NY	$29.9	+32	Beverages, snacks
Unilever	London/Holland	$26.7	+2.5	Diversified
ADM	Decatur, IL	$23.5	+17	Ingredients, grain
Cargill	Minn., MN	$21.5	+3	Grain based
Coca-Cola	Atlanta, GA	$20.0	−2	Beverages
Diageo	London, UK	$16.6	+0.7	Alcoholic beverages
Mars Inc	McLean, VA	$15.3	+7	Confections

to shift their focus to health and wellness in an attempt to remain ahead of the functional food wave and maintain market share (Anon 2003).

Pepsi has announced plans to have half their product portfolio be "more nutritious", while Nestlé is employing a nutrition-focused acquisition strategy to help shift their image to a "wellness and well-being" company rather than food and beverage company. These companies are seeking to improve product portfolios by releasing new products or redeveloping products so that they are perceived as "healthy" products.

41.3.5 Consumers' Focus on Prevention of Illness

Consumers are a critical driving force behind the development of functional food and nutraceuticals. As they strive to maintain good health into old age, they are attempting to take greater control over their health-care needs. With the rising incidence of obesity and the significant increases in the rates of chronic disease, consumers are becoming increasingly aware of the link between diet and medical disorders. Given the serious statistics related to the increasing death rates and of course, the costs of disease, to Western societies, it is no surprise that consumers are seeking alternatives to conventional medicine, which has been dominated for decades by an attitude of "treat" rather than "prevent" illness.

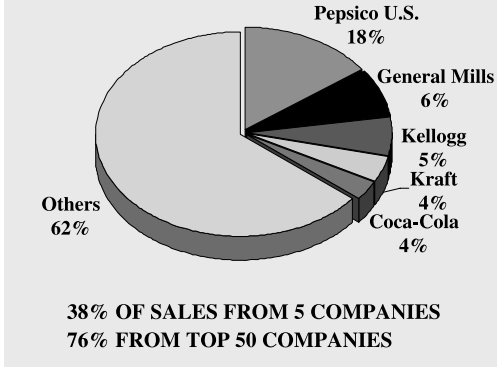

Figure 41.2 *Top functional food companies.*

TABLE 41.2 Top Ten U.S. Functional Food Companies (Sales in $U.S. Billions).

Companies	2000	2001	2002	2001 Growth	2002 Growth
Pepsico U.S.	3113	3441	3806	11%	11%
General Mills	1305	1335	1313	2%	−2%
Kellogg	990	1026	1058	4%	3%
Coca-Cola	565	759	850	42%	12%
Kraft	679	702	738	3%	5%
Red Bull	200	436	690	118%	58%
Campbell Soup	520	559	600	7%	7%
Ocean Spray	455	47	487	5%	2%
Nestle	347	393	459	13%	17%
ConAgra	405	396	415	−2%	5%

41.4 UNITED STATES

41.4.1 Market

In 2004, the sale of nutrition products consisting of dietary supplements and herbs, natural and organic foods, functional foods and natural personal care products, generated $68.6 billion in consumer sales. The dietary supplement market generated $20.9 billion in the United States, growing only 1–3% from 2003. The functional food market grew 9% from sales of $22.7 billion in 2003 to sales of $24.8 billion in 2004, growth generated principally by an expanding range of fortified foods, improved ingredients, and better taste profiles. In comparison, a growth rate of only 1.6% was witnessed for total food sales. Functional foods, however, represent less than 4% of total food sales in the United States. By 2010, however, NBJ expects functional food sales to account for 5.2% of total food sales in the United States, or approximately $31.2 billion (Ferrier 2005). The average rate of growth of the functional foods and dietary supplement segments in the United States is estimated by NBJ to be 6.8% and 4.2%, respectively, for the years 2004 to 2008 (Ferrier 2004).

A key characteristic of the U.S. functional food market is a large focus on disease and its prevention. Products aimed at lowering blood cholesterol levels and cancer risk as well as weight loss, have characterized the U.S. market. The use of botanicals in functional foods is much more popular than in Europe or Japan. Breads and grains, especially enriched breakfast cereals, followed by functional beverages (teas and energy drinks) are the primary functional food products in the U.S. market. Snack foods, including nutrition bars, are one of the fastest growing functional categories, experiencing a 23% rate of growth in 2003 (Ferrier 2004).

41.4.2 Regulatory Review

The ability to link a food or food component to health is based on sound scientific evidence, with the desired standard being replicated, randomized, placebo-controlled, intervention trials in human subjects (Hasler 2002). Once a sound scientific basis has been established for a food, the process for obtaining a health claim for the product can be initiated.

There are three basic types of health claims: structure/function (e.g., calcium helps to build strong bones), risk reduction (e.g., calcium helps reduce the risk and progression of osteoporosis), and therapeutic (e.g., product X is indicated for the treatment of osteoporosis).

Currently the ability to utilize health claims to promote the nutritional value-added attributes associated with functional foods varies internationally.

The United States has a wide variety of fortification policies and health claims labeling, which permit consumers to make informed dietary choices. Health claims that can be used on food and dietary supplement labels fall into three categories: risk reduction claims, nutrient content claims, and structure/function claims. The responsibility for ensuring the validity of these claims rests with the manufacturer, Food and Drug Administration (FDA), or, in the case of advertising, with the Federal Trade Commission (FTC).

The Nutrition Labeling and Education Act (NLEA) of 1990 directed the FDA to change the way that food labels were regulated, in order to make additional nutritional information available to consumers. As defined in this act, a health claim is a "statement that characterizes the relationship of a substance to a disease or a health-related condition, typically in the context that the regular dietary consumption of a substance 'may reduce the risk' of a specific disease or health condition". Within the labeling claims, references that the food is intended to "cure", "mitigate", or "prevent" any disease are not permitted.

In 1994, FDA reviewed several diet–disease relationships and established seven allowable risk reduction health claims that can be made on conventional foods as long as they meet specific nutritional criteria related to fat, saturated fat, cholesterol, sodium, vitamin A, vitamin C, iron, calcium, protein, and fiber.

In January 1997, the FDA approved the first food-specific health claim under the NLEA, in response to a petition from the Quaker Oats Company. The authorized health claim describes the relationship between consumption of whole oat products and coronary heart disease risk reduction.

The FDA Modernization and Accountability Act (FDAMA) became law in November 1997 (U.S. Food and Drug Administration 2001). It contains provisions to reduce the regulatory hurdles in the health claim approval process. Specifically, it directs the FDA to authorize health claims that are based on the published authoritative statements from U.S. Government agencies such as the Centers for Disease Control (CDC), the National Academy of Sciences (NAS), or the National Institutes of Health (NIH). An authoritative statement is "about the relationship between a nutrient and a disease or health-related condition". Within FDAMA, health claims can be made without going through the lengthy FDA review process, if they have already been published by these agencies. Premarket notification to the FDA of 120 days is required. In July 1999, General Mills received no objection for a claim linking whole grain foods to reduced risk of heart disease and cancer, based on statements from the National Academy of Sciences.

In December 2003, the FDA's *Consumer Health Information for Better Nutrition Initiative* was announced (U.S. Food and Drug Administration 2003). The new system allows the use of qualified health claims when there is emerging evidence for a relationship between a food, food component, or dietary supplement and reduced risk of a disease or health-related condition. In this case, the evidence is not well enough established to meet the significant scientific agreement standard required for FDA to issue an authorizing regulation. Qualifying language is included as part of the claim to indicate that the evidence supporting the claim is limited (see Table 41.3). Both conventional foods and dietary supplements may use qualified health claims under this new legislation.

TABLE 41.3 Standardized Qualifying Language for Qualified Health Claims.

Scientific Ranking[a]	FDA Category	Appropriate Qualifying Language[b]
Second level	B	"... although there is scientific evidence supporting the claim, the evidence is not conclusive".
Third level	C	"Some scientific evidence suggests ... however, FDA has determined that this evidence is limited and not conclusive".
Fourth level	D	"Very limited and preliminary scientific research suggests ... FDA concludes that there is little scientific evidence supporting this claim".

[a]From Guidance for Industry and FDA: Interim Evidence-based Ranking System for Scientific Data.
[b]The language reflects wording used in qualified health claims as to which the agency has previously exercised enforcement discretion for certain dietary supplements. During this interim period, the precise language as to which the agency considers exercising enforcement discretion may vary depending on the specific circumstances of each case.

The new regulations mean that substantial agreement among scientists on whether the food or ingredient provides the health benefit claimed will not be required and food manufacturers will be able to petition the FDA to use health claims that are already approved for dietary supplements. The FDA now will use the standard of the "reasonable consumer" and "weight of evidence" to evaluate claims. The weight of the scientific evidence standard is a radical departure from the standard of evidence required for health claims under NLEA (now referred to as "A" claims).

The FDA says it believes that its new policy will enable the distribution to consumers of scientifically supported health information. As of the end of 2005, there are 14 disease-related risk reduction claims allowed in the United States as well as 14 "qualified" claims (U.S. Food & Drug Administration 2006) (Table 41.4).

41.5 EUROPEAN UNION

41.5.1 Market

For dietary supplements like functional foods, the EU represents a dichotomous market with regional differences apparent in market growth and individual product sales. According to The-infoshop (2006), the market is estimated to be worth $6.5 billion (around €5.2 billion) in 2005, the growth rate is expected to peak at 4.4% over the next year, then drop to a steady 4.1% for the subsequent five years. By 2011, the market is predicted to be worth around $8.2 billion (€6.6 billion).

The European market for functional foods in 2002 was worth about €5.7 billion, and is forecast to grow by an average of 7.5% per year, over the next five years, to reach a value of €8.2 billion by 2007, at 2002 prices and exchange rates (Euromonitor 2002).

41.5.2 Regulatory Review

Directives within the EU continue to pose problems for regulators and marketers alike. The EU adopted Directive 2002/46/EC on June 10, 2002, with the requirement that it be passed into national laws by all member states by July 31, 2003 (Hanssen 2004). It deals with laws relating to food supplements and includes only vitamins and minerals.

It should be emphasized that the obstacles to marketing functional foods are high. There are currently EU-wide initiatives to modify health claims regulation, which were expected to be complete by 2005 but have been delayed due to disagreements between the EU Parliament

TABLE 41.4 Allowed Health Claims in the United States (December 2005).

NLEA

- Calcium and osteoporosis
- Sodium and hypertension
- Dietary fat and cancer
- Saturated fatty acids, cholesterol and coronary heart disease
- Fiber-containing grain products, fruits, vegetables and cancer
- Fiber-containing grain products, fruits, vegetables and risk of coronary heart disease
- Fruits, vegetables and cancer
- Folate and neural tube defects
- Dietary sugar alcohols (sorbitol, xylitol, mannitol) and dental caries
- Dietary soluble fiber (whole oats and psyllium) and coronary heart disease
- Soy protein and coronary heart disease
- Sterols/stanols and risk of coronary heart disease

FDAMA

- Whole grains and coronary heart disease and certain cancers
- Potassium and sodium and hypertension

Qualified

CANCER

- Tomatoes and prostate, ovarian, gastric, and pancreatic cancers
- Calcium and colon/rectal cancer and calcium and colon/rectal polyps
- Green tea and risk of breast cancer and prostate cancer
- Selenium and certain cancers
- Antioxidant vitamins and risk of certain cancers

CARDIOVASCULAR DISEASE

- Monounsaturated fatty acids from olive oil and coronary heart disease

OMEGA-3 FATTY ACIDS

- Omega-3 fatty acids and reduced risk of coronary heart disease
- Walnuts and coronary heart disease
- Nuts and coronary heart disease
- Folic acid, vitamin B_6, and vitamin B_{12} and vascular disease

COGNITIVE FUNCTION

- Phosphatidylserine and cognitive dysfunction and dementia

DIABETES

- Chromium picolinate and a reduced risk of insulin resistance, type 2 diabetes

HYPERTENSION

- Calcium and hypertension, pregnancy-induced hypertension, and preeclampsia

NEURAL TUBE DEFECTS

- Folic acid and neural tube defects

and Council on health claims and notification procedures (European Commission 2005). Should EU-wide claims be approved, many industry experts believe that only large EU-based companies will be able to fulfil requirements for the scientific support for health claims that will be required and ensuring accurate translation of claims into over ten different languages.

41.6 JAPAN

41.6.1 Market

The dietary supplement market in Japan remains undeveloped in comparison with the United States, and Europe. The regulatory environment for nutritional supplements is restrictive and cumbersome (International Business Strategies 2001). Most dietary supplements are marketed through nonretail venues including the Internet and multilevel marketing firms.

Although Japan has been slow to recover from an overall economic downturn, its nutritional supplement market has been growing steadily for the last 10 years. In 1994 the market was approximately $5.0 billion, 10 years later it has doubled to $11.1 billion, an average of 11% per year growth (Yamaguchi 2005). In 2001 the market grew 22%, its largest single year growth to date. Between 2002 and 2003, growth slowed to just over a 5% increase, but in 2004, the market bounced back to double digit growth again. Despite years of economic slowdown and a difficult regulatory environment, the Japanese nutritional supplement industry showed its resilience by growing 12% in 2004 (Yamaguchi 2005).

Since the inception of FOSHU in 1991, functional food sales have been growing at an average of 25% annually. Japan is widely recognized as the most developed and established market for functional foods in the world and has the second largest functional food market behind the United States, with a value of approximately $16 billion in 2005 (Yamaguchi 2006). The Japanese spent $130 per person per year on functional foods compared with $77 per person per year in the United States, $46 for Europeans and an estimated $3 or so for other Asian countries.

Since 1990, it is estimated that over 5500 new functional foods have been introduced in Japan, an average of about 400 a year. There are 1500 to 2000 functional foods on the market and 500 of them have qualified for FOSHU status. The FOSHU market currently accounts for nearly $4.1 billion of the total health food industry in Japan, which is estimated to be worth $12 billion in 2004. In 2004, there were approximately 500 products approved by FOSHU (Yamaguchi 2006).

Currently, the "nonhealth claim" functional food market represents the largest sector of Japan's food industry at around $8 billion. This is followed by a newer category known as Foods with Nutrient Function Claims at an estimated $5 billion and including over 1000 products according to a recent Japan market report (Japan Health Food and Nutrition Food Association 2003).

41.6.2 Regulatory Review

Planning a strategy for functional food marketing in Japan is not an easy task. Food and supplement companies are faced with a number of pathways in a maze of regulations. FOSHU is one of the five categories covered under "Foods for Special Dietary Uses". Since the passage of FOSHU, the public's interest in the relationship between nutrition, diet, and life-style-related diseases and disorders has flourished.

A 2005 update to the FOSHU regulation has created three new categories of products: qualified, standardized, and disease risk reduction. Of the seven health benefit categories approved under FOSHU, 54% of products and 67% of sales are generated by the gastrointestinal health foods category. Functional pre- and probiotic drinks and yogurts dominate the market. Other ingredients approved include fiber sources; oligosaccharides; peptides and proteins; lactic acid bacteria; diacylglycerides and minerals such as calcium and iron. Smaller categories include noncariogenic sweeteners, polyphenols, chitosan, β-carotene, green tea catechins, and DHA.

41.7 THE GLOBAL BUSINESS OF FUNCTIONAL FOODS AND NUTRACEUTICALS

The global market for functional foods and ingredients is comprised of companies that see the industry as a growth opportunity and the ability to make higher margins. Although there are significant opportunities for market success, there are many challenges involved in the development and positioning of functional food products. Generally, it requires longer moving of such products into the market, primarily due to the length of time (and resources) required to prove the science behind the products. Long-term strategies require endurance, focus, and patient capital. Many investors are often not prepared to wait for financial returns that may not come to bear for 10–15 years.

Companies that have had market success to date have done so based on a clear understanding of consumer issues. For example, probiotic products have been successful in many areas of Europe because of consumer understanding of the importance of gut health. Eye health on the other hand is of great concern in both North America and Japan but to a much lesser degree in the EU.

Also of importance in building successful functional food companies is a well-established local food and food development industry that can assist with new product development and food applications for ingredients. These traditional food companies have established distribution channels in their respective domestic markets and often export markets as well.

Crucial to tapping into the potential for functional foods and supplements is establishing a market-friendly regulatory framework. Japan was the first jurisdiction globally to put in place regulatory reforms to encourage companies to utilize health claims to develop healthier foods and to communicate those messages to consumers. Part of the reason this system developed in Japan was due to that country's concern over its aging population. Food retailers and marketers are constantly looking for opportunities to directly address problems associated with aging. Europe is another leader in functional food development, benefiting from excellent public awareness of the health benefits of foods as well as a significant focus upon research. The United States is well established as another health-claim friendly environment for both food and supplement products.

41.8 CONCLUSIONS

Several trends have led to an interest in functional foods and dietary supplements by the industry, consumers, health-care professionals, and government, one of the most significant being the movement away from a prescription approach to disease treatment to a

focus upon long-term disease prevention. Functional foods and supplements will continue to grow at a strong and steady pace as consumer interest and acceptance of these products, as well as scientific substantiation of safety and efficacy, increases.

From an industry point of view, functional foods and dietary supplements offer one of the most lucrative ways to add value to existing products and to innovate with new ones. These products are being developed by companies globally in response to growing consumer demand as well as to create higher-margin, value-added products for the manufacturers and inevitably their customers and shareholders. Of extreme importance, functional foods and supplements offer the opportunity to positively impact health-care costs, which will become an increasingly significant burden to governments globally.

42.1 INTRODUCTION

Dietary regime is an integral part of a healthy life-style. Recognition of the role of specific foods in diet for the prevention and control of disease and improvement of body functions is increasing. Present-day consumers are becoming more health-conscious. Accordingly, they are looking for foods associated with health benefits beyond their inherent nutritive

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

value. They are motivated by their desire to control individual well-being, promote health, prevent disease, and manage certain disease states.

The current trend to provide specific health benefits beyond sustenance accorded by food intake has roots in ancient medicine. The prevention and management of disease was recognized in India some 5000 years ago with the development of Ayurvedic (Science of Life) medicine. Use of active ingredients isolated from plants, herbs, minerals, and animals formed the core of this medical practice to prevent disease and treat certain disorders. The emphasis was prevention and management of common disorders by following specific dietary patterns in response to individual body requirements. Later, in the third century B.C., Chinese emperor Shen Nong discovered that certain plants and herbs have medicinal values.

An interactive discipline of nutrition and food science has produced an array of food products that represent a vibrant and dynamic segment of the food industry. Such foods are termed as functional foods, nutraceuticals, wellness foods, or designer foods. Functional foods are characterized by their similarity with conventional foods, but when consumed as a part of the normal diet, they confer a certain health benefit to the consumer. The functional aspect may be ascribed to a naturally occurring functional component of the food or it may be made functional by incorporating functional ingredients.

Dairy products are naturally "functional" because of their calcium content and their ability to contribute specific health-promoting properties such as physiologically active proteins, peptides, conjugated linoleic acid, sphingolipids, and butyric acid (Chandan 2007). The functional attributes are further enhanced by the addition of ingredients demonstrated to possess positive physiological effects, such as probiotics, prebiotics, fiber, phytochemicals, omega-3 (ω-3) polyunsaturated fatty acids, soy proteins, antioxidants, plant sterols, lutein, chondroitin, glucosamine, and other functional ingredients (Shah 2001). In Japan, such foods are defined as foods for specified health use (FOSHU). The Ministry of Health and Welfare in Japan certifies these foods. In other countries, no formal definition of functional foods has been adopted.

The nutrition industry in the United States is of the order of $22 billion. It comprises vitamins and minerals, herbals and botanicals, sports meal and specialty, natural and organics, natural personal care, and functional foods. The functional foods comprise 37% of this industry, totaling about $8 billion. In 2003, the functional food market was 4% of the retail food sales of $555 billion and projected to grow to $45 billion in 2010 (Childs 2005).

The popularity and fast growth rate of functional foods are driven by:

1. A steep rise in health-care costs and an emphasis on prevention of disease at the government and consumer levels.
2. A rise in aging population (65 years and above), which in the United States is projected to be 33% of the total population by 2030. This segment of the population is particularly interested in healthier foods for improving health and quality of life.
3. Advances in nutritional and health sciences, food technology and biotechnology, making it possible to identify health attributes of functional ingredients and foods, and making it feasible to make them available to the consumer.
4. A widespread accessibility of health, nutritional, and medical information through the media, including the Internet.
5. Flexibility of regulatory control, facilitating marketing of functional foods.
6. A growing trend in consumers taking an active role in improving health through foods.

42.2 FUNCTIONAL INGREDIENTS FOR USE IN DAIRY FOODS

Dairy foods contain various constituents known for contributing health benefits. Among the milk constituents, whey proteins are reported to modulate the immune system, decrease hypertension, reduce the risk of cancer and heart disease, and help in nutrient transport and absorption (Hoolihan 2004). Calcium, magnesium, phosphorus, fluoride, and vitamin K in milk play a significant role in bone health and prevention of osteoporosis in later life. The ratio of calcium, phosphorus, and magnesium in milk is ideal for rapid transfer to bone mass. Calcium reduces the risk of colon cancer, formation of kidney stones, and is helpful in obesity control. Several components of milk fat possess functional value. Butyric acid has been shown to reduce the risk of colon cancer. Conjugated linoleic acid is reported to modulate the immune system and protect against cancer of stomach, colon, breast, and prostrate. Sphingolipids may reduce the risk of cancer and cardiovascular disease (Miller and others 2000). The phospholipids act as anticancer agents, antimicrobial agents against gastrointestinal pathogens, and protect against Alzheimer's disease, depression, and stress. Phosphatidylserine is recognized for reducing the risk of dementia in the elderly. The milk fat globule membrane is reported to exhibit health-promoting properties. Its components show cholesterol-lowering attributes, possess inhibitory properties against cancer cell growth, and inhibit stomach-ulcer-causing *Heliobacter pylori*. Butyrophilin, another component of the milk fat globule membrane, is a possible suppressor of multiple sclerosis. Xanthine oxidase has antibacterial characteristics. Although the functional food value of dairy ingredients is well established, it can be further enhanced.

In general, several ingredients for enhancing the functional value of foods have consumer acceptance, including oats, certain fruits including pomegranate and cranberries, vegetables including broccoli, soy, nuts, fish, whole grains, red wine, and olive oil. A number of dairy products and compounds isolated from milk fractions (whey peptides, lactoferrin, conjugated linoleic acid, galacto-oligosaccharides) are also

TABLE 42.1 Modification of Foods to make them Functional Food.

Modification	Health Benefit
Add probiotics	Enhance gastrointestinal health and immune function, lower risk of colon cancer
Add prebiotics	Enhance gastrointestinal health and immune function, lower risk of colon cancer
Add dietary fiber	Increase stool bulk and prevent constipation, reduce cholesterol and risk of heart disease, lower risk of colon cancer
Add minerals (calcium and magnesium) and vitamins	Improve nutritive value, reduce osteoporosis risk, control hypertension, and reduce risk of colon cancer
Add bioactive peptides	Control hypertension, enhance immune function, and increase bioavailability of mineral
Add omega-3 polyunsaturated fatty acids	Reduce risk of heart attack and certain cancers, enhance immune function
Incorporate phytosterols/extracts/concentrates	Provide antioxidants, lower risk of cardiovascular disease and cancer, reduce serum cholesterol and blood pressure
Add soy protein/isoflavones	Reduce risk of certain cancers and heart disease

Source: Adapted from Shah (2001).

members of the functional ingredient group. Ingredients rich in ω-3 fatty acids (docohexanoic acid and eicosapentaenoic acid), plant sterols, lutein, chondroitin, and glucosamine are popular choices for consumers seeking functional foods. Table 42.1 lists approaches to converting foods into functional foods.

In the case of dairy foods, specific ingredients of choice in the marketplace are probiotics, prebiotics, fiber, soy protein, plant sterols, and fortification with vitamins, calcium, and magnesium.

42.2.1 Probiotic Cultures

Probiotics are defined as a food or supplement containing defined strains of living microorganisms that on ingestion in certain doses exert health benefits beyond their inherent basic nutrition. They are believed to contribute to the well-being of the consumer by improving the host's microbial balance in the gastrointestinal tract (Chandan 1989, 1999; Shah 2001; Gilliland 2003). This definition stresses the importance of ingestion of several hundred millions of live and active microbial cultures. Recent advances in probiotic research show much promise in new product development of functional foods based on milk. There has been marked proliferation in the number of probiotic products on the market. Milk is an excellent medium to carry or generate live and active cultured dairy products. Probiotics and associated ingredients add an attractive dimension to cultured dairy foods for effecting special functional attributes (Sanders 1994; Chandan 1999; Schaafsma and Steijns 2000; Mattila-Sandholm and Saarela 2003).

42.2.1.1 Requirements for Effective Probiotics. Criteria for live and active cultures have been established by the industry with a view to maintain the integrity of refrigerated and frozen yogurts. The probiotic organisms must implant and multiply in the gut to avoid them from being expunged entirely. They must not only be able to tolerate and pass through the high acidic condition of the stomach, but also be able to grow and proliferate at physiological levels of bile salts and adhere to the intestinal epithelial cells. Bile salts are essential in helping to emulsify fat before it can be digested in the intestine. The probiotics that can colonize should also be resistant to several antibiotics and a good producer of natural selective antimicrobial bacteriocins. A strain of *Bifidobacterium* should be negative for production of catalase, nitrate reductase, urease, and for the formation of indole. In addition, liquefaction of gelatin, gas formation from glucose, response to rhamnose, sorbose, glycerol, erythritol, adinotol, and dulcitol should be negative. Commercial probiotic strains must have verified safety of use in the human diet. They should possess stability to acid and bile, exhibit colonization and adherence in the gastrointestinal tract, and should be able to elaborate a bacteriocin (Salminen and others 1998).

There are 56 species of *Lactobacillus* and 29 species of *Bifidobacterium*. Probiotic cultures that provide potential health benefits are shown in Table 42.2. The probiotics constitute organisms from mainly the genera *Lactobacillus*, *Enterobacter*, *Streptococcus*, and *Bifidobacterium*. These genera have been shown to be important members of the gastrointestinal microflora and are all relatively beneficial. The strains of lactic acid bacteria used in probiotics are mostly intestinal isolates such as *L. acidophilus*, *L. casei*, *Enterococcus faecium*, and *Bifidobacterium bifidum*. All probiotics, whether intestinal

TABLE 42.2 Probiotic and Beneficial Microorganisms in Commercial Products.

isolates or not, require regular consumption in adequate doses; it should not be assumed that a few doses will allow the organisms to colonize the gut permanently.

L. acidophilus and *Bifidobacterium* spp. are known to differ widely in their ability to grow in the presence of bile salts (Shah 2001). Both are reported to be stable at various concentrations of bile salts. Yogurt bacteria (*Streptococcus thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus*) are included in the list of probiotic cultures because they possess a distinctly high lactase activity, making yogurt easily digestible by individuals with a lactose-maldigestion condition. To bolster probiotic function, most commercial yogurt is now supplemented with *L. acidophilus*, *Bifidobacterium* spp., and *L. casei*. Unfermented milk, ice-cream, and cheese are also being used as carriers of probiotics.

42.2.1.2 Health Benefits of Probiotic Products. The belief in the beneficial effects of the probiotic approach is based on the knowledge that the intestinal microflora provides protection against various diseases. Probiotics have been with us for as long as people have eaten fermented milk. It can be shown that germ-free animals are more susceptible to disease than their conventional counterparts that carry a complete gut flora. This difference has been shown for infections caused by *Salmonella enteritidis* and *Clostridium botulinum*. Another source of evidence that supports the protective effect of the gut flora is the finding that antibiotic-treated animals, including humans, can become more susceptible to disease. Probiotics also deplete the essential nutrients for the pathogenic organisms, thus eliminating their growth. Table 42.3 shows some of the potential health benefits of probiotic cultures.

TABLE 42.3 Potential Health Benefits Related to Probiotics.

Health Condition	Benefit
Gastrointestinal disorders	The balance of various types of intestinal bacteria is disturbed by stress, antibiotic therapy, and age, leading to proliferation of pathogenic organisms and suppression of friendly bacteria, causing clinical disorders, namely, infections, inflammatory diseases, and immune deficiency. Probiotics restore intestinal microbial balance leading to general well-being and intestinal health
Lactose intolerance	Intake of yogurt and some probiotics improve lactose digestion and alleviate lactose intolerance condition.
Diarrhea	Strain-dependent probiotics prevent and treat diarrhea related to rotavirus infection, antibiotic therapy, and travelers' diarrhea
Immune-system-related diseases	Enhanced immune function resulting from stimulation of certain cellular and antibody functions may increase resistance to infections, gastrointestinal disturbances, allergies, and cancer
Infectious diseases	Probiotics may help prevent or treat respiratory infections, postoperative infections and control *Helicobacter pylori*, which is involved in type-B gastritis, ulcers, and possible cancer of the stomach. Possible control of food-borne diseases such as salmonella and *E. coli*
Colon cancer	Intake of yogurt and certain probiotics may reduce the development of precancerous lesions and chemically induced tumors. Enzyme biomarkers of colon cancer are inhibited by specific dairy cultures
Allergy	Probiotics may help in preventing allergic reactions caused by food allergens. They may also prevent recurring atopic eczema in children
Irritable bowel syndrome	Probiotics may reduce abnormal bloating symptoms of diarrhea-predominant IBS
Inflammatory bowel disease	Probiotics influence intestinal microflora and may reduce symptoms for individuals with ulcerative colitis, Crohn's disease, and pouchitis
Coronary heart disease	Certain probiotic strains may reduce serum cholesterol and glycerides and blood pressure, thereby reducing the risk of heart disease
Miscellaneous disorders	Certain probiotics may prevent and treat urinary tract infections, bacterial vaginosis, and yeast vaginitis in women and reduce colic in infants. Probiotics may protect from dental caries, prevent constipation, reduce inflammation of arthritis, and formation of kidney stones

Source: Adapted from Chandan (1999), Shah (2001), Dairy Council Digest (2005).

Balancing Intestinal Microflora. More than 400 different species of bacteria inhabit the human gastrointestinal tract. Their collective diverse population exceeds the total cell counts of the human body. Most of the bacteria do not cause any disease, but some of them do have the potential to cause disease if their level exceeds a critical level. As a result of aging, enhanced stress level in life, antibiotic therapy, and pollution, the balance in intestinal bacteria is disrupted in favor of potentially pathogenic bacteria. The loss of balance leads to increased risk of clinical disorders such as infectious diseases,

inflammatory illnesses, and unfavorable changes in the immune system. Research has shown that probiotic intake helps maintain proper and healthy balance of microbial population in the intestines, conferring upon the host general well-being and several therapeutic benefits (Dairy Council Digest 2005).

Improvement in Lactose Digestion. Other beneficial effects of probiotics include improvement of lactose utilization by the large proportion of the world's population unable to effectively digest lactose. The enzyme responsible for lactose digestion, lactase, although present in the suckling infant, disappears after weaning. Lactose malabsorption refers to incomplete digestion of lactose resulting in a flat or low rise in blood sugar following ingesting lactose in a clinical lactose intolerance test. Normally, the disaccharide lactose is hydrolyzed to glucose and galactose by lactase, and is subsequently absorbed in the small intestine. Lactase is a constitutive, membrane-bound enzyme located in the brush borders of the epithelial cells of the small intestine. In individuals with impaired lactase activity, lactose is not fully metabolized and the intact residual lactose enters the colon where it is fermented by inherent microflora to generate organic acids, carbon dioxide, methane, and hydrogen. The fermentation products, together with the osmotically driven excessive water drawn into the colon, are primarily responsible for abdominal pain, bloating, cramps, loss of appetite, diarrhea, and flatulence. These symptoms associated with lactose maldigestion are experienced when lactose is not fully digested in the small intestine. It is well established now that lactose-deficient subjects tolerate lactose in yogurt better than the same amount of lactose in milk. It has been conclusively demonstrated that intake of yogurt and certain probiotics alleviates symptoms of lactose intolerance. The lactase contained in the yogurt culture is mainly responsible for lactose digestion in the gut lumen. The bacterial cells of the yogurt culture undergo lysis, releasing the enzyme lactase into the small intestine. An increase in lactase activity in the small intestine of humans on yogurt has been shown. The microbial origin of the lactase is shown by the large increase in activity in the gut contents compared with the gut wall.

Prevention of Diarrhea. Probiotics are reported to improve the efficiency of the digestive tract, especially when bowel function is poor. Establishment of probiotics in the gastrointestinal tract may provide prophylactic and therapeutic benefits against intestinal infections. Probiotics may also have role in circumventing traveler's diarrhea (Fernendes and others 1992; Elmer and others 1996). Yogurt and probiotic cultures of *L. rhamnosus* GG as well as a blend of *L. acidophilus*, *B. bifidum*, *L. bulgaricus*, and *S. thermophilus* have been reported to reduce the incidence of traveler's diarrhea.

Yogurt containing probiotics has been found to reduce the duration of diarrhea caused by rotavirus in infants and young children. *L. rhamnosus* GG and a combination of *L. reuteri* DSM 12246 and *L. rhamnosus* 190702 have been found very effective in this regard. Fermented milk with probiotics has been recommended to replace milk during diarrhea treatment because it is tolerated better than milk. A double blind study has shown that only 7% of infants receiving probiotic formula containing *B. bifidum* and *S. thermophilus* developed diarrhea, composed with 31% incidence in the placebo group (Saavedra and others 1994).

Another type of diarrhea is related to antibiotic therapy. The growth of *C. difficile* and other pathogenic organisms are the main causative agents. Clinical trials have shown that yogurt containing live cultures of *L. rhamnosus* GG, *L. acidophilus* LA1, as well as

Saccharomyces boulardi are effective in reducing the incidence or severity of antibiotic-induced diarrhea.

Stimulation of the Immune System. An interesting development in recent years has been the finding that lactobacilli and bifidobacteria administered through the mouth can stimulate macrophage activity against several different species of bacteria (Brassart and Schiffrin 1997; Rangavajhyala and others 1997). For example, *L. casei* given to mice increased phagocytic activity. Lactobacilli injected intravenously survived in the liver, spleen, and lungs, and enhance the natural killer cell activity.

Yogurt, certain lactobacilli, and bifidobacteria enhance cellular and antibody functions of the immune system, resulting in an increase of resistance to infections, cancer, allergies, and gastrointestinal disorders (Dairy Council Digest 2005). In human trials, secretory immunoglobulin A (involved in protection against microbial antigens at the intestinal mucosal surface) was shown to increase as a result of feeding milk fermented with *L. acidophilus.* Macrophages constitute the first line of defense against bacterial invasion. In mice, it was reported that feeding milk fermented individually, or in combination with *L. casei* and *L. acidophilus*, led to a marked rise in macrophages. Cytokines have diverse functions in the immune system and their production is enhanced by feeding milk fermented with probiotics including *L. casei* and *L. rhamnosus* GG. Healthy volunteers given yogurt daily have been shown to markedly increase their gamma interferon level. In elders with poor functioning immune systems, *B. lactis* HNO19 increased their cellular immunity factors, such as total, helper, and activated T-cells, tumor-killing cells, and leukocytes phagocytosis. Studies with *L. rhamnosus* GG have shown that a cellular response to intestinal organisms is enhanced in healthy adults. The probiotic organisms aided in balancing anti-inflammatory and pro-inflammatory cytokines. The probiotic organisms increased the response of peripheral T-lymphocytes to intestinal bacteria. Also, an increase in anti-inflammatory response was observed, possibly due to an increase in the secretion of suppressive cytokines and a decrease in the secretion of pro-inflammatory cytokines.

Prevention of Infectious Diseases and Elaboration of Bacteriocins. Probiotics may be helpful in preventing and treating respiratory infections and postoperative infections. In this regard, *L. rhamnosus* GG has been clinically shown to reduce the incidence and severity of respiratory infections in children. Ingestion of fermented milk containing a mixture of *L. rhamnosus* GG, *Bifidobacterium* spp., *L. acidophilus*, and *S. thenmophilus* has been clinically shown to reduce potentially pathogenic bacteria in the upper respiratory tract of humans (Dairy Council Digest 2005).

Several studies have been reported on the effect of probiotics on *H. pylori*, which causes ulcers of the stomach and B-type gastritis. The results show that *L. casei* Shirota, *Bifidobacterium*, and *L. salivarius* are inhibitory to the growth of *H. pylori*. In human adults with *H. pylori* infection, it was shown that yogurt containing *L. johnsonii* suppressed the growth of *H. pylori* and reduced gastric inflammation.

Probiotics actively produce antibacterial substances called bacteriocins, which kill or inhibit pathogenic bacteria. The bacteriocin acidophilin, produced by *L. acidophilus*, has been shown to kill 50% of 27 different pathogenic bacteria studied. Children with Salmonella poisoning and Shigella infections were cleared of all symptoms using *L. acidophilus*. *Bifidobacterium bifidum* effectively kills or controls *E. coli*, *S. aureus*, and *Shigella* (Fernandes and others 1992).

Anticarcinogenesis. Bifidobacteria, and lactobacilli, and especially *L. acidophilus* have been shown to have anticarcinogenic properties against certain tumors (Goldin and Gorbach 1992). Several reports suggest prevention of cancer initiation by various probiotics. Probiotics have been shown to reduce biomarkers (fecal procarcinogenic enzymes nitroreductase and azoreductase) of colon cancer risk. An epidemiological study reported a positive correlation between probiotic consumption and prevention of colon cancer (Fernandes and others 1992). Live cells of probiotics exhibit inhibition of a large variety of mutagens (Shah 2001).

Reduction in Serum Cholesterol. Elevated levels of serum cholesterol, particularly LDL-cholesterol, have been linked to an increased risk for cardiovascular disease. Feeding of fermented milks containing very large numbers of probiotic bacteria ($\sim 10^9$ bacteria/g) to hypercholesterolemic human subjects has resulted in lowering cholesterol from 3.0 to 1.5 g/L. The role of bifidobacteria in reducing serum cholesterol is not completely understood. Mann and Spoerry (1974) observed a decrease in serum cholesterol levels in men fed large quantities of milk fermented with *Lactobacillus*, possibly due to the production of hydroxymethyl-glutarate by lactic acid bacteria, which inhibits hydroxymethylglutaryl-CoA reductases required for the synthesis of cholesterol.

Klaver and Meer (1993) reported that removal of cholesterol from the culture medium by *L. acidophilus* and other species is not due to bacterial uptake of cholesterol, but results from bacterial bile salt deconjugating activity. The deconjugated bile acid does not absorb lipid as readily as its conjugated counterpart, leading to a reduction in cholesterol level.

Reports by Gilliland and others (1985) showed that *L. acidophilus* itself may take up cholesterol during growth in the small intestine and make it unavailable for absorption into the blood stream. Probiotics effectively help to reduce serum cholesterol levels. Some studies have indicated a modest lowering of serum cholesterol in subjects consuming milk fermented with *L. acidophilus*, *L. rhamnosus* GG, and yogurt cultures (Gilliland 2003).

Anti-inflammatory Effects. Inflammatory bowel diseases (IBD, ulcerative colitis, and Crohn's disease) are related to the intestinal microflora. IBD affects up to two million people worldwide. Symptoms include a disturbance in bowel habits and mucosal inflammation. In the case of IBD, the number of *Lactobacillus* and *Bifidobacterium* in the gastrointestinal tract is lower, and that of coccoids and anaerobes higher. Probiotics are not reported to cure the disease. However, once patients are in remission through treatment with corticosteroids, some probiotics can prolong the remission, thus reducing the relapses and the use of corticosteroids. This improves the quality of life of patients. Several reports have suggested that probiotics reduce symptoms and prevent relapse in patients suffering from ulcerative colitis, Crohn's disease, and pouchitis. Also, probiotics are reported to reduce abnormal bloating, a symptom of irritable bowel syndrome.

Urinary Tract Infections, Vaginitis, and Allergy. The vaginal microflora changes drastically during bacterial infection. Bacteria of genera Escherichia, Proteus, Klebsiella, and Pseudomonas along with the yeast *Candida albicans* are recognized as etiological agents in urinary tract infections among adult women. Normal urethral, vaginal, and cervical flora of healthy females can competitively block the attachment of uropathogenic bacteria to the

surfaces of uroepithelial cells. Lactobacilli strains supplemented in the diet or directly applied will coat the uroepithelial wall and prevent the adherence of uropathogens. Milk fermented with yogurt cultures and *L. casei* influences the intestinal microflora of infants (Guerrin-Danan and others 1998).

Therapeutically, probiotics have been reported to be useful in the treatment of acne, psoriasis, eczema, allergies, migraine, gout, rheumatic and arthritic conditions, cystitis, and candiadiasis.

Potential mechanisms by which probiotics may exert their beneficial effects are:

1. Competition with other microflora for nutrients;
2. Production of acids inhibitory to certain enteropathogens;
3. Production of bacteriocins or inhibitory metabolites;
4. Immunomodulation; and
5. Competition for adhesion to intestinal mucosa.

Future research work with well-designed human studies is needed to make a definitive validation of many health-benefit claims. Several benefits are specifically related to species and strain of the probiotic. Accordingly, identification of beneficial strains in each species is critical in probiotic research. As efficacy of a probiotic is directly related to the number of live and active culture cells consumed, it is important to specify potency or colony-forming units (cfu) of the culture per unit weight or volume of the product. Additionally, the culture should be active in terms of growth potential (Chandan 1997; Chandan and others 1999).

42.2.2 Prebiotics and Synbiotics

The term "prebiotic" refers to a variety of oligosaccharides and other food ingredients, which, on ingestion, promote the growth of beneficial microorganisms in the gastrointestinal tract. Prebiotics remain unaltered by digestive juices and enter the colon intact. In the colon, they are fermented to produce short-chain fatty acids, thereby reducing the pH of the colonic contents. This effect leads to inhibition of the pathogenic inhabitants of the colon and changes the balance in favor of beneficial organisms. Chicory and Jerusalem artichokes are major sources of prebiotics. They are also found in honey and onions. These prebiotics include fructans, inulin, and oligosaccharides. Both fructooligosaccharides (FOS) and galacto-oligosaccharides are widely used as prebiotics. In addition, some lactose derivatives such as lactulose, lactitol, and lactosucrose also function as prebiotics. Starch-based prebiotics include malto- and isomalto-oligosaccharides, polydextrose, and certain resistant starches. Some gums can also act as prebiotics. Supplementation of probiotics with prebiotics can be a very effective functional food. For example, fructooligosaccharide (FOS) is exclusively utilized by a few strains of *Bifidobacterium bifidum* and *L. acidophilus*. Thus, a combination of FOS along with these cultures will induce the proliferation of these cultures in preference to other microflora (Shah 2004). This synergistic combination is termed as synbiotics. This has also been confirmed in human volunteers where FOS consumption increased the levels of bifidobacteria at the expense of less desirable bacterial species. The health benefits of prebiotics are similar to those associated with probiotics. Additionally, FOS supplements have been

shown to substantially improve the absorption of calcium and magnesium, thereby helping improve bone health.

42.2.3 Fiber Addition

The daily values for dietary fiber are 25 and 30 g for a 2000- and 2500-calorie diet, respectively. The main sources of dietary fiber are fruits, vegetables, and whole grains. As dairy products are naturally deficient in fiber, these ingredients should be of much interest in enhancing their functional value. For fortification, an array of dietary fibers is available to choose from. However, for successful product development, the fiber must not alter the perceived sensory properties of the final product.

Apart from the laxation benefit, fiber consumption lowers cholesterol, slows absorption of nutrients into the bloodstream, and promotes healthy gut ecology. Accordingly, dietary fiber confers a positive influence on human health and longevity. Epidemiological, experimental, and clinical research has shown that consumption of diets high in fiber lowers the risk of obesity, colorectal cancer, cardiovascular disease, and possibly type-2 diabetes. For example, a diet containing viscous polysaccharides lowers the low-density lipoproteins (LDL) and total serum cholesterol by bile acid turnover and lipid absorption. Furthermore, the beneficial effect may be ascribed to slow down of the absorption of carbohydrate, increase in stool bulk, and production of short-chain fatty acids in the colon.

Dietary fiber is classified as soluble fiber and insoluble fiber. In general, soluble fiber is beneficial in terms of cardiovascular disease and the insoluble fiber in the prevention of colon cancer. Cellulose and its derivatives are excellent insoluble fibers. Hydrocolloids furnish at least 85% soluble (on a dry weight basis) dietary fiber. Total dietary fiber content of gum acacia and gum tragacanth ranges from 80–90%, whereas their soluble fiber content is 100%. Guar gum has 90% total dietary fiber, but it is 100% soluble fiber. Pectin is 90–100% total dietary fiber and soluble gum. Oat bran is 22% total dietary fiber, 50% soluble fiber. The insoluble dietary fiber is furnished by wheat bran (45–55% total dietary fiber, 2–6% soluble fiber), rice bran (75% total dietary fiber, 4% soluble fiber), oat fiber (85–90% total fiber, 1–3% soluble fiber), and barley bran (50–70% total dietary fiber, 3–9% soluble fiber). Other sources of fibers are cottonseed, soy, and citrus. Even the fructooligosaccharides primarily used as prebiotics act like soluble fiber. Partially hydrolyzed guar gum provides excellent solubility and clarity while maintaining the health-promoting properties of a soluble gum.

Soluble fibers such as pectin and gums form gels in the stomach, thereby slowing the absorption of certain nutrients through the small intestine. Foods containing soluble fiber such as β-glucan are permitted by FDA to make a specific coronary heart disease claim. For example, 0.75 g of soluble fiber from oat ingredients or 1.7 g of soluble fiber from psyllium husk can make such a claim on the package. Insoluble fibers such as polysaccharides (cellulose, hemicellulose), oligosaccharides, and lignin pass through the digestive tract intact until they reach the colon, where they exert positive physiological effects like laxation, attenuation of serum cholesterol, and blood glucose.

Dietary fiber (psyllium, guar gum, gum acacia, oat fiber, soy components) as well as multivitamin–mineral mixes are being incorporated in fat-free milk to provide targeted

niche consumers meal replacements. Such products supply a substantial proportion of daily essential nutrients.

42.2.4 Fortification with Minerals, Vitamins, and Health-Promoting Ingredients

A balance of vitamins and minerals is necessary for optimal health and well-being. Accordingly, a strategy to provide optimal daily requirements of major vitamins and minerals per serving is popular in the market. Traditionally, milk has been fortified with vitamins A and D. Now, popular ingredients of functional significance are being incorporated to enhance market value of dairy foods and dairy-based foods. Some of these ingredients designed to enhance consumer appeal are

1. Calcium, claimed to prevent osteoporosis and cancer, and to control hypertension;
2. Antioxidants (vitamins C and E), claimed to communicate the benefit of prevention of cancer, cardiovascular disease, and cataracts.

Further, it is now known that factors in diet influencing reduction in cardiovascular disease are generally constituents of plant foods: antioxidants, phenolics, carotenoids, and flavonoids. The phytoestrogens (namely, coumesterol) of certain beans may reduce bone loss. Isoflavones present in soy are recognized to be beneficial in reducing the risk of cancer and heart disease. Soy-protein-fortified yogurt is being marketed to enhance its functional value. Plant sterols clinically proven to reduce serum cholesterol levels are available and are being used as an ingredient in "heart healthy" yogurt.

Folic acid is now considered to be significant for its role in preventing heart disease. Folic acid is also significant in lowering the risk of neural tube defect in babies. Thus, new diet strategies for optimum health involve consumption of a much higher level of fruits, vegetables, legumes, nuts, and whole grains than previously believed. Breakfast yogurt containing whole grains and nuts along with vitamin fortification is another commercial approach to increasing the functional food status of yogurt.

Phosphatidylserine is a part of phospholipids. It is heavily concentrated in the cell membranes of the brain. It provides structural support and keeps the cells fluid and flexible. Scientific evidence for reduction of risk between phosphatidylserine and dementia in the elderly is recognized. Accordingly, this ingredient could be used for prevention of cognitive dysfunction in the elderly. The FDA has allowed a qualified health claim on the label "Consumption of phosphatidylserine may reduce the risk of dementia in the elderly" or "Consumption of phosphatidylserine may reduce the risk of cognitive dysfunction in the elderly".

In addition to the infant formula line of products based on fat-free milk, there is a proliferation of energy and weight reduction shake drinks for consumer segments ranging from adults to geriatric populations.

Certain successful ideas from the food industry may have a merit for application to dairy products. Antioxidants have shown promise, but a fortification strategy must include an understanding of their impact on flavor, texture, mouthfeel, and shelf-life of the product. Also, it is imperative to know a meaningful dose–benefit relationship associated with the specific fortified dairy food.

Functional fatty acids belong to a class of ω-3 fatty acids. They provide benefit to infants, children, adults, and the elderly alike. The U.S. FDA has allowed the qualified claim "Limited evidence suggests an association between consumption of fatty acids in

TABLE 42.4 Various Milk-Based Product Categories Containing Milk Fractions.

Category	Food or Supplement
Clinical nutrition	Total enteral formulas containing casein, milk proteins, and their hydrolyzates for tube or oral administration in hospitalized patients
Seniors nutrition	Whey-protein-based drinks promote bone health, provide a good source of biologically active proteins and peptides, rapid digestion rate, and induce high postprandial protein synthesis and balance. Provide essential amino acids, branched-chain amino acids and high cysteine levels for maintenance of glutathione status; improve immune system
Sports nutrition	Drinks, tablets, energy bars, or cookies can deliver bioavailable calcium, easily absorbable protein hydrolyzates, and branched-chain amino acids, antioxidant sulfur- rich amino acids, bioactive peptides and bioavailable milk minerals; glutamine peptide supports immune system and facilitates iron absorption; lowers body fat and builds muscle
Infant nutrition	Demineralized whey, lactose, caseinates, milk protein concentrate, and dairy minerals are constituents of hypoantigenic and hypoallergenic humanized infant formulas
Weight-reduction drinks	Meal replacement milk shakes fortified with such supplements as milk proteins, vitamins and minerals, and prebiotics

Source: Adapted from Chandan (1999).

fish and reduced risks of mortality from cardiovascular disease for general population". The functional fatty acids are docohexanoic acids (DHA) and eicosapentaenoic acids (EPA), which are long-chain polyunsaturated fatty acids, found in fish oil, but which can be derived from marine algae and plant sources like safflower oil. Other polyunsaturated (α-linolenic) and mono-unsaturated fatty acids (oleic) are also beneficial. Epidemiological studies have suggested that individuals at risk for coronary heart disease benefit from the consumption of plant- and marine-derived ω-3 fatty acids. These fatty acids are claimed to inhibit cancer, anti-allergy effects, and improvement in learning ability. They are involved in brain and eye development in infants. Commercially available milk fractions, especially whey proteins and other fractions, are being used in a variety of milk-based products (Table 42.4).

43.1 INTRODUCTION

This chapter provides basic information relative to milk constituents possessing a physiological role in addition to their nutritional contribution.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

TABLE 43.1 Composition of Milk Commonly Used for Consumption in Various Regions of the World.

Animal	(%) Water	(%) Protein	(%) Fat	(%) Lactose	(%) Ash
Cow	87.3	3.4	3.7	4.8	0.7
Buffalo	82.7	3.6	7.4	5.5	0.8
Goat	87.7	2.9	4.9	4.1	0.8
Sheep	80.7	4.5	7.4	4.8	1.0
Horse	88.8	2.5	1.9	6.2	0.5
Camel	86.5	3.1	4.0	5.6	0.8

Source: Adapted from Fox (2003), Aneja and others (2002).

From the chemical standpoint, milk is a complex fluid in which more than 100,000 separate molecules and chemical entities have been found. In the United States, cow's milk for commercial purposes is the whole, clean lacteal secretion of one or more healthy cows properly fed and kept, excluding that obtained within 15 days before calving and 3–5 days after. This would exclude colostrum, the milk secreted immediately after birth of the calf. Colostrum is an established functional food containing high levels of antibodies for protection of the new-born calf.

It is necessary to understand the chemical, physical, and nutritional composition of milk to comprehend the functional aspects of its constituents.

43.2 CHEMICAL COMPOSITION OF MILK

In the food industry, the composition of milk is generally described in terms of its commercially important constituents, milk fat and nonfat Solids (NFS) or milk solids-not-fat (MSNF). The MSNF consists of protein, lactose, and minerals. As per FDA standards of identity, milk is "the lacteal secretion practically free of colostrum, obtained by complete milking of one or more healthy cows, which contains not less than 8.25% MSNF and not less than 3.25% milk fat". The major constituents of milk are given in Table 43.1.

43.3 NUTRITIONAL CHARACTERISTICS OF MILK CONSTITUENTS

Milk is composed of a unique set of a constituents. Milk has been described as nature's nearly perfect food, as it provides vital nutrients including proteins, essential fatty acids, minerals, and lactose in balanced proportions. Leading nutrition experts recognize milk and milk products as important constituents of a well-balanced and nutritionally adequate diet. In this regard, milk products complement and supplement nutrients available from grains, legumes, vegetables, fruits, meat, seafood, and poultry.

TABLE 43.2 Physical State and Particle Size Distribution in Milk Facilitating Nutritional and Physiological Effects.

Physical State	Type of Particles	Size, Diameter (nm)
Emulsion	Fat globules	2000–6000
Colloidal dispersion	Casein–calcium phosphate	50–300
	Whey proteins	4–6
True solution	Lactose, salts, and other substances	0.5

In terms of physical structure (Table 43.2), milk is an opaque, white, heterogeneous fluid in which various constituents are held in multidispersed phases of emulsion, colloidal suspension, or solution. The phase of the milk constituents influences the physiological characteristics of the milk constituents.

43.4 FUNCTIONAL PROPERTIES OF MILK

Various milk constituents contributing physiological effects are proteins, fat, lactose, minerals, and cultures in fermented milk products. Milk proteins have a high nutritional value because of their high essential amino acid content. Thus, they complement and balance the amino acid composition of the relatively lower quality of several vegetable proteins in the human diet. All the dairy constituents perform a nutritional function as well as physiological functions. They act independently and synergistically with each other. The role of major and minor constituents in human nutrition is intertwined with newly discovered physiological benefits.

We will now consider functional aspects of major milk constituents in more detail.

43.4.1 Milk Proteins

The major proteins of milk are casein and whey proteins in the ratio of 80 : 20. Casein further consists of various fractions including α_{S1}- and α_{S2}-casein, β-casein, and κ-casein (Table 43.3). Also shown are the major whey proteins of milk.

A number of proteins and peptides derived from milk proteins have physiological activity:

1. Immunoglobulins, lactoperoxidase, lactoferrin, and folate-binding protein;
2. Insulin-like growth factors (IGF-1 and IGF-2), mammary-derived growth factors MDGF-I and MDGF-II, transforming growth factors ($TGF_{\alpha 1}$, $TGF_{\alpha 2}$, TGF_{β}), fibroblast growth factors, platelet-derived growth factors, bombesin, and bifidus factor;

TABLE 43.3 Proteins of Cow's Milk and Their Fractions.

	Concentration (g/L)
Casein Fractions	
α_{s1}-Casein	10.3
α_{s2}-Casein	2.7
β-Casein	9.7
κ-Casein	3.5
C-terminal β-casein fragments	0.8
Whey Protein Fractions	
N-terminal β-casein fragments	0.8
β-Lactoglobulin	3.4
α-Lactalbumin	1.3
Immunoglobulins	0.8
Bovine serum albumin	0.4

Source: Adapted from Chandan (1999), Schaafsma and Steijns (2000).

3. Peptides derived from milk proteins, such as glycomacropeptides from κ-casein, phosphopeptides from caseins, caseinomorphins, immunomodulating peptides, platelet-modifying peptide, angiotensin-converting enzyme (ACE) inhibitor (which lowers blood pressure), calmodulin-binding peptides, and bactericidal peptides from lactotransferrin (Otter 2003).

Both caseins and whey proteins of milk possess physiological and biological properties. The biological properties of milk proteins are summarized in Table 43.4.

43.4.1.1 Casein. Casein proteins are further divided into α_{s1}-, α_{s2}-, β-, and κ-fractions, which along with whey proteins, β-lactoglobulin and α-lactalbumin, are gene-derived proteins synthesized in the mammary gland. All these proteins are heterogeneous and exhibit genetic polymorphs. There are between 2 and 8 genetic variants differing from each other in 1 to 14 amino acids. The variants may have an impact on protein concentration and the functional properties of milk. The γ-fraction originates from β-casein by the effect of the native proteolytic enzyme of milk.

Caseins display distinctive structure, charge, physical, and biological properties, as well as a nutritional role. The interaction of various caseins and calcium phosphate contributes to the formation of large colloidal complex particles called casein micelles. Hydrophobic interactions with calcium phosphate and submicelles seem to be involved in the formation of micelles. Micelle composition consists of 63% moisture and the dry matter consists of 92–94% protein and 6–8% colloidal calcium phosphate. Other associated salts are magnesium and citrate.

The caseins are phosphorylated proteins, containing 1–13 phosphoserine residues. κ-Casein exists in as many as nine glycosylated forms. It contains two cysteine

TABLE 43.4 Functional Attributes of Milk Proteins.

Protein	Physiological Effect
Caseins	Precursors of bioactive peptides; calcium and phosphorus carrier
Whey proteins	Confer passive immunity for disease prevention; reduce risk of heart disease and lower blood pressure, antiviral and anticancer activity, control of gut microflora, control of cellular glutathione level
β-Lactoglobulin	Binds zinc, calcium, and fat-soluble vitamins. The branched-chain amino acids enhance the immune system
α-Lactalbumin	Lactose synthesis in mammary gland, anticarcinogenic and immune-enhancing effects. May be associated with stress reduction, increase serotonin production in the brain, improve mood, and decrease cortisol level
Immunoglobulins A, M, E, G	Antibodies against diarrhea and GI tract disturbances. Support passive immune function
Bovine serum albumin	Antioxidant and antimutagenic. Binds free fatty acids and pro-oxidant transition metals
Lactoferrin	Bacterial antitoxin binding, antibacterial, antiviral, immune modulating, antinflammatory, antithrombic activity, anticarcinogenic, antioxidant, iron absorption
Lactoperoxidase	Antimicrobial, antioxidant, immune-enhancing properties
Lysozyme	Antimicrobial, synergistic with immunoglobulins and lactoferrin

Source: Adapted from Chandan (1999), Harper (2000), Hoolihan (2004), Kreider (2004).

molecules per molecule. As a result of disulfide bond formation, it can exist as polymers of 2–8 units. Similarly, α_{s2}-casein also contains two cysteines and exists in a dimeric form.

Casein micelles contain α_{s1}-, α_{s2}-, β-, and κ-casein in the ratio of 3 : 1 : 3 : 1. Most of the fractions α_{s1}-, α_{s2}-, and β-casein are located in the interior of micelles, with κ-casein predominantly wrapped around the surface of the micelle. Casein fractions in the interior of the micelles are sensitive to calcium and become insoluble in the presence of calcium. However, κ-casein is not sensitive to calcium and thereby keeps the micelles containing calcium-sensitive caseins intact and suspended in the aqueous phase. κ-Casein is a protein with a hydrophilic carbohydrate moiety (sialic acid) that extends into the aqueous phase. This arrangement further lends stability to the micelle. Casein micelles are stable under most heating, homogenization, and other dairy processing conditions.

Caseins possess a certain distinctive amino acid makeup, which impacts their processing and functional properties. They are rich in apolar and hydrophobic amino acids, namely valine, leucine, isoleucine, phenylalanine, tyrosine, and proline. The apolar amino acids are normally insoluble in water, but their nature is balanced by phosphate groups so that caseins exhibit some solubility. Methionine and cysteine, the sulfur-containing amino acids, are relatively low in caseins. This fact impacts their nutritional deficiency. On the other hand, the essential amino acid lysine content is high. In human diet, the high lysine content is helpful in complementing and balancing the low-lysine plant proteins. The ε-amino group of lysine present in caseins interacts with the aldehyde group of lactose at elevated temperatures, leading to the formation of brown pigments. This also explains browning of heat-sterilized milk and nonfat dry milk during extended storage.

The high prolene content results in low α-helix and β-sheet in their secondary structure, giving them ability to undergo more proteolytic degradation and enhanced digestion (Otter 2003).

Caseins possess limited secondary and tertiary structures. Accordingly, their molecular conformation is fairly flexible, and open. The polar and apolar amino acids in the primary structure of caseins contribute to hydrophilic and hydrophobic regions. This confers surface activity and contributes to the emulsifying and foam-forming characteristics of caseins.

Caseins are very heat stable under natural conditions of protein concentration, environmental pH, and ionic concentrations. Moderate heat has little or no effect on casein molecules, because they exist naturally in an open and extended state. However, heating of milk at an elevated temperature for an appreciable length of time could result in hydrolytic cleavage of peptide and phosphate bonds, which affects the stability of the complex, contributing to coagulation of milk.

Among the minor caseins of milk, γ-casein is the C-terminal fragment of β-casein, a product of attack by natural proteolytic enzyme plasmin. The N-terminal residue is the proteose–peptone fraction. These hydrolysis products of β-casein occur in the range of 3–10% of the total casein content of milk. The stage of lactation and health status of the cow affect their concentration.

Functional Peptides Derived from Casein. Peptides derived from caseins are biologically active and display significant extra nutritional attributes for maintaining normally of physiological functions in human subjects. Table 43.5 lists bioactive peptides originating from caseins.

TABLE 43.5 Some Functional Properties of Bioactive Peptides Derived from Caseins.

Peptide	Origin	Function
Casomorphins	β-caseins	Opioid agonists and ACE inhibitory/hypotensive
Casoxins	κ-casein	Opoid agonists
Casokinins	α- and β-caseins	Antihypertensive
Casoplatelins	κ-casein	Antithrombotic
Casecidin	α- and β-caseins	Antimicrobial
Immunopeptides	α- and β-caseins	Immunostimulants
Phosphopeptides	α- and β-caseins	Mineral carriers
Glycomacropeptide	κ-casein	Suppress appetite, antiplatelet, anticancer, antihypertensive, prevent dental caries, gingivitis, antiviral, antibacterial, bifidogenic

Source: Adapted from Pihlanto-Leppala (2003), Saxelin and others (2003), Aimutis (2004).

Functional peptides are generated during digestive processes in the body and during the fermentation processes used in fermented dairy foods. These peptides are inactive in the native proteins, but assume activity after they are released from them. They contain 3–64 amino acids, display largely hydrophobic character, and are resistant to hydrolysis in the gastrointestinal tract. They can be absorbed in an intact form to exert various physiological effects locally in the gut or may have a systemic effect after entry into the circulatory system. Casomorphins derived from milk caseins are known to be opioid agonists, and casoxins act as opioid antagonists. The opioids have analgesic properties similar to opium. Casokinins are antihypertensive (lower blood pressure), casoplatelins are antithrombotic (reduce blood clotting), and phosphopeptides are mineral carriers.

Casein phosphopeptides may aid in the bioavailability of calcium, phosphorus, and magnesium for optimum bone health. They may be helpful in preventing dental caries. They may also have a role in secretion of enterohormones and immune enhancement. The role of casein peptides in regulation of blood pressure is showing promise. Conversion of angiotensin I to angiotensin II is inhibited by certain hydrolyzates of casein and whey proteins. As angiotensin II raises blood pressure by constricting blood vessels, its inhibition causes lowering of blood pressure. This ACE inhibitory activity would therefore make dairy foods a natural functional food for controlling hypertension. A commercial ingredient derived by the hydrolysis of milk protein has an anxiolytic bioactive peptide with antistress effects. Psychometric tests and measurement of specific hormonal markers have displayed this antistress effect. The ingredient may be incorporated in milk, cheese, or ice-cream.

The glycomacropeptide released from κ-casein as a result of proteolysis may be involved in regulating digestion as well as in modulating platelet function and thrombosis in a beneficial way. It is reported to suppress appetite by stimulating CCK hormone. Consequently, it may be a significant ingredient of satiety diets designed for weight reduction. Furthermore, this peptide may inhibit binding of toxins in the gastrointestinal tract.

Some miscellaneous bioactive factors are being discovered. Specific proteins for binding vitamin B_{12}, folic acid, and riboflavin may assist in enhancing bioavailablity from milk and other foods. The fat globule membrane protein called butyrophilin is a part of the immune system. Other growth factors in milk may help gut repair after radiation or chemotherapy.

43.4.1.2 Whey/Serum Proteins. Whey proteins provide an excellent balance of essential amino acids. The amino acid profile resembles that of skeletal muscle, making the whey proteins effective in stimulating protein synthesis in adult muscle. Thus, they preserve muscle mass and enhance health. Whey proteins enhance fat loss. Whey proteins contain more branched-chain amino acids than any other protein, which are metabolized (to generate energy) in the muscle rather than in the liver. This property makes them suitable for use by athletes engaged in endurance sports like marathon racing. In general, it has been shown that whey proteins enhance humoral immune response. The sulfhydryl-containing amino acids, cysteine and glutathione, are related to the immune response. The branched-chain amino acids stimulate muscle glutamine synthesis. Glutamine is involved in immune function. Glutathione formation is facilitated by the high cysteine content of whey proteins, which in turn controls significant antioxidant defenses and immune function in the body.

Whey proteins are especially rich in cysteine. β-Lactoglobulin contains 33 mg of cysteine per gram of protein, and α-lactalbumin and bovine serum albumin contain 68 and 69 mg cysteine per gram of protein, respectively. The –SH compounds are also involved in quenching toxic free radicals.

In sports nutrition, the high content of arginine and lysine amino acids of whey proteins may help in stimulating the release of growth hormone, leading to an increase in muscle mass and decline in body fat. Furthermore, glutamine protects the immune system from decline caused by overtraining.

Whey proteins consist of β-lactoglobulin and α-lactalbumin, bovine serum albumin, immunoglobulins (mainly IgG1, IgG2, and IgM), lactoferrin, proteose–peptone, and a number of diverse enzymes.

β-Lactoglobulin. This major whey protein of milk displays the presence of four genetic variants. Besides, the two genetic variants A and B, variants C and D have also been reported. β-Lactoglobulin is rich in sulfur amino acids, containing five cysteine residues. It exists as a dimer linked by 1–3 disulfide bonds. It is a fairly heat-labile protein. β-Lactoglobulin stimulates lipolysis and so generates rancidity. It also acts as a carrier of vitamin A. The large numbers of lysine residues can result in lactosylation and accompanying changes in physical properties of the protein.

α-Lactalbumin. In human milk, α-Lactalbumin is a major protein, but in cow milk it is second in preponderance to β-lactoglobulin. Three genetic variants are reported, but Western cow contains variant B only. This protein is rich in tryptophan and the sulfur amino acids cysteine and methionine. There are four disulfides in the molecule and it exists as a monomer. α-Lactalbumin has 54 amino acid linkages, identical to the enzyme lysozyme. It is a glycoprotein as well as a metalloprotein. One molecule of calcium is bound to each protein molecule, which confers heat stability on α-lactalbumin. This protein has been shown to possess a physiological role in the synthesis of lactose in the mammary gland. It is a component of lactose synthetase along with uridine diphosphate-galactosyl transferase, catalyzing the transfer of galactose to glucose to form lactose.

α-Lactalbumin is a calcium-binding protein, therefore enhancing calcium absorption. It is an excellent source of essential amino acids such as tryptophan and cysteine.

Tryptophan regulates appetite, sleep–waking rhythm, and pain perception. Cysteine is important in functions of –SH compounds.

Immunoglobulins. There are five major classes of immunoglobulins: IgA, IgD, IgE, IgG, and IgM. Their concentration is very high (100 g/L) in the first 2–3 milkings after calf birth, but falls to 0.6–1 g/L soon after. Immunoglobulins are antibodies synthesized in response to stimulation by specific antigens. These offer nonspecific humoral response to Gram-negative enteric and aerobic bacteria. Accordingly, they provide passive immune protection to the newly born calf. The basic structure of all immunoglobulins is similar, being composed of two identical light chains (23,000 daltons) and two identical heavy chains (53,000 daltons). The four chains are joined together by disulfide bonds. The complete molecule has a molecular weight of about 180,000 daltons. The antigenic sites are located at the $-NH_2$ terminal of the respective chain. Of the five immunoglobulin classes, IgG is the predominant fraction of milk, comprising about 90% of the total colostral immunoglobulins. Relatively smaller concentrations of IgM and IgA are also present in progressively decreasing amounts.

The immunoglobulins of milk are important for imparting an immune defense for the host. IgG1 is a major component. Other fractions are IgG2, IgA, and IgM, all of which provide passive immunity.

A number of colostrum products are being marketed for use as functional ingredients in foods. Colostrum contains several functional constituents including antibodies, lactoferrin, lactoperoxidase, cytokines, and growth factors. The antibodies act as antimicrobial agents against infection from rotavirus (which causes diarrhea), *Escherichia coli* (which causes food poisoning), *Candida albicans* (which causes yeast infection), *Streptococcus mutans* (which causes dental caries), *Clostridium difficile* (which causes antibiotic-associated diarrhea), *Cryptosporium parvum* (which causes food poisoning), and *Helicobacter pylori* (which causes ulcers and gastritis). Colostrum stimulates an active immune system by enhancing the activity of natural killer cells and phagocytes. The colostrum powder is manufactured by a special drying process to insure activity. Milk protein concentrate prepared from the milk of hyperimmunized cows is claimed to relieve joint pains from arthritis by complementing the body's naturally occurring anti-inflammatory substances.

Bovine Serum Albumin. As the name indicates, this protein originates from blood and, during synthesis in the udder, spills into milk. It is a large molecule with binding ability for fatty acids and metals.

Lactoferrin/Lactotransferrin. This is a glycoprotein, which displays strong tendency to bind ionic iron due to the presence of two metal-binding sites. An average lactoferrin content of 0.32 mg/mL has been found in cow milk. The molecular weight of lactoferrin varies between 73,700 and 74,000 daltons. Lactoferrin displays a very strong chelating tendency for ionic iron and forms a salmon-red-colored pigment. Lactoferrin is a single peptide chain, with two lobes, each of which is capable of binding iron. The iron-free form of lactoferrin is known as apolactotransferrin, which is colorless in appearance. Lactoferrin displays activity against several Gram-positive and Gram-negative bacteria, yeasts, fungi, and viruses. It particularly shows a strong inhibitory effect towards Gram--negative enteropathogenic bacteria by virtue of its ability to bind free ionic iron, which is essentially required for the growth of enteropathogenic microorganisms. In this way,

TABLE 43.6 Some Physiological Attributes of Peptides Derived from Whey Proteins.

Peptide	Origin	Function
β-Lactorphin α-Lactorphin	β-Lactoglobulin, α-Lactalbumin	Opioid agonist, inhibition of angiotensin-I-converting enzyme
Lactkinins	β-Lactoglobulin, α-Lactalbumin	ACE inhibitory (antihypertensive)
Lactoferricin	Lactoferrin	Antimicrobial activity
Lactoferroxins	Lactoferrin	Opioid antagonist

Source: Adapted from Harper (2000), Pihlanto-Leppala (2003), Aimutis (2004).

lactoferrin has a role in nonspecific defense of the host against invading pathogens. Apart from the antibacterial effect in the gut of the calf, a nutritional role in iron metabolism has also been ascribed to lactoferrin. Its iron-binding characteristic aids in enhancing iron absorption. It stimulates and protects cells involved in host defense mechanisms. Furthermore, it controls cytokine response.

Biologically Active Peptides from Whey Proteins. A number of peptides derived from whey proteins have physiological activity (Table 43.6). The bioactive peptides of whey proteins have been shown to exert a positive influence on body composition, satiety, and weight management. In addition, the bioactive peptides have ACE-inhibitory activity.

Milk Enzymes. Milk is a repository of a variety of enzymes. Over 60 indigenous enzymes have been reported in cow milk. They are either associated with the milk fat globule membrane (xanthine oxidase, sulfhydryl oxidase, and γ-glutamyltransferase), or with skim milk serum (catalase, superoxide dismutase), or with micelles of casein (plasmin and lipoprotein lipase).

Lactoperoxidase is an enzyme that breaks down hydrogen peroxide and exerts an antibacterial effect. Therefore, it is considered a natural preservative. Lysozyme has antimicrobial activity against Gram-positive bacteria and acts by lysis of cell walls. The Bifidobacteria flora of the colon imparts health-promoting properties and healthy gut ecology to the host. It has also been suggested that lysozyme may have an indirect effect on the defense systems as an immunomodulator through the stimulation of breakdown products of the peptidoglucan on the immunosystem.

43.4.2 Milk Fat

Milk fat in freshly secreted milk occurs as a microscopic globular emulsion of liquid fat in the aqueous phase of milk plasma. The composition of milk fat is given in Table 43.7. The milk fat of cows consists chiefly of triglycerides of fatty acids, which make up 95–96%. The remaining milk fat is composed of diglycerides, monoglycerides, free fatty acids, phospholipids, and cholesterol.

43.4.2.1 Physiological Effects of Milk Fat Components. The functional properties of milk fat are attributed to its fatty acid make-up. More than 400 distinct fatty acids have been detected in milk. Typical milk fat consists of 62% saturated, 29% monounsaturated, and 4% polyunsaturated fatty acids. It contains 7–8% short-chain fatty acids

TABLE 43.7 Constituents of Bovine Milk Lipids.

Lipid Fraction	Content in Milk (g/L)	Weight (%)
Triacylglycerols/triglycerides	30.7	95.80
Diacylglycerols/diglycerides	0.72	2.30
Monoacylglycerols/ monoglycerides	0.03	0.08
Free fatty acids	0.09	0.28
Phospholipids	0.36	1.11
Cholesterol	0.15	0.46
Cholesterol esters	0.006	0.02
Total	32.056	100.05

(C_4–C_8), which is a unique characteristic of milk fat (Table 43.8). Several positive findings have emerged for the consumption of milk fat.

Milk fat exists in an emulsion form in milk, making it highly digestible. Also, milk fat contains 10% short- and medium-chain fatty acids. Their 1 : 3 positions in the glyceride molecule allow gastric lipase with specificity for these positions to predigest them in the stomach itself. Butyric acid, a characteristic fatty acid of milk fat, is absorbed in the stomach and small intestine and provides energy similar to carbohydrates. Medium-chain fatty acids are transported to the liver for a rapid source of energy. The fatty acids lower the pH for facilitating protein digestion. At the same time, the acid barrier for pathogenic activity is enhanced. Free fatty acids and monoglycerides are surface-tension-lowering agents, thereby exerting an anti-infective effect.

Milk fat is a concentrated form of energy. Fat protects organs and insulates the body from environmental temperature effects. Milk fat functions as a source of fat-soluble vitamins A, D, E, and K and essential fatty acids, linoleic, and arachidonic acids. The essential fatty acids are not synthesized by the human body. They must be supplied by the diet. Arachidonic acid, with four double bonds, is present in traces. Its precursor is linoleic

TABLE 43.8 Milk Fat Fatty Acid Profile.

Fatty Acids	Common Name	Weight (%)
$C_{4:0}$	Butryic	3.8
$C_{6:0}$	Caproic	2.4
$C_{8:0}$	Caprylic	1.4
$C_{10:0}$	Capric	3.5
$C_{12:0}$	Lauric	4.6
$C_{14:0}$	Myristic	12.8
$C_{14:1}$	Myristoleic	1.6
$C_{15:0}$	–	1.1
$C_{16:0\ (branched)}$	–	0.30
$C_{16:0}$	Palmitic	43.7
$C_{16:1}$	Palmitoleic	2.6
$C_{17:0}$	–	0.34
$C_{18:0\ (branched)}$	–	0.35
$C_{18:0}$	Stearic	11.3
$C_{18:1}$	Oleic	27.42
$C_{18:2}$	Linoleic	1.5
$C_{18:3}$	Linolenic	0.59

TABLE 43.9 A Summary of Health Effects of Some Milk Fat Constituents.

Constituent	Physiological Effect
Butyric acid	Reduces colon cancer risk
CLA (conjugated linoleic acid)	Modulates immune function; reduces risk of cancer stomach, colon, breast, and prostate
Sphingolipids	May reduce risk of colon cancer
Stearic acid	May modulate blood lipids to reduce risk of cardiovascular and heart disease
Triglycerides	May enhance long-chain fatty acid and calcium absorption

Source: Adapted from Hoolihan (2004).

acid. Omega-3-linoleic acid and its products EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid) are also present in trace, but significant amounts. The positional location of individual fatty acids in the triglycerides is not random. In fact, the *syn*-1 and *syn*-2 positions on the glycerol molecule are mainly occupied by myristic ($C_{14:0}$), palmitic ($C_{16:0}$), stearic ($C_{18:0}$), or oleic acids ($C_{18:1}$). The *syn*-3 positions contain butanoic ($C_{4:0}$), hexanoic ($C_{6:0}$), or oleic ($C_{18:1}$) acids. A summary of major beneficial effects of milk fat is shown in Table 43.9.

Conjugated Linoleic Acids (*CLA*). Conjugated linoleic acids are a class of fatty acids found in animal products such as milk and yogurt. Rumen flora synthesizes CLA, which has been demonstrated to exhibit potent physiological properties. CLA is a strong antioxidant constituent of milk fat and may prevent colon cancer and breast cancer. It has been shown to enhance immune response. Prostaglandin PGE-2 promotes inflammation, artery constriction, and blood clotting. CLA may reduce the risk of heart disease by reducing levels of prostaglandin PGE-2. Studies have indicated that CLA may increase bone density, reduce chronic inflammation, and normalize blood glucose levels by increasing insulin sensitivity.

Phospholipids. A number of factors influence the unique phospholipids content of milk. The total phospholipids content of cow milk is approximately 2–5 mg/100 mL. They are located mostly in the fat globule and the membrane surrounding the fat in the globule.

Phospholipids are important because they are constituents of membranes and have a role in cell interaction with antibodies, ions, and hormones. They display surface-active properties and act as emulsifiers. Accordingly, they may improve fat absorption in the gastrointestinal tract. They are considered to protect gastric mucosa and may even extend protection from pathogenic microorganisms. Major components of phospholipids are 35% phosphatidyl ethanolamine, 30% phosphatidyl choline, 24% sphingomyelin, 5% phosphatidyl inositol, and 2% phosphatidyl serine. Sphingolipids are hydrolyzed in the gastrointestinal tract to ceramides and sphingoid bases, which help in cell regulation and function. Studies on experimental animals show that sphingolipids inhibit colon cancer, reduce serum cholesterol, as well as elevating the good cholesterol HDL. They could protect against bacterial toxins as well as infection.

Butyric acid is liberated from milk fat by lipase in the stomach and small intestine. It may exert a beneficial effect on the gastric and intestinal mucosa cells. In the colon, butyric acid is formed by fermentation of carbohydrates by the resident microbiota. Butyric acid in that location works as a substrate for colon cells and confers anticancer properties.

Cholesterol. Dietary total fat, saturated fat, and cholesterol are postulated to increase serum cholesterol, which is a risk factor for coronary heart disease. However, not all fatty acids cause elevation in total serum cholesterol. Stearic acid has a neutral effect, and lauric, myristic, and palmitic acids increase blood cholesterol levels. Individuals vary greatly in their blood lipids response to dietary fat and saturated fat. Also, it should be recognized that genetic factors are also responsible for synthesis of cholesterol in the liver; the bulk of serum cholesterol is infact controlled by genetic causes.

In general, the typical cholesterol content of whole milk (3.25% fat) is 10.4 mg/100 mL. It corresponds to 3–4 mg/g fat. In view of consumer preference for low-fat and nonfat dairy products, fat reduction is accompanied by cholesterol reduction. By separating fat from milk, an 80% reduction in cholesterol content can be achieved in skim milk. Thus, nonfat milk/skim milk show a residual cholesterol level of 4.9 mg/8 oz. serving.

43.4.3 Lactose

The content of the major carbohydrate of milk, lactose monohydrate, ranges from 4.8 to 5.2%. Lactose stimulates the absorption of calcium and magnesium. It has a relatively lower glycemic index of 46 as compared to 100 for glucose and 60 for sucrose (Gerdes 2002). This makes lactose in skim milk suitable for diabetics and in weight-control diets. It is less cariogenic than other sugars. Lactose stimulates bifidobacteria in the colon and thereby prevents infection and improves intestinal health.

Lactose absorption in humans is catalyzed by the enzyme lactase or β-D-galactosidase. Lactase is a nonpersistent enzyme in certain individuals, resulting in distressing symptoms of bloating, flatulence, and diarrhea following milk intake. Most individuals can tolerate two cups of milk spread over a day or with meals. In the case of lactose malabsorption, the symptoms are ameliorated by using lactase tablets or by consuming yogurt. Yogurt and some fermented milks contain live and active cultures, which on consumption by an individual furnish the enzyme lactase to assist in digesting lactose. Lactose-reduced milk and ice-cream products are also available.

A compound formed from lactose in heated milk products is lactulose. Heated milk contains up to 0.2% lactulose. As lactulose is not a digestible ingredient, it acts somewhat like a soluble fiber. Lactulose is generally used for treatment of constipation and chronic encephalopathy. Some recent data indicate that lactulose may enhance calcium absorption in the intestine. It stimulates the growth of *Bifidobacterium bifidum* and is thus beneficial in establishing useful microflora in the gut.

43.4.4 Minerals

Milk is an excellent source of minerals. The mineral content of milk is given in Table 43.10.

43.4.4.1 Functional Role of Calcium and Other Minerals. Milk and dairy products are excellent sources of bioavailable calcium. As compared with unfermented yogurt, addition of lactic acid to unfermented yogurt and its fermentation to regular yogurt, an improved bone mineralization has been observed. It is postulated that the acidic pH due to added lactic acid or naturally contained in fermented yogurt converts colloidal calcium to its ionic form and allows its transport to the mucosal cells of the intestine

TABLE 43.10 Major and Minor Minerals of Cows' Milk.

	Mean	Range
Major Mineral (mg/100 mL)		
Calcium, total	121	114–130
Calcium, ionic	8	6–16
Citrate	181	171–198
Chloride	100	90–110
Magnesium	12	9–14
Phosphorus, inorganic	65	53–72
Potassium	144	116–176
Sodium	58	35–90
Trace Elements (μg/100 g of milk)		
Boron	27	–
Chromium	1	0.8–1.3
Cobalt	0.1	0.05–0.13
Copper	20	10–60
Fluoride	12	3–22
Iodine	26	–
Iron	45	30–60
Manganese	3	2–5
Molybdenum	7	2–12

(Fernandes and others 1992). Milk supplies assimilable calcium and phosphorus in an optimum ratio. The major source of dietary calcium is dairy products, supplying as much as 75% of the dietary intake in developed nations. The bioavailability of calcium is further enhanced by the presence of vitamin D, lactose, and phosphoprotein (casein). One of the primary functions of calcium is to provide strength and structural properties to bone and teeth. Lack of adequate calcium intake, particularly during the growth phase, leads to osteoporosis or brittle bones in later life. It is also important in teeth development.

Calcium is involved in muscle contraction (including heart beat), blood coagulation, enzyme reactions, stimulation of hormonal secretions, and cell signaling. It is important in blood pressure control and is a factor in the prevention of colon cancer. Phosphorus is also critical in bone mass formation and takes part in various metabolic processes in the body. It is a crucial component of the genetic material DNA and RNA.

Iron is essential in the formation of hemoglobulin and in cytochrome activity. A deficiency causes anemia. Iron is further involved in brain function, in immunocompetence, and in the synthesis of lipids.

Magnesium is also a part of bone mass. It is involved in many metabolic pathways. Zinc is a component of several metabolic enzymes and DNA. It is involved in immune system functioning. Iodine is necessary for the formation of thyroid hormone, which regulates growth and metabolism. Copper is important in energy metabolism, as an antioxidant, is involved in collagen synthesis and iron utilization. Manganese is a cofactor of many metabolic enzymes. Chloride is an oxidizing agent and constitutes a vital ingredient of

stomach acid. Potassium is a major electrolyte in blood and tissues and helps in blood pressure regulation in conjunction with sodium. Sodium is further involved in nerve conduction, active transport, and bone formation.

43.4.5 Vitamins and Some Other Minor Constituents

In order to promote health and well-being, a balance of minerals and vitamins is required. They have to be supplied by food and supplements because they are not manufactured by the body. Milk contains both fat-soluble and water-soluble vitamins. The concentration of fat-soluble vitamins A, D, E, and K, and water-soluble vitamins B and C, and minor constituents of milk are given in Table 43.11.

Natural vitamin A activity in milk is due to retinol and the pigment β-carotene. Their level as well as those of vitamin D and E varies in milk according to the season and feed profile. Vitamin D is important in bone health and vitamin E is an antioxidant. Vitamin K is present in milk, but its dietary nutritional role is minor.

Milk is an important source of dietary B vitamins. They are stable to the various heating and processing conditions to which milk is normally subjected. Vitamin B_1, thiamin, is a cofactor in carbohydrate metabolism. Vitamin B_2 is involved in the oxidation reactions of glucose, fatty acids amino acids, and purines. Niacin facilitates utilization of carbohydrates, fat synthesis, and tissue respiration. Pantothenic acid participates in fatty acid metabolism. Vitamin B_6 is critical in protein metabolism. Folic acid acts as a growth factor and is involved in DNA synthesis. Vitamin B_{12} is required for growth, blood formation, and nerve tissue functioning. Biotin has a role in metabolism of carbohydrates, lipids, nucleic acid, and proteins. Ascorbic acid (vitamin C) is necessary for collagen formation, healing of wounds, and absorption of nonheme iron. It provides resistance to infections. However, vitamin C content of milk is very low and insignificant.

43.4.6 Enhancement of Functional Properties by Culturing of Milk

Fermented milks like yogurt are enhanced functional foods due to the fact that they contain nutrients of milk as well as products of metabolic activities of starter microorganisms in

TABLE 43.11 Vitamins of Milk.

Vitamins	Concentration in 100 mL Milk
A	40 μg RE*
D	4 IU**
E	100 μg
K	5 μg
B_1	45 μg
B_2	175 μg
Niacin	90 μg
B_6	50 μg
Pantothenic acid	350 μg
Biotin	3.5 μg
Folic acid	5.5 μg
B_{12}	0.45 μg
C	2 mg

**International units.

the product. Furthermore, they contain live and active cultures in significant numbers to effect physiological benefits to the consumer. Bacterial mass content and the products of the lactic fermentation further distinguish yogurt from milk.

43.4.6.1 Probiotics. Probiotics may be defined as a food or supplement containing concentrates of defined strains of living microorganisms that on ingestion in certain doses exert health benefits beyond inherent basic nutrition. Probiotics and associated ingredients might add an attractive dimension to cultured dairy foods for effecting special functional attributes.

Milk is an excellent medium to carry or generate live and active cultured dairy products (Chandan 1999; Shah 2001; Mattila-Sandholm and Saarela 2003). Fermentation adds an attractive dimension to cultured dairy products for augmenting the current demand for functional foods. The buffering action of the milk proteins keeps the probiotics active during their transit through the gastrointestinal tract. In general, worldwide consumption of fermented milk products has increased due to their high nutritional profile, unique flavor, desirable texture, and remarkable safety against food-borne illness.

43.4.6.2 Beneficial Microflora. Cultures associated with health benefits are yogurt bacteria (*Streptococcus thermophilus* and *Lactobacillus delbrueckii* spp. *bulgaricus*), other lactobacilli, and bifidobacteria (Chandan 1999). Table 43.12 gives a list of various probiotics being used in commercial fermented milks. Yogurt organisms possess a distinctly high lactase activity, making it easily digestible by individuals with

TABLE 43.12 Probiotic and Beneficial Microorganisms in Commercial Products.

Lactobacillus acidophilus
Lactobacillus johnsoni LA1
Lactobacillus gasseri ADH
Lactobacillus crispatus
Lactobacillus casei/paracasei
Lactobacillus casei subsp. *Rhamnosus*
Lactobacillus reuteri
Lactobacillus brevis
Lactobacillus delbrueckii subsp. *bulgaricus*
Lactobacillus fermentum
Lactobacillus helveticus
Lactobacillus plantarum
Bifidobacterium adolescentis
Bifidobacterium animalis
Bifidobacterium bifidum
Bifidobacterium breve
Bifidobacterium infantis
Bifidobacterium longum

TABLE 43.13 Potential Health Benefits of Fermenting Milk with Probiotics.

Effects Corroborated by Scientific Evidence	Effects of Potential Nature
Assisting lactose digestion	Controlling Candida and bacterial infections (vaginitis)
Treatment of rotaviral diarrhea	Alleviating constipation
Treatment of infant gastroenteritis	Antimutagenic/anticarcinogenic effects
Treatment of antibiotic-related diarrhea	Lowering cholesterol and blood pressure
Modulating intestinal (microbiota) ecology	Alleviation of microbial overpopulation in small intestine
Reducing harmful fecal enzymes, biomarkers of cancer initiation	Lowering of cholesterol and controlling hypertension
Enhancing/modulating immune system	Prevention and treatment of Crohn's disease
Positive effects on cervical and bladder cancer	Treatment of *Clostridium difficile* diarrhea
Reducing symptoms of atopic dermatitis in children	Prevention of sexually transmitted disease like AIDS

Source: Adapted from: Chandan (1999), Shah (2001), Fonden and others (2003).

a lactose-maldigestion condition. To bolster probiotic function, most commercial yogurt is now supplemented with *Lactobacillus acidophilus* and *Bifidobacterium* spp.

The probiotic preparations are also available in the form of tablets, powder, or capsules. They contain organisms from the genera *Lactobacillus*, *Enterobacter*, *Streptococcus*, and *Bifidobacterium*. These genera are important members of the gastrointestinal microflora and are all relatively beneficial. The strains of lactic acid bacteria used in probiotics are mostly intestinal isolates such as *L. acidophilus*, *L. casei*, *E. faecium*, and *B. bifidum*.

Yogurt starter bacteria, *L. delbrueckii* ssp. *bulgaricus* and *S. thermophilus*, are also included as probiotics in this table because yogurt has been associated with several health benefits in the past. They are now reported to persist and remain viable throughout the human gastrointestinal tract. The continuous ingestion of live products ensures abundant numbers to maintain their functional status. Even with intestinal isolates such as *L. acidophilus*, it is necessary to dose regularly rather than to assume that a few doses will allow the organisms to colonize the gut permanently. Currently, known probiotics are fortified with enzymes, anti-inflammatory compounds, specific amino acids, colostrum, and chelated minerals in probiotic preparations. *L. acidophilus* and *B. bifidum* strains are known to differ widely in their ability to grow in the presence of bile salts. Both are reported to be stable at various concentrations of bile salts.

Potential health benefits of probiotics are given in Table 43.13. Accordingly, as a result of fermentation, the health benefits of milk are considerably further enhanced.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

44.1 INTRODUCTION

Meat and meat products are valuable components of the human diet and the meat industry is one of the most important industries in the world economy. Annual meat production is projected to increase from 218 million metric tons in 1997–1999 to 376 million metric tons by 2030 (WHO 2003). In the past, meat has been considered an important food with great nutritional value. Consumption of meat was associated with good health and prosperity and the consumer selected meat products mainly based on sensory factors. Today, changes in dietary and life-style patterns have refocused consumer criteria to choose meats that will promote health and quality of life. This fact has enormous implications owing to the intense competition in the food industry, which makes it extremely sensitive to consumer demands and perceptions.

Nutrition is now recognized as a major modifiable determinant of noncommunicable chronic diseases. There is increasing scientific evidence supporting the view that diet alterations have strong positive and negative effects on health throughout life (WHO 2003). It is in this context that the so-called *functional foods* have emerged and have come to represent one of the fastest growing segments of the world food industry.

Presently there is no universally accepted definition; however, a working definition has been established in the consensus document concerning Scientific Concepts of Functional Foods in Europe. Functional food is more a concept than a well-defined group of food products that fits the following definition: "A food can be regarded as a functional food if it is satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects, in a way that is relevant to an improved state of health and well-being and/or reduction of risk of disease. Functional foods must remain foods and they must demonstrate their effects in amounts that can normally be expected to be consumed in the diet: they are not pills or capsules, but part of a normal food pattern" (Diplock and others 1999).

The meat industry has been slow to follow the functional trends, despite the fact that it is one of the sectors whose development may be of major interest. Over the last several decades, one of the reasons meat products have come under increasing scrutiny by medical, nutritional, and consumer groups is because of the associations between the consumption of meat constituents (i.e., fat, cholesterol) and the risk of major society diseases (i.e., ischemic heart disease, cancer, hypertension, and obesity). Based on nutrient and dietary goal recommendations, meat-based functional foods have the opportunity to improve their image and better serve the needs of consumers. Aside from meat's current relative importance, meat also constitutes a means for achieving a needed diversification in taking a position in emerging markets with great implications for the future. Therefore, developments in food processing and technology that enable the production of functional foods are increasingly important.

The beneficial effects of functional foods are associated with the role of one or more physiologically active components (functional or bioactive components). Knowledge of these substances is essential for the identification, design, and development of functional foods in general, and meat-based functional foods in particular. This chapter will address the functional foods based on the different strategies that the meat industry can utilize to affect potential functional components. The production of functional meat products requires the fullest possible understanding of the health implications, both positive and negative, of meat components. It is only through this

knowledge that it is possible to devise proper strategies for the modulation of their characteristics as needed.

44.2 MEAT COMPONENTS AND HEALTH

Foods are made up of thousands of biologically active components that have the potential to cause functional effects (improvement of health status and well-being and/or reduction of risk of disease). Although most of the biologically active components are produced by plants, some are also found in meat and meat products. These components include important sources of highly available forms of proteins, vitamins, and minerals. Meat contains bioactive constituents known to have protective effects (Arihara 2004; Biesalski 2004). Meats also contribute to components that, when ingested in excess, can have unhealthy implications (e.g., fat, saturated fatty acids, cholesterol, salt).

44.2.1 Proteins

Meat is a fundamental source of proteins of high biological value. Meat provides a well-balanced source of amino acids that satisfies human physiological requirements such as tissue growth and reconstruction. Supplying sufficient amino acids to maintain the protein reserves of the body is also an important factor in antibody synthesis, thus promoting acquired immunity to disease (Romans and others 1994). Certain amino acids present in meat have favorable effects on the nervous and immune systems. Recently it has been identified that some peptides released either during food processing or during digestion are related to reducing the risk of cardiovascular disease (CVD) or hypertension and alleviating the effects of alcohol (Garnier 2004).

44.2.2 Lipids

A variety of evidence has led to the establishment of a relationship between dietary fat and obesity, CVD, and certain types of cancer (WHO 2003). To prevent diet-related chronic diseases, the following goals for dietary nutrient intake have been established: Total dietary fat should provide between 15 and 30% of the calories consumed, with saturated fatty acids (SFA) supplying less than 10% of said calories, polyunsaturated fatty acids (PUFA) from 6% to 10% (ω-6, 5–8%; ω-3, 1–2%), and trans fatty acids less than 1%, while cholesterol intake should be limited to less than 300 mg/day (WHO 2003). Meat and meat products are important sources of dietary fat. The fat content in meat can vary widely depending on factors such as species, type of cut, and extent of fat trimming (carcass processing, primal cuts, retail cuts), among others. Meat lipids usually contain less than 50% SFA (of which only 25–35% have atherogenic properties) and up to 65–70% unsaturated (monounsaturated, MUFA, and PUFA) (Table 44.1). Ruminant meat is also a source of trans fatty acids, which are formed during biohydrogenation in the rumen.

Conjugated linoleic acid (CLA), a mixture of geometric and positional isomers of linoleic acid, is only found in useful amounts in meat and milk, especially from ruminants. The majority of the CLA present is in the form of 9-*cis*, 11-*trans* octadecadienoic acid. Its importance as a functional component lies in the fact that it appears to behave as an anticarcinogenic and antiatherogenic agent, and it induces a decrease in body fat and an increase in protein content. Products obtained from ruminants constitute the main

[b]In parentheses, % of total fatty acids.
[c]In parentheses, % of calories from fat.
SFA: saturated fatty acids; MUFA: monosaturated fatty acids; PUFA: polyunsaturated fatty acids.

source of CLA. Beef fat contains 3.1–8.5 mg/g fat (Hasler 1998) and lamb fat about 6 mg/g fat (Cassens 1999), while the lowest levels are found in the tissues of monogastric animals: 0.6 mg/g fat for pork (Higgs 2000) and chicken (Takenoyama and others 1999).

The amount of cholesterol in meat and meat products depends on numerous factors. In general, there is less than 75 mg cholesterol/100 g meat or meat product (Table 44.1). The exceptions are some edible offal (heart, kidney, brain, and so on) where the concentrations are much higher (Chizzolini and others 1999).

44.2.3 Micronutrients

Many of the apparent beneficial effects of animal source foods on human health and function are mediated in part by the micronutrients they contain. Meat is a good source of iron, zinc, and phosphorus, with significant amounts of other essential trace elements such as selenium, magnesium, and cobalt. Meat constitutes an excellent, highly bioavailable source of iron (Table 44.1); 50–60% of this iron comes in the heme form and contributes about 14–22% of total dietary iron intake (Schweitzer 1995; Higgs 2000). Iron deficiency is one of the most prevalent nutritional deficiencies worldwide, both in developing and developed nations (Neumann and others 2002). Menstruating women in particular constitute a group at risk for iron deficiency. Surveys carried out in France and North America reported iron deficiency in nearly 20% of these women (O'Sullivan and others 2002). A reduction in the consumption of meat of 50% could result in an excessively low iron intake (less than 8 mg/day) in one-third of women. This fact raises serious questions about the appropriateness of the general message to reduce meat intake, especially in certain populations (Carbajal 2004).

Meat is the richest food source of zinc, supplying approximately 20–40% of the amount absorbed (Higgs 2000). Increasing attention is being paid to the global prevalence of mild to moderate zinc deficiency both in developing countries and in disadvantaged groups in industrialized countries. Because of the widespread effects of zinc deficiency on morbidity, mortality, growth, and development, policy-makers must pay much more attention to improving diet quality through food-based approaches or supplementation where needed to address severe deficiency (Neumann and others 2002).

Selenium is one of the major antioxidants considered to protect against coronary heart disease and cancers (Higgs 2000). Table 44.1 shows that meat also contains significant amounts of selenium and provides about 25% of the daily requirement of this essential mineral.

Meat and meat products are an excellent source of the B-group vitamins thiamine (B_1), riboflavin (B_2), niacin, pantothenic acid, vitamin B_6, and vitamin B_{12}. Meat does not contain significant amounts of vitamins A, C, D, E, or K, although vitamin A is abundant in certain organs (liver, kidney). Recent analyses of meat and liver reveal significant amounts of 25-hydroxycholecalciferol, assumed to have a biological activity five times that of cholecalciferol. This seems to indicate that the role of meat and meat products in vitamin D intake has been underestimated, and that the importance of meat in the prevention of rickets in children and osteomalacia in adults, as well as its effect on bone metabolism, should be reviewed (Higgs 2000). Meat is an important source of folate; a folate-deficient diet has been associated with increased risk for different types of cancer resulting from low intake of fruits and vegetables. However, it has been considered that the bioavailability of folate from meat and liver is much better than that from fruits and vegetables (Biesalski 2004).

Meat also contains other micronutrients such as carnitine, creatine, choline, and so on; their importance in human physiology is only just beginning to be recognized (Garnier 2004).

44.2.4 Other Components

Meat is one of the richest natural sources of glutathione, which is an important reducing agent providing a major cellular defense against a variety of toxicological and pathological processes. The importance of glutathione in the defense against chronic disease signals a positive potential for meat (Higgs 2000). Natural polyamines (putrescine, spermidine, and spermine), which are ubiquitous components of meat, are involved in a multitude of basic metabolic processes with significant implications for human health; for example, they are essential for the maintenance of the high cell turnover rate of organs such as the gastrointestinal tract, pancreas, and spleen or of the high metabolic activity of the normally functioning and healthy gut. However, in other cases, the intake of polyamines should be minimized in an attempt to slow down the growth and progress of a tumor (Bardócz 1995).

44.3 MEAT AND MEAT PRODUCTS AS FUNCTIONAL FOODS: TECHNOLOGIES AND STRATEGIES

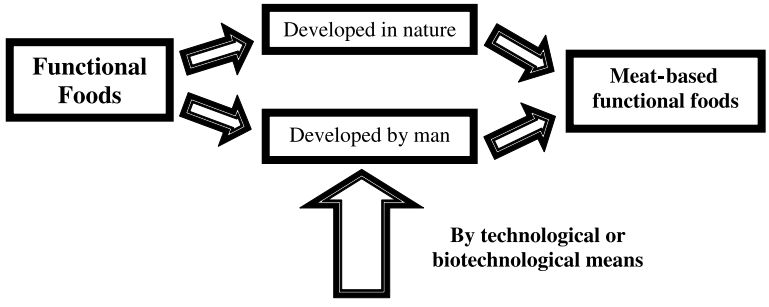
A functional food can be a natural food, a food to which a component has been added, or a food from which a component has been removed by technological or biotechnological means. It can also be a food in which the nature of one or more components has been modified, one in which the bioavailability of one or more components has been modified, or any combination of these possibilities (Diplock and others 1999). Functional foods include whole foods and fortified, enriched or enhanced foods (Hasler and others 2004). A number of the approaches for functional food production (Roberfroid 2000; Jiménez-Colmenero and others 2006) can be applied to meat processing (Fig. 44.1).

There are a number of ways to alter the presence of different functional components that can result in the development of meat-based functional foods. Some strategies used to achieve this are: genetic and nutritional, implemented through animal production practices; strategies dependent on transformation systems (preparation of meat raw materials, reformulation and processing), relative to distribution and storage; and finally, targeting the conditions in which products are consumed (Jiménez-Colmenero and others 2006).

Described in the following is an impact analysis of these strategies on the functional components, as well as the procedures followed to improve meat and meat product composition, and procedures that affect the bioavailability of certain components with functional effects. Likewise, the formation of some components whose presence may cause a deterioration of health status and well-being and increase the risk of disease are considered.

44.3.1 Improvement of Meat Components for Designing Meat-Based Functional Foods

From the farm to the table, there are a number of stages in which, either intentionally or incidentally, the composition of meat and meat products can be changed . These changes affect the presence of several functional components (Fig. 44.2).



- ELIMINATING/REDUCING a component known to have deleterious effects.
- INCREASING the concentration of a component naturally present in food (nutritive or nonnutritive) to a level known to produce beneficial effects.
- ADDING a component (macro or micronutrient or nonnutrient) that is not normally present in food but the beneficial effects of which have been demonstrated.
- REPLACING a component, usually macronutrient, whose intake is usually excessive and thus a cause of a deleterious effect, by a component for which beneficial effects have been demonstrated.
- MODIFICATION of the nature or bioavailability of one or more components with beneficial effects.
- COMBINATION of these possibilities.

Figure 44.1 *Approaches for meat-based functional food production.*

44.3.1.1 Animal Production Practices for Meat-Based Functional Food Production. Animal production practices represent the first opportunity to condition the presence of functional components. The composition of animal tissues, and hence carcasses and commercial cuts (and meat raw materials), varies not only according to species, but also according to breed, age, sex, type of feed, and so on. Several strategies are available for inducing changes (*in vivo*) in meat constituents. These strategies include genetic selection, gene manipulation, nutrition and feeding management, growth-promoting and nutrient-partitioning agents, and immunization of animals against target circulating hormones or releasing factors.

Lipid Modification. As meats (and meat products) are among the major sources of dietary fat, the attempt to approximate meat lipid characteristics (quantitative and qualitative) to recommended dietary nutrient goals is considered essential.

FAT CONTENT REDUCTION. The fat content in meat has significantly decreased in recent decades. Carcass fat has been reduced by about 6–15% in beef, 15–30% in pork, and 10% in lamb. Further reductions are anticipated for beef and lamb over the next few years (Goutefongea and Dumont 1990; Higgs 2000). The extent of and method for accomplishing the reductions depend on the species.

Although animal fat has been reduced by traditional genetic means (selective breeding), new alternatives have emerged with some of the genetic manipulation techniques more recently made available. Genomic maps of farm animals used for meat production have lately been constructed. This will enable the determination of regions within the

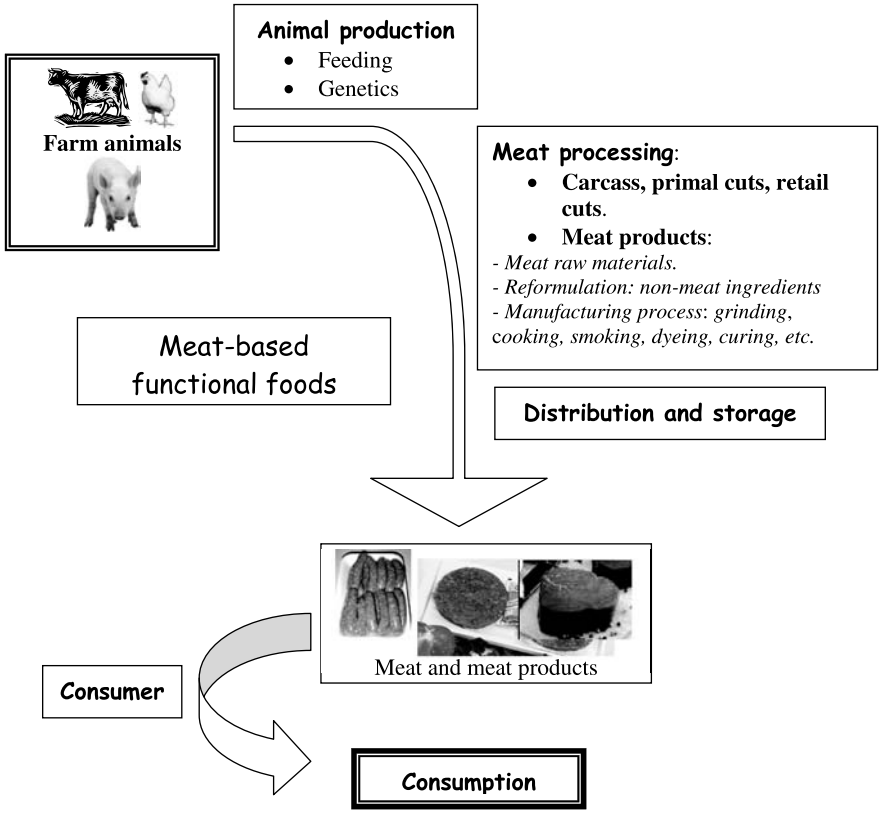


Figure 44.2 *From farm to table: strategies to affect meat and meat products components with potential implications in human health.*

genome that contain one or more genes with potential implications for quantitative parameters (fat distribution) of interest for selection (Kirton and others 1997; Barroeta and Cortinas 2004).

Carcass fatness can be manipulated in cattle, sheep, pig, and poultry by production practices. Nutritional strategies are easier to apply in monogastric animals than in ruminants. These strategies are determined largely by the composition of diets and by the levels of feeding, particularly the energy and protein intake (Hays and Preston 1994; Dikeman 1997). Using partitioning agents like anabolic steroids, growth hormones, and so on, or immunization strategies, it is possible to alter some metabolic processes that regulate the utilization of nutrients during growth in order to promote protein synthesis and reduce fat deposition (Bass and others 1990; Byers and others 1993). Additional management options to reduce carcass fat include elimination of castration, selection according to maturity, size, and sex, and others (Bass and others 1990; Dikeman 1997).

CHANGES IN FATTY ACID COMPOSITION. There are several ways to modify the fatty acid composition in farm animal fat, although the extent and procedure depend on the species. Genetic methods now enable the modification of fatty acid composition, specifically the

contents in palmitic, palmitoleic, myristic, linoleic, and linolenic acids, of pork (Clop and others 2003).

Lipid deposition in animal tissues can be endogenous, that is, synthesized *de novo*, or exogenous, caused by diet. Dietary fatty acid composition is an extremely important part of the fatty acid profiles of monogastric animals (pigs, poultry) and less important in ruminants (cattle). For this reason, numerous animal feeding trials have been carried out in the attempt to make the meat fatty acid composition more consistent with current human health recommendations and consumer requirements. Feeding strategies in beef, pork, lamb, or chicken have shown that plant (vegetable oils, plants rich in ω-3, forages) and marine sources (fish oil or fish meal) have been successfully used to significantly increase the levels of ω-3 PUFA (up to six-fold) and, more specifically, of eicosapentaenoic acid (EPA, 20:5ω3; e.g., up to 10-fold in beef), docosahexaenoic acid (DHA, 22:6ω-3; e.g., up to 60-fold in chicken), and linolenic acid (18:3ω-3) (Enser 2000; Sloan 2000; Barroeta and Cortinas 2004; Raes and others 2004). With these strategies, 100 g of chicken meat can provide 90% of the recommended daily allowance of EPA + DHA (Barroeta and Cortinas 2004).

Epidemiological, clinical, and biochemical studies have provided evidence of the chemopreventive activity of these fatty acids against some of the more common cancers (breast and colon cancer), rheumatoid arthritis, inflammatory bowel diseases, and CVD (Hoz and others 2004). Dietary modification of fatty acid composition has also made it possible to lower the ω-6/ω-3 ratios in farm animal tissues. This is important because evidence has been accumulated that suggests that increased intake of ω-6 and associated relative ω-3 deficiency, not cholesterol, is the major risk factor for cancers, coronary heart disease, and cerebrovascular disease (Okuyama and Ikemoto 1999).

Dietary supplementation has been used to enrich chicken, pork, beef, and lamb with CLA (Enser 2000; Lynch and Kerry 2000; Barroeta and Cortinas 2004; Raes and others 2004). Meat containing CLA has been described as a functional food (Pennington 2002; Hasler and other 2004).

REDUCTION OF CHOLESTEROL. Selecting animals with the right genetics, feeding them diets rich in unsaturated fats and treating them with growth-promoting or repartitioning agents are the most common strategies for modifying the cholesterol content in living animals. However, most of them have a negligible impact on cholesterol levels (Clarke 1997). Although variations can be observed among species, muscles, or certain breeds, between sexes or in relation to certain feeding regimes, their magnitude generally appears to be too low for them to be of real use in the diet-related reduction of cholesterol intake (Chizzolini and others 1999). The most promising method for selective reduction of the muscle tissue cholesterol content in a living animal (by 20.4% in breast muscle) appears to be through the provision of elevated dietary copper (Clarke 1997).

Vitamins. Increasing the presence of unsaturated fatty acids in meat causes heightened susceptibility to oxidation, a process that leads to undesirable changes in sensory characteristics. Food lipid oxidation is considered to pose a risk to human health. Some lipid oxidation products are considered atherogenic and appear to have mutagenic, carcinogenic, and cytotoxic effects (Chizzolini and others 1998). There are several means of minimizing lipid oxidation associated with animal feeding. These means represent the only technologies available to alter the oxidative stability of intact muscle foods.

Supplementing with dietary vitamin E (α-tocopherol) significantly in excess of physiological levels reduces lipid oxidation as well as myoglobin oxidation in the meats of poultry, pigs, cattle, and rabbits. The accumulation depends on species, muscle characteristics, levels of supplementation, and duration of feeding. (Morrissey and others 1998; Lynch and Kerry 2000; Dal Bosco and others 2001).

In addition to improving muscle quality, this strategy converts meat from a poor source of vitamin E to at least a moderate one (Lynch and Kerry 2000). It has been suggested that just 100 g of chicken can supply up to 30% of the recommended vitamin E intake (Barroeta and Cortinas 2004). Tocopherols are known for their efficient antioxidant activity in foods and biological systems; their ingestion helps to potentiate the antioxidative capacity of the organism (Surai and Sparks 2001). Epidemiological studies have provided evidence of an inverse relationship between coronary artery disease and vitamin E supplementation (Pryor 2003).

Dietary supplementation with the remaining fat-soluble vitamins or the water-soluble vitamins does not significantly change their concentration in muscle (Lynch and Kerry 2000).

Minerals. Apart from selenium and, to a lesser extent, iron, these muscle minerals are not responsive to dietary supplementation (Lynch and Kerry 2000).

Supplementation of the farm animal diet with iron increases muscle iron. However, diets low in iron produce anemic animals and the paler meat that is preferred by consumers (Lynch and Kerry 2000). It has been suggested that the use of supplemental iron (from hemoglobin) to increase pig meat iron levels could play an important role in reducing iron deficiency in some risk groups (O'Sullivan and others 2002; Ramírez and others 2002).

Dietary selenium supplementation makes it possible to increase the selenium levels in pork, beef, veal, and poultry (Wenk and others 2000; Surai and Sparks 2001). This strategy is presently utilized in most farm animal diets (Wenk and others 2000) and produces high-selenium pork that contains about ten times the selenium content of traditional pork (Anon. 2000).

The elimination of supplemental copper from the diet of broilers improves the oxidative stability of the meat, although the muscle copper concentration is not affected (Morrissey and others 1998).

Other Components. As animals cannot synthesize carotenoids, their presence in tissues depends completely on diet. They are absorbed from the food and transferred along the food chain. Carotenoids are used in animal feeds principally to enhance the color of poultry meat, eggs, and the flesh of some species of fish. Their potential role as antioxidants has increased the interest in achieving their incorporation into animal tissue (Morrissey and others 1998; Lynch and Kerry 2000). Carotenoids have been related to CVD risk reduction, cancer prevention, and immune function enhancement in mammals (Torrissen 2000). Diets enriched with different carotenoids (β-carotene, lycopene, zeaxanthin, lutein, and so on) have been employed to feed poultry (Morrissey and others 1998; Torrissen 2000; Sagarra and others 2001).

Inclusion in animal diets of other compounds with potential antioxidant activity (ubiquinone, plant phenolics, glutathione, phytoestrogens, carnosine, carnitine, and so on) has been described as a method to increase the oxidative stability of muscle food

(Decker and Xu 1998; Lynch and Kerry 2000). Feeding pigs certain types and amounts of soybean meal increases the amount of isoflavin in the meat, a circumstance that should justify the claims that pork is a functional meat as isoflavones have been shown to improve cardiovascular health in humans (Quaife 2002).

44.3.1.2 Meat Transformation Systems Tailored to Meat-Based Functional Food Production. Meat processing is another level at which it is possible to introduce changes in the amounts and types of functional components in processed meats (Table 44.2). Several basic approaches (Fig. 44.2) can be used to successfully induce the desired effects (Jiménez-Colmenero and others 2006). These measures focus on the treatment of the ingredients in order to secure a raw material suitable in terms of composition, reformulation of meat products to induce certain changes in their composition, and

TABLE 44.2 Approaches for Improving the Composition of Meat-Based Functional Products.

Reducing
• Lipid components: – Total fat – Saturated fatty acids – *Trans*-monosaturated fatty acid – *Trans*-polyunsaturated fatty acids – ω-6/ω-3 PUFA ratio – Cholesterol
• Sodium
• Unhealthy compounds (formed during processing, distribution, storage or consumption): nitrosamines, biogenic amines, polycyclic aromatic hydrocarbons, heterocyclic amines, lipid oxidation products
Replacing
• Lipid: animal fat by vegetable and fish oils
Increasing
• Lipid fraction – *cis*-monounsaturated fatty acids – ω-3 polyunsaturated fatty acids (linolenic acid 18:3ω-3; eicosapentaenoic acid, 20:5ω-3; docosahexaenoic acid, 22:6ω-3) – Conjugated linoleic acid
• Vitamin E
• Minerals (Ca, Se, Fe, Mg, Mn)
• Other compounds
Adding
• Plant-based protein
• Dietary fiber
• Probiotics
• Carotenoids
• Vitamin C
• Plant sterols
• Phytate
• Other substances

adaptation of the processing technologies. There are numerous aspects to be taken into account in the development of the new meat product and they all must respond to the same quality criteria (technological, sensory, nutritional, safety, convenience, and so on) as any other product.

Modification of the Meat Raw Material Composition. Whether for direct consumption or transformation into meat products, meat can be subjected to different treatments that modify the composition, generally regarding fat and cholesterol. The desirability of limiting the fat content in commercial cuts and meat products has encouraged the development of various procedures designed to separate and/or extract both visible fat and fat that is located in less accessible parts of the muscle tissue The most immediate system consists in extensive trimming to remove external and internal fat from the carcass; further trimming is done on primal cuts and, where necessary, the defatting can be completed on retail cuts. The final fat percent is limited by the intramuscular fat content and in some cases is truly low.

In products involving more structural breakdown, a number of procedures have been developed to reduce the percentage of fat in meat raw materials. These procedures require the reduction of meat particle size, followed by a preparatory phase (modification of pH, ionic strength of medium, and so on) prior to actual separation or removal using cryoconcentration, centrifugation, decantation, and so forth (Giese 1992; Jiménez-Colmenero 1996). Supercritical fluid extraction to remove fat and cholesterol from meat has been performed with beef, pork, and chicken. This innovative technique is very effective when the meat is partially dehydrated, with fat and cholesterol extraction even surpassing 90–95%. At normal moisture levels, the results of supercritical fluid extraction have been poor (Clarke 1997).

Modification of the Formulation Process. The most versatile manner of modifying the composition of meat products includes a wide range of options for changing the ingredients employed in their preparation and, consequently, these options alter the content of different endogenous and exogenous bioactive compounds. This strategy makes it possible to apply a number of the approaches proposed for the production of functional foods: reducing, increasing adding and/or replacing different functional components (exogenous and endogenous) (Fig. 44.1). The technological difficulties involved depend on the type of product (composed of identifiable pieces of meat, coarsely or finely ground, emulsions, heat treatment, curing, and so on) and on the modification to be introduced. The different types of reformulation approaches for designing meat-based functional foods, many of which can be applied simultaneously, are analyzed below.

REDUCTION OF COMPONENTS. Because some components normally present in meat and meat products have been associated with the development of certain diseases, the first approach to the reduction of disease risk (functional effect) involves reducing their concentration to appropriate limits (Table 44.2).

Reduction of Fat and Caloric Contents. The fat content of lean meat is less than 6%; meat products, however, can contain fat levels as high as 50% (Table 44.1). For humans in western societies, the major fat intake from meat products is the backfat of the pig, which is present in many processed meat products; subcutaneous fat from ruminants is generally consumed less often (Raes and others 2004).

The major effort to reduce dietary fat focuses on frequently consumed foods having the highest fat percentages. Fat-reduction techniques are usually based on two main criteria: the utilization of leaner meat raw materials and the reduction of the fat density (dilution) by adding water and other ingredients. In the development of low-fat products, factors associated with meat raw materials, nonmeat ingredients (fat replacements or substitutes: proteins, carbohydrates, lipids), and manufacturing and preparation procedures should be taken into account (Keeton 1994; Jiménez-Colmenero 1996). Low-fat foods (e.g., meats) are functional foods (Thomson and others 1999) that are currently available in markets.

Population nutrient-intake goals for preventing diet-related chronic diseases (WHO 2003) take into account both the percentage of total fat energy and the relative contribution of different types of fatty acids. They are, therefore, a key consideration in designing the new composition of any product.

In general, in industrialized countries, the caloric intake from fat has been decreasing. The proportion of calories from fat is now roughly 36–40% (still quite far from the 30% recommended). Almost a fourth of the fat calories come from the consumption of meat and meat products (Sheard and others 1998; Chizzolini and others 1999). Fat contains twice the kilocalories per gram as proteins or carbohydrates (9 for fat versus 4 for protein and carbohydrates). Caloric intake is most frequently limited by reducing the proportion of fat. Depending on several factors, the calories can be reduced by nearly 50% with respect to normal-fat meat products (Wirth 1991; Sandrou and Arvanitoyannis 2000).

Reduction of Cholesterol Content. The amount of fat is not always directly related to cholesterol level (Table 44.1). In dry matter, the amount of cholesterol in lean beef, pork, lamb, and poultry tissue may be as much as twice that present in adipose tissue, but in wet matter, the cholesterol content of lean tissues is slightly lower than that of adipose tissue (Mandigo 1991). Therefore, reduction of the percentage of fat does not seem to be a suitable method of reducing cholesterol in meat products (Jiménez-Colmenero and others 2001).

It has even been suggested that if fat reduction is achieved by increasing the proportion of lean meat, it can actually increase the cholesterol level in the product (Mandigo 1991). The way to obtain meat products with less cholesterol is by replacing meat raw materials–fat and protein–with others that are devoid of cholesterol, particularly plant products or vegetable oils. The original composition of a number of meat products (ground beef, frankfurters, pork patties, and so on) has been modified by reducing animal fat and/or partially replacing it with vegetable oils (olive, corn, sunflower, soybean) and by incorporating different plant-based proteins (soy, corn, oat, wild rice, wheat gluten) or gums (Clarke 1997). This dilution method has made it possible to significantly reduce cholesterol content. For example, a cholesterol reduction of around 20% with respect to conventional meat products has been reported in low-fat ground-beef and pork sausages (Sandrou and Arvanitoyannis 2000). Replacement of 60% of the beef fat in frankfurters containing 29% fat with peanut oil reduced the cholesterol content by more than 35% (Marquez and others 1989). Using olive, cottonseed, and soy oils, Paneras and others (1998) obtained frankfurters (10% fat) with up to 59% less cholesterol than regular frankfurters containing 30% animal fat.

Reduction of Sodium Content. High salt intake has been related to high blood pressure, one of the major risk factors for CVD (Antonios and MacGregor 1997). The sodium intake in most developed countries greatly exceeds physiological requirements. The current level of salt consumption ranges between 6 and 20 g per day (Antonios and MacGregor 1997),

much higher than the <5 g per day recommended (WHO 2003). Although meat in itself is relatively low in salt, meat products with an elevated salt content present much higher sodium levels (Table 44.1). Over 80% of the current salt intake now comes from that added by food manufacturers (Antonios and MacGregor 1997), 20% being attributed to meat products (Wirth 1991). There is growing interest among consumers and processors in reducing the use of salt (minimizing sodium) in meat processing.

A variety of approaches for reducing the sodium content of meat products has been reported, including partial substitution of the sodium chloride added to meat products by other compounds (potassium and magnesium salts, phosphates, alginates, lactates, hydrolysates of collagen and peptides, and microbial transglutaminase). These substitutes can produce similar effects on sensory, technological, and microbiological properties. The extent to which salt levels can be limited depends on the type of meat product (Wirth 1991). In recent years, the salt content in meat products has been reduced to the point that there are now several commercially available salt-free meat products.

Reduction of Nitrites. Sodium nitrite is traditionally added to cured meat products to give meat products a characteristic color, to contribute to the aroma and taste, to inhibit the development of certain microorganisms (*Clostridium botulinum* and other food-borne pathogens), and as a potent antioxidant. In recent years, dietary nitrite has been associated with methemoglobinemia and the formation of nitrosamines, which are considered to be chemical agents with proven carcinogenic, mutagenic, and teratogenic activities. These compounds occur in a number of foods, including heat-cured meat products. They can form either in the food itself (depending on the heat-treatment conditions, salt, nitrite, and ascorbate concentrations, or pH) or in the stomach of the consumer (Pegg and Shahidi 1997).

As nitrosamine production depends on the residual nitrite level, the reduction of the latter will reduce the risk of these carcinogenic compounds forming. Another strategy is to use nitrosamine inhibitors. In fact, residual nitrite has been substantially reduced (up to 80%) in recent years. This change can be attributed to reduced nitrite addition, increased use of ascorbate, improvements in manufacturing processes and changes in composition (Cassens 1999). In coming years, Europe could increase the legal restrictions on nitrate and nitrite levels in meat processing.

REPLACING, ADDING AND INCREASING DIFFERENT COMPOUNDS IN MUSCLE FOOD PRODUCTS. A good way to increase the dietary intake of functional components is to incorporate them into common foods (Jiménez-Colmenero and others 2006). Meat product processing makes it possible to replace, add, or increase nonmeat ingredients (familiar or unfamiliar) with potential functional effects. Although replacement has focused mainly on lipids (and to a lesser extent on proteins), adding or increasing (fortified, enriched, or enhanced foods) involves a wide range of bioactive substances, unfolding myriad potential strategies (Table 44.2). Food fortification, which is considered to be one of the most successful approaches to functional foods (Wahlqvist and Wattanapenpaiboon 2002), plays an important role. The functional components have been used

1. In the form of specific preparations (of greater or lesser purity) utilized intentionally, and as constituents of certain nonmeat ingredients (extracts, flours, concentrates, homogenates, and so on); and

2. For different purposes (technological, sensory, nutritional, microbiological, economical) in the meat industry.

In reality, many of those nonmeat ingredients are of plant origin (oats, soybean, wheat, sunflower, rosemary, apple, mushroom, walnut), and their composition includes a wide range of beneficial components (phytochemicals) (Pennington 2002). Thus, their utilization as nonmeat ingredients implies the assurance of the presence of added bioactive components in many commercially processed meats. On the other hand, new possibilities arise as a consequence of migratory waves that introduce novel ethnic and regional specialties. These new foods and tastes enable the introduction of additional, more healthful products that may require expanding the array of components and technology.

The different types of functional components employed in the production of meat-based functional food are described below. Although they are presented individually here, in many cases the use of nonmeat ingredients containing complex mixtures of bioactive substances involves the coexistence of several types of interventions.

Modification of the Fatty Acid Profile. Meat product fatty acid composition can be modified by the formulation approach through the ingredients employed: meat raw material and nonmeat ingredients (Fernández-Ginés and others 2005). The first case entails the use of meat that, as a result of animal production practices (Section 44.3.1.1), presents a more favorable lipid profile in terms of improving the health status of the population (increased MUFA or ω-3 PUFA contents and reduced ω-6/ω-3 PUFA ratio). Several types of products have been prepared in this manner. Frankfurters and low-fat sausages containing high concentrations of MUFA have been made with meat raw materials from pigs fed on safflower, sunflower, and canola oils (St. John and others 1986; Shackelford and others 1990). Dry fermented sausages, cooked ham, and pork liver pâté with a healthier ω-6/ω-3 PUFA ratio have been manufactured using materials (backfat and meat) enriched in ω-3 PUFA, obtained from pigs fed on linseed-oil-enriched diets (Hoz and others 2004; Santos and others 2004; D'Arrigo and others 2004).

The second procedure consists in replacing part of the animal fat normally present in the product with another more suited to human needs – that is, with less saturated fatty acids and more MUFA (oleic acid) or PUFA and, moreover, without cholesterol. Simple fat replacement does not reduce the caloric content. Fish oils (ω-3 polyunsaturated oil) have been used for this purpose in low-fat frankfurters (Park and others 1989). Different vegetable oils (corn, cottonseed, palm, peanut, soybean, high-oleic acid sunflower, olive, linseed) have been used to replace animal fats (pork backfat or beef fat) in meat products such as frankfurters (Marquez and others 1989; Paneras and others 1998), ground beef patties (Liu and others 1991), and fermented sausages (Bloukas and others 1997; Muguerza and others 2002; Ansorena and Astiasaran 2004). Other types of nonmeat ingredients, such as walnut, have been utilized to produce healthier changes in the fatty acid profiles of frankfurters and restructured beefsteaks (Jiménez-Colmenero and others 2003). Walnuts display a high fat content (62–58%), being rich in MUFA (oleic acid) and PUFA (with linoleic and linolenic acids constituting 58% and 12%, respectively, of PUFA content). Besides modifications in the diet of the animals (Section 44.3.1.1), the interest in increasing the presence of CLA has led to its direct addition to meat products (Joo and others 2000).

On the other hand, the varying effects of fats (in part, depending on fatty acid composition) on satiety signals could be used in the development of fat-containing food (meat

products) that modulates satiety. Specific manipulations of fats (as well as proteins and carbohydrates) have the potential to act as functional foods for appetite control (Dye and Blundell 2002).

Factors associated with both the nature of the lipid material used for replacement and the type of product (degree of structural disintegration, fresh, cooked, fermented, and so on) condition its impact on the properties of the product and, consequently, the amount of meat fat that can be replaced.

Plant-based-Proteins. Several plant-based proteins have been used as ingredients in meat products essentially for technological (as binders and extenders), economical (reduce formulation cost), and compositional (nutritional and health) purposes. Examples of these protein additives are wheat flour, vital wheat gluten, soy flour, soy protein concentrate, soy protein isolate, textured soy protein, cottonseed flour, oat flour, corn germ meal, and rice flour, among others. Some of them have been used as fat replacements in low-fat meat products (Keeton 1994). Several of these nonmeat ingredients also contain bioactive compounds (Pennington 2002). For this reason, soy protein products have been widely studied. Owing to the presence, in addition to soy protein, of other compounds such as fiber, isoflavones, saponins, and so on they have been associated with health benefits such as reduced risk of heart disease, prevention of cancers and osteoporosis, and reduced menopausal symptoms (Hasler 1998). Other plant proteins also employed in meat products (sunflower, walnut) contain high proportions of arginine (a nitric oxide precursor) having a low lysine/arginine ratio. Many studies support the hypothesis that arginine or the low lysine/arginine ratio reduce arteriosclerosis and report beneficial effects on heart failure, blood pressure, and stroke (Feldman 2002).

Dietary Fiber. Regular fiber intake has a number of beneficial effects. Fiber is involved in regulating blood glucose and blood lipids, reducing the risk of diabetes, and preventing CVD, colon cancer, and regulating intestinal transit time. Europeans generally consume around 20 g/day, versus the more than 25 g/day recommended (WHO 2003). The incorporation of fiber into commonly consumed foods, like meat products, could help correct this deficiency. Fiber has been widely added to meat products, not only for its known physiological effects, but as a technological ingredient to improve water-binding properties, texture, and emulsion stability, helping to overcome the effects on the characteristics of meat products produced by composition changes (e.g., the fat reduction process).

Dietary fiber from oats, sugar beets, soy, rice, apples, peas, citrus fruits (lemon, orange), and so on, have been added to the formulation of several meat products such as ground meat and sausages (Keeton 1994; Kim and others 2000; Jiménez-Colmenero and others 2001; Fernández-López and others 2004; Fernández-Ginés and others 2005). Of special importance is inulin, a soluble dietary fiber composed of a blend of fructose polymers extracted from chicory that is being incorporated into numerous foods, including meat products (Pszczola 1998; Sloan 2000). The addition of antioxidant dietary fiber and chitosan to meat products also raises interesting possibilities.

Probiotics. Probiotics are living microbial food ingredients that are beneficial in such health concerns as gastrointestinal disorders, food allergies, inflammatory bowel diseases, and immune function. Examples of probiotics are lactic acid bacteria or bifidobacteria,

primarily of the *Lactobacillus* species (Työppönen and others 2003). The idea of using probiotic bacteria as fermenting agents in meat products is just beginning to develop.

Dry sausages are nonheated meat products that may be suitable carriers to deliver probiotics into the human gastrointestinal tract. Several of these products have been inoculated with *Bifidobacterium lactis, Lactobacillus casei, Lactobacillus paracasei*, and *Lactobacillus rhamnosus*. One essential aspect consists in ensuring that they survive the processing conditions (presence of nitrite, sodium chloride, or hostile environment) and the environment of the gastrointestinal tract. In order to achieve a health effect, the minimum daily intake of probiotic bacteria is estimated to be 10^{9-10} viable microbes. Thus, 10–100 g of dry sausage containing 10^8 viable microbes/g could be the minimum daily dose (Työppönen and others 2003). Dry sausages with an added probiotic culture are already being commercialized.

Tocopherols. Diet supplementation with vitamin E improves the oxidative capacity of meat (Morrissey and others 1998). Supplementation of meat products, such as reformed and restructured cured turkey products (Walsh and others 1998), cooked ham (Santos and others 2004), and dry fermented sausage (Hoz and others 2004) are also improved with vitamin E.

The antioxidant nutrient profile of meat products also has been improved by adding vitamin E during the manufacturing process, either as a specific preparation or as a component of nonmeat ingredients. Vitamin E has been added *in vitro* to several meat products (sausages, ham) and, in some cases, such as certain cured products, has been shown to decrease the production of nitrosamines (Gray and others 1982). Of the different plant sources that have been employed in the formulation of meat products, of particular interest are the wheat germ in frankfurters (Gnanasambandam and Zayas 1992) and walnut in restructured steak (Jiménez-Colmenero and others 2003). Although walnuts contain very low amounts of α-tocopherol (compared with other nuts), they have a high γ-tocopherol content, constituting an excellent dietary source of this vitamin.

Interestingly, γ-tocopherol exhibited a high antioxidant activity with potentially important physiological implications (Olmedilla and others 2006). Kim and others (2000) improved the oxidative stability of roast beef by incorporating the natural antioxidants (vitamin E vitamers and oryzanols) present in rice bran oil. Honey, which also has considerable antioxidant properties including α-tocopherol, ascorbic acid, catalase, and flavonoids, has been added to muscle food to protect against lipid oxidation (Pszczola 1998). At the present time, there are a number of commercially available vitamin-E-enriched meat products.

Carotenoids. In addition to nutritional strategies to incorporate carotenoids into intact muscle (Section 44.3.1.1), the use of carotenoids as an exogenous antioxidant additive in meat products with a certain structural disintegration has also been tested. Carotenoids are naturally present in different vegetables (Pennington 2002) employed as nonmeat ingredients in various processed meats (beef patties, restructured beef steak, frankfurters, and meat/liver loaves). Such is the case for tomato pulp (rich in lycopene) (Sánchez-Escalante and others 2003), carrot and sweet potato (rich in provitamin A) (Saleh and Ahmed 1998; Devatkal and others 2004), and spinach (rich in lutein and zeaxanthin) (Pizzocaro and others 1998).

Vitamin C. Ascorbic acid supplementation offers beneficial health effects as this vitamin produces a number of physiological effects that enhance immune function and help to prevent heart diseases and certain types of cancer (Johnston 2003). It is added to meat products either in the form of ascorbic acid or as part of certain nonmeat ingredients (mainly vegetables) employed in the formulation of meat products. Ascorbic acid has been incorporated into beef patties (Sánchez-Escalante and others 2001). Citrus byproducts have been added to cooked and dry-cured sausages as a source of ascorbic acid (Fernández-López and others 2004). The antioxidant properties of honey, resulting from its special composition (rich in ascorbic acid, among other substances), has led to its use as a protective agent (functional) against lipid oxidation in roasted chicken (Pszczola 1998) and cooked pork meat (O'Connell and others 2002).

Minerals. Certain meat products (e.g., sausages and turkey sausages) have been enriched with calcium (Harris 2000) and fluoridated salt. Their consumption is aimed at children to aid in bone and tooth development. On the other hand, the utilization of some nonmeat ingredients in processed meat can increase the levels of copper, magnesium, and manganese.

Plant Sterols. Plant sterols are present in most plants (Pennington 2002), some of which are used as nonmeat ingredients in processed meats. Structurally, plant sterols and stanols (saturated derivatives of sterols) are very similar to the cholesterol with which they compete during absorption in the intestinal tract. Stanol esters reduce the blood total cholesterol and low-density lipoproteins (LDL), without affecting the high-density lipoprotein (HDL) or triglyceride content. In 2000, the FDA authorized health claims for plant sterol and stanol esters based on evidence that they may help to reduce the risk of CVD. Several products have been developed in the form of foods typically consumed on a daily basis, including meat products such as frankfurters and broiler meatballs (Leino 2001).

Phytates. Phytate (myo-inositol hexaphosphate) is a natural antioxidant present in many plants (most cereals, nuts, and legumes). These phytochemicals also exhibits other health effects. Although phytate has antinutritional properties affecting mineral absorption, it also has anticarcinogenic effects, decreases kidney stones, lowers blood cholesterol in humans, and improves the glycemic index in human foods (Lee and others 1998). Phytates have been added to meat products; either in the form of commercial preparations (sodium phytate) in restructured beef (Lee and others 1998), or as components of several phytate-rich plants used as additives in different meat products; for example, rice fiber added to beef roast (Kim and others 2000).

Other Compounds. A number of other compounds are added to meat products during processing. They may be incorporated intentionally to achieve specific objectives or as components of one of the ingredients (soybean, nuts, onions) employed in the formulation. Examples of the intentional use are the addition of taurine, carnosine or spices to enhance lipid stability (Morrissey and others 1998; Sánchez-Escalante and others 2001) or limit the formation of mutagenic/carcinogenic heterocyclic amines (Gibis and others 1999). Other compounds are added unintentionally as ingredient components. Examples of unintentional use are isoflavones present in soy products (Sadler 2004) or the flavonols (which inhibit human platelet aggregation and prevent atherosclerosis) and allyl sulfides in onion (Pennington 2002; Fista and others 2004).

Consequences of Manufacturing Procedures on Meat Product Components Implicated in Human Health. In addition to the steps related to meat raw material and formulation, meat processing involves many other interventions that can modify the composition of the already formulated product. They can affect the content of (increasing or decreasing) some nutrients or other food components naturally present in food or the formation of others, as well as alter the microbial systems in functional foods (Knorr 1998). Some of these changes may have notable implications for human health. They can produce an increase in the density of some nutrients (e.g., due to cooking, drying) or the loss of others (due to cooking). On the other hand, meat and meat products undergo major chemical changes during processing (grinding, cooking, frying, smoking) that result in the formation of numerous compounds, many of which impart desirable characteristics to the food. Others, however, can have negative implications for human health. For example, although fermentation is intended to produce probiotics (Knorr 1998), in other cases, substances that possess potentially harmful biological properties may be formed, as is the case of nitrosamines, polycyclic aromatic hydrocarbons (PAH), heterocyclic amines, biogenic amines, and lipid oxidation products.

Cooking of cured meats may enhance nitrosamine formation. Polycyclic aromatic hydrocarbons result from the combustion of organic matter in the cooking and smoking of meat and meat products, as in many other foods. Their presence is determined by a number of factors, among them the composition of the product and the heat treatment applied. The importance of these hydrocarbons in certain meat products lies in the fact that some of them are carcinogenic (Hotchkiss and Parker 1990). Biogenic amines are compounds that are present in a large number of foods, including meat products. The biogenic amine concentration is conditioned by numerous factors, among them processing (curing) and preservation conditions. Consumption of foods with high concentrations of biogenic amines can cause migraine, headaches, gastric and intestinal problems, and pseudo-allergic responses, chiefly brought about by the toxic action of histamine and tyramine (Smith 1980).

Processing operations that disrupt the oxidation balance of skeletal muscle include particle size reduction (facilitates contact between oxygen and oxidizable lipids), cooking (causes a loss of antioxidant enzyme activity and release of protein-bound iron), and salting (increases the catalytic activity of iron and reduces antioxidant enzyme activity). These processing operations can dramatically increase lipid oxidation in muscle foods. Technological strategies to minimize the development of unhealthy products (Decker and Xu 1998) would help to reduce the risk of disease.

Recent research is disclosing the role of the proteins in meat as precursors of bioactive peptides, that is, fragments that are inactive within the precursor protein, but that can be released *in vivo* or *in vitro* by means of hydrolysis, and may exert different physiological functions in the organism. Arihara and others (1999) detected angiotensin-I-converting enzyme (ACE) inhibitory peptides in several commercial fermented meat products (e.g., cured loin of pork from Spain) and model sausages fermented with lactic acid bacteria. ACE plays an important physiological role in regulating blood pressure. Those authors suggested that ACE inhibitory activities can be generated from muscle proteins and could be utilized to develop functional foods (Arihara 2004). Some peptides from collagen hydrolysates inhibit fibrin polymerization and platelet formation, important elements of CVD (Garnier 2004).

Interestingly, CLA increases in foods that are cooked and/or otherwise processed (Arihara 2004). This is significant in view of the fact that many mutagens and carcinogens have been identified in cooked meats (Hasler 1998).

44.3.1.3 Distribution and Storage Conditions. From manufacture to consumer, meat products (like all other foods) must go through stages of distribution and storage, During this time changes can take place favoring the formation of harmful compounds such as those derived from lipid oxidation and biogenic amines. These changes can compromise the viability of probiotic strains (Knorr 1998).

44.3.1.4 Influence of Preparation and Consumption. Initially, in the selection of products, and later, during their preparation and consumption, consumers may modify food components that have implications for human health. Many foods, among them meats, undergo certain treatments before being consumed that markedly affect their composition.

The amount of fat ingested from a given product can vary widely depending on factors associated with the conditions of preparation and consumption. Cooking methods appear to be important. The fat content of cooked meat is sometimes higher than that of the corresponding raw meat, when expressed on a percentage basis, due to loss of large quantities of water during cooking. However, with respect to dietary fat intake, it is more meaningful to calculate the fat content on an absolute basis, based on an initial 100 g. Expressed thus, the cooking process reduces fat content in a proportion that depends on the type of product, its fat percentage, and the cooking method used: deep frying, grilling, roasting, boiling, or pan frying. In some cases, up to 25% or even 35% of the fat initially present can be lost during cooking (Sheard and others 1998). To make the most of this circumstance, pads have even been designed to absorb fat lost during the cooking process (microwave), minimizing the fat contact with food (Giese 1992). Even though the cholesterol content (per 100 g of meat) normally increases on a wet tissue basis after the cooking process (mainly due to loss of water), no changes in cholesterol content are observed in dry matter (Chizzolini and others 1999).

The amount of fat ingested also varies according to the manner in which it is separated from the meat during its preparation for cooking or when it is being eaten. The consumer can remove fat from meat, reducing the overall fat intake by variable amounts. Thus, trimming fat is a more effective means of reducing fat intake than simply reducing red meat consumption. The situation is rather different with meat products where the fat is present in a highly comminuted form and evenly distributed throughout the product (Sheard and others 1998).

44.3.2 Bioavailability Considerations

The presence of bioactive components in functional foods is not only to be considered. Other aspects that affect the bioavailability of the components are also relevant (Diplock and others 1999; Roberfroid 2000). In the different stages between meat production and its consumption, including processing, distribution, and storage, there are a number of factors that can affect the bioavailability of some components, modifying their functional effect and, thus, the role of meat products as functional foods.

44.3.2.1 Synergistic Effect of Absorption of Nutrients in Muscle Foods. It is believed that muscle foods possess intrinsic factors ("meat factors"), most of which have not been entirely delineated. These factors improve the bioavailability of a variety of nutrients. The most clearly established intrinsic effect of muscle food on a nutrient involves heme iron (Godber 1994). Meat enhances iron absorption from plant foods, so the presence of meat in a meal can double the amount of iron absorbed from other components of the meal.

Zinc absorption and retention are greater with high-meat diets, compared to low-meat or zinc-supplemented diets (Higgs 2000). The bioavailability of trace minerals such as zinc and copper is lower in plant foods than in muscle foods, which may even promote the bioavailability of calcium and/or magnesium given the apparent effect of these foods on bone mineralization. It has also been suggested that certain other nutrients, including vitamin B_6, folic acid, and niacin, are more readily available from animal sources than from plant sources (Godber 1994).

44.3.2.2 Effect of Processing on Bioavailability of Meat Product Components. A variety of processing procedures used in the manufacture of meat products, their distribution and storage, and even consumer practices can have an impact on the efficiency of absorption of some nutrients, and interactions between different food components can affect the bioavailability of some of them. These interactions can take place during meat processing involving certain nonmeat ingredients, such as fiber or phytic acid. These ingredients bind a number of minerals, which decreases mineral bioavailability (Godber 1994; Kim and others 2000). However, meat provides an assured source of iron, as heme-iron is unaffected by the numerous inhibitors of iron absorption such as phytate (Higgs 2000). In addition to the formation of several compounds that have negative effects on health, lipid oxidation also leads to the loss of nutrients susceptible to oxidative degradation, as is the case for fat-soluble vitamins A and E and certain water-soluble vitamins, including thiamin and folic acid (Godber 1994).

Studies have shown that, depending on different factors, cooking (whether by the meat processor or the consumer) can reduce the bioavailability of some bioactive compounds in muscle tissue, such as taurine, carnosine, coenzyme Q_{10} (ubiquinone), and creatine. These compounds are associated with several health benefits. For example, carnosine and coenzyme Q_{10} have antioxidant properties and taurine presents antioxidant activity and protects against exercise-induced muscle damage, but, under certain circumstances, creatine contributes to the formation of muscle mass (Purchas and others 2003). Losses of carnitine during storage and cooking of meat have been reported. This small molecule is essential for fat metabolism as a vitamin-like material and has a relation with various diseases (Wakamatsu 1999).

44.4 CONCLUSIONS

The meat industry is changing rapidly, impelled by changes in food technology and demand. Functional foods pertain to a category of products that clearly respond to consumer preferences, and a good way to increase functional components into the diet is to incorporate them into common foods. As meat is one of those most widely consumed, it would appear to be an excellent vehicle for functional component delivery.

Although the idea of functional foods is more closely associated with other foods, meat and meat products contain a number of compounds (naturally present or added) that confer the properties of functional food to them. A number of technological and biotechnological strategies make it possible to modify the content and/or bioavailability of functional components from different sources, a circumstance that raises considerable expectations concerning the possibility of generating meat products better adapted to the specific needs of large sectors of society. Meat-based functional foods would help to integrate meat and meat products into healthful diets.

Most of the studies on meat-based functional foods (like those dealing with most functional foods) focus mainly on production systems, concentrating on the presence of one or more functional components. One aspect that may place in doubt the benefits of some of these practices is modifications affecting the bioactive components of meat products that may decrease the quantitative importance at a dietary level. However, dietary diversification and modification is one of the intervention strategies recommended to increase the intake of certain food components and reduce the occurrence of micronutrient malnutrition (Gibson and Hortz 2001).

Although essential, there are few studies designed to elucidate the behavior and biological activity of the different functional components of meat products (or other functional foods) in terms of the processing conditions, as well as their functional impact on the organism. In this respect, it is crucial to assess the possible changes in the bioavailability of the functional components after the many stages of preparation and preservation of foods for human consumption.

It is also of the utmost importance to clearly establish the optimal levels of most of the biologically active components in order to ensure that their effects are truly beneficial at the doses and under the conditions in which they are consumed (Hasler 1998). Foods can be regarded as functional if they can be demonstrated to affect beneficially one or more target functions in the body, beyond an adequate nutritional effect, in a way that is relevant to an improved state of health and well-being and/or reduction of risk of disease. In-depth studies that provide scientific evidence of the functional effects of meat-based functional foods are indispensable.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

45.1 INTRODUCTION

The demand for gluten-free foods is constantly rising, due to the increased number of consumers suffering from food intolerances or a disorder referred to as celiac disease. The majority of the gluten-free products on the market are of very poor quality and, due to the unique properties of gluten, in the production of cereal products it is a great challenge for the food scientist to create products comparable to their wheat counterparts.

45.2 CELIAC DISEASE

In recent years there has been a slow and steady increase in consumer interest in wheat-free foods, driven in part by an increasing awareness of the relatively unfamiliar condition known as celiac disease (Lovis 2003). Celiac disease, also known as nontropical sprue, celiac spru, idiopathic steatorrhoea, primary malabsorption, Gee–Herter disease, gluten-induced enteropathy, and adult celiac disease (Cooke and Asquith 1974), is a gluten-sensitive entropy characterized by the damage of the small-intestinal mucosa caused by the gliadin fraction of wheat gluten and similar alcohol-soluble proteins (prolamins) of barley and rye in genetically susceptible people (Murray 1999; Fasano and Catassi 2001; Farrell and Kelly 2002). Table 45.1 (Feighery 1999) outlines the most commonly encountered reactions to gluten by sufferers of celiac disease.

45.2.1 Epidemology

Celiac disease was once thought to be a rare condition and confined to childhood (Green and Jabri 2003), with a uniform clinical presentation of weight loss and diarrhea. Due to improved diagnostic procedures (antigliadin antibody serological tests) and increased

TABLE 45.1 Symptoms (and Related Signs) of Celiac Disease.

Infancy (0–2 years)
Diarrhea (miserable, pale)
Abdominal distension (enlarged abdomen)
Failure to thrive (low weight, lack of fat, hair thinning)
Anorexia, vomiting
Psychomotor impairment (muscle wasting)
Childhood
Diarrhea or constipation
Anemia
Loss of appetite (short stature, osteoporosis)
Adulthood
Diarrhea or constipation
Anemia
Aphthous ulcers, sore tongue and mouth (mouth ulcers, glossitis, stomatitis)
Dyspepsia, abdominal pain, bloating (weight loss)
Fatigue, infertility, neuropsychiatric symptoms (anxiety, depression)
Bone pain (osteoporosis)
Weakness (mypoathy, neutopathy)

Source: Feighery (1999).

TABLE 45.2 Prevalence of Celiac Disease Based on Clinical Diagnosis or Screening Data.

Geographic	Prevalence on Clinical Diagnosis	Prevalence on Screening Data
Denmark	1 : 10,000	1 : 500
Finland	1 : 1000	1 : 130
Germany	1 : 2300	1 : 500
Italy	1 : 1000	1 : 184
Netherlands	1 : 4500	1 : 198
Norway	1 : 675	1 : 250
Sweden	1 : 330	1 : 190
United Kingdom	1 : 300	1 : 112
United States	1 : 10,000	1 : 111
Worldwide Average	1 : 3345	1 : 266

Source: Fasano and Catassi (2001).

awareness of celiac disease, the rate of diagnosis has significantly increased. In Europe, the prevalence of celiac disease is estimated to be 1 in 300 to 1 in 500 persons, but recent population-based screening studies suggest that the prevalence may be as high as 1 in 100 (Mustalahti and others 2002). Table 45.2 (Fasano and Catassi 2001) illustrates the prevalence of celiac disease based on clinical diagnosis and screening data. However, a review by Farrell and Kelly (2002) suggests that the true prevalence of celiac sprue is difficult to ascertain, because many patients have atypical symptoms or none at all. Celiac disease is more frequent throughout Europe than previously thought. From Table 45.2, it is evident that the prevalence of celiac disease is as frequent in the United States as in Europe (Fasano and Catassi 2001). From results obtained from screening data, Fasano and Catassi (2001) concluded that celiac disease is one of the most frequent genetically based diseases (Catassi and others 1994; Ascher and others 1991).

45.2.2 The Iceberg Model

The iceberg is a common model (Fig. 45.1) used to explain the epidemiology of celiac disease (Visakorpi and others 1996). The few cases that have been properly clinically diagnosed with the classical symptoms of chronic diarrhea, unexplained iron deficiency, failure to thrive, and the presence of a flat mucosa form the small top of the iceberg (Fasano and Catassi 2001). Patients who have been recently diagnosed and who are now living with gluten-free diets and show a normal mucosa form the lower part of the tip. The ratio of diagnosed to undiagnosed cases gives the so-called "waterline". A relatively large group of "silent" cases are situated below the waterline. These cases have not been identified and show a small bowel mucosa lesion but may remain undiagnosed because the clinical symptoms are lacking (Feighery 1999). The bottom end of the iceberg consists of a small group of people with latent celiac disease. These patients show a normal musosa while ingesting gluten. They have the potential to develop the disease at any stage in their life.

45.2.3 Possible Causes

According to Murray (1999), celiac disease is the end result of three processes that culminate in intestinal mucosal damage: genetic predisposition, environmental factors, and immunologically based inflammation.

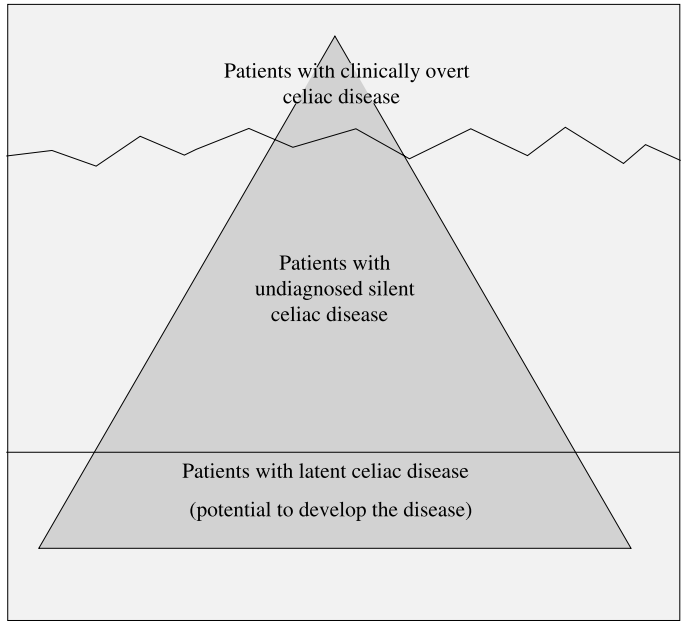

Figure 45.1 *Iceberg model depicting prevalence of celiac disease (Adapted from Feighery 1999).*

45.2.4 Consequences of Gluten Intolerance

With prolonged exposure to gluten in the diet, the consequences of celiac disease both internally and externally increase over time. The internal effects are the continued presence of a flat intestinal mucosa, quite often followed by a reduction in enzyme activity and hence lack of vitamins and minerals, which in turn may lead to different deficiencies. The external effects include dermatitis herpetiformis or the appearance of pale skin, dry hair roots, or abdominal distention, especially in children younger than two years of age.

45.2.5 Treatment and Dietary Requirements

The only way that celiac disease can be treated is the total lifelong avoidance of gluten ingestion (Fasano and Catassi 2001; Mowat 2003). The removal of gluten from the diet results in an improvement of the clinical symptoms and the mucosal lesions (Hansson 1999). Patients with celiac disease are unable to consume some of the most common products on the market today, namely breads, baked goods, and other food products made with wheat flour (Lovis 2003). Hidden ingredients, for example, byproducts or processed foods that contain wheat and gluten-derivates as thickeners and fillers, must also be avoided, These include hamburgers, salad dressings, cream sauces, dried soup mixes or canned soups, and processed cheese. Medications may include wheat proteins as binders and therefore must also be excluded. Other cereals such as rye, barley, malt, kamut, einkorn, dinkel, and spelt are prohibited. As celiac disease can in fact result in lactose intolerance due to the lack of lactase production (Murray 1999), persons with lactose intolerance due to celiac disease must avoid cow's milk.

45.2.6 Codex Alimentarius

The Codex Standard for gluten-free foods was adopted by the Codex Alimentarius Commission of the World Health Organization (WHO) and by the Food and Agriculture Organization (FAO) in 1976. In 1981 and 2000, draft revised standards stated that so-called gluten-free foods are described as

1. Consisting of, or made only from ingredients that do not contain any prolamins from wheat or all *Triticum* species such as spelt, kamut, or durum wheat, rye, barley, oats or their crossbred varieties with a gluten level not exceeding 20 ppm; or
2. Consisting of ingredients from wheat, rye, barley, oats, spelt or their crossbred varieties, which have been rendered gluten-free, with a gluten level not exceeding 200 ppm; or
3. Any mixture of two ingredients as mentioned in (1) and (2) with a level not exceeding 200 ppm.

In this context the WHO/FAO standard gluten was defined as a protein fraction from wheat, rye, barley, oats or their crossbred varieties (e.g., Triticale) and derivatives thereof, to which some persons are intolerant and which is insoluble in water and 0.5 M NaCl. Prolamins are defined as the fraction from gluten that can be extracted by 40–70% aqueous ethanol. The prolamin from wheat is gliadin, from rye is secalin, from barley is hordein, and from oats is avenin. The prolamin content of gluten is generally taken as 50%. In the United States and Canada, the gluten-free diet is devoid of any gluten, and is based on naturally gluten-free ingredients such as rice. However, in the United Kingdom and most European countries, products labelled as being gluten-free may still contain an amount of wheat starch.

45.3 DEVELOPMENT OF GLUTEN-FREE CEREAL PRODUCTS

In view of the fact that gluten is responsible for the viscoelastic properties in wheat bread, its replacement is one of the biggest challenges when developing gluten-free cereal products. The structure of gluten is complex, and is stabilized by intermolecular disulfhide, hydrogen, and hydrophobic bonds. The gluten proteins present in the wheat flour are embedded in the flour particles along with the other flour components, mainly starch granules as indicated in Figure 45.2. This micrograph shows large starch granules (dark gray areas) embedded in a continuous protein network (white areas). Gluten also contributes to the texture and crumb structure of the final baked product (Faubion and Hoseney 1990; Stear 1990).

A marketing review by Arendt and others (2002), reported that most of the gluten-free products were of inferior quality and very often showed off-flavours. The structure of the products was mostly crumbly and very dry. According to Gujral and others (2003a), gluten-free breads are usually characterized by deficient quality characteristics as compared to wheat breads. Problems related to volume and crumb texture are associated with gluten-free breads, even when rice flour is used, which seems to be the best raw material for this type of bread (Gujral and others 2003a). Several studies have been conducted by O'Brien and others (2002), Gallagher and others (2002), Schober and others (2003), and Moore and others (2004a,b,c), in which novel ingredients such

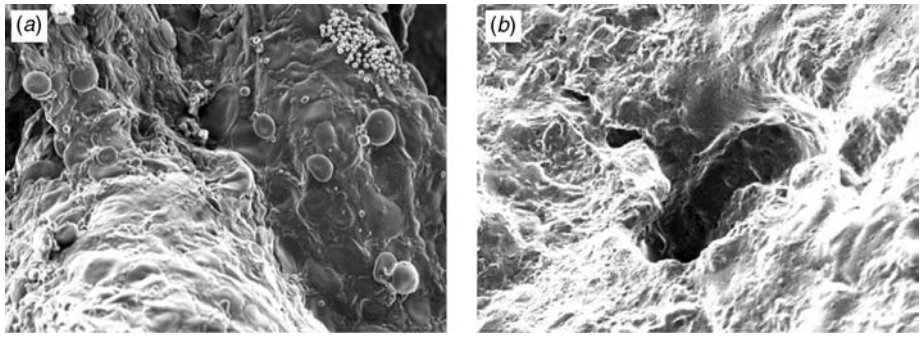

Figure 45.2 *Scanning electron micrographs of wheat bread (a) and gluten-free bread (b). Magnification* $\times$ *430.*

as dairy powders, sorghum, rice, starches, pseudocereals, and so on, in combination with hydrocolloids replaced gluten. Gluten-free products, for instance, must not contain wheat, rye, and barley or the protein-containing constituents of these (Paulus 1986). Gluten-free breads require a different technology. The properties of the dough are more fluid than wheat doughs and closer in viscosity to cake batters (Cauvain 1998; Moore and others 2004a) due to the lack of a gluten network. These batter-type doughs have similar handling properties to cake batters rather than typical wheat doughs. Furthermore, gas holding is more difficult, and the use of gums, stabilizers, and pregelatinized starch has been suggested to provide gas occlusion and stabilizing mechanisms (Cauvain 1998; Satin 1998).

45.3.1 Dietary Fiber

Cereals are an important source of dietary fiber, contributing to about 50% of the fiber, intake in western countries. The role of dietary fiber in providing roughage and bulk, and in contributing to a healthy intestine, has long been recognized. Diets that contain moderate quantities of cereal grains, fruits, and vegetables are likely to provide sufficient fiber. Due to the fact that gluten-free products are generally not enriched/fortified, and are frequently made from refined flour or starch, they may not contain the same levels of nutrients as the gluten-containing counterparts they are intended to replace. Therefore, uncertainty still exists as to whether celiac patients living on a gluten-free diet are ensured a nutritionally balanced diet, in particular regarding dietary fiber intake. Grehn and others (2002) screened the intake of nutrients and foods of 49 adults diagnosed with celiac disease and following a gluten-free diet. They were found to have a lower intake of fiber when compared to a control group of people on a normal diet. Similarly, Lohiniemi and others (2000) found that the average fiber consumption amongst celiacs in Sweden was lower than recommended. In their studies with celiac adolescents, Mariani and others (1998) concluded that adherence to a strict gluten-free diet worsens the already nutritionally unbalanced diet of adolescents. (Dietary levels of nutrients and fiber were found to be low.) Similar findings were revealed by Thompson (2000).

The enrichment of gluten-free baked products with dietary fibers has, therefore, been a topic of research for various teams of technologists. Studies have shown that the addition of high-fiber foods can give texture, gelling, thickening, emulsifying, and stabilizing properties to certain foods (Dreher 1987; Sharma 1981). Inulin is a nondigestible

polysaccharide that is classified as a dietary fiber. Inulin, a fructooligosaccharide, is used either as a macronutrient substitute or as a supplement added in foods mainly for its properties (Zimeri and Kokini 2003). Inulin consists of fructose molecules linked by β (2-1). It also acts as a prebiotic by stimulating the growth of "healthy" bacteria in the colon (Gibson and Roberfroid 1995). When added to wheat bread, it improves loaf volume and sliceability, increases dough stability, and produces a uniform and finely grained crumb texture (Anon 1999). Gallagher and others (2002) incorporated inulin (8% inclusion level) into a wheat-starch-based gluten-free formulation. The dietary fiber content of the bread increased from 1.4 (control) to 7.5% (control + inulin). The overall quality of the gluten-free bread was also improved by the addition of inulin.

45.3.2 Sourdough

Sourdough fermentation has a well-established role in improving the flavor and structure of bread. However, the significant potential of sourdough fermentation to improve the nutritional properties of rye, oat, and wheat products has gained much less attention, although interest is currently increasing. Sourdough fermentation improves the nutritional value of cereal products in a number of ways: it can improve texture and palatability of whole grain, fiber-rich, or gluten-free products, stabilize or increase levels of various bioactive compounds, retard starch bioavailability (lower glycemic index products), and improve mineral bioavailability. Many new interesting applications for sourdough remain still to be explored, such as the use of prebiotic starter cultures or production of totally new types of bioactive compounds (Katina and others 2004).

Gluten-free breads tend to show quick staling and a flat aroma. It has been reported for wheat bread that both of these disadvantages can be overcome by the application of sourdough (Moore and others 2004b). Moore and others (2004b) carried out a study in which they evaluated over a five-day storage period the influence of sourdoughs made from different strains of lactic acid bacteria on the quality of gluten-free bread. In this study, sourdough-containing breads were compared to a nonacidified control and a chemically acidified control. Changes in dough structure could not only be detected by small-deformation viscoelastic measurements but also by confocal laser-scanning microscopy (Fig. 45.3). The protein fraction of the gluten-free sourdough was degraded over time (Fig. 45.3); this process was, however, far less obvious in a gluten-free system than with gluten isolated from wheat-based sourdough (Fig. 45.3). When the sourdoughs were incorporated at a 20% level into the gluten-free batter, no significant differences were observed in the structure (Fig. 45.3), which is not the case in wheat dough containing 20% sourdough (Fig. 45.3). These authors concluded that with the application of sourdough, the onset of staling was delayed, which led to an improvement in the gluten-free bread.

45.3.3 Pseudocereals

Buckwheat, amaranth, and quinoa, due to their unique chemical structures, are classified as pseudocereals. There are two major subclasses of flowering plants: monocots (one seed leaf) and dicots (two seed leaves). Wheat, rye, and barley are monocots, whereas buckwheat, amaranth, and quinoa are dicots and very distantly related to grains in the monocot subclass (Kasarda 1994, 1997, 2001). The unique protein structure and amino acid composition imply that buckwheat might be a very valuable functional food resource and will benefit people in treating some chronic diseases such as diabetes and

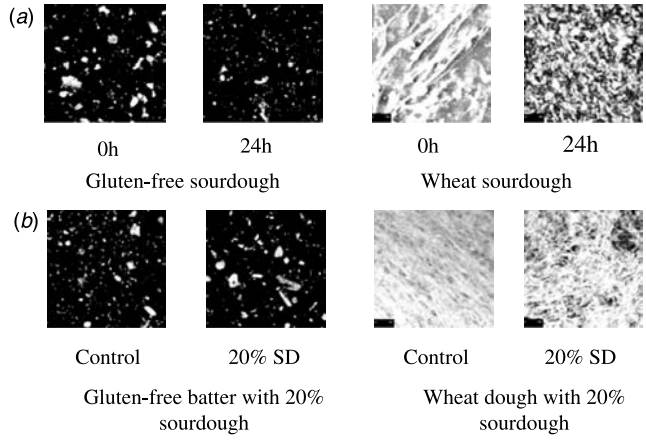

Figure 45.3 *Confocal laser-scanning micrographs of (a) gluten-free sourdough and wheat sourdough at 0 h and after 24 h (magnification bar corresponds to 50 μm) and (b) gluten-free batter with 20% sourdough and wheat dough with 20% sourdough. (Adapted form Clarke and others 2004.)*

hypertensionas well as other cardiovascular diseases (Li and Zhang 2001). The addition of buckwheat, amaranth, and quinoa would add nutritional value to the diet of a person with celiac disease. Many gluten-free cereal foods (e.g., bread, pasta, cold cereal) are made from refined flour and/or starch and most are not enriched with iron and B vitamins (Thompson 1999). As a result, a gluten-free diet may contain inadequate amounts of fiber, iron, thiamine, riboflavin, niacin, and folate (Thompson 1999, 2000). Buckwheat, amaranth, and quinoa are all good sources of fiber and iron. In addition, the riboflavin content of quinoa, and the niacin content of buckwheat flour compare favorably with that of enriched wheat flour (U.S. Department of Agriculture 2000).

Moore and others (2004a) produced a high-quality gluten-free bread (Fig. 45.4c) containing buckwheat. These authors reported that bran particles from brown rice flour or buckwheat contain high concentrations of fiber and swell extensively. Water absorption for the bread formulation increased upon the addition of buckwheat, but at the expense of volume. Even though these authors concluded that this particular bread was firmer in texture, the staling rate was lower in comparison to the starch-based commercial gluten-free bread (Fig. 45.4). Also, with the addition of buckwheat to gluten-free bread, the nutritional properties of the bread were enhanced. Furthermore it may also be used in the production of gluten-free beers, especially as a popular adjunct (Maccagnan and others 2004). Wijngaard and others (2004) carried out a study on the impact of germination temperature on the quality of buckwheat malt using both hulled and unhulled buckwheat. Their objective was to produce gluten-free beer using buckwheat as a replacement for barley. These authors concluded that buckwheat malt has great potential as a brewing ingredient.

Several studies have been carried out by Lorenz (1981) on the physico-chemical properties of the amaranth starch. This author found that the water-binding capacity of the amaranth starch was higher than that of wheat starch, but the swelling power values for the amaranth starch were lower than those of wheat starch and solubility values higher. Lorenz (1981) suggested that the small size of the amaranth starch granules was the possible reason for the observed differences. Gambus and others (2002) replaced cornstarch with amaranthus flour to enhance the protein and fiber contents of gluten-free breads. At a 10% replacement level, protein and fiber levels increased by 32 and 152%

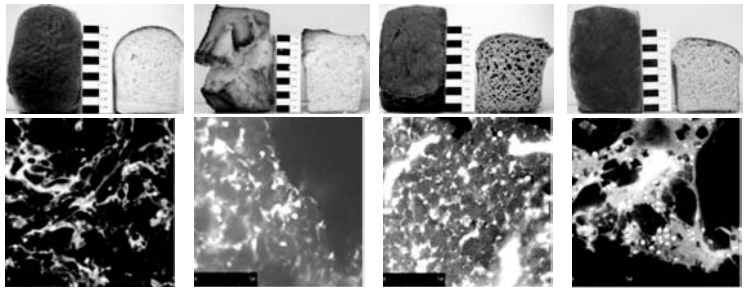

Figure 45.4 *Wheat bread control and gluten-free breads (bread from commercial gluten-free flour, nondairy recipe, dairy recipe. Mean values for a given storage time labeled with a common upper case letter are not significantly different ($p < 0.01$).*

respectively, but sensory quality was unaffected. Tosi and others (1996) described the use of amaranth in gluten-free products. They formulated a gluten-free mix using wholemeal amaranthus flour. Taylor and Parker (2002) discussed the application of quinoa as a novel application in the production of enriched gluten-free bakery goods. Both quinoa and amaranth are pseudocereals, which have a high nutritional value and only recently are being utilized as novel/functional ingredients.

45.3.4 Sorghum

Sorghum (*Sorghum Bicolour (L.) Moench*) is an important cereal grain and belongs to the grass family *Graminae* and tribe *andropoggonae*. Like other cereal grains, the primary component of sorghum is carbohydrate in the form of starch (Rooney and Waniska 2000). Sorghum has a similar chemical composition to maize. However, sorghum is often reported to have a slightly lower protein and starch digestibility when compared to maize. This is especially true for cooked sorghum and has been attributed to increased cross-linking of the proteins during cooking (Hamaker and Bugusu 2003; Schober and others 2006). The average protein content of sorghum is 11–12% (Hoseney and others 1981). Sorghum is often recommended as a safe food for celiac patients, because it is more closely related to maize than to wheat, rye, and barley (Kasarda 2001). Sorghum might therefore provide a good basis for gluten-free bread. However, the majority of studies dealing with leavened loaf breads containing sorghum have focused on composite breads from wheat and sorghum, in which a maximum of only 30% low-tannin sorghum is regarded as acceptable (Munck 1995). Although such breads have been found acceptable by consumers (Carson and others 2000), they are inappropriate for celiac patients.

Recent research on sorghum has shown that it has tremendous potential as a "functional" food (Schober and others 2006). Specific types of sorghum have a very high content of tannins, which are polyphenolic compounds. Tannins are powerful antioxidants and are found in tea, chocolate, and wine. The potential health benefits of tannins for humans have recently been

reviewed by Awika and Rooney (2004). These authors reviewed the health benefits of a number of other phytochemicals in sorghum, including phenolic acids, anthocyanins, phytosterols, and policosanols. Phytochemicals found in sorghum were reported to have a potential impact against cancer and obesity as well as promoting cardiac health. Policosanols are found in the wax surrounding the sorghum kernel. These compounds and others in the wax, namely long-chain fatty acids, may have important cardiac health benefits such as lowering cholesterol (Hwang and others 2004; Hargrove and others 2004).

Only a limited number of studies have addressed such wheat-free sorghum breads and most have used relatively complex recipes incorporating xanthan gum (Satin 1988), carboxymethyl cellulose, and skimmed milk powder (Cauvain 1998), egg (Keregero and Mtebe 1994; Cauvain 1998), or rye pentosans (Casier and others 1997). Schober and others (2004) investigated the impact of different sorghum varieties on the quality of gluten-free bread. Significant differences were observed between the various sorghum varieties. The addition of skim milk powder and xanthan gum led to an improvement of the gluten-free bread quality. The formulation used in that paper was mainly based on sorghum and was very simple.

45.3.5 Oats

There is much debate on whether or not oats may be used in the production of gluten-free products. A review by Thompson (2003) reports that most adults with celiac disease can consume moderate amounts of uncontaminated oats without causing damage to the intestinal mucosa. Studies have been carried out by Janatuinen and others (1995), Srinivasan and others (1996), Hardman and others (1997), in which they concluded that oats cereal is neither toxic nor immunogenic in celiac disease. According to Hardman and others (1997), oats belong to a different tribe, Aveneae, than that of wheat, rye, and barley. Oat prolamin (avenin) has a lower proline content than the prolamins present in wheat, rye, and barley (gliadin, secalin, and hordein, respectively). The sequence glutamine-glutamine-glutamine-proline-phenylalanine-proline is found in prolamins of wheat, rye, and barley, but so far has not been found in oats (Janatuinen and others 1995; Srinivasan and others 1996; Hardman and others 1997). The ability of oat prolamins to induce an immune response in intestinal biopsy specimens *in vitro* as well as the cross-reactivity of monoclonal antibodies to enterotoxic wheat peptides with oat peptides are some of the reasons cited for continued caution (Parnell and others 1998). Furthermore the risk of contamination of oats with wheat, rye, or barley before reaching the consumer is considered high. The Gluten Intolerance Group, Celiac Disease Foundation (Celiac Disease Foundation/Gluten Intolerance Group 2000), Celiac Sprue Association (2001), and the American Dietetic Association (Inman-Felton 1999; American Dietetic Association and Dieticians of Canada 2000) all advise against the use of oats, but the Finnish Celiac Society considers them safe for consumption by adults (The Finnish Celiac Society 2001) as does the Celiac Society in the United Kingdom (in moderate amounts) (The Celiac Society 2001).

Oats contain many beneficial properties. According to Oomah and Mazza (1999), oat β-glucan is involved in carbohydrate and lipid metabolism. It has beneficial effects in the treatment of diabetes, and lowers serum cholesterol. Oats also contain a multitude of other compounds, such as phytates, phenolics, vitamins, and minerals, which confer other physiological benefits. These include powerful antioxidants and are utilized by the pharmaceutical and cosmetics industries. Furthermore, high consumption of oat meal, oat bran, or oat flour can reduce the risk of coronary heart disease.

45.3.6 Transglutaminase

Transglutaminase (TG: protein-glutamine γ-glutamyltrans-ferase, EC 2.3.2.13) is a promising enzyme for the food industry. Transglutaminase is an enzyme capable of catalysing acyl-transfer reactions, introducing covalent crosslinks between proteins (Nonaka and others 1989) as well as peptides and various primary amines. Crosslinking occurs when the ε-amino groups of lysine residues in proteins act as an acyl-receptor, and ε-(γ-Glu)Lys bonds (isopeptide bonds) are formed both intra- and intermolecularly (Ando and others 1989).

Transglutaminase is a highly functional enzyme and may be obtained from a range of different sources. These include animal tissue, fish, plant, and microorganisms (Kuraishi and others 1996). According to Aeschlimann and Thomaz (1999), transglutaminase can be connected with several biological phenomena such as blood clotting, wound healing, as well as with a number of pathologies including neurodegenerative disease, cancer metastasis, and celiac disease. The transglutaminases used in baking applications are aminotransferases and are obtained from microbial cultures. Transglutaminase has the ability to link proteins of different origins: casein and albumin from milk, animal protein from eggs and meat, soya protein and wheat protein. Transglutaminase has been mainly used in the dairy and meat industry to improve water-holding capacity.

Moore and others (2004c) reported that microbial transglutaminase can be used to create a network-like structure in gluten-free bread (Fig. 45.5) and therefore has the potential to improve the quality of gluten-free bread. However, the use of transglutaminase in gluten-free bread is very much dependent on the protein source used in the bread formulation.

45.3.7 Hydrocolloids

Hydrocolloids have been essential ingredients in the formulation of gluten-free cereal products. Hydrocolloids or gums are substances consisting of hydrophilic long-chain, high-molecular-weight molecules, usually with colloidal properties, which in water-based systems produce gels, that is, highly viscous suspensions or solutions with low dry-substance content (Hoefler 2004). They are derived from seeds, fruits, plant extracts, seaweeds, and micro organisms, being of polysaccharide or protein nature (Norton and Foster 2002). They are generally polysaccharides, but gelatin (a protein) is included because its functionality is very similar to that of the polysaccharide-based gums (Hoefler 2004). Hydrocolloids or gums serve two basic functions in food systems: They

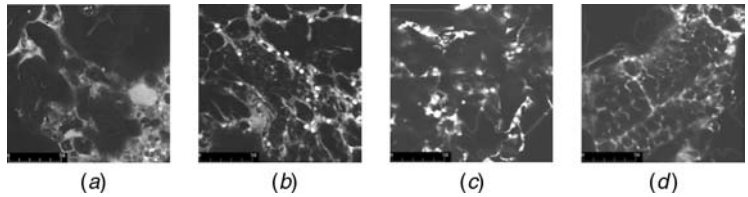

Figure 45.5 *Confocal laser-scanning micrographs of gluten-free breads, Egg 0 unit TG/g Protein (control) (a), Egg 1 unit TG/g Protein (b) SMP 0 unit TG/g Protein (control) (c), and SMP 10 unit TG/g Protein (d). The magnification bar corresponds to 50 μm for the objective x63.*

stabilize the product, and they affect the texture of the product, and are widely used in the food industry for these functional properties. These functional properties lead to the improvement of food texture, they retard starch retrogradation, increase moisture retention, and extend the overall quality of the product over time (Armero and Collar 1996a,b; Davidou and others 1996).

Hydrocolloids have been found to affect dough rheological performance, as they mimic the viscoelastic properties of gluten in bread doughs (Smith 1971; Toufeili and others 1994; Collar and others 1998) and also swelling, gelatinization, pasting properties, and staling of starch. According to Toufeili and others (1994) and Guarda and others (2004), the utilization of polymeric substances such as xanthan gum or hydroxypropylmethylcellulose (HPMC) are required for the production of gluten-free breads. The lack of a gluten network determines the properties of the gluten-free dough, which is more fluid than wheat doughs and closer in viscosity to cake batters (Cauvain 1998; Moore and others 2004a) and thus has also to be handled in a similar manner to cake batters rather than doughs. Most gluten-free breads are formulated using gluten-free starches and require the addition of hydrocolloids to provide structure and gas retaining properties in the dough (Ylimaki and others 1998; Moore and others 2004a). Schwarzlaff and others (1996) used combinations of guar gum and locust bean gum to partially replace flour in bread. They found that the introduction of guar gum resulted in a crumb structure with a more even cell size distribution, and locust bean gum inclusion increased the height of the bread loaves; both gums retarded bread staling. Optimum levels for locust bean gum and guar gum were 2–4%. For gluten-free bread production, the most commonly used hydrocolloids are pectin, guar gum, xanthan gum, and locust bean gum (Smith 1971; Igoe 1982; Okubo and others 1994). Kang and others (1997) carried out studies in which they looked at the effect of various hydrocolloids on a rice bread formulation. The inclusion of many gum types such as hydroxypropylmethylcellulose (HPMC), locust bean gum, guar gum, carageenan, xanthan gum, and agar gave successful formation of rice bread, and HPMC gave optimum volume expansion (Kang and others 1997).

Konjac gum is a polysaccharide that has the ability to form cohesive, tough films that remain stable in hot and cold systems (Tye 1991). Konjac is therefore considered a useful hydrocolloid in the production of gluten-free bread. Moore and others (2004a) produced good quality gluten-free bread using a mixture of both konjac and xanthan gum in a dairy-based gluten-free formulation. Furthermore research by Tye (1991) showed that konjac flour and xanthan gum interact to form a gel with unique viscoelastic properties. Xanthan gum has been used as a thickener, or mixed with other gel-forming polysaccharides. According to Christiansson and others (1974) and Christiansson (1976), to obtain a good crumb structure in the absence of gluten, xanthan, a hydrophilic polysaccharide of microbiological origin, was added to a starch-based bread. In the preparation of gluten-free bread, xanthan has been found to confer a crumb structure similar to that of bread made from normal wheat flour. It is suggested by Van Vliet and others (1992) that xanthan may act by improving the strain hardening properties of the dough. These authors suggest that a material shows strain hardening if the resistance to deformation is higher for relatively more extended test pieces. Hydroxypropylmethylcellulose (HPMC) is a popular hydrocolloid for gluten replacement in gluten-free bread systems. One of the properties of HPMC is revealed on exposure to water or biological fluid; the dry polymer becomes hydrated, swells, and forms a gel barrier layer (Kavanagh and Corrigan 2004).

45.3.8 Protein Sources in Gluten-Free Breads

The replacement of gluten with other protein sources such as soya and dairy proteins is another approach used in the production of gluten-free products. Several studies have been reported, where the inclusion of dairy proteins in gluten-free systems plays an important role. Dairy proteins, for instance, have functional properties similar to gluten. They are capable of forming networks and they have good swelling properties. Dairy proteins are highly functional ingredients and, due to their versatility, can be readily use in many food products (Gallagher and others 2003). They may be used in bakery products for both nutritional and functional benefits, including flavor and texture enhancement, and storage improvement (Cocup and Sanderson 1987; Mannie and Asp 1999; Kenny and others 2001; Gallagher and others 2003). They contribute to a number of critical characteristics for food products. These include the emulsifying and stabilizing ability of caseinates, the gelling properties of whey protein concentrates and isolates, the water-absorption capacity of high-heat nonfat dry milk, and the browning of lactose during heat processing (Chandan 1997). Furthermore, they may be used in gluten-free bread formulas (Fig. 45.4) to increase water absorption and therefore enhance the handling properties of the batter (Gallagher and others 2003). Gallagher and others (2003) found that dairy powders used in gluten-free bread formulations resulted in improved volume, appearance, and sensory aspects. However, the supplementation of gluten-free breads with high-lactose-content powders is not suitable for persons with celiac disease who have significant damage to their intestinal villi. They may not be able to utilize the lactose due to the absence of the lactase enzyme, which is normally generated by the villi.

Surimi, soyabean, and egg proteins are alternative protein sources used in baking applications. Surimi is a concentrate of myofibrillar proteins obtained after mixing and water washing of fish flesh (Han-Ching and Leinot 1993). Gormley and others (2003) focused on the supplementation of a control gluten-free bread based on rice flour and potato starch with fish surimi (as a structure enhancer and protein replacer) at a 10% inclusion level (of starch weight), and found that the addition of surimi improved the overall quality of the bread. Furthermore, regarding sensory analysis, no significant negative effects were found with the addition of the surimi to the bread.

Soya has several functional properties. Soya isoflavones (plant components of soya) have been shown to have positive effects on bone tissue in controlled *in vitro* experiments on bone cell lines and animal studies and, as well as the first results from human studies, point to a promising future for soya isoflavones for use in functional foods that target a reduction in the risks of osteoporosis (Brouns 2002). Furthermore, soya isoflavones are reported to reduce the risk of cardiovascular disease, reduce the oxidation of low-density lipoproteins (LDL), and have a role in preveting osteporosis and breast cancer. Finally soya isoflavones possess antioxidant properties. Soya flour is widely used in the production of gluten-free products. Sanchez and others (2002) reported that the inclusion of 0.5% soya to optimized gluten-free bread enhanced the crumb grain score, bread, volume, and overall bread score. Research by Jonagh and others (1968) showed that proteins such as egg albumen and gliadin at low concentrations were able to link starch granules together. According to Moore and others (2004a), egg proteins, part of the soya protein, or colloidal solutions such as caseins swell and form viscous solutions in a gluten-free bread system. Confocal laser-scanning microscopy revealed filmlike continuous protein structures similar to wheat gluten (Fig. 45.4).

45.3.9 Starch Sources in Gluten-Free Bread

In cereal-based products, starch gelatinization, as well as subsequent reorganization, controls texture and stability of the final product. Starches such as wheat starch (less than 200 ppm), rice, potato, and cornstarch are most commonly used in the production of gluten-free products. The suitability of rice flour is attributed to its low levels of prolamins (Gujral and Rossel 2004). Optimal rice bread formulations have been developed using carboxymethylcellulose and hydroxypropylmethylcellulose, which meet wheat bread reference standards for specific volume, crumb and crust color, firmness, and moisture (Collar and others 1999; Gallagher and others 2002). Rice flours can be used in baking applications in many different forms. The addition of whole-grain rice to gluten-free breads improves the quality of the bread and subsequently enhances the nutritional value. Potato starch has desirable characteristics, which differ significantly from those of starch from other plant sources (Madsen and Christensen 1996). Its functional characteristics include high swelling power, water-binding capacity, and freeze–thaw stability. Ács and others (1996a,b) used binding agents (xanthan, guar gum, locust bean gum, and tragant) as a substitute for gluten in a gluten-free bread formulation based on cornstarch. These authors concluded that the binding agents resulted in an increase in loaf volume and loosening of the crumb structure.

45.4 CONCLUSION

Celiac disease, which is an autoimmune enthalpy characterized by the inflammation of the small-intestinal mucosa, is more common than originally estimated. According to epidemiological studies, approximately 1 in 80 of the world population is suffering from this disorder. This segment of the population has been deprived of good quality cereal products, which is part of the staple diet for the majority of human beings. One of the biggest problems for the food scientist will be to provide the consumer with good quality products. Gluten has unique properties in relation to production of good quality cereal products, which make its replacement so very difficult. From the evidence gathered, it becomes apparent that a mixture of different flour, gums, and proteins is necessary to replace gluten and produce good quality gluten-free cereal products. The development of gluten-free cereal products is an opportunity to diversify cereal products as a market, keeping in mind the need to provide the consumer with products of high nutritional value.

46.1 INTRODUCTION

The role of proteins as physiologically active components in the diet is being increasingly acknowledged. Many of the proteins which occur naturally in raw food materials exert their physiological action either directly or upon enzymatic hydrolysis *in vitro* or *in vivo*. In recent years it has been recognized that dietary proteins provide a rich source

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

of biologically active peptides. Such peptides are inactive within the sequence of the parent protein and can be released in three ways: (1) through hydrolysis by digestive enzymes, (2) through hydrolysis of proteins by proteolytic microorganisms, and (3) through the action of proteolytic enzymes derived from microorganisms or plants. It is now well established that physiologically active peptides are produced from several food proteins during gastrointestinal digestion and fermentation of food materials with lactic acid bacteria. The state-of-the-art of bioactive peptides derived from various dietary proteins has been reviewed in many recent articles (Clare and others 2003; FitzGerald and Meisel 2003; Korhonen and Pihlanto 2003a; Pellegrini 2003; Pihlanto and Korhonen 2003; Li and others 2004). Once bioactive peptides are liberated, they may impart in the body different physiological effects on, for example, the gastrointestinal, cardiovascular, endocrine, immune, and nervous systems. For this reason, the potential of distinct dietary peptide sequences to promote human health by reducing the risk of certain chronic diseases and boosting natural immune protection has aroused a lot of scientific interest over the past few years. These functions may be attributed to numerous known peptide sequences exhibiting, for example, antimicrobial, antioxidative, antithrombotic, antihypertensive, and immunomodulatory activities (FitzGerald and Meisel 2003; Korhonen and Pihlanto 2003a). The activity is based on their inherent amino acid composition and sequence. The size of active sequences may vary from two to 20 amino acid residues, and many peptides are known to reveal multifunctional properties (Meisel and FitzGerald 2003). At present, milk proteins are considered the most important source of bioactive peptides, although corresponding peptide sequences have been found in other animal and plant proteins as well (Schanbacher and others 1998; Meisel 1998, 2001; Clare and Swaisgood 2000; Korhonen and Pihlanto-Leppälä 2001, 2004; Darragh 2002; Matar and others 2003; Korhonen and Pihlanto 2003b; FitzGerald and others 2004; Silva and Malcata 2005).

This chapter reviews the current knowledge about bioactive peptides derived from various food proteins, with emphasis on their production, natural occurrence in food products and potential applications in functional foods.

46.2 FUNCTIONALITY OF BIOACTIVE PEPTIDES

Dietary proteins are traditionally known to provide a source of energy and amino acids essential for growth and maintenance of various body functions. In addition, they contribute to the physiochemical and sensory properties of protein-rich foods. Over the last two decades, food proteins have gained increasing value due to the rapidly expanding knowledge about physiologically active peptides released from a parent protein source. Bioactive peptides have been defined as specific protein fragments that have a positive impact on body function or condition and may ultimately influence health (Kitts and Weiler 2003). Upon oral administration, bioactive peptides, depending on their amino acid sequence, may affect the major body systems: that is, the cardiovascular, endocrine, immune, and nervous systems (see Fig. 46.1). Below are examples of peptides which are known to exert direct or indirect physiological effects on the above systems.

The first reference to bioactive peptides in the literature was made by Mellander in 1950, who suggested that casein-derived phosphorylated peptides, caseinophosphopeptides (CPPs), enhanced vitamin D-independent bone calcification in rachitic infants (Mellander 1950). Bovine α_{s1}-, α_{s2}- and β-casein contain phosphorylated regions which

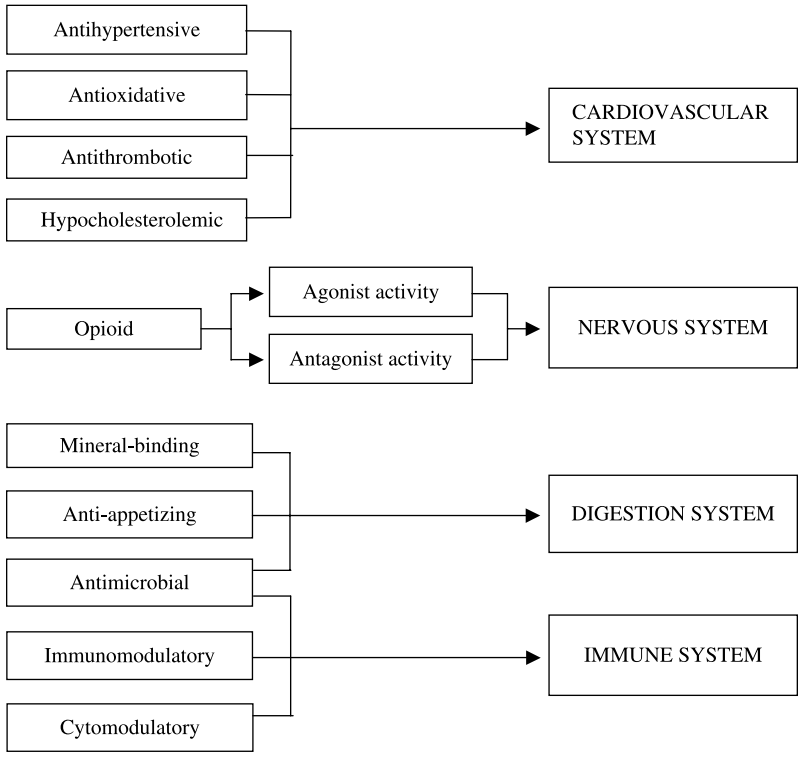

Figure 46.1 *Physiological functionality of food-derived bioactive peptides.*

can be released by digestive enzymes. Specific CPPs can form soluble organophosphate salts and lead to enhanced calcium absorption by limiting the precipitation of calcium in the distal ileum. Published data on the effect of CPPs on mineral solubility and absorption are inconsistent, however, partly due to the diversity of the experimental approaches used (FitzGerald 1998; Meisel and FitzGerald 2003). CPPs have also been shown to exert cytomodulatory effects. Cytomodulatory peptides derived from casein fractions inhibit cancer cell growth or stimulate the activity of immunocompetent cells and neonatal intestinal cells (Meisel and FitzGerald 2003).

Peptides with opioid activity have been found in milk protein and wheat gluten hydrolysates (for a review see Teschemacher 2003). Opioid peptides are opioid receptor ligands with agonistic or antagonistic activities. β-Casein opioid peptides (β-casomorphins) have been detected in the duodenal chyme of minipigs and in the human small intestine as a consequence of *in vivo* digestion of casein or milk (Meisel 1998; Meisel and FitzGerald 2000; FitzGerald and Meisel 2003). Opioid peptides may influence the gastrointestinal function in two ways: first, by affecting smooth muscles, which reduces the transit time, and second, by affecting the intestinal transport of electrolytes, which explains their anti-secretory properties. The actual physiological effects of dietary opioid peptides remain to be confirmed.

The angiotensin I-converting enzyme (ACE, peptidyldipeptide hydrolase, EC 3.4.15.1) has been associated with the renin-angiotensin system, which regulates peripheral blood pressure. Inhibition of this enzyme can exert an antihypertensive effect. ACE-inhibitory peptides have been isolated from the enzymatic digest of various food proteins and they

are, at present, the most studied group of bioactive peptides. A great number of hypotensive peptides have been identified in milk proteins and a few of these have proven clinically effective in animal model and human model studies (for reviews see Yamamoto and Takano 1999; Yamamoto and others 2003; FitzGerald and others 2004; Gobbetti and others 2004; Li and others 2004; Vermeirssen and others 2004). It was shown recently that apart from ACE inhibition, milk whey protein-derived peptides may exert antihypertensive effects through other mechanisms, such as inhibition of the release of endothelin-1 by endothelial cells (Maes and others 2004).

Peptide sequences which inhibit the aggregation of blood platelets and the binding of the human fibrinogen γ-chain to platelet surface fibrinogen receptors have been identified in caseinomacropeptide (CMP), which is split from κ-casein in milk coagulation with rennin (Fiat and others 1993). The potential physiological effects of these antithrombotic peptides have not been established, but such peptides have been detected in the plasma of newborn children after breastfeeding or ingestion of cow milk-based infant formulae (Chabance and others 1995).

Milk protein hydrolysates and peptides derived from caseins and major whey proteins can enhance immune cell functions, measured as lymphocyte proliferation, antibody synthesis and cytokine regulation (Gill and others 2000). Of special interest are casein peptides released during milk fermentation with lactic acid bacteria, as these peptides have been found to modulate the proliferation of human lymphocytes, to down-regulate the production of certain cytokines and to stimulate the phagocytic activities of macrophages (for reviews see Korhonen and Pihlanto 2003a,b,c; Matar and others 2003). The protective effect of a casein-derived immunopeptide on resistance to microbial infection by *Klebsiella pneumoniae* has been demonstrated in mice (Migliore-Samour and others 1989). Also, it has been suggested that immunomodulatory milk peptides may alleviate allergic reactions in atopic humans (Korhonen and Pihlanto 2003a).

Antimicrobial peptides have been purified from several bovine milk protein hydrolysates, but also from edible plants, fish and eggs (Clare and others 2003; Floris and others 2003; Pellegrini 2003; Gobbetti and others 2004). The most studied are the lactoferricins, derived from bovine and human lactoferrin (Kitts and Weiler 2003; Wakabayashi and others 2003). These peptides exhibit antimicrobial activity against various Gram-positive and -negative bacteria, yeasts and filamentous fungi. The disruption of normal membrane permeability is at least partly responsible for the antibacterial mechanism of lactoferricins. The antimicrobial mechanisms exerted by other active food-derived peptides have not been elucidated in detail and their physiological importance remains to be established.

Recent studies have shown that antioxidative peptides can be released from caseins, soybean and gelatine in hydrolysis by proteolytic enzymes (Korhonen and Pihlanto 2003a). Peptides derived from α_s-casein have been shown to have free radical-scavenging activity and to inhibit enzymatic and nonenzymatic lipid peroxidation (Suetsuna and others 2000; Rival and others 2001a,b). Nagaoka and others (2001) identified a novel hypocholesterolemic peptide (Ile-Ile-Ala-Glu-Lys) from the tryptic hydrolysate of β-lactoglobulin. This peptide suppressed cholesterol absorption by Caco-2 cells *in vitro* and elicited hypocholesterolemic activity *in vivo* in rats upon oral administration of the peptide solution. The mechanism of the hypocholesterolemic effect remains to be clarified.

Moreover, the α_{s1}-casein derived peptide f(91–100) has been demonstrated to possess anxiolytic-like stress-relieving properties not only in animal model studies but in human studies as well (Lefranc 2001).

Many milk protein-derived peptides have more than one functional role; for example, peptides from the sequence 60−70 of β-casein show immunostimulatory, opioid and ACE-inhibitory activities. This sequence has been defined as a strategic zone (Meisel 1998; Migliore-Samour and Jollès 1988). The sequence is protected from proteolysis because of its high hydrophobicity and the presence of proline residues. Other examples of the multifunctionality of milk-derived peptides include the α_{s1}-casein fraction 194 − 199 showing immunomodulatory and ACE-inhibitory activity, the opioid peptides α- and β-lactorphin also exhibiting ACE-inhibitory activity and the caseinophosphopeptides, which possess immunomodulatory properties (Korhonen and Pihlanto 2003a).

46.3 PRODUCTION OF BIOACTIVE PEPTIDES

Basically, biologically active peptides can be produced from precursor proteins in the following ways: (1) through enzymatic hydrolysis by digestive enzymes, (2) through fermentation of protein-rich material with proteolytic starter cultures, (3) through the action of proteolytic enzymes derived from microorganisms or plants, (4) through chemical or enzymatic synthesis, and (5) with recombinant DNA technology. In the following, examples are given of methods (1), (2), and (3), with a focus on peptides released from milk proteins. Methods (4) and (5) are currently not considered appropriate for industrial-scale production of food-grade peptides and are discussed only briefly in this review.

46.3.1 Enzymatic Hydrolysis

At present, the most common way to produce bioactive peptides is through enzymatic hydrolysis of whole protein molecules. As shown in Table 46.1, gastrointestinal enzymes, preferably pepsin and trypsin, have been used for the production of many known bioactive peptides. For example, ACE-inhibitory peptides and CPPs are most commonly produced by trypsin (see reviews Yamamoto and others 2003; FitzGerald and others 2004; Gobbetti and others 2004; Vermeirssen and others 2004). Moreover, ACE-inhibitory peptides have recently been identified in the tryptic hydrolysates of bovine α_{s2}-casein (Tauzin and others 2002) and in bovine, ovine, and caprine κ-casein macropeptides (Manso and López-Fandino 2003). Other digestive enzymes and different enzyme combinations of proteinases – including alcalase, chymotrypsin, pancreatin, pepsin, thermolysin, as well as enzymes from bacterial and fungal sources – have also been utilized to generate bioactive peptides from various proteins (see Table 46.1) (Kilara and Panyam 2003; Korhonen and Pihlanto 2003a). Recent studies have identified several antihypertensive peptides from egg white proteins hydrolyzed by pepsin, trypsin, or chymotrypsin (Miguel and others 2004) and from rapeseed proteins digested with subtilisin (Marczak and others 2003). Also, hypotensive peptides have been found in porcine skeletal muscle and corn protein hydrolysates after digestion with thermolysin (Arihara and others 2001; Nakashima and others 2002).

Recombinant DNA techniques have been employed for the production of specific peptides or their precursors in microorganisms. The sequence encoding antihypertensive peptide Arg-Pro-Leu-Lys-Pro-Trp, for example, has been introduced into the gene for soybean β-conglycin α′ subunit. This subunit was expressed in *Escherichia coli* recovered from the soluble fraction and purified by chromatography. The Arg-Pro-Leu-Lys-Pro-Trp

TABLE 46.1 Bioactive Peptides Derived from Various Animal and Plant Proteins.

Protein Source	Treatment	Peptide	Activity	Reference
Casein	Trypsin	Phe-Phe-Val-Ala-Pro	ACE inhibition	Migliore-Samour and Jollés (1988)
	Trypsin-chymotrypsin	Val-Glu-Pro-Ile-Pro-Tyr	Immunomodulation	Fiat and others (1993)
		Gly-Leu-Phe		Suetsuna and others (2000)
	Pepsin	Tyr-Phe-Tyr-Pro-Glu-Leu	Antioxidative

		Ile-Ala-Tyr-Lys-Pro-Ala-Gly		
Rapeseed	Subtilisin	Ile-Tyr	ACE inhibition	Marczak and others (2003)
		Arg-Ile-Tyr	Antihypertensive	
		Val-Trp		
		Val-Trp-Ile-Ser		

peptide was released from the recombinant-containing subunit after digestion with trypsin and chymotrypsin (Matoba and others 2001). Feeney and others (2001) reported that the construction of glutenin genes and their expression in *E. coli* is a viable method for producing peptides. In addition, Kim and others (1999) succeeded in expressing recombinant human α_{s1}-casein in *E. coli* and in purifying it. The trypsin digest of this protein contained several ACE-inhibitory peptides. Rao and others (2004) demonstrated the release of a bioactive peptide, H-Arg-Tyr-Leu-Pro-Thr-OH, in a transgenic tobacco plant, expressing a specifically designed precursor gene. Antimicrobial peptides derived from shrimp have been successfully expressed in the yeast *Sacchramoyces cerevisiae*, but the expression levels were relatively low (Desteoumieux and others 1999). Methylotrophic yeast, *Pichia pastoris*, has emerged as a powerful and inexpensive expression system for the production of high levels of functionally active recombinant proteins and several antimicrobial peptides (Li and others 2005). Despite significant advances, the synthesis of short sequences using genetic engineering methods often remains impractical, due to the low expression efficiencies obtained and difficulties encountered in the extraction and recovery of the product. Genetic engineering can, however, be used to produce enzymes with specific activity in such a manner that they are able to release the desired peptides from the precursor proteins.

46.3.2 Microbial Fermentation

Many industrially utilized dairy starter cultures are highly proteolytic. Bioactive peptides can, thus, be generated by the starter and non-starter bacteria used in the manufacture of fermented dairy products. The proteolytic system of lactic acid bacteria (LAB), such as *Lactococcus lactis*, *Lactobacillus helveticus*, and *Lactobacillus delbrueckii* ssp. *bulgaricus*, is already well characterized. This system consists of a cell wall-bound proteinase and a number of distinct intracellular peptidases, including endopeptidases, aminopeptidases, tripeptidases, and dipeptidases (Kunji and others 1996). Rapid progress has been made in recent years in elucidating the biochemical and genetic characterization of these enzymes. At least 16 peptidases responsible for the conversion of the released peptides into free amino acids have been identified and chemically characterized from LAB (Christensen and others 1999). The activities of peptidases are affected by growth conditions, making it possible to manipulate the formation of peptides to a certain extent (Williams and others 2002). Table 46.2 gives a list of experimental studies that have investigated the release of bioactive peptides upon fermentation of milk and plant materials using different live proteolytic microorganisms or proteolytic enzymes derived from such microorganisms.

The release of various bioactive peptides from milk proteins through microbial proteolysis has been reviewed in many recent articles and book chapters (Korhonen and Pihlanto-Leppälä 2001; Gobbetti and others 2002, 2004; Korhonen and Pihlanto 2003; Matar and others 2003). Most studies have reported the production of ACE-inhibitory or antihypertensive peptides, and also immunomodulatory, antioxidative, and antimicrobial peptides have been identified. *Lb. helveticus* is widely used as a dairy starter in the manufacture of traditional fermented milk products, such as Emmental cheese. Highly proteolytic *Lb. helveticus* strains capable of releasing ACE-inhibitory peptides, in particular, have been demonstrated in several studies. Nakamura and others (1995a,b) identified two ACE-inhibitory peptides (Val-Pro-Pro, Ile-Pro-Pro) in milk fermented with *Lb. helveticus.* Pihlanto-Leppälä and others (1998) studied the potential formation

of ACE-inhibitory peptides from cheese whey and caseins during fermentation with various commercial dairy starters used in the manufacture of yogurt, ropy milk, and sour milk. No ACE-inhibitory activity was observed in these hydrolysates. Further digestion of the above samples with pepsin and trypsin resulted in the release of several ACE-inhibitory peptides. Gobbetti and others (2000) demonstrated the formation of ACE-inhibitory peptides with two dairy strains, *Lb. delbrueckii* ssp. *bulgaricus* and *Lc. lactis* ssp. *cremoris*, after fermentation of milk separately with each strain for 72 h. The most inhibitory fractions of the fermented milk mainly contained β-casein-derived peptides with inhibitory concentration (IC_{50}) values ranging from 8.0 to 11.2 μg/mL. Belem and others (1999) fermented cheese whey with *Kluyveromyces marxianus* var. *marxianus* and identified in the hydrolysate a sequence of β-lactorphin (Tyr-Leu-Leu-Phe), a peptide suggested to have antihypertensive properties. Yamamoto and others (1999) identified an ACE-inhibitory dipeptide (Tyr-Pro) from a yogurt-like product fermented with *Lb. helveticus* CPN 4 strain. This peptide sequence is present in all major casein fractions, and its concentration increased during fermentation, reaching a maximum concentration of 8.1 μg/mL in the product. Fuglsang and others (2003a,b) tested a total of 26 strains of wild-type LAB, mainly belonging to *Lc. lactis* and *Lb. helveticus*, for their ability to produce a milk fermentate with inhibitory activity towards ACE. All test strains produced ACE-inhibitory substances in varying amounts, and two of the strains had a high ACE inhibition and a high OPA index, which correlates well with peptide formation. The inhibitory effect of active fermentates on *in vivo* ACE activity was demonstrated in normotensive rats. More recently, Ashar and Chand (2004) identified an ACE-inhibitory peptide from milk fermented with *Lb. delbrueckii* ssp. *bulgaricus*. The peptide showed the sequence Ser-Lys-Val-Tyr-Pro-Phe-Pro-Gly-Pro-Ile from β-casein with an IC_{50} value of 1.7 mg/mL. In combination with *Str. salivarius* ssp. *thermophilus* and *Lc. lactis* biovar. *diacetylactis*, a peptide structure with a sequence of Ser-Lys-Val-Tyr-Pro was obtained from β-casein with an IC_{50} value of 1.4 mg/mL. Both peptides were markedly stable to digestive enzymes, acidic and alkaline pH, as well as during storage at 5 and 10°C for four days. Furthermore, a peptide containing alanine, phenylalanine, and histidine and showing ACE-inhibitory activity has been isolated from soybeans fermented with *Bacillus natto* and chunggugjang fermented with *Bacillus subtilis.* In both studies, the optimal conditions for production were 60 h fermentation at 40°C (Cho and others 2000).

A number of studies have demonstrated that hydrolysis of milk proteins by digestive and/or microbial enzymes may produce peptides with immunomodulatory activities (Gill and others 2000; Knowles and Gill 2004). Matar and others (1996, 2001) detected immunostimulatory peptides in milk fermented with a *Lb. helveticus* strain. Sütas and others (1996a) demonstrated that digestion of casein fractions with both pepsin and trypsin produced peptides that provoked *in vitro* immunomodulatory effects on human blood lymphocytes. Peptides derived from total casein and α_{s1}-casein mainly suppressed the proliferation of lymphocytes, while those derived from β- and κ-casein primarily stimulated the proliferation rate. When the caseins were hydrolyzed by enzymes isolated from a probiotic strain of *Lactobacillus GG* var. *casei* prior to pepsin-trypsin treatment, all hydrolysate fractions were immunosuppressive and the highest activity was again found in α_{s1}-casein. The same hydrolysates also down-regulated *in vitro* the generation of interleukin-4 by lymphocytes (Sütas and others 1996b). These results suggest that LAB may modulate the immunological properties of milk proteins prior to or after oral ingestion of the product. Such modulation may be beneficial in the down-regulation of

hypersensitivity reactions to ingested proteins in patients with food protein allergies. In a clinical study, supplementation of an extensively hydrolyzed whey formula with *Lactobacillus* GG or *Bifidobacterium lactis* B12 has been shown to be more effective on eczema alleviation in infants with atopic eczema than an unsupplemented formula (Isolauri and others 2000). Further studies are needed to elucidate the potential synergistic role of probiotic bacteria and immunomodulatory milk protein peptides in the development of oral tolerance and in the management of atopic diseases.

Antioxidative peptides have been observed in milk fermented with dairy starters. Kudoh and others (2001) demonstrated that an antioxidative peptide was formed from κ-casein during *Lb. delbrueckii* ssp. *bulgaricus* fermentation. The relatively long peptide Ala-Arg-His-Pro-His-Pro-His-Leu-Ser-Phe-Met showed about five times stronger antioxidative activity than the widely used synthetic antioxidant, butyl hydroxyl toluene (BHT).

In addition to live microorganisms, proteolytic enzymes isolated from LAB have been successfully employed to release bioactive peptides from food proteins. Yamamoto and others (1994) reported that casein hydrolyzed by the cell wall-associated proteinase from *Lb. helveticus* CP790 showed antihypertensive activity in spontaneously hypertensive rats (SHR). Several ACE-inhibitory and one antihypertensive peptide were isolated from the hydrolysate. Maeno and others (1996) hydrolyzed casein using the same proteinase and identified a β-casein-derived antihypertensive peptide from the hydrolysate. The antihypertensive effect of this peptide (Lys-Val-Leu-Pro-Val-Pro-Gln) was dose-dependent in SHR at a dosage level from 0.2 to 2 mg of peptide per kg body weight. The peptide did not show strong ACE-inhibitory activity as such, but a corresponding synthetic hexapeptide without Gln (Lys-Val-Leu-Pro-Val-Pro) exhibited both strong ACE-inhibitory activity and a significant antihypertensive effect in SHR as well. These results suggested that both the proline residue in the C-terminus and the amino acid sequence might be important for ACE inhibition of the hexapeptide. In a recent study, Mizuno and others (2004) measured the ACE-inhibitory activity of casein hydrolysates upon treatment with nine different commercially available proteolytic enzymes. Among these enzymes, a protease isolated from *Aspergillus oryzae* showed the highest ACE-inhibitory activity *in vitro* per peptide. The *A. oryzae* peptide also had the highest antihypertensive effect in SHR when systolic blood pressure was measured 5 h after oral administration of 32 mg/kg of various enzymatic hydrolysates. The effect was found to be dependent on the peptide dosage. These results suggested that the casein hydrolysate contained short peptides of X-Pro and X-Pro-Pro sequences. Most of the documented ACE-inhibitory peptides are usually short peptides with a proline residue at the carboxyl terminal end. Also, proline is known to be resistant to degradation by digestive enzymes and may pass from the small intestines into the blood circulation in the sequence of short peptides (Yamamoto and others 2003). This hypothesis is supported by a study by Pan and others (2004), who hydrolyzed skimmed milk with a cell-free extract of *Lb. helveticus* JCM1004 and purified the antihypertensive tripeptides Val-Pro-Pro and Ile-Pro-Pro from the hydrolysate with three runs of HPLC. The IC_{50} values of the peptides were 9.13 ± 0.21 and 5.15 ± 0.17 μM, respectively. A significant decrease ($p < 0.01$) in systolic blood pressure in SHR was measured after a single gastric intubation of Val-Pro-Pro or Ile-Pro-Pro at 8 or 4 h, respectively. Recently, Ueno and others (2004) purified and characterized an endopeptidase from *Lb. helveticus* CM4 and demonstrated that this peptidase can generate the above two antihypertensive peptides using synthetic pro-peptides as a substrate.

46.3.3 Enrichment of Bioactive Peptides

Industrial-scale production of bioactive peptides from food proteins has been limited by a lack of suitable technologies. Until now, membrane separation techniques have provided the best technology available for the enrichment of peptides with a specific molecular weight range (for a review see Korhonen and Pihlanto 2003b). Ultrafiltration has been routinely employed to enrich bioactive peptides from protein hydrolysates. Enzymatic hydrolysis can be performed through conventional batch hydrolysis or continuous hydrolysis using ultrafiltration membranes. The traditional batch method has several disadvantages, such as the relatively high cost of the enzymes and their inefficiency as compared with a continuous process.

Use of enzymatic membrane reactors for the continuous production of specific peptide sequences was introduced during the 1990s. It has already been widely applied for total conversion of food proteins of various origins to hydrolysates with improved nutritional and/or functional properties (Perea and Ugalde 1996; Martin-Orue and others 1999). Ultrafiltration membrane reactors have been shown to improve the efficiency of enzyme-catalyzed bioconversion and to increase product yields, and they can be easily scaled up. Furthermore, ultrafiltration membrane reactors yield a consistently uniform product with desired molecular mass characteristics. Continuous extraction of bioactive peptides in membrane reactors has been mainly applied to milk proteins. Bouhallab and Touzè (1995) employed this technique for the recovery of antithrombotic peptides derived from hydrolyzed CMP. Bordenave and others (1999) demonstrated that α-lactorphin could be successfully generated with continuous hydrolysis of goat whey in an ultrafiltration reactor. Gauthier and Pouliot (1996) combined enzymatic hydrolysis and ultrafiltration in order to produce emulsifying peptides from β-lg. They noted severe fouling problems with peptide–membrane interactions, especially in ultrafiltration of casein hydrolysates. A better understanding of the surface properties of the ultrafiltration membranes is therefore critical for the development of novel applications of milk protein hydrolysates. Righetti and others (1997) proposed a multicompartment enzyme reactor operating under an electric field for continuous hydrolysis of milk proteins. This technique allowed for the continuous harvesting of some biologically active peptides, such as phosphopeptides and precursors of casomorphins from the tryptic digest of β-casein.

Stepwise ultrafiltration using cut-off membranes of low molecular mass have been found useful for separating out small peptides from high molecular mass residues and remaining enzymes. Turgeon and Gauthier (1990) used a two-step ultrafiltration process and were able to produce a mixture of polypeptides and a fraction rich in small peptides with a molecular mass below 2000 Da. Pihlanto-Leppälä and others (1996) applied selective ultrafiltration membranes (30 kDa and 1 kDa) for the enrichment of the opioid peptides α-lactorphin and β-lactorphin from pepsin-hydrolyzed α-lactalbumin and from pepsin- and trypsin-hydrolyzed β-lactoglobulin, respectively. The same technique was successfully used to enrich ACE-inhibitory peptides from purified α-la and β-lg (Pihlanto-Leppälä and others 2000).

Several ion exchange chromatographic methods have been developed for the enrichment of CPPs from casein hydrolysates, but the production costs of this technique have been prohibitive for large-scale operation. Ellegård and others (1999) developed a process-scale method for the isolation of high-purity CPPs using acid precipitation, diafiltration and anion-exchange chromatography. Promising novel techniques have been developed since, based on ion exchange membrane chromatography. Recio and Visser (1999) described a method where the protein of interest was concentrated within a chromatographic

medium and hydrolyzed in situ by an appropriate enzyme. The resulting active peptides were retained on the ion exchanger, while the other peptides were washed out. Finally, the fraction containing the active peptides was eluted from chromatographic medium. With this method it was possible to isolate and enrich cationic antibacterial peptides from lactoferrin and α_{s2}-casein, as well as negatively charged phosphopeptides from β-casein. The advantage of this process is that isolation of the precursor protein is unnecessary, which significantly reduces the costs of production. Furthermore, since the enzyme used in this process can be recovered, the price of the final product can be reduced. These techniques provide new possibilities for enriching peptides with low molecular mass, and are easy to up-scale to yield gram or even kilogram quantities (Recio and others 2000).

46.4 OCCURRENCE OF BIOACTIVE PEPTIDES IN FOODS

46.4.1 Milk and Dairy Products

It is now well established that bioactive peptides can be generated during milk fermentation with the starter cultures traditionally employed by the dairy industry. As a result, peptides with various bioactivities can be found in an active form even in the final products, such as in fermented milks and cheese (for reviews see Meisel and Bockelmann 1999; Korhonen and Pihlanto-Leppälä 2001; Gobbetti and others 2002; Korhonen and Pihlanto 2003b,c, 2004; Matar and others 2003). Such traditional dairy products may, thus, under certain conditions carry specific health effects when ingested as part of the daily diet. Table 46.3 lists a number of studies which have established the occurrence of peptides in various fermented milk products. Some of these studies are described in more detail below.

A great variety of peptides are formed during cheese ripening, many of which have been shown to exert biological activities. CPPs have been found as natural constituents in fermented cheese (Roudot-Algaron and others 1994; Singh and others 1997), and secondary proteolysis during cheese ripening may lead to the formation of other bioactive peptides. ACE-inhibitory activity has been observed in many studies to be dependent on the ripening stage of the cheese. Meisel and others (1997) detected higher ACE-inhibitory activities in middle-aged Gouda cheese than in short-termed or long-termed ripened cheese. These results suggest that the concentration of active peptides in cheese increases with cheese maturation, but starts to decline when proteolysis exceeds a certain level. Accordingly, ACE-inhibitory activity was low in products having a low degree of proteolysis, such as yogurt, fresh cheese, and quark. The above findings are consistent with the results obtained by Ryhänen and others (2001), who observed that ACE-inhibitory peptides developed gradually during cheese ripening and their concentration was highest in a Gouda-type cheese at the age of 13 weeks, declining slowly thereafter. Saito and others (2000) observed ACE-inhibitory activity in several cheese varieties and measured the highest activity in Gouda cheese aged two years. In feeding experiments on SHR, the decrease in systolic blood pressure was statistically significant with four cheese varieties (Gouda, Blue, Edam, and Havarti) at 6 h after gastric intubation. Several peptides were isolated and identified from 8-month-old Gouda cheese, and two peptides derived from α_{s1}-casein f(1–9) and β-casein f(60–68), respectively, showed potent ACE-inhibitory activity. For Manchego cheese, which is prepared from ovine milk, only cheese that was at least 15 days old showed comparatively low ACE-inhibitory

TABLE 46.3 Bioactive Peptides Identified in Fermented Milk Products.

Product	Examples of identified bioactive peptides	Bioactivity	Reference
Parmigiano-Reggiano cheese	β-cn f(8-16), f(58-77), α_{s2}-cn f(83-33)	Phosphopeptides, precursor of β-casomorphin	Addeo and others, (1992)
Cheddar cheese	α_{s1}- and β-casein fragments	Several phosphopeptides	Singh and others (1997)
Italian cheeses varieties: Mozzarella, Crescenza, Italico, Gorgonzola	β-cn f(58-72)	ACE inhibitory	Smacchi and Gobbetti, (1998)
Enzyme modified cheese	β-cn f(60-66)	Opioid activity, ACE inhibitory	Haileselassie and others (1999)
Gouda cheese	α_{s1}-cn f(1-9), β-cn f(60-68)	ACE inhibitory	Saito and others (2000)
Festivo	α_{s1}-cn f(1-9), f(1-7), f(1-6)	ACE inhibitory	Ryhänen and others (2001)
Emmental cheese	α_{s1}- and β-casein fragments	Immunostimulatory several phosphopeptides, antimicrobial	Gagnaire and others (2001)
Manchego cheese	Ovine α_{s1}-, α_{s2}-, and β-casein fragments	ACE inhibitory	Gomez-Ruiz and others (2002)
Emmental cheese	Active peptides not identified	ACE inhibitory	Parrot and others (2003)
Sour milk	β-cn f(176-188)	Precursor of ACE inhibitory	Kahala and others (1993)
Sour milk	β-cn f(74-76, f(84-86) κ-cn f(108-111)	Antihypertensive	Nakamura and others (1995a)
Yoghurt	Active peptides not identified	Weak ACE-inhibitory	Meisel and others (1997)

Abbreviations: α_{s1}-cn, α_{s1}-casein; β-cn, β-casein; κ-cn, κ-casein.

activity (Gomez-Ruiz and others 2002). Furthermore, this inhibitory activity decreased during the first four months, increased when proteolysis advanced, and decreased again in 12-month-old cheese. A total of 22 peptide fragments were identified in the chromatographic fractions, corresponding to the sequences of ovine α_{s1}-, α_{s2}- and β-casein. Interestingly, peptides isolated from several Italian cheese varieties have been observed to be able to inhibit the activity of the proteolytic enzymes of LAB and ACE (Smacchi and Gobbetti 1998). Furthermore, these ACE-inhibitory peptides isolated from Italian cheeses were shown to be inhibitory to spoilage by microbial enzymes, such as thermostable proteinases from psychrotrophic *Pseudomonas fluorescens*, which causes bitterness in ultra-high temperature (UHT) treated milk, contributes to age gelation of UHT milk, and drastically reduces the shelf-life of dairy products. Active opioid peptides or casomorphins have not been found in matured Cheddar cheese, perhaps due to their degradation during the ripening process (Muehlenkamp and Warthesen 1996). On the other hand, Sabikh and Mathur (2001) detected a small quantity of β-casomorphin-3 in Edam cheese during ripening, whereas longer casomorphins were not detectable. These studies suggest that the presence of bioactive peptides which are naturally formed in cheese depends on the equilibrium between their formation and the degradation exerted by the proteolytic systems involved in the ripening process. In another study, Gagnaire and others (2001) identified a total of 91 peptides in Emmental cheese, 28 of which showed various bioactivities *in vitro*, for example, mineral-carrying, antimicrobial, antihypertensive, and immunostimulatory activities. Besides the well-known action of plasmin on β- and α_{s2}-caseins, two other proteinases seem to be involved in the hydrolysis of α_{s1}-casein in Emmental cheese: cathepsin D originating from milk and cell-envelope proteinase from thermophilic starters. Moreover, peptidases released from both starter and nonstarter LAB seem to contribute to the formation of bioactive peptides throughout the ripening period. Apart from generation during the ripening process, more bioactive peptides are likely to be formed in the gastrointestinal tract upon ingestion of a piece of cheese. This was demonstrated under *in vitro* conditions by Parrot and others (2003), who showed that the consecutive digestion of the water-soluble extract (WSE) of Emmental cheese with pepsin and trypsin, respectively, induced an increase in ACE inhibition as compared with undigested WSE. On the other hand, a 10 kDa ultrafiltered WSE lost a part of its ACE-inhibitory activity after the above digestion process. These results suggest that the generation of ACE-inhibitory peptides during digestion depends on the molecular weight of the precursor peptides present in the cheese. Hernández-Ledesma and others (2004a) evaluated the ACE-inhibitory activity of several commercial fermented milks and fresh cheeses and found that most of these products showed moderate inhibitory activity. The ACE-inhibitory activity of these commercial products remained stable or increased after simulated gastrointestinal digestion with pepsin and Corolase PP (from pig pancreas, showing mainly trypsin and chymotrypsin activities). In further studies, Hernández-Ledesma and others (2004b) evaluated the ACE-inhibitory activity of several infant formulas and found that most of these products showed moderate inhibitory activity, except for two extensively hydrolyzed milk protein-based formulas (one whey and one casein formula). A nonhydrolyzed milk protein-based formula and an extensively hydrolyzed whey formula were subjected to the same simulated gastrointestinal digestion treatment as described above. It was observed that the ACE-inhibitory activity of the nonhydrolyzed formula increased during the treatment, while no significant change was noted in the activity of the hydrolyzed whey formula after digestion. The results support the view that physiological digestion may promote the formation of bioactive

peptides from the proteins and oligopeptides present in dairy products and that at least part of the active peptides survive the digestion process.

The occurrence of various bioactive peptides in fermented milks, such as yogurt, sour milk, and "Dahi", has been reported in many studies (see Table 46.3). ACE-inhibitory, immunomodulatory, and opioid peptides, for example, have been found in yogurt and in milk fermented with a probiotic *Lb. casei* ssp. *rhamnosus* strain. In most studies, strongly proteolytic *Lb. helveticus* strains have been employed for the production of antihypertensive peptides in fermented milk products (FitzGerald and others 2004; Gobbetti and others 2004; Li and others 2004). At present, at least two fermented sour-milk products containing the ACE-inhibitory tripeptides Val-Pro-Pro (VPP) and Ile-Pro-Pro (IPP) have been launched commercially in Japan and Finland, respectively. The Japanese product "Calpis" is fermented with a culture containing *Lb. helveticus* and *S. cerevisiae* (Takano 1998) and the Finnish product "Evolus" contains peptides produced with *Lb. helveticus* LBK-16 H strain (Seppo and others 2002). In animal model studies, single oral administration of these products has been shown to have an antihypertensive effect in SHR (Nakamura and others 1995b; Sipola and others 2002), and "Evolus" has also been demonstrated to prevent the development of hypertension in SHR (Sipola and others 2001). As described in Chapter 5, both of these fermented drinks have proven effective in the reduction of blood pressure in mildly hypertensive human subjects.

An increasing number of ingredients containing specific bioactive peptides based on casein or whey protein hydrolysates have been launched on the market within the past few years or are currently under development by international food companies. Such peptides possess, for example, anticariogenic, antihypertensive, mineral-binding, and stress-relieving properties (Korhonen and Pihlanto 2003b).

46.4.2 Eggs

Even though eggs are a very valuable source of proteins for human nutrition, very few bioactive peptides have been described as arising from egg proteins. Hydrolyzed egg yolks have been shown to inhibit ACE action *in vitro* and to suppress the development of hypertension in SHRs after oral administration for 27 weeks (Yoshii and others 2001). Chymotryptic digestion of ovalbumin yields a vasorelaxing peptide, ovokinin (2–7) (Arg-Ala-Asp-His-Pro-Phe), which corresponds to residues 359–364 of ovalbumin (Matoba and others 1999). Much attention has been directed towards clarifying the vascular effects of ovokinin (2–7). Oral administration of this peptide has been shown to reduce systolic blood pressure in SHR, for example, but not in normotensive Wistar-Kyoto rats (WKY). On the other hand, intravenous administration of ovokinin (2–7) caused no significant changes in blood pressure except for the highest tested concentration (100 mg/kg), at which level the peptide produced a small, transient fall in blood pressure. Furthermore, ovokinin (2–7) caused an endothelium-dependent vasorelaxation in isolated mesenteric arteries in SHR – but not in WKY – mediated via nitric oxide and insensitive to B_1 and/or B_2 bradykinin receptor antagonists (Matoba and others 2001). The cardiovascular response of ovokinin is mediated by the activation of vascular B_2 receptors (Scruggs and others 2004). Ovokinin derivatives obtained by differential cleavage of ovalbumin or site-directed mutagenesis also showed hypotensive properties. For example, ovokinin Phe-Arg-Ala-Asp-His-Pro-Phe-Leu, which corresponds to residues 358–365 of ovalbumin, relaxes isolated canine mesenteric vessels (Fujita and others 1995).

Contrary to most orally active antihypertensive peptides derived from food proteins, ovokinins do not inhibit ACE (Matoba and others 2001; Yamada and others 2002). ACE-inhibitory activities were further observed in ovalbumin hydrolysates, and six peptides with IC_{50} values ranging from 0.4 to 15 μM were isolated. Five of these peptides also showed antihypertensive activities in SHR (Fujita and others 2000). Miguel and others (2004) isolated several ACE-inhibitory sequences from a peptic digest of egg white. The peptides were derived from ovalbumin and their IC_{50} values ranged from 3.2 to 435.7 μM.

Dávalos and others (2004) isolated four peptides from crude egg white hydrolyzed by pepsin which showed oxygen radical scavenging activity higher than that of Trolox. The peptides were derived from ovalbumin. The peptide Tyr-Ala-Glu-Glu-Arg-Tyr-Pro-Ile-Leu was also a strong ACE inhibitor and delayed the oxidation of the low-density lipoprotein lipid.

46.4.3 Meat

Relatively little is known at present about the derivation of bioactive peptides from the muscle proteins of domestic animals (i.e., meat animals). Arihara and others (2001) purified two ACE-inhibitory peptides from the thermolysin digest of porcine myosin. The sequences Met-Asn-Pro-Pro-Lys and Ile-Thr-Thr-Asn-Pro were found in the primary structure of the myosin heavy chain. Also, six tripeptides having parts of the sequences of the myopentapeptides demonstrated activity with IC_{50} values ranging from 66.6 to >1000 μM. An ACE-inhibitory nonapeptide (Arg-Met-Leu-Gly-Gln-Thr-Pro-Thr-Lys) has been isolated from the peptic hydrolysate of porcine troponin C (Katayama and others 2003). This peptide proved to be a stronger inhibitor than the previously reported myopentapeptides and also a noncompetitive inhibitor. The nonapeptide was slowly hydrolyzed by ACE and was estimated to be a substrate-type inhibitor. The peptide showed relatively high resistance against gastrointestinal endoproteases, that is, pepsin, chymotrypsin, and trypsin. However, it was quickly hydrolyzed by aminopeptidase M and carboxypeptidase A and B, and most of the hydrolysis products showed weak ACE inhibitory activities (Katayama and others 2004). Sarcoplasmic protein extracts from beef rump were hydrolyzed with three enzymes or their paired combination, resulting in ACE-inhibitory activity. The peptide sequence was determined as Val-Leu-Ala-Gln-Tyr-Lys (Jang and Lee 2005). Fujita and others (2000) purified several ACE-inhibitory peptides from the thermolysin digest of chicken muscle. The tripeptides Ile-Lys-Trp, Leu-Lys-Pro and Leu-Ala-Pro also exhibited antihypertensive activities following intravenous administration in SHR. In addition, peptides with antioxidant activity have been obtained from porcine myofibrillar proteins with papain treatment. The Asp-Ala-Gln-Glu-Lys-Leu-Glu showed the highest antioxidant activity among the identified peptides (Saiga and others 2003).

46.4.4 Fish

Peptides inhibitory to ACE have been isolated from fish hydrolysates. Marine ACE-inhibitory peptides can be obtained, for example, with thermolysin digestion of dried bonito. Dried bonito was first hydrolyzed using several enzymes including pepsin, chymotrypsin, trypsin, and thermolysin, followed by subsequent measurement of the ACE-inhibitory activity. The results showed that the peptide fractions derived from thermolysin digestion had the highest ACE-inhibitory activity, and initially eight peptides

were isolated and identified (Yokoyama and others 1992). Fujita and others (1999, 2001) reported further *in vivo* work on ACE-inhibitory activity derived from bonito. When the thermolysin hydrolysate was ultrafiltrated, two-fold higher ACE-inhibitory and antihypertensive activity was observed in SHR after oral administration, as compared with the original digest. This hydrolysate contained a peptide (Leu-Lys-Pro-Asn-Met) which showed long-lasting and dose-dependent antihypertensive activity in SHR after oral administration. A reduction in blood pressure by 30 mmHg was recorded in SHR given an intravenous dose of 100 μg/kg of Leu-Lys-Pro-Asn-Met. In comparison, the administration of the Leu-Lys-Pro peptide at a dose of 30 μg/kg lowered systolic blood pressure by 50 mmHg. The long-term administration (e.g., seven weeks) of dried bonito-derived peptides was noted to suppress the elevation of systolic blood pressure in a dose-dependent manner. A study conducted over an eight-week period in humans, involving 30 subjects with hypertension and borderline hypertension, produced a surprising result: blood pressure was reduced by 60–66% in individuals fed a thermolysin digest of dried bonito (Fujita and Yoshikawa 1999). Other marine sources of ACE-inhibitory peptides are Indonesian dried fish hydrolyzed by pepsin (Atswan and others 1995), sea bream scales hydrolyzed by alkaline protease (Fahmi and others 2004), and yellowfin sole frame protein hydrolyzed by α-chymotrypsin (Jung and others 2005).

Sorensen and others (2004) found that peptide fractions from fish hydrolysates and autolysates inhibited the prolyl endopeptidase activity. The highest activity was found in cod, salmon, and trout samples. The prolyl endopeptidase degrades a variety of proline-containing peptides by cleaving the internal peptide bonds at the carboxyl side of proline residues. Since neuropeptides contain proline residues, any treatment that could positively modulate central neuropeptide levels would provide a promising therapeutic approach to the treatment of cognitive deficits associated with aging and/or neurodegenerative diseases.

Acid peptide fractions from a cod stomach hydrolysate have been reported to include medium-sized peptides (500–3000 Da) with immunostimulatory activity (Gildberg and others 1996). Four peptide fractions were shown to possess an affinity to simulate leukocyte super oxide anion production from Atlantic salmon.

Carnosine, a dipeptide composed of β-alanine and L-histidine, is found in high concentrations in muscle cells including fish. Carnosine has been reported to exhibit extensive antioxidative and hydrogen buffering properties (Chan and Decker 1994). Nagasawa and others (2001) demonstrated the antioxidant activity of carnosine both *in vitro* and *in vivo*. Carnosine was found to inhibit lipid peroxidation and oxidative modification of protein in rat muscle tissue exposed to a hydroxyl radical generated from Fenton radicals. The hydrolyzed gelatin extracted from Alaska pollack skin showed antioxidative activity. Two peptides, composed of 13 and 16 amino acid residues, were isolated from the hydrolysate. The longer peptide protected rat liver cells from oxidant injury by t-BHT (Kim and others 2001). Moreover, Je and others (2005) isolated the antioxidative peptide Leu-Pro-His-Ser-Gly-Tyr from Alaska pollack frame protein hydrolysate.

Various fish sources have yielded antimicrobial peptides. Liver tissue from Atlantic salmon contains an antimicrobial peptide with a molecular mass of 20,734 Da. This purified peptide has been identified as a histone protein and is termed histone H1 (Richards and others 2001). Histone proteins are normally found in chromatin and are involved in the structural organization of DNA. Three antibacterial basic polypeptides have been isolated from acetic acid extracts of Channel catfish (*Ictalurus punctatus*) skin (Robinette and others 1998). Catfish (*Parasilurus asotus*) also contains a strong antimicrobial peptide termed parasin I, consisting of 19 amino acids that include three arginine and five

lysine residues and have a molecular mass of 2000 Da (Park and others 1998). Parasin I showed strong antimicrobial activity towards both Gram-negative and Gram-positive bacteria as well as fungi without any hemolytic activity. The peptide forms a β-strand in both a hydrophilic and a hydrophobic environment, instead of the more common linear amphipathic α-helix structure found in many other antimicrobial peptides. It has been suggested that protease digestion of histone H2A may yield a potent antimicrobial peptide, which is supported by the fact that other antimicrobial peptides, such as lactoferricin generated by pepsin digestion of bovine and human lactoferrin, also exhibit greater antimicrobial activity than the native lactoferrin.

46.4.5 Plants

Peptides with ACE- and PEP-inhibitory, immunomodulating, antimicrobial, antioxidative, and opioid activities have been isolated from food plants. Gibbs and others (2004) detected several bioactive peptides in soy-fermented foods digested with proteolytic enzymes. The activities ranged from ACE-inhibitory and antithrombotic to surface-active and antioxidative properties. Peptides inhibitory to ACE have been isolated from a tryptic isolate of zein (maize), hordein (barley) and gluten (wheat) (Gobbetti and others 1997). Three strong ACE inhibitors isolated after thermolysin hydrolysis of α-zein and characterized as Leu-Arg-Pro, Leu-Ser-Pro, and Leu-Gln-Pro contained a common C-terminal proline residue. IC_{50}-values denoting the potency to inhibit ACE *in vitro* for all these peptides were found to be very low. However, it is noteworthy that oral administration of these peptides to SHR produced a significant decrease in systolic blood pressure compared with the control at 6 h after administration (Matsumura and others 1993). ACE-inhibitory peptides prepared from soy protein hydrolyzed by alcalase were stable to gastrointestinal protease *in vitro* and also active *in vivo* in SHR (Wu and Ding 2001). Kuba and others (2004) hydrolyzed the soybean proteins β-conglycinin and glycinin by acid proteinase from *Monascus purpureus*. Four ACE-inhibitory peptides were isolated from the hydrolysates. The activities of the peptides Leu-Pro-His-Phe and Trp-Leu were preserved after digestion *in vitro*. Moreover, the inhibitory activity of Leu-Ala-Ile-Pro-Val-Asn-Pro markedly decreased whereas that of Ser-Pro-Tyr-Pro markedly increased after digestive treatment. Yang and others (2003) isolated four ACE-inhibitory peptides from a pepsin-pancreatin digest of spinach Rubisco. The peptides Met-Arg-Trp and Met-Arg-Trp-Asp showed an antihypertensive effect after oral administration at a dose of 20 and 30 mg/kg. The maximal decrease was observed 2 or 4 h after administration. The peptide Ile-AlaTyr-Lys-Pro-Ala-Gly exerted antihypertensive activity after oral administration at a dose of 100 mg/kg. Four potent ACE inhibitory peptides (Ile-Tyr, Arg-Ile-Tyr, Val-Trp-Val, and-Trp-Ile-Ser) were isolated from a subtilisin digest of rapeseed protein (Marczak and others 2003). The peptides were relatively stable to digestion with the enzymes present in the digestive tract. All isolated peptides and the subtilisin digest of rapeseed protein lowered blood pressure in SHR following oral administration. The hydrolysate significantly lowered blood pressure even at a single dosage of 0.15 g/kg. Moreover, sunflower seed proteins were recently found to be a potential source of ACE-inhibitory peptides when hydrolyzed by pepsin and pancreatin (Megias and others 2004).

Wheat gluten is a well-known source of opioid peptides among food proteins (Fukudome and Yoshikawa 1993). A peptide named oryzatensin (Gly-Tyr-Pro-Met-Tyr-Pro-Leu-Pro-Arg) with immunomodulatory activity causing smooth muscle contraction has been obtained from a rice tryptic hydrolysate. Shorter, C-terminal fragments of

oryzatensin demonstrating similar activity were also reported. Phagocytosis by leukocytes from human blood was induced *in vitro* by oryzatensin and the production of superoxide anions in leukocytes was also stimulated (Takahashi and others 1996). Six peptide fragments with antioxidant activity were isolated from digests of the soybean protein β-conglycinin (Chen and others 1995, 1996). The Leu-Leu-Pro-His-His domain played a major role in the noted antioxidative activity of this peptide. The results indicated that the Pro-His-His sequence exerted the greatest antioxidative activity among all tested peptides and had synergistic effects with nonpeptide antioxidants, for example, tocopherol, butylated hydroxyanisole, and butylated hydroxytoluene.

Many plants produce antimicrobial peptides which have a role in the defence of the plant against infection or natural invaders. A class of small, basic peptides, referred to as thionins, have been found in seeds of wheat, barley, rye, and oats (Garcia-Olmedo and others 1998). Thionins are cysteine- and lysine-rich polypeptides that contain 43–46 amino acid residues and have considerable homology among different species. Futhermore, they exhibit antimicrobial activity against plant pathogenic fungi and bacteria *in vitro*. Zhang and Lewis (1997) isolated two antimicrobial peptides, fabatins, by acid extraction from the broad bean *Vicia faba.* Fabatins have an overall positive charge and contain 47 amino acid residues and eight cysteine residues that probably derive from four disulfide bridges characteristic of thionins. Fabatins were found to exhibit activity against Gram-positive and Gram-negative bacteria, but were inactive against the yeasts *Saccharomyces cerevisiae* and *Candida albicans*. Macrocyclic cysteine-knot peptides containing 29–31 amino acid residues have been isolated from coffee plants. The macrocyclic peptides were active against Gram-positive and -negative bacteria and against fungi. Furthermore, they were cytotoxic and lysed human red cells. The potent antimicrobial activity of macrocyclic peptides is salt-dependent and their initial interactions with microbial cell surfaces may be electrostatic (Tam and others 1999).

46.5 BIOLOGICAL EFFECTS OF BIOACTIVE PEPTIDES

The potential beneficial biological effects of food protein-derived peptides have been a subject of growing commercial interest in the context of health-promoting functional foods. So far, milk protein-derived hypotensive, mineral-binding, and anticariogenic peptides have been most studied for their physiological effects in animal models and human subjects. The major reason for screening hypotensive peptides has been their ability to inhibit ACE activity, but a few studies also suggest that the hypotensive effect of peptides can be mediated by other mechanisms as well, for example, through the vasodilatory action of binding to opiate receptors or modulation of endothelin-1 release by endothelial cells (Nurminen and others 2000; Maes and others 2004). To exert an antihypertensive effect after oral ingestion, active peptides must be absorbed in an intact form from the intestine and further be resistant to degradation by plasma peptidases in order to reach the target sites. In fact, it has been demonstrated that small ACE-inhibitory peptides can be absorbed intact through the intestine by paracellular and transcellular routes, but the potency of bioactivity after absorption is inversely correlated to chain length. It is also known that proline-containing peptides are generally resistant to degradation by digestive enzymes. Many animal studies, reviewed by Li and others (2004), have shown a dose-dependent hypotensive effect in SHR after single oral administration of small di- and tripeptides. Masuda and others (1996) detected two ACE-inhibitory

tripeptides (Val-Pro-Pro and Ile-Pro-Pro) in the abdominal aorta of SHR after oral administration of sour milk containing these tripeptides. On the other hand, some peptides with weak ACE-inhibitory activities *in vitro* show strong antihypertensive activities after oral administration. One reason for this phenomenon may be that such weak peptides are converted into stronger ones through degradation by gastrointestinal proteases. These smaller peptides can thereafter be absorbed intact into the blood circulation and exhibit antihypertensive effects (for a review see Li and others 2004).

A number of *in vivo* studies with SHR and hypertensive human volunteers have reported significant blood pressure-reducing effects after consumption of specific milk protein hydrolysates and fermented dairy products (see reviews by FitzGerald and others 2004; Li and others 2004; Vermeirssen and others 2004). Table 46.4 lists human clinical studies carried out using these products. In a placebo-controlled trial with mildly hypertensive subjects a significant reduction in blood pressure was recorded after daily ingestion for four weeks of 95 mL of "Calpis" sour milk containing the potent ACE-inhibitory peptides Val-Pro-Pro and Ile-Pro-Pro. It is noteworthy that the ingested dose of these peptides was small, about 2.6 mg per day. Blood pressure was reverted gradually to pretrial level after the intervention period ceased. No major changes in blood pressure were observed in the placebo group (Hata and others 1996; Yamamoto and others 2003). These results were supported by a recent double-blind randomized controlled study (Mizushima and others 2004) in which the effect of 'Calpis' was assessed in borderline hypertensive men upon oral administration of 160 g of the product for four weeks. Systolic blood pressure in the test group decreased significantly after two and four weeks of ingestion of "Calpis." No significant change in blood pressure was observed in the placebo group, which was administered unfermented acidified milk. Similar results were obtained with the "Evolus" product in two double-blind, placebo-controlled studies with mildly hypertensive subjects who ingested 150 mL of the product daily. "Evolus" was found to decrease both systolic and diastolic blood pressure during the eight-week and 21-week treatment periods, respectively. No such influence was reported in subjects with normal blood pressure (Seppo and others 2002, 2003). Another recent placebo-controlled study (Ashar and Chand 2004) tested the effect of "Dahi" fermented milk containing the ACE-inhibitory peptide Ser-Lys-Val-Tyr-Pro (SKVYP) on hypertensive subjects. The product was produced by fermentation of milk with *Lb. delbrueckii* ssp. *bulgaricus*, *Str. salivarius* ssp. *thermophilus*, and *Lc. Lactis* biovar. *diacetylactis.* The subjects received either 100 mL of the test product or the placebo product for four weeks. In the test group, a significant decline in systolic blood pressure was recorded after two and four weeks from the start-up of the trial. No significant change in blood pressure was noticed in the placebo group during the intervention period. The placebo product was prepared using the same starters as the test product, but these strains did not produce the above ACE-inhibitory peptide.

Many animal and human studies have reported the presence of caseinphosphopeptides (CPP) *in vivo* following ingestion of milk, fermented dairy products, casein, and crude CPP preparations (Meisel and FitzGerald 2003). The stomach and intestinal contents of adult humans fed milk or yogurt were found to contain CPPs (Chabance and others 1998). CPPs have been detected in the distal small ileum (ileum) of humans administered milk or crude CPP preparations orally (Meisel and others 2003). Since CPPs can bind and solubilize minerals, they have been considered physiologically beneficial in the prevention of osteoporosis, dental caries, hypertension, and anemia. Conflicting results have been obtained in animal studies which have assessed the potential of CPPs to enhance

TABLE 46.4 ***In Vivo*** **Human Studies on Bioactive Peptides.**

Product Administered	Peptide Precursor/ Peptides Identified	Effect Observed	Reference
Rice-based cereal gruel + CPP	Caseinphospho peptides (CPP)	Improvement of calcium and zinc absorption	Hansen and others (1996)
Tryptic casein hydrolysate	α_{s1}-casein	Reduction of blood pressure	Sekiya and others (1992)
Sour milk	β-casein, κ-casein Val-Pro-Pro/ Ile-Pro-Pro	Reduction of blood pressure	Hata and others (1996)
Sour milk	Val-Pro-Pro/Ile-Pro-Pro	Reduction of blood pressure	Seppo and others (2003)
Sour milk	Val-Pro-Pro/Ile-Pro-Pro	Reduction of blood pressure	Mizushima and others (2004)
Sour milk (Dahi)	β-casein Ser-Lys-Val-Tyr-Pro	Reduction of blood pressure	Ashar and Chand (2004)

Abbreviations: α_{s1}-cn, α_{s1}-casein; β-cn, β-casein; κ-cn, κ-casein.

mineral (primarily calcium) bioavailability. In general, animal studies with the use of tracers have revealed a positive effect of CPPs on calcium absorption, whereas most of the balance studies have failed to find any effect of CPP addition (FitzGerald 1998). In human studies, increased calcium and zinc absorption has been demonstrated in adults administered a rice-based infant gruel. This beneficial effect was abolished when the volunteers were fed cereal-based meals containing phytate (Hansen and others 1996). More recently, Narva and others (2004) showed that *Lb. helveticus* fermented whey and the tripeptides Val-Pro-Pro and Ile-Pro-Pro stimulated the proliferation of osteoblasts *in vitro*, whereas sour-milk whey and calcium had no effect. The fermented whey contained 26 mg/L of these peptides. No significant effects on osteoclast formation were observed *in vitro* with any of the studied products. More cell culture and human studies are necessary to demonstrate the potential of CPPs and other peptides to enhance dietary mineral bioavailability and to modulate bone formation. Another interesting property associated with CPPs is their potential to enhance mucosal immunity. This idea is supported by a study (Otani and others 2000) which showed that oral administration of a commercial CPP preparation enhanced the intestinal IgA levels of piglets.

The anticariogenic effect of CPPs has been well documented in both human and animal studies (Meisel 2001). CPPs can have an anticariogenic effect by promoting recalcification of tooth enamel, whereas glycomacropeptide (GMP) derived from κ-casein seems to contribute to the anticaries effect by inhibiting the adhesion and growth of plaque-forming bacteria on oral mucosa (Brody 2000; Malkoski and others 2001). Various dental care products containing CPPs and/or GMP have been launched on the market in some countries.

46.6 FUTURE APPLICATIONS OF BIOACTIVE PEPTIDES

The occurrence of biologically active peptide sequences in dietary proteins is now well established. A few peptides have proven effective in the provision of specific physiological activities *in vivo* upon oral administration. The optimal exploitation of bioactive peptides for human nutrition and health poses an exciting scientific and technological challenge, while at the same time offering potential for commercially successful applications. Bioactive peptides can be incorporated in the form of ingredients in functional and novel foods, dietary supplements, and even pharmaceuticals with the purpose of delivering specific health benefits. Such tailored dietary formulations are currently being developed worldwide to optimize health through nutrition. This approach has been taken initially at target group level but will ultimately address individuals. To this end, bioactive peptides offer an excellent basis for the novel concept of "personalized nutrition." Many scientific, technological and regulatory issues must, however, be resolved before these substances can be optimally harnessed to this end.

Firstly, there is a need to develop novel technologies, such as chromatographic and membrane separation techniques, to enrich active peptide fractions from the hydrolysates of various food proteins (Korhonen 2002). In addition to enzymatic hydrolysis, microbial fermentation provides a natural technology applicable for the production of bioactive peptides either from animal or plant proteins. The potential of this approach is already well demonstrated by the presence of bioactive peptides in fermented dairy and soybean products. Production of bioactive peptides from protein-rich raw materials may be scaled up to industrial level using controlled fermentation in bioreactors with known LAB. In

future, the commercial production of specific peptide sequences is likely to employ recombined enzyme technology and specific production strains or alternatively make use of peptidases isolated from suitable microorganisms.

Secondly, it is important to study the technological properties of active peptide fractions and to develop model foods that contain these peptides and retain their activity for a guaranteed period. It is recognized that, due to their lower molecular weight, peptides can be more reactive than proteins, and the peptides present in the food matrix may react with other food components. The interaction of peptides with carbohydrates and lipids, as well as the influence of the processing conditions (particularly heating) on peptide activity and bioavailability, should also be addressed (Korhonen and others 1998). In this respect, the possible formation of toxic, allergenic, or carcinogenic substances warrants intensive research. In fact, modern analytical methods need to be developed to study the safety of foodstuffs containing biologically active peptides.

Thirdly, molecular studies are needed to assess the mechanisms by which bioactive peptides exert their activities. This research area is currently considered highly challenging, as the majority of the known bioactive peptides are not absorbed from the gastrointestinal tract into the blood circulation. Their effect is, therefore, likely to be mediated directly in the gut lumen or through receptors on the intestinal cell wall. In this respect, the target function of the concerned peptide is of utmost importance. It is anticipated that such targets will be related to various lifestyle-related disease groups, such as cardiovascular diseases, cancers, diabetes, osteoporosis, stress, and obesity. Bioactive peptides derived from dietary proteins offer a promising approach to prevent, control and even treat such disease conditions through a controlled diet.

47.1 INTRODUCTION

47.1.1 Functional Foods: a New Concept in Nutrition

There is no doubt that our view of foods has changed enormously throughout history, and this has driven the development of technology applied to the processing of products that we consume daily along with it. But it is in the last few years that the change in dietary concepts has been most significant, revolutionizing the food industry and food science. In the past, consumers' main concerns were the risks of the presence of contaminants and the deficiencies in processing that could affect their health. These concerns now have changed to the perceived benefits of nutrients ingested in an appropriate manner and provided for healthy development and maintenance. Food was once seen as carriers of substances potentially harmful to our health, and some epidemiological and diet studies recommended the reduction or avoidance of the consumption of certain ingredients in foods. It left behind a preventive and restrictive tendency that changed the type of food and its production. However, scientific advances changed this tendency and have reached a different approximation from the diet-health binomial. Currently, our diet composition is regulated by the inclusion of positive components and the correct dosage of others, which if consumed in excess are not beneficial, instead of promoting their simple exclusion. The discovery of the positive effects on health by minority components in food (more commonly found in fruit and vegetables) brought about the change in the previously mentioned tendency, and when the positive view was extended to macronutrients, it gave rise to the concept of functional food.

A generally accepted definition of functional food would be any food or ingredient that has a positive impact on an individual's health, physical performance, or state of mind, in addition to its nutritive value (Goldberg 1994). To distinguish functional foods from nutraceuticals, it should be kept in mind that the former are foods of similar composition presented to those normally consuming them and should be included in the normal daily diet.

The market for functional food is growing at a steady rate (20% annually). The current dietary products included in this type of food are present in categories such as milk products, drinks, cereals, and meat. These foods include any or some ingredients which provide this functionality such as, for example, fiber, oligosaccharides, amino acids, peptides and proteins, isoprenoids and vitamins, minerals, polyunsaturated fatty acids, antioxidants, and phytochemicals. Despite the relevance of the functional aspect of these components, it is not easy to distinguish them from the nutritional ones, which are also present. For some of these ingredients, it is this last aspect which characterizes and defines them in a more classical way, as in the case of the vitamins.

47.1.2 Nutritional and Functional Properties of the Vitamins

The existence of specific essential components for adequate nutrition was sensed throughout history. Many observations have been described relating to the absence or deficiency of some elements in the diet (fruit, vegetables, meat, and fish) with the development of certain diseases. When the diet included, or was fortified with these elements, these diseases were not present or remitted in the population. However, it is not until the beginning of the 20th century, when specific ingredients, which enabled a proper development

and healthy state of the body, began to be identified. These investigations had the same foundations as early observations with the discovery of the vitamins:

- Absence or presence of a diet component;
- Effect on human health;
- Isolation, identification, and extraction of the responsible ingredient.

This leads to the discovery of the vitamins. The importance of the vitamins in human nutrition and health, along with the deficiencies suffered by certain population groups (and they still suffer today), brought about their cost-effective production. They were first produced by extraction from natural sources and later by synthesis. This reduced the price considerably and enabled them to be used on a large scale in the food industry. This revolutionized the market, which is inundated with foods fortified with vitamins and multivitamin preparations. The existence of these types of dietary product makes it easier for the population to complement the quantity of vitamins ingested through the normal daily diet to reach an optimal vitamin status. This status is achieved by ingesting the recommended daily amount (RDA) set by the public health authorities for each vitamin, whose objective is to avoid the manifestation of those diseases caused by the absence or deficiency of these nutrients.

More specifically, and according to the Food and Nutrition Board, the RDAs of vitamins are defined as the level of ingestion that, based on scientific knowledge, are adequate to cover the nutritional needs of, practically, all healthy individuals. A level which includes a minimum requirement for a maximum protection, is derived from each function dependent on the vitamin, as well as a minimum requirement for an adequate reserve of these nutrients.

Bearing in mind the definition of functional food and the common use of vitamins, these appear to be standardized in other types of foods more than in functional ones. In this way, they are common ingredients in food categories such as dietary supplements, medicinal foods, fortified foods, and special dietary foods (Kwak and Jukes 2001). How can the concept of functionality be defined in the vitamins? Only from the state of health reached with RDA and the objectives achieved by it, is when we can begin to distinguish and characterize the functionality of the vitamins. For this reason it is appropriate to consider two important points:

1. Only deficient and toxic levels of vitamins have negative clinical manifestations. However, the effect on health produced by levels in between those is unknown.
2. Their positive implication in the prevention of diseases that are not due to their absence or deficiency, an implication which appears when amounts greater than those recommended are ingested.

Both points highlight the current discrepancy between the RDA – defined to achieve an optimal nutritional status to avoid the diseases caused by their deficit – and the amount with which optimal functional status is acquired, a situation that is illustrated in Figure 47.1. The quantity of vitamin D adequate to prevent rickets is known but the quantity required for the prevention of other degenerative processes and chronic diseases is unknown. Within this discrepancy is where the functional character of the vitamins and their additional biological actions should be established, and supported by the scientific evidence which is continually being provided. Their role as antioxidants, immune

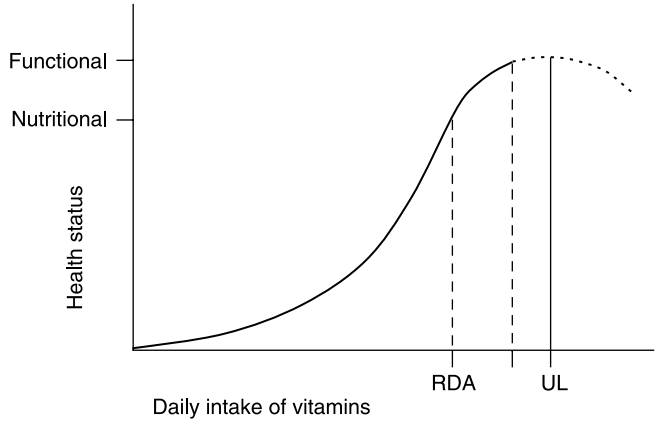

Figure 47.1 *Possible discrepancy between the RDA of vitamins and the amount with which optimal functional status is acquired, and their effects in health status of the individual.*

system stimulators, intercellular communication enhancers, and in the reduction in the risk of diseases, which occur with advanced age, determines the functionality of the vitamins (Walter and others 2000).

This area of investigation has been fairly active in the last few years, and has been given a boost by the success of functional foods. Apart from the commercial aspects, the scientific interest is seen in the determination of additional functions that the vitamins will carry out, by analyzing the mechanisms of action, the involvement of their metabolites, and the establishment of new recommended levels of ingestion. If the tendency is to increase the daily dose it, places special emphasis on the toxic effects they can produce (Walter 2001).

The present chapter deals with the most relevant nutritional and functional properties of the lipid soluble vitamins, including in each case a short introduction describing the structural characteristics of each vitamin, which make possible their interaction with other biomolecules and the development of their biological functions.

47.2 VITAMIN A

Since McCollum and Davis adopted the term "fat soluble A" in 1913, the knowledge of vitamin A has advanced enormously. Initially, discoveries such as the conversion of β-carotene into vitamin A in hepatic tissue and deficiencies of this vitamin in specific population groups were notable. In 1930, the structure of this compound was determined and that of its most active precursor (β-carotene). A decade later, Isler established a process for its synthesis from a precursor (β-ionone), making the production of this vitamin significantly cheaper. In the middle of the 20th century, many of the concepts and metabolic pathways of vitamin A were defined, which are still valid today (Olson 2001).

The group of substances known as vitamin A have a structure differentiated in two zones, a β ring and a chain with nine carbon atoms with four alternated double bonds and two side-chain methyl groups. The final carbon atom presents oxygen functions, from which a varied group of compounds is denoted, being retinol, retinal, and retinoic acid the most representative. Vitamin A occurs in its esterified form, and it is in

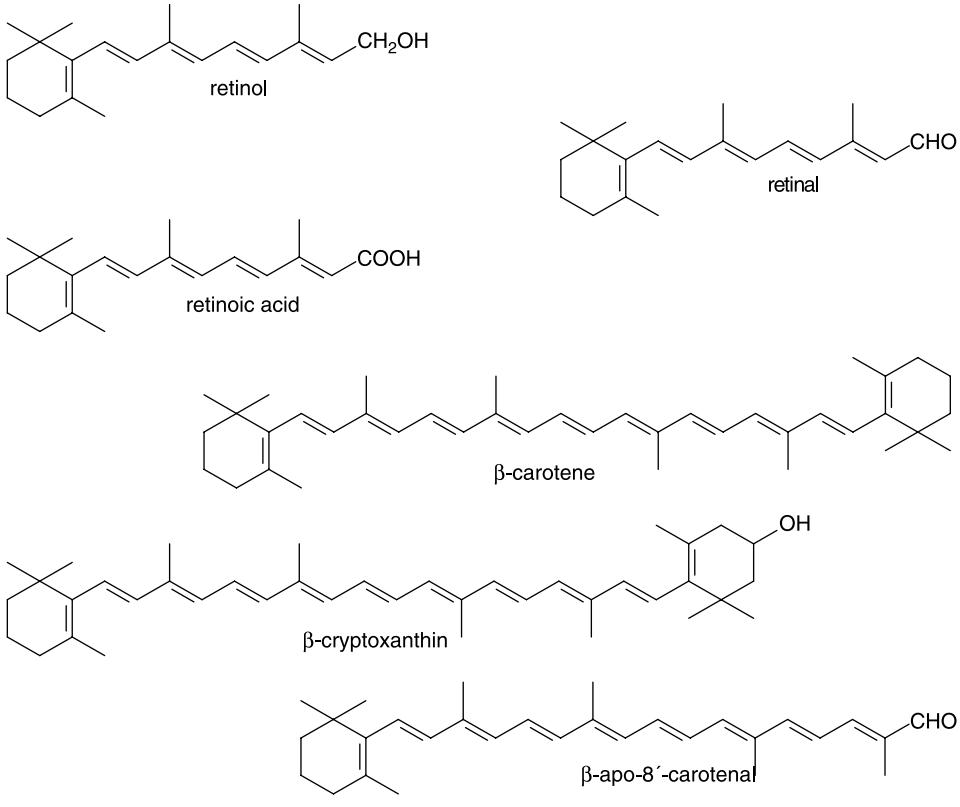

Figure 47.2 *Structure of retinol and its derivatives, and main carotenoids with provitamin A activity.*

this state that it is normally marketed (acetate esters of retinyl and retinyl palmitate). The precursors of vitamin A, the carotenoids, have a wide diversity of structures (in nature, more than 600 carotenoids are known) but only 10% show provitamin A activity in complying with the structural requirements for this (a β ring without oxygen functions). In Figure 47.2, the structures of the most representative retinoids and carotenoids with provitamin A activity are shown.

47.2.1 Nutritional Properties of Vitamin A

The dietary requirements of vitamin A are usually supplied by retinol (mainly in esterified form) and the carotenoids with provitamin A activity. The most common foods in which this vitamin is obtained are milk products, liver, and fish oils. The carotenoids present in carrots, green vegetables such as spinach, fruits like sweet peppers, mango, and papaya, and vegetable oils such as that from palm generally contain one or several precursors with provitamin A activity (Booth and others 1992).

The role of vitamin A is seen in many different metabolic processes and is involved in growth and development, immune function, reproduction, maintenance of the integrity of epithelial cells, and the correct functioning of the visual system. The RDA for adults is reduced from the recommended values of 1000/800 μg retinol/day (males/females) (National Research Council 1989), to currently 900/700 μg retinol/day. As was

mentioned in the introduction, this amount prevents the appearance of specific symptoms of deficiency such as xerophthalmia and irreversible blindness and other nonspecific ones such as lack of development and growth, and increasing risk of anemia and infectious diseases. Even today, vitamin A deficiency is a problem on a world scale. WHO estimates that annually, three million children develop some type of xerophthalmia and another 250 million are deficient in this vitamin. It is no surprise that plans are continually being put into operation to avoid these problems in the developing countries (Gibson and others 2000); the most well known amongst them is the development of a type of rice rich in β-carotene known as "golden rice." On occasions the development and production of functional foods in western countries copy these strategies, which increase the bioavailability of this and other micronutrients.

47.2.2 Functional Properties of Vitamin A

Apart from the nutritional properties of the group of substances which encompasses vitamin A (retinoids and carotenoids with provitamin A activity), they carry out other biological actions important to human health. The retinoids are loosely classified as antiproliferative agents. Although they are also proposed as antioxidants, this action appears to be associated more with the antioxidant capacity of the provitamin A, β-carotene, and the synergy effect of this compound with the antioxidant vitamins E and C (Combs 1998).

Regarding the decrease in the risk of developing degenerative diseases, such as cancer, it is stated in the control of cellular differentiation and proliferation, and the induction of apoptosis, actions mediated by vitamin A (Harris 1990; Prowse and others 2002). These processes are of special importance in those tissues which are exposed to an increased cycle of cellular loss and renewal such as the digestive tract. In this case, the induction of apoptosis controls the number of damaged, pre- and neoplasic cells, an effect which the retinoids induce by means of the activation of calcium-dependent transglutaminases (Fesus and others 1996).

Another two important processes in the functionality of the retinoids are their roles as transcriptional regulators (Murakami and others 2002) and stimulators of intercellular communication (GJC). This activity is deficient in many cancerigenic cells and the stimulation or restoration of GJC should produce a decrease in their proliferation. Since an effective function of the immune system is based on intercellular communication, the provision of GJC by the retinoids collaterally boosts immune activity.

Like all lipid soluble vitamins, excessive storage of vitamin A, mainly in the liver, generates toxicity. The Food and Nutrition Board stipulates a maximum daily dose of 3000 μg to avoid the appearance of secondary effects derived from the toxicity of this vitamin, such as headaches and vomiting, desquamation of the skin and hepatic damage. More recently effects harmful to bone health have been reported. The publications regarding this effect suggested a correlation between chronic ingestion of vitamin A in amounts greater than the RDA and hip fractures (Promislow and others 2002; Penniston and Tanumihardjo 2003).

Epidemiological studies on the possible harmful effect of the carotenoids with provitamin A activity, specifically β-carotene, have generated more controversy. The negative effect that supplementation with β-carotene produced in risk groups (such as heavy smokers), has highlighted that the metabolism of this provitamin A produces oxidized compounds similar in structure to that of the retinoids, interfering in the signaling pathways, and that an excess of these components can induce the activity of cytochrome

P450 enzymes (Wang and Russell 1999). This situation produces an increase in the catabolism of retinoids and with this a reduction in the control of cellular differentiation and proliferation. The individualization and excess ingestion of these micronutrients are factors which trigger their negative effects on human health.

47.3 VITAMIN E

Although the discovery of vitamin E occurred in 1922, when Evans and Bishop determined the essentiality of a lipophilic substance in rodent reproduction, it was not until the 1960s that the importance of this vitamin in humans was recognized with the association of its deficiency with the development of anemia in premature babies (Machlin 1991). The term vitamin E encompasses a group of lipophilic substances (four tocopherols and four tocotrienols) whose main activity is as an antioxidant against free radicals.

The structure of these compounds has a 6-chromanol ring (head) and a phytyl side chain (tail). The position and number of methyl groups differentiate each component, whilst the presence or absence of double bonds in the tail characterizes the tocotrienols and tocopherols, respectively (Fig. 47.3). Each tocopherol/tocotrienol has a different antioxidant ability depending on its structural characteristics; α-tocopherol (the most abundant in nature) shows the greatest capacity (Foote 1979; Fukuzawa and Gebicki 1992).

47.3.1 Nutritional Properties of Vitamin E

Vitamin E, due to its great capacity and synergy, represents the nonenzymatic antioxidant system, which along with the enzymatic antioxidant group, controls oxidative stress, its

Substituent groups	Tocopherol	Tocotrienol
$R_1=R_2=R_3=CH_3$	α	α
$R_1=R_3=CH_3$ $R_2=H$	β	β

adverse effects and the reactive intermediates that they produce. A severe deficiency of vitamin E produces anemia and neuromuscular abnormalities. Except for those individuals with a defect in the gene that regulates the α-tocopherol transfer protein, vitamin E deficiency is not normal in humans and with the supply coming from the diet it reaches an adequate optimum status (Ouahchi and others 1995; Traber and Sies 1996). Vegetable oils, such as soya and corn, margarines, enriched cereals, tomato, and whole milk products, eggs, and meat are common sources of vitamin E. The Food and Nutrition Board sets a RDA of 15 mg/day, assigning antioxidant activity as the main function of this vitamin. As it will be mentioned in the following section, the metabolic functions of this group of substances are not wholly defined but it appears that it goes beyond their activity as antioxidants.

The implication of free radicals in the genesis of diseases, such as arteriosclerosis, cataracts, certain types of cancers, neurodegenerative disorders, and other processes related to aging (Ferrari and Torres 2003), and the control which the antioxidants exercise over them, turn the antioxidant vitamins into key functional ingredients. The mechanism of action of vitamin E against lipid auto-oxidation has been widely described (Kamal-Eldin and Appelqvist 1996). The most interesting aspect of this action is its integration into the complex antioxidant system where vitamin E acts in synergy with other species such as selenium, vitamin C, and β-carotene. These components complement the activity of vitamin E through different mechanisms such as its regeneration or restoration after it has carried out its antioxidant function (Niki and others 1982; Wefers and Sies 1988). The interrelationship with sulfur-containing amino acids appears to be more related to the requirement of these in the synthesis of glutathione which regenerates vitamin E. In the case of transition metals such as Fe^{+2} and Cu^{+} its relationship with them is in their capacity to catalyze the decomposition of peroxides producing more free radicals and reducing the antioxidant effect of vitamin E.

47.3.2 Functional Properties of Vitamin E

Currently, studies of vitamin E point to the involvement in other activities not related to its capacity as an antioxidant, and concentrate more on its functionality. Among them, they describe cellular signaling and the improvement in the immune response. The first activity is related to the regulation of protein kinase C and other proteins or enzymes implicated in atherogenesis, reducing cell proliferation (Mahoney and Azzi 1988; Boscoboinik and others 1991; Chan 1998;). In particular α-tocopherol promotes the segregation of prostacyclin, a powerful vasodilator and platelet aggregation inhibitor. The role of vitamin E in the prevention of cardiovascular diseases is due to the existence of pathways, sensitive to this vitamin, which modifies cellular adhesion and proliferation, an activity that is supplementary to the control of oxidative stress. In regards to its functionality on the immune system, studies in humans have found an association between vitamin E and the immune response. Although this effect seems to be related to a decrease, induced by vitamin E, in the production of free radicals and related species, the role of this vitamin is not totally defined (Calder and Kew 2002). A recent work (Brigelius-Flohé 2003) summarizes how the different forms of vitamin E interact in the synthesis and activity of the enzymes responsible for the metabolism of drugs and xenobiotics.

Since the main activity provided by vitamin E is as an antioxidant, studies on its metabolism have been focused on the determination of compounds produced after this activity. In the last decade new metabolites, such as the carboxyethyl-hydrochromans (CEHC) that

keep the structure of chroman intact and do not take part in an antioxidant process, have been discovered (Shuelke and others 2000). The function of these metabolites as well as the catabolic pathways they generate, are areas still being investigated regarding each specific form of vitamin E. In particular, γ-tocopherol exhibits anti-inflammatory properties and its metabolite, γ-CEHC, shows natriuretic activity (Jiang and others 2001). With the high consumption of γ-tocopherol in diets such as in North America, the differences in bioavailability as compared to other E vitamers and the previously mentioned activities have increased interest in this tocopherol.

47.4 VITAMIN D

Vitamin D encompasses a group of compounds, very similar in structure, which possess antirickets activity of which ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) are notable. The former is derived from a vegetable steroid, ergosterol, while the latter is produced in the body from its precursor 7-dehydrocholesterol. This fact establishes that vitamin D is seen as a prohormone, which is metabolized in the liver and kidneys to its active form ($1\alpha,25(OH)_2D_3$), it functions as a steroid hormone. The discovery of this vitamin is associated to the prevention of the rickets and initially its activity was confused with that of vitamin A. It was not until 1922 when McCollum and others showed that the antirickets factor was a new substance, different to vitamin A and called it vitamin D (McCollum and others 1922). The need for ultraviolet (UV) light to obtain this vitamin, although sensed, was discovered years later. In 1970, the structure of the previously mentioned biologically active metabolite of vitamin D was determined.

Figure 47.4 shows the structure of the two main forms of vitamin D as well as their precursors and the metabolites $25(OH)D_3$ (which represents the vitamin D status in the individual) and $1\alpha,25(OH)_2D_3$, the active form. Starting from the cyclopentanoperhydrophenanthrene ring system present in the precursors and using UV radiation, a fission is produced in ring B which gives rise to a system of three double bonds, characteristic in all forms of vitamin D. Each particular form differs in the structure of the chain appended to the group of rings.

47.4.1 Nutritional Properties of Vitamin D

Vitamin D can be obtained from fortified foods, although its absorption efficiency is not very high, practically 50%, so that our body relies on the synthesis route to obtain the necessary amount of this vitamin. The Food and Nutrition Board sets a RDA of 5 μg/day for adults although this value is hard to specify due to the endogenous synthesis of this vitamin and its requirement depends on multiple factors (among them, the level of exposure to light, calcium, and phosphorous levels, development state of the individual). Vitamin D is found in appreciable quantities in fish such as salmon, sardines, and fish and liver oils. Other foods such as vegetables are poor sources of this vitamin; eggs, milk, and margarine contain very small amounts. For this reason, the fortification of foods such as pasta and cereals with vitamin D had become a normal practice for years and had almost eliminated rickets in the United States (Welch and others 2000). However, recent studies show a reemergence of deficiency in this vitamin and additional fortifying has been recommended (Moore and others 2004). The population groups in which this deficiency is most common are children, the elderly, and the obese. The lack of

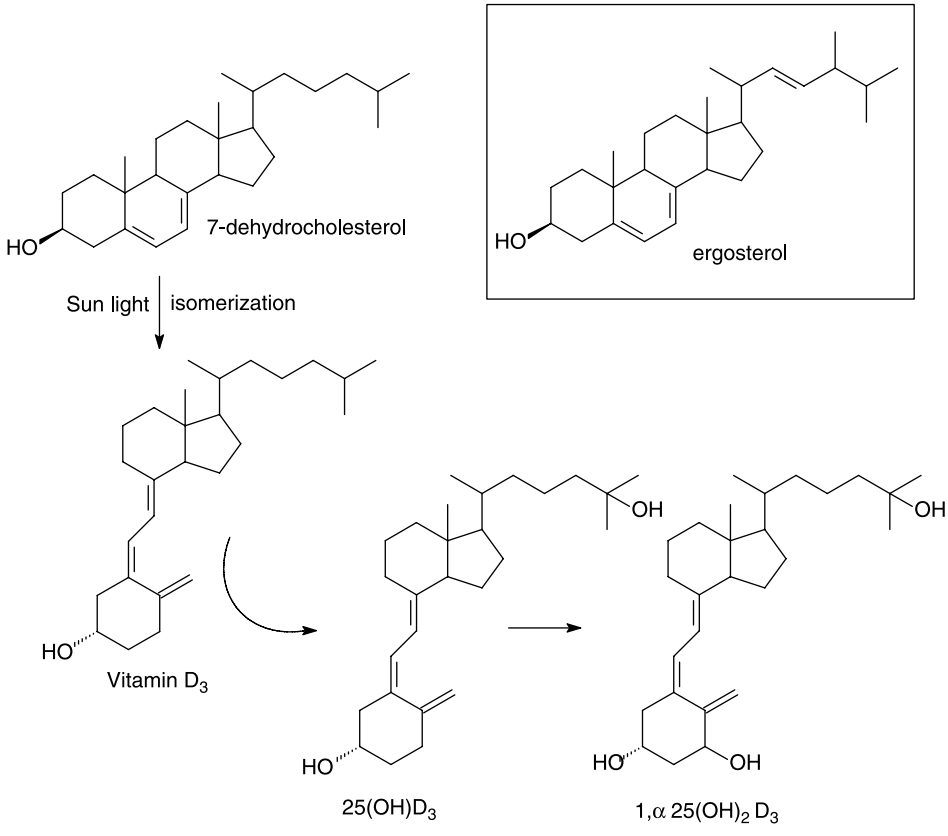

Figure 47.4 *Structure of previtamin D compounds 7-dehydrocholesterol and ergosterol, vitamin D_3, and the metabolites 25(OH)D_3 and 1α,25(OH)$_2D_3$.*

supplementation during breastfeeding (maternal milk does not contain vitamin D), lifestyle, and the loss of bioavailability are the main reasons why each population group suffers from vitamin D deficiency, which is also, very frequently, poorly diagnosed (Glerup and others 2000).

Vitamin D is principally involved in the maintenance of calcium and phosphorous homeostasis, and the health of the bones. Deficiency reduces the efficiency of calcium absorption (absorption is decreased by 10–15%), resulting in a drop in its concentration in the blood, which triggers off the mobilization of this mineral from the bones (Underwood and DeLuca 1984). Some osteoblast functions are regulated by the active metabolite of vitamin D, such as their proliferation, and the production of collagen and osteocalcin (Kurihara and others 1984; Pan and Price 1984).

47.4.2 Functional Properties of Vitamin D

Two decades ago the existence of nuclear receptors specific for vitamin D was verified. Since then an endocrine system associated with this vitamin has been defined, which has general effects over cell regulation and differentiation, effects not related to the maintenance of calcium homeostasis. Many degenerative processes are related to vitamin D

status, not only those that affect the bones, but also others involving the skin, liver, kidneys, intestine, pancreas, and lungs. Initially only the first were associated with its production, until the discovery of a large variety of tissues able to produce $1\alpha,25(OH)_2D_3$ (Cross and others 2001; Tangpricha and others 2001). Recently Lin and others (2002) demonstrated the existence of 150 genes regulated by this vitamin, and involved in very different functions such as the cell cycle, modulation of the redox system, and cellular signaling. Both factors highlight the importance of vitamin D in the handling of cell differentiation and proliferation which has ended up in implicating this vitamin with the prevention of cancer. This activity is also associated with the role of this vitamin in the regulation of the immune system, affecting the activity of T and B lymphocytes (Rigby and others 1985; Lemire 1992).

The biological functions of this vitamin-hormone carried out in our body closely related with the maintenance of health. There is also a reappearance of vitamin D deficiency states in particular population groups. Therefore, the functional foods have a decisive role in alleviating the possible deficiencies, producing a suboptimal health state that will become apparent immediately or in the longer term. For example, children with vitamin D deficiency are more prone to developing illnesses later in life such as type 1 diabetes, multiple sclerosis, and cancer (Holick 2004). A moderate exposure to the sun and the consumption of foods enriched with vitamin D, such as milk, juices, cereals, and fish oils are recommendations to be instilled into the population in general.

47.5 VITAMIN K

In 1935 Henrik Dam proposed, in two research articles, the existence of a new, lipid soluble, essential component, involved in the coagulation of blood, which he called vitamin K (Dam 1935a,b). Its existence enabled the discovery of the proteins involved in blood coagulation (prothrombin and fibrinogen). It was not until 1950 that the factors involved in the regulation and production of thrombin were defined. Subsequently, other factors (VII, IX, and X) also dependent on vitamin K for their synthesis were discovered.

The term vitamin K is designated to a group of compounds that have a common 2-methyl-1,4-naphthoquinone nucleus and are differentiated in the structure of the side chain in position 3. Figure 47.5 shows the structure of the three large groups of substances which exhibit anti-haemorrhagic activity. Vitamin K_1 (2-methyl-3-phytyl-1,4-naphthoquinone) is preferably called phylloquinone. A group of compounds which constitutes another member of K vitamins (such as menaquinone-7) and presents unsaturations in the side chain, is denoted multiprenyl-menaquinones (vitamin K_2). And finally, 2-methyl-1,4-naphthoquinone, vitamin K_3, is correctly named menadione.

47.5.1 Nutritional Properties of Vitamin K

The unequivocal role of vitamin K in health is the maintenance of normal blood coagulation. It functions similarly to that of a co-enzyme involved in the synthesis of a group of proteins, which include the clotting factors II, VII, IX, and X, and the anticoagulant proteins C and S. Its activity is also fundamental for the synthesis of proteins involved in bone metabolism, such as osteocalcin and MGP (matrix gamma-carboxy-glutamic acid protein) which regulate the growth and deposition of minerals in the bones. The requirement for

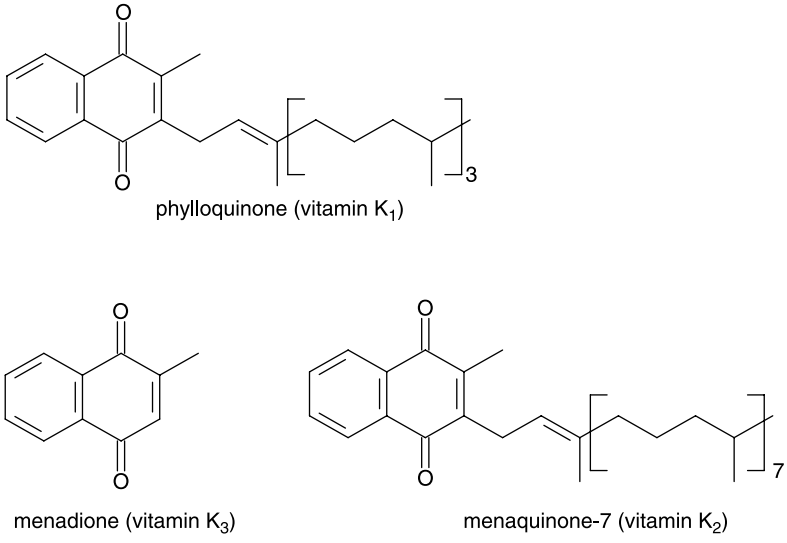

Figure 47.5 *Structure of the three groups of substances which exhibit antihaemorrhagic activity: phylloquinone, multiprenyl-menaquinones, and menadione.*

vitamin K in adults is extremely low. The Food and Nutrition Board establishes an adequate intake (AI) of 120/90 μg/day (males/females) without determining a maximum ingestion level. The risk of deficiency of this vitamin is very rare and a normal diet ensures reaching the recommended levels of ingestion. The development of high performance liquid chromatography has enabled the configuration of suitable tables which give the vitamin K content in common foods (Booth and others 1994, 1995). In general, the major sources of this vitamin are green vegetables along with edible oils. The only group at risk is the newborns; although rarely, they develop vitamin K deficiency bleeding. However, some authors recognize that this risk constitutes a public health problem (Shearer 1995). For this reason it is common practice to give oral supplements of vitamin K to newborns as well as fortifying baby foods with this vitamin so as to provide an intake higher than that of breast milk.

47.5.2 Functional Properties of Vitamin K

The involvement of vitamin K in the metabolism and health of the bones is receiving increasing attention and it is even being suggested that the recommended intake levels are not adequate for this vitamin to carry out its functional role. Some studies associate an increase in the risk of bone fractures and a decrease in mineral density with high levels of undercarboxylated osteocalcin, thus putting forward the hypothesis of a suboptimal vitamin K physiological state in relation to bone health (Bügel 2003). Shearer (1997) suggested that the carboxylation of nonhepatic Gla proteins is more susceptible to dietary influences than those proteins involved in blood coagulation. All this confers an important role of vitamin K in the pathogenesis of osteoporosis.

For this reason, techniques have been developed for determining vitamin K status based on functional markers, the undercarboxylated species of the vitamin K-dependent proteins being the most important markers. Vermeer and others proposed that

concentration of undercarboxylated species of osteocalcin is a reflection of an optimal state or deficiency of vitamin K (Vermeer and others 1995). The advantage of this procedure is to detect whether a deficiency of this vitamin exists in a specific tissue, such as bone, so that the needs of an individual or population group could be defined with greater accuracy, in order to decrease the risk of degenerative processes affecting that tissue in particular.

As was commented earlier, adequate databases on the vitamin K content of foods have not been developed until recently. Perhaps the fact that vitamin K requirements are very low, has brought about a certain lack of interest in the compilation of data. The functional role of this vitamin, the possibility that population groups need to increase their intake, and the discovery of new functional foods (which have a higher concentration of this micronutrient) are aspects, which require a currently expanding study.

48.1 INTRODUCTION

The word "phytochemicals" is commonly used to indicate thousands of chemically different natural metabolites used in medicine and food preparations (Table 48.1). Natural medicines have been used from the infancy of human history for their

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

TABLE 48.1 Main Classes of Phytochemicals (Craig 1997).

Phytochemicals	Foods
Allyl sulfides	Garlic and onion
Phytates	Grains and legumes
Glucarates	Citrus, grain, and solanaceous vegetables
Lignans	Flax and soybeans
Isoflavones	Soybeans
Saponins	Legumes
Indoles, isothiocyanates, and dithiolthione	Cruciferous vegetables
Ellagic acid	Grapes, strawberries, raspberries, and nuts
Phthalides and polyacetylenes	Umbelliferous vegetables
Flavonoids, carotenoids, and terpenoids	Various plants and vegetables
Other phenolic compounds	Various plants and vegetables

pharmacological activity against many diseases or as simple folk remedy. Traditionally these medicines were obtained from plants, herbs, roots, and seeds, which could be used in their primary form or combined into mixtures. Nowadays, these preparations can be also formulated in pills, tablets, or liquids and are commercially available as natural medicines especially in Asian countries (Table 48.2).

Traditional Chinese medicine uses antioxidant-rich medicinal plants for the prevention of many diseases. These medicinal plants have a concentration of phenolic compounds

TABLE 48.2 Plants Found in Herbalists' Shop in Jordan (Afifi and others 2000).

Family Name	Scientific Name	Parts Used	Recommended Uses
Boraginaceae	Echium judaeum	Roots	Nervosity, hyperactivity, general weakness, dermatological disorders
Cruciferae	Brassica campestris	Seeds, leaves, roots	Hypercholesteremia, inflammation
Cucurbitaceae	Cucurbita maxima	Seeds	Ulcer, diabetes
Fagaceae	Quercus coccifera	Fruits	Kidney sands and stones, post delivery syndrome
Labiateae	Menta piperita	Leaves, stem	Common cold, cough, influenza, constipation, nervosity
	Ocium basilicum	Leaves	Common cold, cough, influenza, kidney sands, and stones, gynaecological disorders, alopacia
Leguminosae	Glycyrrhiza glabra	Roots	Common cold, cough, influenza, constipation, kidney sands, and stones
Liliaceae	Aloe vera	Leaves, juices	Abdominal pain, diabetes, weaning
Punicaceae	Punica granatum	Fruits, roots, and stem coat	Common cold, cough, influenza, ulcer
Rosaceae	Rosa damescana	Flowers	Common cold, cough, influenza, abdominal pain, gall-bladder stones, general weakness
Rutaceae	Citrus aurantium	Leaves, flowers fruits, peel, fruits	Weakness in myocardium, gynaecological disorders
Umbrelliferae	Petroselinum sativum	Leaves, steam	Urinary tract infections, arthritis

TABLE 48.3 Protective Effects Reported for Soy Isoflavones.

Cancer	Epidemiological studies show a protective effect of soy consumption against hormone-dependent cancer of the breast and prostate (Barnes and others 1998) and against bowel, stomach, olon, rectum, and lung cancer (Messina and Messina 1991; Messina and others 1994; Adlercreutz and others 1995; Herman and others 1995)
Heart disease	Soy protein has a hipocholesterolemic effect (Fukui and others 2002) and may reduce the risk of atherosclerosis (Anderson and others 1995; Potter 1995) and of coronary heart diseases (Anderson and others 1999; Hermansen and others 2001; Nicolosi and others 2001; Hasler 2002). Isoflavones are thought to be an important hypocholesterolemic component in soy protein (Anthony and others 1996,1997; Kirk and others 1998; Ni and others 1999)
Osteoporosis	Isoflavones protect against osteoporosis (Potter and others 1998; Wiseman 2000; Scheiber and others 2001)
Antioxidative effect	Isoflavones acts as antioxidants and scavengers of reactive oxigen species (ROS) and reactive nitrogen species (RNS) (Arora and others 1998; Yen and Lai 2003)
Other	Soy isoflavones also exhibit biological activities such as inhibition of cell proliferation (Coward and others 1993; Fotsis and others 1995) and enzyme-inhibitory effects (Keung and others 1993)

(phenolic acids, flavonoids, tannins, coumarins, lignans, quinines, stilbenes, and curcuminoids) significantly higher than vegetables and fruits (Cai and others 2004).

The dietary intake phytochemicals in Western countries is related more to the consumption of fruits and vegetables than to the use of specific medicinal plants or extracts. In the last decade soybeans and related products, traditionally consumed especially in Asia, have been conquering Western markets thanks to their biological effects on humans. The positive effects on health exerted by these foods (Table 48.3), previously attributed only to their high isoflavones content (genistein, daidzein, glycitein), are recently thought to be due to the combination of many compounds such as proteins, amino acids, peptides, saponins, phytic acids, trypsin inhibitors, fiber, and isoflavones (Barnes and others 1998; King and Bignell 2000; Fukui and others 2002).

Beside the bioactive vegetable compounds naturally present in foods and medicinal plants, the phenomenon of phytochemical-rich ingredients used as components of commercial food preparation is becoming of nutritional relevance. Many phytochemicals have been used by food industries to increase the shelf-life of their products. For example, meat industries largely add phytochemical mixtures to prevent the oxidation of its products.

Lipid oxidation is the most important factor implicated in meat spoilage during storage, and thus in the reduction of its shelf-life due to off-flavor and off-color development (Pearson and others 1983). The losses of nutritional value and functionality (Matsushita 1975) could be reduced using synthetic antioxidants (BHA, BHT, and citric acid) but many investigations performed in model systems showed that natural antioxidants are as effective as synthetic antioxidants in retarding oxidation (MacNeil and others 1973; Madsen and Bertlesen 1995). Nissen and co-workers (2000) showed that rosemary extract had the same efficacy of BHT and octyl gallate in protecting the dehydrated chicken meat against oxidative deterioration, followed by tea and coffee extract, while grape skin extract was the less efficient among the tested extracts. Moreover, consumers are more willing to accept natural extracts than synthetic antioxidants.

Addition and integration of phytochemicals, especially antioxidants, for technological and nutritional purposes is a fascinating field of food technology. From this point of view

many traditional recipes of the Mediterranean diet give unexpected opportunities when the behavior of antioxidant compounds during the technological processes is considered. In Mediterranean countries the large consumption of tomatoes and virgin olive oil, which are present in many traditional recipes, ensures a high intake of antioxidant phytochemicals, such as carotenoids and polyphenols, respectively. This is due to the high natural occurrence of these compounds, but also, as we will show in the following pages, to the type of processes usually adopted for the preparation of these food.

In this chapter we discuss phytochemicals present in these staple foods of Mediterranean diet, tomato and olive oil, focusing our attention on their natural content in raw materials and the positive influence of technological processes from the nutritional point of view.

48.2 TOMATO AND OLIVE OIL PHYTOCHEMICALS

The widespread use of tomatoes and tomato-based products in Mediterranean diet make this fruit an important source of minerals, vitamins, and healthy phytochemicals such as carotenoids and flavonoids. The concentration of secondary metabolites in tomatoes depends on many factors. Carotenoid biosynthesis is influenced by the variety, cultivation area, stage of ripening at harvest, agronomical practices (i.e., irrigation, fertilization, etc.), and the storage conditions. Leonardi and co-workers (2000) reported that the concentration of carotenoids in commercial tomatoes ranges from 0.6 to 13 mg per 100 g of green salad and full ripe cherry tomatoes, respectively. On the other hand, flavonoid biosynthesis is poorly correlated with ripening stage, while it seems more dependent on climatic and solar radiation conditions; in fact, tomatoes leading to the same variety results richer in flavonoids when grown in Mediterranean area than fruits cultivated in North Europe (Stewart and others 2000).

Since tomatoes are an excellent source of carotenoids, but a modest source of flavonoids, there is considerable interest in the production of fruits containing increased levels of flavonoids with a consequent wider range of potential health beneficial properties. Several breeding companies and research institutes obtained tomato mutants containing higher levels of carotenoids and flavonoids than commercial varieties.

Tomato micronutrient content is also influenced by industrial process, which represents another important factor determining antioxidant intake considering that more than 75% of tomatoes consumption derives from processed products. All tomato-based products undergo a more or less severe thermal treatment, which can affect the stability of tomato bioactive compounds. It is generally accepted that carotenoids are poorly affected by processing; on the other hand, data for flavonoids are not conclusive, also because flavonoids are mainly located in the skins, which are usually discarded in processed tomatoes. In fact, while literature data (Crozier and others 1997; Stewart and others 2000) report that industrial canning causes a severe reduction of flavonols content, a recent work performed by our group showed that, when tomatoes are canned without the previous peeling, no thermal degradation of flavonoids was observed (Pernice and others in press). As far as olive oil phytochemicals the absolute concentration of phenolic compounds is the result of complex interactions between several factors, including cultivar, ripening degree, climate, and extraction process (Caponio and others 1999; Fogliano and others 1999). The amount of phenolic compounds is also affected by oxidative and hydrolytic modification during storage (Della Medaglia and others 1996).

TABLE 48.4 Effect of Heating Time on Lycopene Concentration in Peeled Tomato Puree and in Peeled Tomato Puree Added of 5% Virgin Olive Oil.

	Lycopene Concentration (mg/100 g of Dry Matter)	
Heating Time	Peeled Tomato Puree	Peeled Tomato Puree + 5% Virgin Olive Oil
0	61.12 ± 3.7	70.37 ± 5.5
0.5	59.26 ± 3.7	62.96 ± 5.6
1	55.56 ± 1.8	64.81 ± 7.1
2	53.70 ± 5.5	62.95 ± 3.7
4	46.30 ± 1.8	59.26 ± 3.6
9	37.04 ± 3.7	59.26 ± 3.8

The phenolic fraction consists of the so-called secoiridoid derivatives, formed by *p*-hydroxyphenylethanol (*p*-HPEA) or by dihydroxyphenylethanol (DHPEA) linked to elenolic acid. Phenolic compounds, particularly *o*-dihydroxy derivatives, have strong antioxidative activity and are essential to preserve the fatty acid moiety of VOO from oxidative damage during processing and storage (Baldioli and others 1996; Litridou and others 1997). Furthermore, *o*-dihydroxyphenolic compounds contribute to the stability of the oil, due to their ability to donate a hydrogen atom and form an intramolecular hydrogen bond between their hydroxyl group and phenoxyl radicals (Visioli and Galli 1998).

In the last few years, we have investigated the effect of industrial process and home cooking on the interactions between carotenoid and flavonoid of tomatoes and polyphenol of virgin olive oil in tomato sauces. Home-made tomato sauces are prepared by mixing 3–5% of extra-virgin olive oil to fresh or canned tomatoes and cooking them for a period ranging from few minutes to many hours, as it happens in traditional recipes of southern Italy. During thermal treatment phytochemicals degradation could be expected. However, the presence of a two phase-system (oil-in-water), causes a peculiar phase partition of virgin olive oil polyphenols, as well as tomato carotenoids and flavonoids.

A model system study (Graziani and others 2003) showed that, heating in laboratory-scale conditions, a mixture of tomato and 5% olive oil, the latter had a protective effect on tomato antioxidants (Table 48.4). Lipid matrix favored the extraction and the detection of tomato carotenoids (Fig. 48.1) and at the same time olive oil phenolic

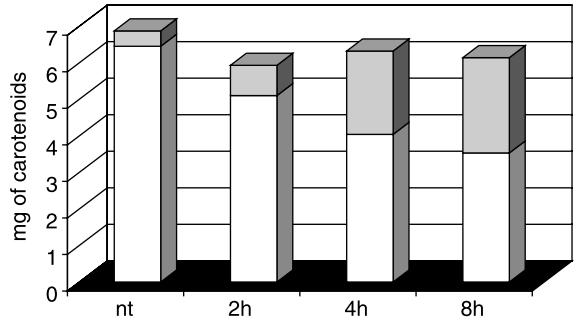

Figure 48.1 *Effect of heating time on carotenoid repartition in an oil-tomato mixture. The gray bars correspond to oil carotenoids while the white ones correspond to tomato carotenoids; "nt" is for not thermal treated samples.*

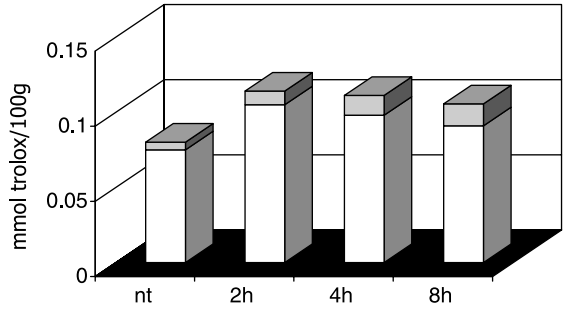

Figure 48.2 *Antioxidant activity of water and oil phases measured during heating in a tomato olive oil system. Note: The grey bars correspond to oil antioxidant activity while the white ones correspond to tomato antioxidant activity; "nt" is for not thermal treated samples.*

compounds protected carotenoids from oxidation thus resulting in an enhanced antioxidant activity of the heated mixture (Fig. 48.2). Accordingly, Anese and co-workers (2002) showed that using industrial-like treatment on tomato–olive oil system there were no significant change in lycopene concentration.

The positive interaction between the various classes of antioxidants in this system have implications in the stability and storage of tomato sauces, and these findings are very important from the stand point of the physiological effects that these compounds may have on humans.

48.3 PHYSIOLOGICAL EFFECTS

The *in vivo* physiological effects of carotenoids are related to their bioavailability. Many studies demonstrated that the uptake of carotenoids is greater from heat processed than from unprocessed tomato, and that the absorption efficiency is also affected by the contemporary presence in the diet of other food components such as dietary fats and proteins (Dimitrov and others 1988; Rock and Swendseid 1992; Stahl and Sies 1992; Gärtner and others 1997). Giovannucci and co-workers (1995) found that the intake of tomato sauce was significantly correlated with lycopene concentrations in plasma, while the administration of tomato juice did not cause any increase of lycopene plasma concentrations. A slight increase was also correlated to the intake of fresh tomatoes. These findings were attributed to the common practice to consume tomato sauce and fresh tomatoes together with oil. The fat matrix has two positive effects on carotenoid bioavailability: in the stomach it favors carotenoid extraction from food matrix. In the upper gut the presence of oil stimulates the excretion of biliary acids, the consequent formation of chylomicrons and therefore the absorption of all lipophilic phytochemicals.

On the basis of this consideration an antioxidant-rich functional food (FF) constituted by a tomato puree mixed with 10% extra-virgin olive oil was produced in an industrial plant and a pilot bioavailability study of carotenoids was performed. For this purpose five healthy volunteers (2M and 3F) that were asked to consume 100 g/day of the FF (23 mg carotenoids/day) for a week were enrolled. The control group was constituted of three volunteers (2M and 1F) that did not consume the FF. Blood samples were drawn before (T_0), after a week of FF administration (T_7) and after a week of wash-out (T_{14}). Serum samples collected were analyzed for carotenoid composition. In particular

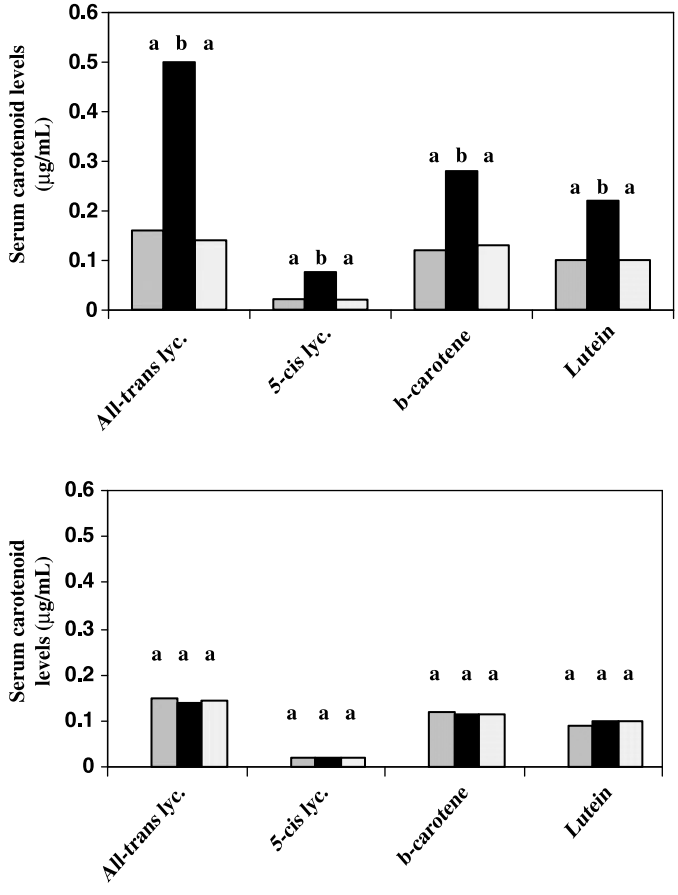

Figure 48.3 *Top Panel: average serum carotenoid concentration in subjects that consumed the FF. Bottom Panel: average serum carotenoid concentration in subjects of control group. Shaded bars T_0; black bar T_7; pointed bar T_{14}.*

all-trans- and *5-cis*-lycopene, lutein and β-carotene were quantified by HPLC as described by Holloway and others (2000).

The results (showed in Figure 48.3) demonstrate that in all the subjects that consumed the FF, an increase of the bioactive compounds directly related to FF antioxidant contents was found. In particular after the week of administration, β-carotene and lutein levels doubled the basal levels (0.28 ± 0.17 μg/mL vs. 0.12 ± 0.09 μg/mL and 0.22 ± 0.13 μg/mL vs. 0.10 ± 0.08 μg/mL respectively) while *all-trans* lycopene levels were four-fold higher (0.50 ± 0.15 μg/mL vs. 0.16 ± 0.03 μg/mL). After the wash-out period the carotenoid serum concentration come back to the basal levels ($p < 0.05$).

Heating tomatoes in the presence of fat increases the bioavailability of carotenoids, but it is important to underline that the composition of fat can also affect this parameter. On this regard, Lee and others (2000) carried out a study to value the effect of cooking tomatoes with two different oils, extra-virgin olive oil and sunflower oil, on plasma lycopene concentration and plasma antioxidant activity. Six subjects (5F and 1M) were asked to consume for a week, 200 g of tomato soup (33 mg lycopene) and 230 g of

TABLE 48.5 Effect of Supplementation of Tomato Products with Olive Oil and Sunflower Oil (Lee and others 2000).

	Tomato Products with Olive Oil		Tomato Products with Sunflower Oil	
	Baseline	Week 1	Week 4	Week 5
Dietary lycopene	<5	46 ± 10	<3	46 ± 12
Plasma lycopene (μmol/L)	0.66 ± 0.26	1.20 ± 0.20	0.67 ± 0.27	1.14 ± 0.35
Plasma antioxidant activity (μmol/L)	930 ± 150	1118 ± 184	1049 ± 186	1009 ± 181

canned tomatoes (13 mg lycopene) with 20 mL of extra-virgin olive oil, followed by three weeks of washout, then they were supplemented for another week with the same amount of tomato products plus 20 mL of sunflower oil. The results (Table 48.5) showed that the supplementation of tomato products (about 46 mg/day of lycopene) with olive oil and sunflower oil produced respectively 80% and 70% increase of the plasma lycopene levels. The increase was not significantly different between the two oils. On the contrary, plasma antioxidant activity (measured with FRAP assay) increased only with consumption of tomato products with olive oil, while with sunflower oil the plasma antioxidant activity is slightly below the control level. Again, this result is likely due to the amazing integration between the antioxidant component of olive oil and that of tomato.

48.4 CONCLUSIONS

The link between diet and chronic diseases is very well documented. Medical research is focused on prevention of major chronic diseases to reduce the current high cost of medical care. As a consequence, nowadays major attention is referred to food components note for their capability to exert positive effects on human health, such as phytochemicals, whose activities have been demonstrated by many scientific studies. Among phytochemicals, antioxidants have been hypothesized to play a major role as an enhanced production of free radicals and/or significant decrease of antioxidant defence is correlated to many diseases (Weisburger 1999). Moreover, antioxidant-rich foods have been shown more effective than pills, tables and other synthetic nutraceuticals.

In recent years, the consumer demand of enjoyable foods that are able to satisfy senses, but also maintain an healthy status, is continuously increasing. This tendency is coupled with the large diffusion of Mediterranean diet in the world, as this alimentary regime is considered a model for a healthy diet. Mediterranean diet is characterized by a greater intake of cereal, fruit, and vegetables respect to animal-derived foods, thus assuring a large intake of bioactive compounds. Among the staple foods of Mediterranean diet tomatoes and virgin olive oil represent an optimal antioxidant mixture by nutritional and technological point of view.

The phytochemicals presence in raw foods and their capability to undergo to the industrial processing should be taken in serious account by the food industry. In fact, the selection of antioxidant-rich raw foods, and better control of processing conditions could ensure the highest bioactive compound content in the final products, thus increasing the functionality of the offered products also thanks to a particular interaction and synergism among food compounds that improve the bioavailability (Beecher 1998). As consequence the bioavailability of phytochemicals used as food ingredients, and the choice of food matrix, must be carefully considered.

49.1 RATIONALE FOR THE DEVELOPMENT OF GI TRACT TARGETING FUNCTIONAL FOODS

There is a growing demand for developing foods with specific functionalities increasing the health and well-being of the consumers. This need originates from the notion that consumers at critical ages, especially children and elderly, are prone to food-related diseases

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

and gastrointestinal (GI) disorders. The symptoms of many GI disorders and diseases can be alleviated and prevented by consuming foods with specific functionality for health (see references in Table 49.1).

Emerging scientific developments enable the rational development of foods with increased functionality. This notably holds for foods that target the GI tract, the primary site of food conversion and uptake, where food-borne or systemic disorders are abundant, and the innate immune system is stimulated. This body's metabolically most active organ is colonized by a myriad of microbes that contribute to food conversion, communicate with the host, and induce specific responses that contribute to a wide variety of important physiological functions. Hence, the gut represents the site where the host's well-being is affected by foods either directly or by modulating the interplay between microbes and host (Salminen and others 1998).

The scientific development in the gut-health area is also facing challenges. This includes the genomics-related and high throughput molecular tools aimed to provide insight into the molecular mechanisms of food functionality, gut health, and microbial function. Insight in the basic mechanisms of gut health is required to further develop biomarkers for probiotics (live microbial food supplements with a beneficial effect on human health: Anon. 2002), as well as prebiotics and other dietary components that stimulate specific microbial groups in the human gut (Vaughan and others 2000).

Furthermore, the development of functional foods includes a major investment on technology development. Probiotic functional foods face high technological demands because probiotics have to retain their viability during all the production steps and even in the GI tract of the consumer. Therefore the new manufacturing process and formulation technologies are often required for probiotic bacteria primarily selected for their functional health properties (Saxelin and others 1999; Saarela and others 2000).

49.2 REQUIREMENTS FOR AN EFFECTIVE PROBIOTIC

Microorganisms used for health purposes are generally classified as either probiotics or functional foods in the EU or as biotherapeutic agents or dietary supplements in the United States. Unfortunately, the use of a specific term in the product label does not provide any basis by which the consumer can judge the functional validity of the product. Although lactic acid bacteria (LAB) have a long history of use in Europe and Asia, the scientific evidence for their efficacy and safety has not been rigorously addressed until fairly recently. Scientific credibility of these products will only evolve after well-controlled clinical trials in humans are performed, up-to-date methodologies are used, and conclusive evidence of benefits is obtained.

In general, probiotic microbes have been given to humans in the form of encapsulated lyophilized powder or in a food vehicle (e.g., fermented or nonfermented dairy products or fruit/berry juices). The types of microbes tested for their probiotic potential include *Lactobacillus* sp. (*L. acidophilus*, *L. reuteri*, *L. casei*, *L. johnsonii*, *L. plantarum*, *L. rhamnosus*), *Bifidobacterium* sp. (*B. bifidum*, *B. infantis*, *B. animalis/lactis*, *B. longum*, *B. breve*), some other bacteria (*Enterococcus faecalis*, *Escherichia coli*, and *Bacillus cereus*) and yeasts (*Saccharomyces boulardii*, *S. cerevisiae*) (Alvarez-Olmos and Oberhelman 2001; Table 49.1).

For a microbe to become a successful biotherapeutic agent, several important requirements need to be fulfilled. The most critical are survival to the active site, association with

Lactobacillus plantarum DSM 9843 (299v)	Modulation of intestinal flora, increase in fecal short-chain fatty acid content, lowering of fibrinogen and cholesterol levels, reducing the symptoms of IBS, reduction in cardiovascular disease risk factors in smokers	Johansson and others 1993, 1998; Bukowska and others 1998; Nobaek and others 2000; Niedzielin and others 2001; Naruszewicz and others 2002

mucosal surfaces, ability to survive in the presence of normal flora, survival in the presence of metabolic substances and enzymes, along with the production of a beneficial action or product (McFarland and Elmer 1997).

Survival of probiotic bacteria through the upper gastrointestinal tract to reach the target site (usually the caecum or colon) has been documented in several publications (e.g., Goldin and others 1992; Marteau and others 1992; Johansson and others 1993, 1998; Alander and others 1997, 1999). The survival rates vary greatly, depending on a strain and preparation (e.g., capsule vs. fermented milk vs. fruit juice) used (Saxelin and others 2003). For example, in the study of Marteau and others (1992) two probiotics, *L. acidophilus* and a *Bifidobacterium* species, survived passage through the small intestine and the percent recovery of the oral dose was 1.5% for *L. acidophilus* and 37.5% for the *Bifidobacterium*. It is extremely important that in recovery experiments using therapeutic microbes, the strain that is given orally can be identified separately from resident microbiota. For this, highly discriminatory genetic fingerprinting techniques or strain-specific direct detection methods are essential.

49.3 HEALTH CLAIMS ATTRIBUTED TO PROBIOTICS

The health claims attributed to probiotics are broad. These include alleviation of lactose intolerance symptoms, treatment of viral and antibiotic associated diarrhea, treatment of infant gastroenteritis, reduction of symptoms of antibiotic treatment of *Helicobacter pylori*, alleviation of atopic dermatitis symptoms in children and prevention the risk of allergy in infancy, alleviation of symptoms of IBD (inflammable bowel disease) and IBS (irritable bowel syndrome), enhancing the immune response, modulation of intestinal microbiota, lowering the levels of harmful fecal enzymes, and positive effects on superficial bladder cancer and cervical cancer. There are also several potential effects, which have not been adequately established, including, for example, lowering the activity of rheumatoid arthritis, prevention of urinary tract infection, and so on (Tables 49.1 and

TABLE 49.2 Probiotic Health-Effects. Note that not all Effects can be Attributed to a Single Probiotic Strain (Saarela and others 2000, 2002; Reid and others 2003).

Established Effects	Potential Effects
Alleviation of lactose intolerance symptoms	Improvement of constipation
Treatment of viral (rotavirus) diarrhea	Antimutagenic/anticarcinogenic activity
Treatment of infant gastronteritis	Lower the activity of rheumatoid arthritis
Treatment of antibiotic associated diarrhea	Treatment of candidal and bacterial vaginitis
Alleviation of atopic dermatitis symptoms in children	Prevention of urinary tract infection
Preventing the risk of allergy in infancy	Treatment of cystic fibrosis
Alleviation of IBD symptoms	Protective agents in primary prevention of atherosclerosis in smokers
Alleviation of IBS symptoms	Lowering of cholestrol and blood pressure
Immune modulation	Eradication of multidrug-resistant microbes
Adjuvant in *H. pylori* treatment	Prevention of transmission of AIDS and sexually transmitted diseases
Lowering biomarkers (harmful fecal enzymes)	Infection control
Positive effects on superficial bladder cancer and cervical cancer	

49.2). Probiotics have been found to be most effective when an alteration of the normal microbiota is involved. Several studies of diseases involving the intestinal tract have found good clinical evidence of efficacy from placebo controlled clinical trials (see references in Table 49.1).

49.4 MIXTURES OF PRO- AND PREBIOTICS, SYNBIOTICS

A synbiotic has been defined as a "mixture of probiotics and prebiotics that beneficially affects the host by improving the survival and implantation of live microbial dietary supplements in the GI tract, by selectively stimulating the growth and/or activating the metabolism of one or a limited number of health-promoting bacteria, and thus improving host welfare" (Gibson and Roberfroid 1995; Salminen and others 1998). The use of a combination of a probiotic and a prebiotic (substrates that selectively stimulate the proliferation and/or activity of advantageous groups of bacteria already present in the intestinal microbiota) has distinct advantages. A problem with probiotics is their survival, both in the product and after ingestion, as most probiotics are only effective if viable (Fuller and Gibson 1997; McFarland and Elmer 1997; Ouwehand and Salminen 1998). The problem may be overcome by using the live microbial addition in conjunction with a specific substrate for growth (i.e., synbiotics). As such, improved survival and growth of the probiotic ought to occur. New product developments may more fully exploit the synbiotic approach. Although synbiotic approach holds a lot of promise, only a few clinical trials using synbiotic preparations have been reported so far (Kanamori and others 2002; Kiessling and others 2002; Anderson and others 2004).

49.5 PROBIOTIC TECHNOLOGY: MAINTAINING AND ENHANCING THE FUNCTIONALITY AND VIABILITY OF MICROBES WITH HEALTH BENEFITS

Probiotic production technologies should provide in a cost effective manner high-quality, safe end-products with long enough shelf-life. High quality in this connection mainly means products containing high numbers of living probiotics, but no contaminating microbes. For the food industry the easy formulation of probiotics into foods is of utmost importance. For this reason probiotics are usually provided as DVI (direct vat inoculation), which are highly concentrated and can be used at the production site without including a propagating step for probiotic cells (Gomes and Malcata 1999; Saarela and others 2000).

For the successful production of high-quality probiotic products a solid knowledge on the characteristics of the production strain is necessary. Working with living microbes is demanding since viability losses occur easily if the microbial cultures encounter stressful situations and conditions. Microbes can become stressed for several reasons: they have unique optimal growth conditions (nutrients, pH, gas atmosphere, temperature) and maintaining these optimal conditions in batch cultures in fermenters is difficult since, due to the growth and diminishing nutrient concentrations, their environment changes constantly (Rallu and others 1996). Various downstream processing steps of probiotic production unavoidably cause stress to microbes. These include, for example, harvesting, freezing, and drying. The main results of stress in cells is damage of various molecules, especially

important being the damage in proteins. If the stress is sublethal, microbial cells try to cope with it by producing so-called stress proteins (Cotter and Hill 2003). Some stresses lead into a situation where cells enter a nonculturable state (some of these can revert back to culturable and some not). However, if the stress is severe, loss of viability is unavoidable (Barer and Harwood 1999; Edwards 2000).

When working with probiotics their special features have to be kept in mind. Probiotics have usually been isolated from the human GI tract and they are well adapted to that special environment (nutrients, oxygen pressure, pH, temperature, etc.). Microbes that survive and thrive in the GI tract can therefore be difficult to propagate in the laboratory. However, to function properly, probiotic products should contain high enough levels of the specific probiotic strain(s) during the storage and consumption. Thus, great demands are imposed on probiotic production; probiotic strains have to be amenable to industrial-scale production and they have to survive and retain their functionality during storage as frozen or freeze-dried cultures, during formulation into foods and food storage, and finally in the GI tract.

Studies on the quality of commercial probiotic products have revealed deficiencies in a number of them especially regarding labeling and viability of probiotic strain(s). This problem is even enhanced in probiotic supplements such as capsules and powders, which often have both quantitative and qualitative problems (Canganella and others 1997; Hamilton-Miller and others 1999; Fasoli and others 2003; Temmerman and

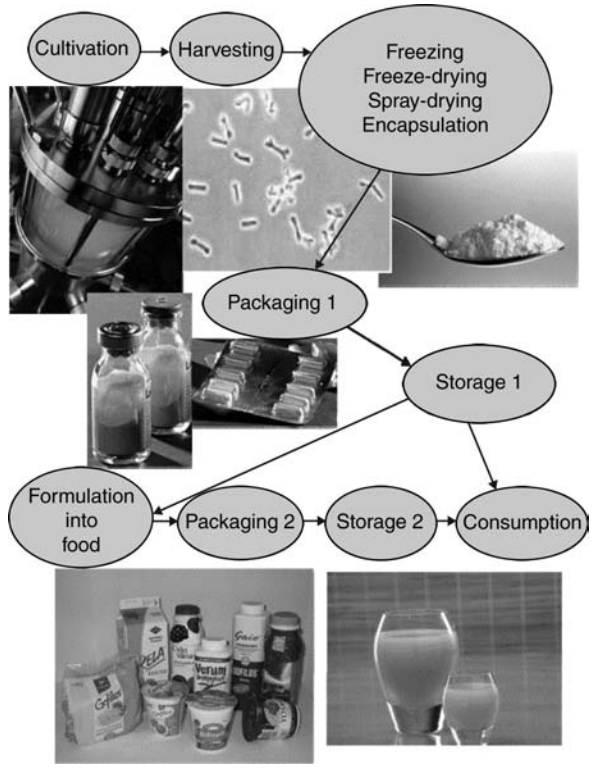

Figure 49.1 *Different steps of production and processing of probiotic products.*

others 2003a,b). These findings indicate that problems in producing probiotic products too often result in deficient quality of the end products. Typical problems are difficulties in obtaining high cell concentrations in fermenter scale and retaining viability during downstream processing. In addition, probiotics often have poor stability in the end product. Factors that effect probiotic viability during production and formulation include, for example, strain characteristics (even strains within species can show differences), nutrients or matrix to which the strain is formulated, pH, atmosphere, possible accompanying microbes, storage time, and temperature (Nighswonger and others 1996; Dave and Shah 1997; Kailasapathy and Rybka 1997; Micanel and others 1997; Gardini and others 1999; Saxelin and others 1999; Godward and others 2000; Saarela and others 2000; Vinderola and others 2000; Heller 2001; Oliveira and others 2001).

There are several steps of probiotic production where probiotic viability and stability can be enhanced. These steps include strain selection and improvement of strain properties, production conditions, formulation, and packaging and storage (Fig. 49.1). If possible, production strain should be chosen based both on functional properties and technological robustness. Since both functional and technological properties can vary remarkably within a genus and even within a species, a practical approach, which can save resources during the production step, is to screen for novel probiotic strains based on their technological properties. Among the technologically feasible strains, a strain with good functional properties should then be selected. However, in a situation when we have a functionally good but technologically poor strain in our hands we can attempt to improve its technological properties. This can be done in two ways; by activating the stress genes of the strain during processing with suitable sublethal treatments (van de Guchte and others 2002), or by genetically modifying the strain to make it more robust (e.g., by transfer, multiplication, and/or additional activation of genes responsible for stress response). Stress response in cells is inducible and nonpermanent. This means that the treatment has to be done immediately prior to harvesting and downstream processing.

Probiotic strains can vary in their requirements for nutrients, for suitable pH and gas atmosphere, fermenting, and harvesting time. During the propagation and downstream processing of probiotic cultures strain-specific demands have to be considered (Saxelin and others 1999). A suboptimal pH at the end of fermentation induces the stress response in the culture and can help it to survive better during downstream processing steps. The most suitable harvesting time is usually the early stationary phase. Cells that enter into stationary-phase develop a general stress-resistance and are thus more resistant to various types of stresses (including downstream processing and storage) than cells in the log-phase (Brashears and Gilliland 1995; Lorca and de Valdez 1999; van de Guchte and others 2002).

After harvesting cells are frozen, freeze-dried, spray-dried, or encapsulated. To enhance the survival of the culture during these steps protectants are needed. For the cryoprotection of LAB a large selection of compounds has been used. These include skim milk with or without supplements such as polyethylene glycol, dextran, bovine albumin, glycogen, sucrose, trehalose, glycerol; disaccharides such as sucrose, lactose, maltose, and trehalose; Me_2SO, glycerol, betaine, sodium ascorbate and glutamate, and maltodextrine (for a review see Hubalek 2003). Some of these compounds can also be used as thermoprotectants. For the LAB encapsulation carriers/supporting material used include alginate, carrageenan, cellulose acetate phthalate, chitosan, gelatine, gum arabic, and starch (Krasaekoopt and others 2003). Basic encapsulation techniques

are extrusion and emulsion, but cells can also be encapsulated during freeze- and spray-drying.

Unless probiotics are consumed as capsules or powders they are further formulated into food-stuffs. During this formulation step several things need to be considered such as the composition (nutrients, antimicrobials), structure (oxygen permeability, water activity), pH of the matrix, and interactions with starter microbes in fermented food matrices. Growth of probiotics in nonfermented foods is not desirable (due to possible off-flavour formation), but their growth during the production of fermented foods can lower process costs and increase the adaptation of probiotics leading to enhanced viability. In fermented foods possible antagonisms between starter and probiotic bacteria needs to be checked. Starters can inhibit probiotics but they can also enhance their survival by producing beneficial substances or by lowering the oxygen pressure (Dave and Shah 1997; Kailasapathy and Rybka 1997; Saxelin and others 1999; Saarela and others 2000; Vinderola and others 2002).

The final step in probiotic production process is packaging. The packaging material should be a good oxygen barrier (e.g., aluminum foil) to promote the survival of especially anaerobic probiotic bacteria (bifidobacteria) (Saarela and others 2000). For most probiotic products, transportation and storage at constant refrigerated temperatures is necessary (some dry products may tolerate storage at room temperature). Storage temperature is an important determinant of the shelf-life; with increasing temperatures viability losses can occur rapidly (Saxelin and others 1999).

49.6 PROBIOTIC FOOD MARKET: "HEALTHY FOODS ARE HERE TO STAY"

Probiotic foods have become the fastest growing European food market with an annual growth of over 10% in the EU (Anon 2004). An extensive range of probiotic foods are on the market in different European countries (Table 49.3), most of these being produced by the dairy industry. The application of science-based technology in diet-linked health effects will have a substantial impact in increasing the size of this market. The rapidly moving postgenomic revolution is markedly influencing the nutritional sciences. Key to this is a more thorough understanding of gut microbiota and its interactions with the host and mechanisms contributing to health benefits of pro- and prebiotic intake. Importantly, the European consumer is now increasingly exposed to pro- and prebiotic foods and the public profile for their use is high. The consumer can rightfully demand and expect mechanistic explanations of effects. Further, consumers will expect the pro- and prebiotic foods to be of high quality, which in the case of probiotic foods means that the product has to contain the specific microbe in high enough viable numbers. Surveys reporting sometimes severe quality problems in probiotic products on the market indicate that although probiotic products have gained increasing popularity and their health effects have been assiduously studied, research and development of processes aiming at improving the technological properties of probiotics are still inadequate. Technological improvements are especially important when aiming at diversified application of probiotics in novel and nontraditional products. Technological developments will, however, enable the enhancement of viability of probiotic cultures by, for example, optimizing fermentation and downstream processing conditions, protection of

TABLE 49.3 Examples of Probiotic Food Products on European Market (Information Obtained Mainly from www-pages).

Product Name	Product Type	Manufacturer (Country)	Probiotic Microorganisms in the Products as Stated by the Manufacturer (Information on Product Labels and/or on Web-Pages)*
A-fil	Cultured buttermilk	Arla (Sweden)	*Lactobacilus acidophilus*
A-fil/Lätt A-fil	Cultured buttermilk	Norrmejerier (Sweden)	"Acidophilus bacteria"
A-fil original	Cultured buttermilk	Milko (Sweden)	"Acidophilus bacteria"
Actimel	Dairy drink	Danone (France)	*Lactobacillus casei* immunitass
Aktifit	Dairy drink	Emmi (Switzerland)	*Lactobacillus* LGG
AB-piimä	Cultured buttermilk	Ingman, Valio (Finland)	*L. acidophilus, Bifidobacterium*
Bella Vita	Yogurt drink	Milchhof Meran (Italy)	*L. acidophilus*
Bifisoft	Yogurt type of product	Juustoportti (Finland)	"Bifidobacteria, acidophilus bacteria"
Bifidus	Yogurt drink, yogurt	Emmi (Switzerland)	"Bifidus (and acidophilus bacteria)"
Bighurt	Yogurt	Onken (Germany)	*L. acidophilus, "L. bifidus"*
Biofit (Trink) Jogurt	Yogurt drink, yogurt	Natur pur (Austria)	*L. acidophilus, "Lb. bifidus"*
BiogardePlus family	Yogurt, quark	Almhof (The Netherlands)	*L. acidophilus, L. casei, "Bifidobacterium"*
Biola	Cultured buttermilk, yogurt, yogurt drink	Norwegian Dairies (Norway)	*Lactobacillus* LGG
Biologic Bifidus	Yogurt	Nutrifrais (Switzerland)	*"Bifidobacterium"*
Casilus	Cultured buttermilk	SataMaito (Finland)	*L. casei* 431
Cultura product family	Yogurt drink, fruit drink, cultured buttermilk	Arla Foods (Sweden)	*Lactobacillus casei* F19
Cultura Dofilus	Yogurt	Arla Foods (Sweden)	*Lactobacillus casei* F19, *L. acidophilus, B. lactis*
Dexal pro	Recovery drink	Orion (Finland)	*L. acidophilus, Bifidobacterium*
Dujat Bio Aktiv	Yogurt, yogurt drink	Lura (Slovenia)	*Lactobacillus* LGG
Ekologisk jordgubbs yogurt	Yogurt	Änglamark (Sweden)	*Lactobacillus acidophilus, Bifidobacterium lactis*
Emmifit	Dairy drink	Emmi (Germany), Emmi AG (Portugal)	*Lactobacillus* LGG
Everybody	Yogurt drink	Glanbia Plc. (Ireland)	*Lactobacillus* LGG
Fit & Aktiv	Yogurt, dairy drink	Bauer (Germany)	*Lactobacillus acidophilus* LA5, *Bifidobacterium* BB12
Fjällyoghurt	Yogurt	Milko (Sweden)	*Lactobacillus acidophilus, Bifidobacterium bifidum*
Fundo	Cultured buttermilk	Milka (Finland)	*Lactobacillus rhamnosus* 271

(*Continued*)

cells with carriers (e.g., with probiotics), activation of cells' stress response machineries, and by developing suitable food matrices.

The market pull for functional foods has been so rapid that it has resulted in certain knowledge gaps in the scientific understanding of the mechanisms by which these foods impact health. This has a bearing on the consumer who cannot make an informed choice, the producer who is limited in the reliable development of new and improved products, and authorities that implement new legislation on food claims. This specifically relates to the growing number of probiotic and other functional foods that modulate the human gut. Today, probiotics and prebiotics are marketed successfully since they appeal to the consumer, are bring a positive image and attributes. However, there is a lack of scientific basis for the rational development of probiotic products or for a mechanistic explanation of effects. This prevents further innovation of marketable products that have a clearly demonstrated benefit to the consumer. Gut-related diseases and disorders are very common and the prophylactic management of these problems has a huge market potential. Hence, the current products need to be complemented and an understanding of the scientific basis of their positive attributes to become competitive in the long run and thus meet the demands of European Authorities such as DG Sanco and EFSA, since claims will need mechanistic based evidence of proof in future marketing strategies (Regulation 178/2002/EC, Directives 84/450/EEC, 90/496/EEC, 2000/13/EC, and COM/2003/424).

50.1 INTRODUCTION

Bacteria of the genus *Enterococcus* or enterococci (formerly the "fecal" or Lancefield group D streptococci) are ubiquitous microorganisms, but have a predominant habitat in the gastrointestinal tract of humans and animals. Enterococci are not only associated with warm-blooded animals, but they also occur in large numbers in soil, surface waters, vegetables, plant material, and foods, especially those of animal origin such as fermented sausages and cheeses. By intestinal or environmental contamination, enterococci can then colonize raw foods (e.g., milk and meat) and multiply in these materials during fermentation because of their ability to survive adverse environmental conditions such as extreme pH, temperatures, and salinity. Consequently, these bacteria can withstand normal conditions of food production. They also can contaminate finished products during food processing. Therefore, enterococci can become an important part of the microflora of fermented food.

In processed meats, enterococci are generally not desirable because they can cause spoilage. On the contrary, enterococci have important implications in the dairy industry. They play an acknowledged role in the development of organoleptic characteristics during ripening of many traditional cheeses and they have also been suggested as components of cheese starter cultures. Some enterococci of food origin share also a number of useful biotechnological traits such as bacteriocin production and probiotic characteristics.

Unfortunately, enterococci have also recently assumed major importance in clinical microbiology. Enterococci are low grade pathogens but their intrinsic resistance to many antibiotics and their acquisition of resistance to the few antibiotics available for treatment in clinical therapy, such as the glycopeptides, have led to difficulties and a need for new drugs and therapeutic options. Enterococci can cause food intoxication through production of biogenic amines and can be a reservoir for worrying opportunistic infections and for virulence traits, such as production of adhesins and aggregation substances.

50.2 TAXONOMY, PHYSIOLOGY, AND *HABITAT* OF ENTEROCOCCI

50.2.1 Taxonomy and Physiology

The genus *Enterococcus* consists of Gram-positive, oxidase negative, catalase negative, nonsporeforming, ovoid cells arranged in single cells, pairs, or chains. Enterococci are facultative anaerobes with an optimum growth temperature of 35°C. In 1937, Sherman defined them as organisms growing from 10°C to 45°C, in 6.5% NaCl and at a pH of 9.6, surviving heating at 60°C for 30 min, and reacting with Lancefield group D antisera. Since then, besides the original description of *Enterococcus faecium* and *Enterococcus faecalis*, a variety of species have been described. Presently, 31 species are validly published within the genus *Enterococcus*, although recent taxonomic data indicate that two species (i.e., *Enterococcus porcinus* and *Enterococcus villorum*) are synonymous,

whereas *Enterococcus flavescens* is a biovar of *Enterococcus casseliflavus* (Table 50.1; updated September 25, 2004). Newly described species include *Enterococcus canis*, *Enterococcus phoeniculicola*, and *Enterococcus pallens*. However, not all the recently described species meet the physiological and biochemical traits of the typical enterococci (*Enterococcus durans*, *E. faecalis*, *E. faecium*, *Enterococcus gallinarum*, *Enterococcus hirae*, and *Enterococcus mundtii*). There are some species (*Enterococcus cecorum*, *Enterococcus columbae*, *Enterococcus dispar*, *Enterococcus pseudoavium*, *Enterococcus saccharolyticus*, and *Enteroccocus sulfureus*) that do not react with group D antiserum. Other exceptions include *Enterococcus dispar*, *E. sulfureus*, and *Enterococcus malodoratus*, which do not grow at 45°C, and *E. cecorum* and *E. columbae*, which do not grow at 10°C. Although enterococci are generally nonmotile and able to grow in 6.5% NaCl, these traits also seem to create some discordance. For example, *Enterococcus italicus* does

TABLE 50.1 Species Included in the Genus *Enterococcus*.

Species	*Habitat*/Isolation Source
Enterococcus asini	Donkey intestine
Enterococcus avium	Poultry (rare) and mammalian intestines
Enterococcus canis	Dog anal swabs
Enterococcus casseliflavus	Grass, silage, plants, soil
Enterococcus cecorum	Clinical origin, animals
Enterococcus columbae	Pigeon intestine
Enterococcus dispar	Human origin
Enterococcus durans	Clinical isolate
Enterococcus faecalis	Human and other animal intestines
Enterococcus faecium	Human and other animal intestines
Enterococcus flavescens[a]	Clinical origin
Enterococcus gallinarum	Poultry intestine
Enterococcus gilvus	Human clinical specimens
Enterococcus haemoperoxidus	Water/surface waters
Enterococcus hermanniensis	Packaged broiler meat; canine tonsils
Enterococcus hirae	Animal intestines; chicken pathogen
Enterococcus italicus	Italian cheeses
Enterococcus malodoratus	Gouda cheese
Enterococcus moraviensis	Water
Enterococcus mundtii	Grass, silage, plants, soil
Enterococcus pallens	Human clinical specimens
Enterococcus phoeniculicola	Uropygial gland of the Red-billed Woodhoopoe
Enterococcus porcinus[b]	Animal enteric disorders
Enterococcus pseudoavium	Bovine skin
Enterococcus raffinosus	Clinical origin
Enterococcus ratti	Animal enteric disorders
Enterococcus saccharolyticus	Bedding and skin of cattle
Enterococcus seriolicida	Fish pathogen
Enterococcus solitarius	Clinical isolate
Enterococcus sulfureus	Plant material
Enterococcus villorum[b]	Animal enteric disorders

[a]The data of several authors suggest that *Enterococcus flavescens* should be considered an *Enterococcus casseliflavus* biovar rather than a separate species (Descheemaeker and others 1997).

[b]As no phenotypic or genotypic differences were found between these two species, the name *Enterococcus porcinus* is considered to be a junior synonym of *Enterococcus villorum* (de Graef and others 2001).

Source: List of Bacterial Names with Standing in Nomenclature – Genus *Enterococcus* – last update: September 25, 2004. http://www.bacterio.cict.fr/e/enterococcus.html#r.

not tolerate 6.5% NaCl and 0.4% sodium azide. Reliable identification of enterococci to differentiate them both from other Gram-positive, catalase-negative cocci and within the genus often appears difficult. Different media and phenotypical identification schemes have been described and used for routine testing of dairy products. However, given the variability in the biochemical and phenotypic traits of enterococci, molecular based methods are essential for reliable and fast identification, especially from sources with a heterogeneous microflora.

50.2.2 Habitat

The ecology of the genus *Enterococcus* appears greatly diverse (Table 50.1). The main *habitat* of enterococci is the gastrointestinal tract of animals, although the species distribution shows some peculiarities. *E. faecalis* and *E. faecium* are the predominant, Gram-positive cocci in human stools. In production animals like poultry, cattle, and pig., *E. faecium* is the prevalent species but other species such as *E. faecalis*, *E. cecorum*, *E. gallinarum*, and *E. durans* may occur. Some enterococci are also found in the upper and lower human urogenital tracts and in the oral cavity. In addition, *E. casseliflavus* and *E. mundtii* are typical enterococci isolated from plants. Finally, enterococci are also found in water, soil, vegetables, birds, and insects.

50.3 ECOLOGY IN DAIRY PRODUCTS

Many fermented foods made from meat and milk (especially fermented meats and cheeses) contain enterococci. The presence of enterococci in dairy products has long been considered as an indication of insufficient sanitary conditions during the production and processing of milk. On the contrary, their presence in foods has often been shown to be unrelated with direct faecal contamination. Many authors suggested that the presence of certain strains of enterococci may be desirable in some cheeses on the basis of their positive contribution to flavor development during the cheese ripening. This beneficial role has suggested the inclusion of enterococcal strains in starter cultures used in the production of some traditional artisan cheeses.

50.3.1 Presence in Milk and Starter Cultures

Enterococci may enter milk either directly from human or animal faeces or indirectly from contaminated water sources, exterior of the animal and/or from the milking equipment and bulk storage tank. Due to their ability to grow at low temperatures, their heat resistance, and their adaptability to different substrates and growth conditions, enterococci can increase in number during milk refrigeration and survive after pasteurization. Therefore, enterococci are a part of both the raw and pasteurized milk microflora. A variety of enterococci species are found in dairy products but *E. faecalis* and *E. faecium*, and in some cheeses also *E. durans*, remain the species of greatest importance (Giraffa and others 1997; Franz and others 1999, 2003; Giraffa 2003).

Enterococci may occur in natural milk (or whey) starter cultures, which are still widely used for the manufacture of a variety of cheeses, mostly traditional artisan cheeses, produced both in Southern and Northern European countries from raw or pasteurized milk (Giraffa and others 1997). The presence of enterococci in artisan milk starter cultures, which are usually composed of thermophilic lactic acid bacteria, can be explained by their

thermal resistance coupled with their thermophilic nature. In fact, such cultures are still made following the tradition by pasteurising a good quality raw milk and by incubating it at 42–44°C for 12–15 h, thus promoting the natural selection of thermophilic and heat resistant lactic acid bacteria, usually belonging to *Streptococcus thermophilus* and *Enterococcus* spp. Enterococci also are components of the microflora of artisan whey cultures utilized as starters in the manufacture of mozzarella cheese produced by traditional technology from raw water-buffalo milk. The presence of enterococci in these starters is due to their presence in the raw milk, from which the whey is derived, coupled with the mild acidity reached by these cultures after incubation of the whey at the end of cheese-making.

50.3.2 Presence in Cheeses

Enterococci occur as nonstarter lactic acid bacteria (NSLAB) in a variety of cheeses. Their thermal resistance explains their presence in cheeses produced from pasteurized milk exposed to enterococci via natural cheese starter cultures or from adventitious microflora, through post-pasteurization environmental contamination. Consequently, enterococci can be found in cheeses made with both raw and pasteurized milk and their levels depend on the extent of milk contamination, the cheese type, the starter used, and the technology applied, that is, cheese manufacture and ripening conditions. The recovery and persistence of the enterococci during cheese ripening can be attributed to their wide range of growth temperatures, their tolerance to heat, wide pH ranges, and salt.

In some cheeses, especially fresh or soft industrial cheeses made with pasteurized milk and selected lactic starter culture, the presence of enterococci can be deleterious. Some authors have reported that they can cause deterioration in flavor. Their presence, especially at high levels, is the result of a poor hygienic practice during cheese manufacture (Giraffa and others 1997). Therefore, the presence of enterococci in these cheeses is undesirable. Moreover, enterococci are commonly found in high numbers in traditional cheeses produced in Italy, France, Portugal, Spain, and Greece from raw or pasteurized goats', ewes', water buffaloes' or cows' milk. In these cheeses, enterococci can be desirable. Several studies have indicated that strains of enterococci may have a positive influence on the production and ripening of cheeses like Manchego, Armada, Cebreiro, Picante, Majoero, Feta, Teleme, Mozzarella, Monte Veronese, Fontina, Caprino, Serra, Venaco, Comté, and the Irish, Cheddar-like, Baylough cheese. In these cheeses, enterococci comprise a major part of the fresh cheese curd microflora and in some cases they are the predominant microorganisms in the fully ripened product. Levels of enterococci in cheese curd may range from 10^4 to 10^6 CFU/g and in the fully ripened cheese from 10^5 to 10^7 CFU/g. *E. faecium* and *E. faecalis* are the most prevalent species recovered (Franz and others 2003; Giraffa 2003). Table 50.2 summarizes some of the European, artisan cheese varieties in which enterococci have been found.

Since enterococci may dominate the NSLAB microflora of many cheeses, it is supposed that they can positively contribute to the flavor development during cheese ripening. Not only can enterococci influence the flavor and taste of cheeses with their primary and secondary metabolisms, but enterococci also can produce several enzymes that interact with milk components, thus promoting other important biochemical transformations.

TABLE 50.2 Examples of European Cheeses in which Enterococci have been found (Giraffa and others 1997; Franz and others 2003).

Cheese Variety (Country)	Predominant Species in End Product
Manchego (Spain)	*Enterococcus faecium*
Cebreiro (Spain)	*Enterococcus faecalis*
Arzua (Spain)	*Enterococcus faecalis*
Cabrales (Spain)	*Enterococcus faecium*
La Serena (Spain)	*Enterococcus faecium*
Majorero (Spain)	*Enterococcus faecalis*
Picante (Portugal)	*Enterococcus faecium*; *Enterococcus faecalis*
Serra (Portugal)	*Enterococcus faecium*
Feta (Greece)	*Enterococcus faecium*; *Enterococcus faecalis*
Teleme (Greece)	*Enterococcus* spp.
Water-buffalo Mozzarella (Italy)	*Enterococcus faecium*; *Enterococcus faecalis*
Monte Veronese (Italy)	*Enterococcus* spp.

50.3.3 Presence in Other Dairy Products

The hazardous presence of enterococci in industrial cheeses, fermented milks and other dairy products (i.e., milk powders) has sometimes been reported. High levels of contaminating enterococci in some cheeses, although not related to a direct fecal contamination, may result from poor hygienic practices during cheese manufacture and lead to deterioration of sensory properties of these products. Apart from some cheeses and artisan starters, therefore, enterococci belong to the spoilage microflora in dairy products.

50.4 BIOCHEMICAL PROPERTIES OF TECHNOLOGICAL INTEREST

The positive influence enterococci may have on cheese seems due to specific biochemical traits such as acidifying, proteolytic, and lipolytic activities, citrate utilization, and production of aromatic volatile compounds. (for extensive reviews, see Giraffa and others 1997; Franz and others 1999, 2003; Sarantinopoulos and others 2001; Giraffa 2003).

In general, enterococci exhibit low milk acidifying ability. The poor acidifying capacity of these microorganisms in milk has been recently reported on strains of dairy origin. *E. faecalis* seems generally a stronger acidifier than *E. faecium*, though its acidifying activity is not comparable with that of other lactic acid bacteria such as *S. thermophilus.*

Proteolysis and lipolysis are the principal reactions responsible for the flavor development in cheeses. Generally enterococci show weak proteolysis, although some strains of *E. faecalis* may have a very strong proteolytic activity. Literature data indicate a marked strain-to-strain variation and no clear relationship has been observed between proteolytic and acidification activities.

The lipolytic activity in enterococci is very variable. Low and often species- or strain-dependent lipolytic activity has been reported. An increase in fatty acids has often been

observed in Cheddar, Feta, Picante, and Cebreiro cheeses. However, only *E. faecalis* showed a degree of lipolysis to permit it to serve as adjunct "lipolytic" starter. The esterolytic system of enterococci is rather complex and more efficient than their lipolytic system. Enterococci show higher activity than strains of most other genera of lactic acid bacteria, with *E. faecium* being the most esterolytic species within enterococci.

Citrate and pyruvate metabolism are important phenotypic traits of many LAB. Citrate in milk is cometabolized by many LAB species into important flavor compounds such as acetate, acetaldehyde, and diacetyl. The ability of enterococci to metabolize pyruvate has been extensively studied, but little is known about their ability to metabolise citrate, in which pyruvate is also an intermediate (Rea and Cogan 2003a,b). Enterococci produce significant amounts of acetate, formate, and ethanol depending on the growth conditions. Pyruvate is the immediate precursor of these products. Furthermore, the breakdown of lactose and citrate during cheese ripening gives rise to a series of volatile compounds, such as acetaldehyde, diacetyl, acetone, and acetoin, which may further contribute to flavor.

Overall, enterococci seem to possess the metabolic potential to actively contribute to the flavor development in fermented dairy products.

50.5 PRODUCTION OF BACTERIOCINS

Bacteriocins produced by LAB are small, ribosomally synthesized, antibacterial peptides or proteins that display a limited inhibitory spectrum against Gram-positive bacteria, particularly closely related strains. Since their inhibitory activity often encompasses food spoilers and foodborne pathogens, they are considered as interesting, natural food biopreservatives. Enterococci are capable of producing a variety of bacteriocins, called enterocins, with activity against *Listeria monocytogenes*, *Staphylococcus aureus*, *Clostridium* spp., including *Clostridium botulinum* and *Clostridium perfringens*, and *Vibrio cholerae*. Enterocins are small, heat stable nonantibiotics bacteriocins with a generally strong antilisterial effect. Such properties meet some of the characteristics required for compounds to be used as antimicrobials in food products (Giraffa 1995, 2003; Franz and others 1999, 2003).

Considerable research has been carried out on characteristics of enterocins, or enterocin-producing strains, for a potential application in dairy technology. Dairy-grade traits of enterocins often have been reported, such as production and stability in milk in the temperature range 30–37°C, insensitivity to rennet and heat, a general compatibility with starter LAB species, and stability over a wide range of pH values. It also has been observed that enterocins may lyse starter cells, thus potentially increasing the bacterial enzyme pool in the cheese curd and accelerating cheese ripening and flavor production. Therefore, the application of enterocins, either as a food additive or through in situ production by an appropriate starter culture or co-culture, for the manufacture of cheese, seems promising.

50.6 FUNCTIONALITY OF ENTEROCOCCI IN DAIRY TECHNOLOGY

As stated above, enterococci usually represent an important part of the bacterial flora of many ripened cheeses. Therefore, their possible role and functionality in dairy fermented products has been thoroughly studied. Examples of the most important applications of enterococci in dairy products are given below (for a review, see Giraffa 2003).

50.6.1 Enterococci as Starters

Two important observations have encouraged the application of enterococci as starters:

- Presence of strains with good technological properties within *E. faecium* and *E. faecalis* isolated from cheeses;
- Frequent isolation of enterococci from milk starter cultures used for the manufacture of Italian artisan cheeses.

However, from the early works on Cheddar cheese no significant research reports followed. The generally low acidifying and proteolytic activities of enterococci limits their application as starter cultures for cheese production.

50.6.2 Enterococci as Starter Adjuncts

Starter adjuncts are defined as cultures added to cheese for purposes other than acid formation, which is mostly devoted to starter activity. Starter adjuncts can be added to accelerate ripening, produce desirable flavor, or act as probiotics. Several research works have been carried out to evaluate the feasibility of selected enterococci to act as starter adjuncts in cheese production. *E. faecium*, *E. faecalis*, and *E. durans* have been proposed in combination with both mesophilic and thermophilic LAB species as a part of defined starter cultures for different European cheeses such as Italian semicooked cheeses, water-buffalo Mozzarella, Venaco, Cebreiro, and Hispanico. Generally, the presence of the added enterococcal flora throughout ripening positively affects taste, aroma, color, and structure, as well as the overall sensory profile, of the full-ripened cheeses. This seems linked to the increased amount of soluble nitrogen, total free amino acids, volatile free fatty acids, long-chain free fatty acids, and diacetyl and acetoin in cheeses made with enterococci.

Many European cheeses are characterized by complex bacterial surface flora, which generally consists of yeasts, coryneform bacteria, and micrococci or coagulase-negative staphylococci. However, also enterococci can often be found as nondominant, surface bacteria. Within bacterial surface ripening flora of French and German smeared cheeses, different *Enterococcus* spp. strains colonizing the cheese rind are able to inhibit *Listeria.* Therefore, enterococci can be promising candidates for the development of a defined surface-smear ripening flora.

50.6.3 Enterococci as Probiotics

Enterococci possess properties that allow them to be used as probiotics. To this regard, the Advisory Committee on Novel Foods and Processes decided to allow the use of *E. faecium* strain K77D as a starter culture in fermented dairy products (ACNFP 1996). It is generally known that products for human consumption containing probiotic organisms may be grouped into three categories: infant foods, cultured milks, and pharmaceutical preparations. However, a relatively new frontier in the probiotic technology is the use of cheeses as delivery systems of probiotic strains used as functional starters. A strain of *E. faecium* has been used as probiotic adjunct culture in Cheddar cheese. This strain has a number of properties required of a probiotic microorganism, including the ability to relieve irritable bowel syndrome, intestinal origin, no pathogenicity, and tolerance to

bile and acid (therapeutic adjuncts). Compared with the control, increased proteolysis and higher levels of odor-active volatile compounds were observed in cheese containing the *E. faecium* adjunct throughout the ripening period. The strain maintained viability in Cheddar cheese during nine to 15 months of ripening at 8°C.

50.6.4 Enterococci as Protective Cultures

Bacteriocin-producing strains, defined as "protective cultures" when applied to food, belong to a particular class of starter adjuncts. Several studies in milk, soft cheeses, and soy milk demonstrate the inhibitory effect of enterocin-producing *E. faecium* and *E. faecalis* against *L. monocytogenes* and *S. aureus*. The presence and the anti-*Listeria* activity of enterocins produced by protective cultures in cheese persist throughout the ripening process. Generally, enterocins have little effect on both the commercial starter activity and the organoleptic characteristics of the products. In some cases, the complex curd (or cheese) environment may interfere with bacteriocin production levels. Alternatively, the lack of growth of the enterocin-producing strains, may affect the in situ bacteriocin efficiency.

The functionality of enterocin-producing strains under industrial, cheese processing conditions seems, therefore, strongly dependent on the cheese system and the technology applied.

50.7 THE OTHER SIDE OF THE STORY

Over the last two decades, enterococci, formerly viewed as organisms of minimal clinical impact, have emerged as important hospital-acquired pathogens in immunosuppressed patients and intensive care units. The newly accentuated ambiguity concerning the relationships of these bacteria with human beings is related to their enteric *habitat*, their entering the food chain, their possible involvement in foodborne illnesses due to the presence of virulence factors, such as production of adhesins and aggregation substances, and their antibiotic resistance (for a review, see Giraffa 2002).

The clinical significance of enterococci in human infections is poorly understood because of the scarcity of well-documented reports confirming their occurrence in mixed cultures. Table 50.3 summarizes hospital acquired infections in which enterococci have been somehow implicated (Moellering 2000; Kayser 2003).

50.7.1 The Antibiotic Resistance

Development of antibiotic resistance in bacteria is mainly based on two factors, the presence of resistance genes and the selective pressure by the use of antibiotics. Antibiotic resistance, which can be both intrinsic and acquired, makes enterococci effective opportunists in nosocomial infections. The extremely high level of intrinsic antibiotic resistance within enterococci, coupled with the selective pressure imposed by the use of antibiotics both in clinical therapy and animal husbandry, led to increased selection of resistant strains. The widespread finding of these microorganisms in raw foods could be the key factor contributing to the spreading of antibiotic resistant enterococci (ARE) in both unfermented and fermented foods. ARE have been found in meat products, dairy products, ready-to-eat foods, and even within enterococcal strains proposed as probiotics (Giraffa 2002). In this regard, resistance to the glycopeptides

TABLE 50.3 Summary of the Most Frequent Infections Caused by Enterococci (Moellering 2000; Kayser 2003).

Pathology[a]	Remarks
Urinary tract infections	Often associated with catheterisation in hospitalised patients
Bacteremia	Enterococci are observed in approx. 6–7% of all bacteria isolated from the blood stream. Portal of entry: urinary tract infections; intra-abdominal infections; burn wounds; diabetic foot infections; intravascular catheters
Intra-abdominal and pelvic infections	Enterococci are found as part of a mixed flora
Wound and tissue infections	Enterococci are found as part of a mixed flora
Endocarditis	Enterococci are observed in approx. 5–15% of all cases. Common sources: genitourinary and biliary portals
Rare enterococcal infections	Meningitis; respiratory tract infections

[a]In patients with severe underlying diseases.

vancomycin and teicoplanin is the widest known example of antibiotic resistance of enterococci.

50.7.1.1 The Resistance to Glycopeptides. The selection and spreading of enterococci resistant to the glycopeptide antibiotics vancomycin and teicoplanin have become a clinically significant emergence in the hospital environment (for reviews, see Giraffa 2002; Klein 2003). The use of this class of antimicrobials is of utmost importance in clinical therapy against multiple antibiotic-resistant strains, especially for patients allergic to other antibiotics, for example, ampicillin and penicillin. Although nosocomial acquisition and subsequent colonization of vancomycin-resistant enterococci (VRE) has been emphasized among hospitalized persons, colonization appears to occur frequently in persons not associated with the healthcare setting. Several studies conducted in European countries and the United States in recent years indicate that colonization with VRE frequently occurs in the community and that many animal, food, and environmental reservoirs can act as sources for VRE outside the health care setting. In this mechanism, the transport of these resistances via the food chain to humans seems likely to occur and dairy products could act as vectors. From literature data, however, the presence of VRE in cheeses is still controversial and not so frequent as reported for meat products.

An association has been suggested among the use of avoparcin and other antibiotics in livestock, the selection of VRE, and bacterial colonization of humans via the food chain. This led to a European ban for use of avoparcin (by 1997) and other growth promoters in animal feeds.

The increasing resistance of enterococci to antibiotics is exacerbating the increased occurrence of these bacteria as nosocomial opportunists. Additionally, the finding of resistant strains outside the nosocomial environment widens the risk of human exposure to opportunistic pathogens. Those at greatest risk include the elderly and children who, for opposite reasons, may have deficient immune status. However, the antibiotic resistance alone cannot explain the virulence of these bacteria in the absence of pathogenicity factors and active mechanisms of gene transfer.

50.7.2 Presence of Virulence Factors and Genetic Exchange Mechanisms

Virulence traits in enterococci include adherence to host tissue, invasion and abscess formation, resistance to, and modulation of, host defense mechanisms, secretion of cytolysins and other toxic products and production of plasmid-encoded pheromones. A number of genes encoding for virulence factors in enterococci have been sequenced and characterized and their effects have been shown in human and animal studies. The incidence of virulence determinants among food isolates studied so far appears to be strain-dependent. Furthermore, it may be argued that strains which possess multiple virulence determinants associated with various phases of infection may pose a higher risk than strains which possess a single virulence trait (Franz and others 2001).

It has recently been suggested that enterococcal disease is a two-step process. Colonization of the gastrointestinal tract by strains carrying virulence determinants and/or antibiotic resistance is followed by population spreading. It could be deduced, therefore, that strains lacking virulence and antibiotic-resistance determinants introduced into the human gut via dairy products would not be of risk for immunocompetent individuals. A well-documented example is *E. faecium* strain SF68, used in pharmaceutical preparations (Franz and others 1999).

Many of these enterococcal virulence traits, such as haemolysin-cytolysin production, adhesion ability, and antibiotic-resistance, have been shown to be transmissible by gene transfers mechanisms. Trans-conjugation in which starter strains acquire virulence determinants from clinical-associated strains also has been demonstrated (Giraffa 2002).

50.7.3 Involvement of Enterococci in Food-borne Illnesses or Food Poisoning

High levels of biogenic amines in many fermented foods, such as fermented sausages, cheeses, wines, fermented olives, and fish products, involved in food intoxication, may be a clinical concern. Food intoxication caused by ingestion of biogenic amines determines a number of symptoms of increasing complexity that include headache, vomiting, increased blood pressure, and allergic reactions even of strong intensity.

Microbial agents involved in biogenic amine production in foods may be derived from either starter and nonstarter LAB or contaminating microflora. Cheeses may represent a good substrate for production and accumulation of biogenic amines, especially tyramine, from enterococci able to decarboxylate free amino acids into the matrix. The ability to produce biogenic amines in cheese and fermented sausages has been reported for bacteria of the genus *Enterococcus* (Giraffa and others 1997; Giraffa 2002).

50.8 CONCLUDING REMARKS

There is no consensus on the acceptance of enterococci in foodstuffs and their role as primary pathogens is still a question mark. On one hand, there is positive evidence that enterococci can be useful in dairy technology. Some well defined strains with a long

history of safe use as probiotics are known. In addition, enterococci could be beneficial, as starter adjuncts, for the biopreservation or improvement of organoleptic characteristics of different cheeses. On the other hand, the emergence of enterococci resistant to glycopeptides and other antibiotics, the production of biogenic amines in cheese, and the finding of virulence traits within both clinical and foodborne isolates raise questions about the safety of enterococci in foods. It has been suggested that application of enterococci in cheeses could proceed once pathogenic and nonpathogenic strains are defined on the basis of careful selection and case-by-case studies. However, the finding of effective gene transfer mechanisms within enterococci weakens this statement. Clearly, the barrier separating enterococci as commensals (and/or opportunistic pathogens) from pathogens appears most fragile.

It is expected, therefore, that cheeses (especially those made with raw milk) could contain enterococci with virulence traits and resistances to clinically important antibiotics, due to the occurrence of direct environmental contamination. Therefore, while some time ago enterococci were put forward as co-cultures in food, now scientists are aware of the possible health hazard enterococci can pose. Teuber and others (1999) recommended as a drastic measure that cheese should be produced only with pasteurized or microfiltered milk. That means starter cultures should be used in cheese manufacturing. But in many artisan European cheeses, producers still establish the quality of the product on the use of raw milk, often without starter addition. On the other hand, in the Directive 2000/54/CE of the European Parliament, concerning risks of exposure to biological agents, *Enterococcus* spp. are allocated into risk-group 2, which includes microorganisms harboring potential virulence factors. Therefore, more research efforts on clinical and epidemiological techniques to discriminate between pathogenic and nonpathogenic *Enterocccus* spp. are needed. Moreover, the still unclear taxonomy of enterococci will demand molecular tools to achieve more effective identification and characterization of natural isolates in epidemiological and clinical studies. A grouping of the strains on the basis of virulence traits, as well as case-by-case studies on overall phenotypic and genotypic characteristics, could enable the development of pathogenicity schemes within the enterococcal population to better comprehend the microbial ecology of this heterogeneous group of bacteria.

51.1 INTRODUCTION

The fermentation of foods, especially of dairy origin, presents one of the oldest methods of food preservation known to mankind. The origin of fermented milk was placed in the Middle East before the Phoenician era. As early as 7000 BC, the Egyptian consumed their, now traditional, fermented milk products, Laban Rayeb and Laban Khad. Persian

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

tradition claims that Abraham owed his longevity to consumption of sour milk (Kosikowski and Mistry 1997). Similarly, peasants of Thrace enjoyed benefits of "Prokish", made by souring of sheep milk. Traditional production of fermented milk established in the middle and Far East was spread throughout the east Europe and Russia by the Tartars, Huns, and Mongols during their invasions. Consequently, a wide range of fermented dairy products still exists in these regions and some popular products such as yogurt and kefir are claimed to originate from the Balkans and Eastern Europe. Although our knowledge has expanded tremendously in recent decades shading some light on the role of microbial agents involved in the fermentation processes, initially traditional fermentation approaches were artisinal in nature without any appreciation for the role of microorganisms. Nonetheless, continuous observations and experience resulted in establishment of certain procedures by which handling and storage of milk in a certain manner would produce products than not only had a very good keeping quality but also pleasant sensory characteristics. By the middle of the 19th century, the industrial revolution resulted in the concentration of large masses of population in cities requiring a manufacturing of products in large quantities. Clearly, the natural fermentation and traditional manufacturing approach such as back-slopping were inappropriate bases for any large-scale industrial process. By the end of the 19th century, the microorganisms involved in dairy fermentations were isolated and characterized leading to a large scale production of defined starter cultures.

51.2 TRADITIONAL HEALTH CLAIMS ASSOCIATED WITH FERMENTED MILK

Although the preservative role of fermented dairy products was appreciated early, it was not until the late 19th century that scientists realized that a wide range of traditional sour milk might have had additional benefits in addition to prolonged shelf-life and pleasant sensory properties. At the beginning of the 20th century, Nobel Laureate Ilya Metchnikoff (Metchnikoff 2004) noticed that Bulgarian peasants had an average lifespan of 87 years, exceptional for the early 1900s, and that four out of every thousand lived past 100 years of age. One of the major differences in their lifestyle in comparison to the contemporary diet was large consumption of fermented milk. In his well known autointoxication theory, Metchnikoff suggested that the human body was slowly poisoned by toxins present in the diet, and body's resistance steadily weakened by proliferation of enteric pathogens, all of which successfully prevented by consumption of milk and lactic acid producing bacteria. In the early 1900s, his statement resulted in a surge in the consumption of fermented milk. The bacterium responsible for this fermentation was termed *Bacillus* and was believed to have a substantial positive effect on health. However, in the 1920s, it was demonstrated that this bacterium, later called *Lactobacillus bulgaricus*, could not survive the passage through the gastrointestinal tract, which disputed Metchnikoff's theory. Nonetheless, the scientists continued to investigate possible benefits of bacteria to the health. In the 1930s, certain strains of *Lactobacillus acidophilus* were isolated and found to be capable of colonizing the human digestive tract where they exerted appreciable physiological activity. These findings led to the production of a fermented dairy product in which a single strain of *L. acidophilus* was used in the fermentation (Burke 1938). Since that time, a number of fermented milk products containing live microbial flora has been introduced on the market supported by an extensive research that lead to introduction of probiotic concept (Fuller 1992).

Another astonishing example of the effect of diet on the longevity is seen in the Hunza Valley, located between the borders of China, India, Pakistan, and Russia at nearly 2500 m. The Hunzakuts, inhabitants of this valley, have been attracting the attention of the scientific community because of their excellent health and extremely long lifespan (Hoffman 1968). Similarly, Abkhasians and Georgians, from an area that used to be known as part of the Soviet Union, have been highlighted by their amazing history of longevity. The absence of diseases, active lifestyle and sound basic diet have resulted in people living to be 100, 110, or 120, and occasionally as much as 140 years of age. Importantly, a substantial part of the diet (one to two glasses per day) is composed of fermented milk (Benet 1974). The Georgians strongly believe that health depends very much on consumption on fermented milk. A known Georgian saying claims that the longevity comes with consumption of sour milk.

51.3 PRODUCTION OF FERMENTED MILK

Food fermentation has been carried out for centuries in an attempt to long-term preserve perishable foods such as milk. As a consequence, a great variety of fermented dairy products has been developed, each with distinct sensory characteristics. The fermentation process in general involves the fermentation of an organic material, mainly carbohydrates, resulting in a range of products, which include principally organic acids, alcohol, and carbon dioxide (de Vos 1996). These metabolites proved a preservative effect by inhibiting the growth of spoilage and/or pathogenic microflora in fermented products. Additionally, a number of other metabolites may be produced that would affect the quality of the final fermented milk including the flavor compounds such as diacetyl and acetaldehyde, as well as compounds that may have positive health implications such as vitamins, antioxidants, and bioactive peptides. When considering dairy fermentations, a bacterial group commonly referred to the lactic acid bacteria (LAB) is primarily responsible for majority of the microbial transformations. This group is composed of a number of genera including *Lactococcus*, *Lactobacillus*, *Enterococcus*, *Streptococcus*, *Leuconostoc*, and *Pediococcus*. They are strictly fermentative, producing lactic acid as the main end-product. They also lack the ability to synthesize haeme thus they are consequently catalase-negative and lack a terminal electron transport chain (Stiles and Holzapfel 1997). Members of the LAB are usually subdivided into two distinct groups based on their carbohydrate metabolism. The homofermentative group consisting of *Lactococococcus*, *Pediococcus*, *Enterococcus*, *Streptococcus*, and some lactobacilli utilize the Embden–Meyerhof–Parnas (glycolytic) pathway to transform a carbon source chiefly into lactic acid. By this pathway, 1 mol of glucose will be converted into 2 mol of lactate with subsequent generation of 2 mol of ATP. As opposed to homofermentors, heterofermentative bacteria produce equimolar amounts of lactate, CO_2, ethanol, or acetate from glucose exploiting phosphoketolase pathway. The utilization of carbohydrates by this route generates only half the energy of the homofermentative group. Members of this group include *Leuconostoc*, *Weissella*, and some lactobacilli. The species belonging to *Enterococcus* genus are frequently found in traditional fermentations and may be included as a component of some mixed starters. However, their deliberate utilization in dairy fermentations still remains controversial, especially since some of the species have been now recognized as opportunistic human pathogens associated with hospital-acquired and urinary tract infections (Franz and others 1999).

Dairy LAB are fastidious in nature requiring a wide range of essential growth promoters. Although considered a rich growth medium, milk contains small amounts of peptides and free amino acids to efficiently support growth of LAB (Vasiljevic and others 2005). In response to this limitation, LAB have developed a complex proteolytic system consisting of proteinases and peptidases, which enable them to utilize casein as an additional source of amino acids and nitrogen (Smid and others 1991). The structural components of the proteolytic systems of LAB can be divided into three groups on the basis of their function including proteinases (that break down caseins to peptides), peptidases (that degrade peptides), and transport systems (that translocate the breakdown products across the cytoplasmic membrane) (Kunji and others 1996). The first step in casein degradation is mediated by cell wall-located proteases, which cleave caseins to oligopeptides. Further degradation to smaller peptides and amino acids that can pass through the cell membrane is performed by peptidases (Shihata and Shah 2000). Furthermore, dairy LAB grow rapidly at ambient temperature, converting lactose to lactic acid. Consequently, pH of milk is reduced and, around pH 4.6, the isoelectric point of caseins is reached, at which a gel is formed as one of the main sensory detriments of the fermented dairy products. A wide range of fermented milk has been developed since the first documented production and some 400 generic names have been applied to the traditional and industrialized fermented milk throughout the world (Kurmann and others 1992). However, most of these products are basically very similar and very accurate description would include only several varieties. In this paper, we aimed to classify all these products taking into

account the type of milk used, the dominating microbial flora and principal metabolic products (Tamime and Marshall 1997). The proposed scheme divided fermented milk into three broad categories: (1) lactic fermentations, (2) yeast-lactic fermentations, and (3) mold-lactic fermentations. Some products based on this classification are listed in Table 51.1 with yogurt being the most important type.

51.4 REGULATORY ASPECT PERTAINING FERMENTED MILK

The existing legislation regulating production of fermented milk in many countries classifies the product based on the chemical composition or fat content (full, semiskimmed, or medium; and skimmed or low). According to general standards published by the International Dairy Federation (IDF 1992a,b), fermented milk could be defined as product prepared from milk and/or milk derived components, produced from raw materials that were at least pasteurized by the action of specific microflora, which results in a pH reduction and subsequent casein coagulation. Additional IDF specifications recommend that (1) the starter cultures be viable, active and abundant having concentration of at least 10^7 colony forming units (cfu) per g of a product throughout the shelf-life; (2) raw materials used in production must be at least pasteurized, optionally homogenized and addition of certain additives such as thickeners is rather optional; (3) final products should have a shelf-life of up to 30 days stored at 4–7°C; (4) as the presence of live culture is required at the time of sale, heat-treatment to prolong the storage stability be not permitted; and (5) syneresis (wheying off) in the final product needed to be avoided with the exception of concentrated fermented milk products such as labneh and ymer.

The properties of the final product are substantially affected by the culture used for the fermentation, thus the identity of the starter cultures is well defined. Traditionally, yogurt is the coagulated milk produced by lactic acid fermentation using a mixed starter culture consisting of thermophilic strains of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus*. In some countries, a provision has been made to include other species of LAB. Consequently, some yogurt manufacturers use *Lactobacillus helveticus* and *Lactobacillus jugurti* during production. Similarly, yogurt can be made using an ABT starter cultures composed of *S. thermophilus*, *Lactobacillus acidophilus*, and *Bifidobacterium* spp. as practiced in Australia. The fermentation greatly depends on the rapid acid production by *S. thermophilus*. On the other hand, the U.S. standard prohibits the use of any other starter culture but *L. delbrueckii* ssp. *bulgaricus* and *S. thermophilus* in yogurt-making (Shah 2003).

The fermented milk can also be produced by mesophilic starter cultures giving products that are generally included under lactic and yeast–lactic fermentations. The mesophilic LAB belong to the genera of *Lactococcus* (*Lac. lactis* ssp. *lactis*, *Lac. lactis* ssp. *lactis* biovar *diacetylactis*, and *Lac. lactis* ssp. *cremoris*) and *Leuconostoc* (*Leu. mesenteroides* ssp. *cremoris* and *Leu. mesenteroides* ssp. *dextranicum*). These organisms are usually used in the production of fermented milk as defined, mixed cultures. On the other hand, products such as kefir and kumys (kumiss, koumiss) are made by yeast–lactic fermentations utilizing the ability of mixed starter cultures that are rather complex consisting of numerous species of LAB, yeasts, and molds.

Kefir is a refreshing drink originating from the northern slopes of the Caucasian mountain range. Artisinal production included addition of starter culture in the form of "kefir grains" to bovine or caprine milk and prolonged storage in leather sacks at different

environmental temperatures–during the day exposed to the sunlight and at night protected from the overly low temperature (Koroleva 1991). The mixture was frequently shaken to allow for an even distribution of metabolites as well as to enhance the fermentation. The final product usually contained substantial amount of lactic acid, ethanol, and carbon dioxide. The continuous production was achieved by either back-slopping, adding fresh milk to small quantities of kefir, or sieving off of kefir grains that would subsequently be reused in the production of new batches (IDF 1984). Kefir grains are composed of a complex microbial mixture consisting of mesophilic, homofermentative lactococci, usually *Lac. lactis* ssp. *lactis* and *Lac. lactis* ssp. *cremoris*; obligate heterofermentative lactobacilli such as *L. kefir*; mesophilic heterofermentative leuconostoc; acetic bacteria such as *Acetobacter* and yeasts such as *Kluyveromyces marxianus*, *Saccharomyces cerevisiae*, and *Candida kefir* (Koroleva 1991). The presence of each of these groups results in noticeable effect on properties of the final product.

Kumys is another fermented milk product produced by a mixed yeast–lactic fermentation of mare's milk. Similar to kefir, kumys has a long tradition dating some 25 centuries back when the Scythian tribes enjoyed benefits of this refreshing drink (Koroleva 1991). Traditionally, fresh mare milk was filled into leather sacks and agitated with a wooden paddle. The mixed culture involved in the fermentation consisted of several types of yeasts, such as *Saccharomyces lactis* and *Sac. cartilaginosus*, and thermophilic strains of *L. delbrueckii* ssp. *bulgaricus* and mesophilic strains of *L. causasicum* (Koroleva 1991). Nowadays, modern manufacturing of kumys includes a controlled fermentation of bovine skim milk by defined starter cultures. Another example of a product produced through mixed yeast–lactic fermentation comes in the form of "dadih," an Indonesian fermented milk. Traditionally it was produced by filling a bamboo tube with fresh buffalo milk; the tube was closed with banana leaves and fermentation performed at room temperature for about two days. The LAB cultures involved in fermentation included *Leuconostoc* sp. and *Lactobacillus* sp. and several genera of yeasts (Surono 2003).

Simultaneous growth of yeasts and LAB in fermented dairy products leads to possible interactions that may affect final product characteristics and quality. The substantial amounts of carbon dioxide and ethanol are produced due to presence of yeasts imparting desirable characteristics to products such as kefir and kumys. Co-existence may result in either stimulation or suppression of growth of the co-cultured strains. Competition for essential nutrient or the production of growth factors may play a role in any of these occurrences (Gadaga and others 2001). Importantly these interactions occur during very short period of time, usually during main fermentation that takes two to three days.

Final fermented products are consumed immediately after production or stored at low temperature that halts the growth of the cultures. During this short fermentation time, a range of compounds may be produced that would influence flavor and/or the consistency of the product due to the formation of an acid gel, production of extracellular polysaccharide and carbon dioxide. In some instances, the growth appears to be symbiotic, where a compound produced by one organism is utilized by another. Mesophilic strains of *Leuconostoc* are capable of metabolizing acetaldehyde produced by lactococci strains (Tamime and Marshall 1997). The main product of LAB metabolism is lactic acid; the presence of this in milk results in a gel formation as well as imparts a sour taste to the product. Citrate metabolism plays an important role resulting in formation of various flavor compounds such as diacetyl, acetic acid, and carbon dioxide (Hugenhotlz 1993). The proteolytic activity of LAB releases a range of peptides and free amino acid that serve as precursors of numerous flavor compounds, that is, malty flavor is imparted by branched

chain amino acids through the metabolism of several strains belonging to *Lactococcus* and *Lactobacillus* genera (Ayad and others 1999). Also acetaldehyde, the characteristic flavor compound in yogurt, is produced from threonine.

51.5 NUTRITIONAL AND PHYSIOLOGICAL BENEFITS OF FERMENTED MILK

Considering their nutritional profile, fermented dairy products resemble a dairy base that they are made of, most frequently full-fat or skim milk. The natural function of milk is to provide complete nutritional requirements to the neonatal mammal. The composition of milk is a species dependant resulting in great interspecies differences (Fox 2003). Although very similar in the total solids content, major differences between human and bovine milk are found in protein, 1–3.4%, respectively, and lactose content, 7–4.8%, respectively (Fox and McSweeney 1998). Bovine milk is composed of well-balanced micronutrients including carbohydrate, fat, and protein. It contains on average 4.8% lactose, 3.4% protein, 3.7% fat, and 0.7% ash. Milk proteins, in general grouped into two classes: caseins and whey proteins, have high nutritive value due to favorable balance of essential amino acids (Buttriss 1997). In addition to macronutrients, milk contains a range of bioavailable micronutrients such as calcium, phosphorus, riboflavin (vitamin B_2), thiamin (vitamin B_1), and vitamin B_{12}, as well as folate, niacin, magnesium, and zinc.

In addition to exceptional nutritional attributes, milk and milk-derived products such as fermented milk contain components that possess a range of different bioactivities, some of them summarized in Table 51.2. Consequently, some of the milk native and derived constituents are being frequently considered functional, thus making dairy products an important part of functional foods and nutraceuticals. Although the concesus regarding an appropriate definition of functional foods has not been reached yet, many attempts have described them as foods similar in appearance to a conventional food, consumed as a part of regular diet, and have shown a particular physiological benefit and/or demonstrated a potential in reducing the risk of chronic disease beyond basic nutritional functions (Lucchina 2003).

TABLE 51.2 Biogenic Activity of Native Milk Macro-components (Compiled from Pariza 2004; Schmelz and others 2000; Shah 2000).

Component	Form	Bioactivity
Protein	Caseins	Mineral carriers, antiosteoporotic, precursor of bioactive peptides
	α-lactalbumin	Modulation of lactose metabolism, Ca carrier, immunomodulation
	β-lactoglobulin	Retinol carrier, fatty acid binder, presumed antioxidative activity
	Immunoglobulins	Immune activity
	Lactoferrin	Antimicrobial, antioxidative, immunomodulation, anticarcinogenic
	Lactoperoxidase	Antimicrobial
	Lysozyme	Antimicrobial
Fat	Conjugated linoleic acid	Anticarcinogenic, modulation of lipid and protein metabolism, antiinflamatory, hypotensive, antiatherosclerotic
	Sphingolipids	Anti-inflamatory, anticarcinogenic
	Butyric acid	Anticarcinogenic
Carbohydrates	Oligosaccharides	Prebiotic, antimicrobial (antiadhesive), Ca absorption

Milk proteins exert an appreciable range of different physiological activities in their native form. Specific immunoglobulins provide the first line of defense to suckling neonates through passively acquired immunity. Other nonspecific antimicrobial milk factors such as iron-binding protein, lactoferrin, and several enzymes including lactoperoxidase and lysozyme are more actively involved in preventing a microbial proliferation (Floris and others 2003). More importantly, the functionality of dairy proteins is further enhanced upon liberation of bioactive peptides by proteolysis (Gobbetti and others 2002). Proteolysis is performed by naturally occurring enzymes in milk, bacterial from starter cultures as well as enzymes of the digestive tract, resulting in release of a great deal of peptides with different biogenic activities such as opioid, hypotensive, immunomodulating, antithrombotic, and antimicrobial activities.

Milk also contains a quantity of complex lipids, particularly phospholipids and sphingolipids. Their excessive concentration is a result of milk fat globule formation during which the globules are encapsulated in an entire layer of epithelial cell plasma membrane. A variety of sphingolipids showed a substantial influence on cell proliferation. They were very successful in reducing a number of neoplatic cells during early stages of cancer development (Schmelz and others 2000). The key factor determining the efficiency of cancer suppression appears to be a product of sphingolipids hydrolysis, ceramides.

In 1979, Pariza and others (1979) reported that grilled ground beef contained both bacterial mutagens and a substance that inhibited mutagenesis. The group later went on to identify the new anticarcinogen as conjugated linoleic acid (CLA) (Ha and others 1987). This discovery led to further investigations, not only on the establishment of the underlying mechanism(s) for the prevention of carcinogenesis but also identifying other potential applications. The potential benefits are numerous ranging from anticancer activity, immune enhancement and antiinflammatory activity over to obesity and weight control as well as antiatherosclerotic effect (Pariza 2004). Initially it was believed that all these effects were expressed by a single compound. However, CLA is a term describing a class of dieonic isomers of linoleic acid, with several of them possessing biological activity. So far, only two isomers have been identified to have known physiological effects: *c*9,*t*11-CLA and *t*10,*c*12-CLA (Pariza 2004). CLA is produced as a metabolic intermediate from polyunsaturated fatty acids, specifically linoleic (18 : 2n-6) and linolenic acids (18 : 3n-3), by rumen bacteria, namely *Butyrivibrio fibrisolvens* and *Megasphaera elsdenii* (Kramer and others 2004). Consequently, the richest sources of CLA are products of animal origin with milk and yogurt containing between 0.46–1.78 and 0.43–1.12 g per 100 g of total fatty acids, respectively (Gnädig and others 2003). Several studies showed that dairy LAB were capable of producing CLA *in situ* during fermentation of milk. However, this ability was interspecies dependant as well as some other factors such as culture concentration and fermentation time (Kim and Liu 2002; Coakley and others 2003).

51.6 HEALTH BENEFITS OF FERMENTED MILK

51.6.1 Alleviation of Lactose Intolerance

The decline of the intestinal β-galactosidase (β-gal; commonly know as lactase) activity is a biological characteristic of the maturing intestine in the majority of the world's population (Lee and Krasinski 1998). With the exception of the inhabitants of northern and central Europe and Caucasians in North America and Australia, over 70% of

adults worldwide are lactose malabsorbers (de Vrese and others 2001). Upon ingestion of lactose, it is hydrolyzed by lactase in the brush border membrane of the mucosa of the small intestine into constitutive monosaccharides, which are readily absorbed in the blood stream (Shah and Jelen 1991). However, the activity of the intestinal lactase in the lactose intolerant individuals is usually less than 10% of childhood levels (Buller and Grand 1990). This decline, termed hypolactasia, causes insufficient lactose digestion in the small intestine, characterized by an increase in blood glucose concentration or hydrogen concentration in breath upon digestion of 50 g lactose, conditions designated as lactose maldigestion (Scrimshaw and Murray 1988). Hypolactasia and lactose malabsorption accompanied with clinical symptoms, such as bloating, flatulence, nausea, abdominal pain, and diarrhea, are termed lactose intolerance. Symptoms are caused by undigested lactose in the large intestine, where lactose is fermented by intestinal microflora and osmotically increases the water flow into the lumen. The severity of the symptoms depends primarily on the size of the lactose load ingested (Savaiano and Levitt 1987). The development of the intolerance symptoms also depends on the rate of lactose transit to the large intestine, influenced by the osmotic and caloric load, and the ability of the colonic microflora to ferment lactose (Martini and Savaiano 1988). Lactose intolerance usually leads to self-imposed dietary restrictions of dairy products, which in turn may have deleterious nutritional consequences in later life, such as low calcium absorption resulting in osteoporosis (Pietschmann and others 1991).

Numerous studies have shown individuals with hypolactasia could tolerate fermented dairy products better than an equivalent quantity in milk (Martini and others 1987a,b; Rosado and others 1992). Various explanations have been suggested in order to clarify this phenomenon. At least three factors appear to be responsible for a better tolerance of lactose in fermented milk including (1) starter culture, (2) intracellular enzyme β-galactosidase or lactase expressed in these cultures, and most importantly, (3) oro-caecal transit time. The traditional cultures used in dairy fermentations utilize lactose as an energy source during growth thus at least partially reducing its content in fermented products. Furthermore, the bacterial lactase may resist luminal effectors avoiding denaturation and can be detected in the duodenum and terminal ileum after consumption of products containing live bacteria. The presence of this enzyme may lead to lactose hydrolysis and improved lactose tolerance (Martini and others 1991). On the other hand, other studies could not support this theory finding no difference in digestion and tolerance to lactose in several fermented dairy products with substantially different lactase activities (Vesa and others 1996). It was suggested that increased viscosity of fermented milk, in this case yogurt, slowed gastric emptying and consequently prolonged transit time through the gastrointestinal tract improving absorption and lactose tolerance (Shah and others 1992).

51.6.2 Antiosteoporotic and Antiobesity Effect

In addition to major macronutrients, fermented milk are excellent source of important minerals, namely calcium and phosphorus and several vitamins, especially those belonging to the B group. In general, dairy products provide for up to 75% of recommended dietary intake of calcium (Narva and others 2004b). Calcium plays a major role in bone formation and mineralization and daily requirements are influenced by age, pregnancy, and lactation. However, recent studies showed an acutely low calcium intake in pregnant women (Adolfsson and others 2004). Additionally, postmenopausal women

are at greater risk due to absent estrogen activity that otherwise governs bone recalcification (Heaney 2000). Due to low pH in fermented milk, calcium is readily solubilized and presented in its ionic form. Initially it was believed that this predominant factor influenced a good bioavailability of dairy calcium. However, the evidence has been rather contradictory. Some authors pointed out the role caseinophosphopeptides (CPP), small proteinaceous fractions liberated by proteolytic activity of either gastrointestinal or microbial proteases, in mineral binding and adsorption. Several *in vitro* studies have shown that these phosphorylated peptides were capable of binding and solubilizing calcium, thus preventing precipitation in the presence of phosphates at physiological pH (Holt and others 1996, 1998). However, *in vivo* studies have not been able to confirm these findings. Fermented milk indeed enhanced the calcium absorption, which was substantially higher in comparison to that of unfermented milk; however, the mechanisms still remained unclear with CPPs playing no apparent role (Narva and others 2003, 2004a,b).

In addition to prevention of osteoporosis, preliminary findings suggest that dairy products as a part of an energy-controlled diet may prevent obesity by enhancing the weight loss. The prevalence of obesity has increased dramatically over the years. The latest National Health and Nutrition Examination Survey, analysing data from 1999 to 2002, showed that one-third of all adults (at least 20 years of age) in the United States were obese with an additional one-third being considered overweight (Hedley and others 2004). As demonstrated by several epidemiological studies (Heaney and others 2002; Skinner and others 2003; Zemel and others 2004), after controlling for energy intake and physical activity, body fat was lower in people with the highest calcium intake. The risk for obesity decreased with an increase in calcium intake, reaching 85% at the RDI level. Studies also showed that fermented dairy products produced a superior effect on both fat loss and fat distribution in comparison to equivalent amounts of supplemental calcium. Various mechanisms have been proposed to explain this inverse relationship between dairy consumption and body mass index (BMI). Apparently, intracellular calcium plays a major role in modulation of human adipocyte metabolism. Higher levels of calcitrophic hormones in blood, resulting from a low-calcium intake stimulate the influx of calcium into human adipocytes. Consequently, this influx causes a metabolic switch from lipolysis to lipogenesis, thus fat is rather stored than burnt (Zemel 2003). On the other hand, concentrations of calcitrophic hormones may be maintained at low level by increasing calcium intake, reversing the calcium flow and therefore increasing lipolysis. Although dairy consumption may not be a sole answer to the prevalence of obesity, owing its multifactorial dependence, these findings indicate that dairy products may present an important part in the prevention of obesity accompanied with other dietary measures and physical activity.

51.6.3 Physiological Activity

Dairy starter cultures used in production of fermented milk have appreciable proteolytic activity enabling their rapid growth in milk. During fermentation, milk proteins, namely caseins, undergo a slight proteolytic degradation resulting in a number of potentially bioactive peptides (Table 51.3). Strains of *Lactobacillus helveticus* have been identified as highly proteolytic and peptidolytic towards caseins and their derivatives and, if used in fermentations, they can produce products with a

TABLE 51.3 Some Examples of the Identified Bioactive Peptides in Fermented Milk and Their Corresponding Physiological Activity (Gobbetti and others 2000; Hernandez-Ledesma and others 2005; Nakamura and others 1995; Robert and others 2004; Seppo and others 2003; Yamamoto and others 1999).

Sequence	Microbial Agent	Precursor	Bioactivity
Val-Pro-Pro, Lle-Pro-Pro	*Lb. helveticus* CM4 and *S. cerevisiae*	β-and κ-casein	Hypotensive
Val-Pro-Pro, Lle-Pro-Pro	*Lb. helveticus* LBK16H	β-and κ-casein	Hypotensive
Phe-Pro-Glu-Val-Phe-Glu-Lys	Commercial products and digestion	α_{s1}-casein	ACE inhibition
Lys-Val-Leu-Pro-Val-Pro-Glu	Commercial products and digestion	β-casein	Antioxidative
Lys-Thr-Thr-Met-Pro-Leu-Trp	Commercial products and digestion	α_{s1}-casein	Possible immunomodulation
Asn-Leu-His-Leu-Pro-Leu-Pro-Leu-Leu	*Lb. helveticus* NCC 2765	β-casein	ACE inhibition
Tyr-Pro-Phe-Pro-Glu-Pro-Ile-Pro-Asn	*Lb. helveticus* NCC 2765	β-casein	Opioid
Tyr-Pro	*Lb. helveticus* CPN4	caseins	ACE inhibition
Leu-Asn-Val-Pro-Gly-glu-Ile-Val-Glu	*Lb. delbrueckii* ssp. *bulgaricus* SS1	β-casein	ACE inhibition
Asn-Ile-Pro-Pro-Leu-Thr-Glu-Thr-Pro-Val	*Lc. lactis* ssp. *cremoris* FT4	β-casein	ACE inhibition

range of bioactivities such as opioid and hypotensive activity (Maeno and others 1996; Matar and others 1996).

Casein- and potentially whey proteins-derived bioactive peptides released through the proteolytic action of dairy starters may function as regulatory compounds or exorphins. These peptides with a morphin-like activity may act as opioid agonists such as α- and β-casomorphins, and lactorphins or opioid antagonists presented by casoxins. The opioid peptides are generally short containing between five and 10 amino acid residues. They have the ability to bind to opioid receptors on intestinal epithelial cells exhibiting a range of physiological functions such as modulation of social behavior, antidiarrheal action and stimulation of endocrine responses (Clare and Swaisgood 2000). Casomorphins appear to be resistant to digestion by gastrointestinal enzymes expressing an appreciable activity in the gut (Trompette and others 2003). This activity slows down the rate of the gastric emptying enhancing the uptake rate of amino acids and electrolytes by epithelial cells. Casomorphin activity is dependant on consensus amino acid sequences that require the presence of a Tyr residue at the N-terminal end and presence of another aromatic amino acid residue, Phe or Tyr, in the third or fourth position (Clare and Swaisgood 2000).

Another group of bioactive peptides, termed angiotensin I-converting enzyme (ACE) inhibitors, have been extensively studied due to their hypotensive role. Hypertension is a risk factor in the development of a number of cardiovascular diseases such as stroke and coronary infarction. The risk of acquiring these diseases is dramatically diminished by even slight reduction in diastolic pressure, which can be achieved by certain dietary modifications (Conlin and others 2000). In some cases, drug treatments may be employed producing a range of effects such as vasodilation and inhibition of angiotensin I-converting enzyme (ACE, EC 3.4.15.1) activity. Blood pressure is controlled by different interacting biochemical pathways but, in general, it is associated with the renin-angiotensin system. This system begins with the inactive precursor angiotensinogen,

a glycopeptide that is the only known precursor of angiotensin I as well as the only known substrate for renin (EC 3.4.23.15). Renin is responsible for liberation of angiotensin I from angiotensinogen (Inagami 1994). Angiotensin I, the decapeptide released from the N-terminal portion of angiotensinogen, is further cleaved by ACE, which removes the C-terminal dipeptide Hys-Leu, resulting in the formation of angiotensin II, a potent vasoconstrictor. At the same time, ACE removes the C-terminal dipeptide from bradykinin, a potent vasodilator, resulting in the formation of inactive peptide fragments (Inagami 1994).

Milk proteins contain a number of ACE inhibiting peptides encrypted within their primary structures. These peptides are liberated by proteolytic action of extracellular and intracellular enzymes of LAB proteolytic system. Recently several studies surveyed commercial fermented milk products on the European market in regard to ACE inhibitory activity (Hernandez-Ledesma and others 2004, 2005). The moderate inhibition was observed depending on the origin of milk and strains employed. Surprisingly, the ACE activity was not further suppressed by peptides released after additional treatment with pancreatic enzymes. On the contrary, Pihlanto-Leppälä and others (1998) reported that the *in vitro* release of ACE inhibitory peptides from casein or whey by yoghurt cultures required further incubation with pepsin and trypsin. Strains of *Lactobacillus helveticus* appeared to be superior in regard to production of ACE inhibitory peptides in comparison to other species tested (Leclerc and others 2002; Ashar and Chand 2003; Fuglsang and others 2003). Several commercial products containing highly proteolytic strains of *L. helveticus* were developed and products have been marketed as possessing hypotensive activity. One of them, Calpis® sour milk (Calpis Co. Ltd., Tokyo, Japan), is prepared by fermenting milk using mixed culture containing *L. helveticus* CM4 (CP790) and *Saccharomyces cerevisiae*. These organisms are responsible for a release of a range of potent bioactive peptides including two tripeptides, Val-Pro-Pro and Ile-Pro-Pro (Nakamura and others 1995). Another antihypertensive fermented milk is marketed by Valio Ltd. (Finland) under Evolus® brand. The brand covers a range of fruit flavored, sugar-free products produced by fermenting ability of the highly proteolytic *L. helveticus* LBK-16H. The strain produced similar amounts of hypotensive tripeptides as *L. helveticus* CM4, but it substantially delayed the development of hypertension in spontaneously hypertensive rats indicating additional contribution of other product constituents (Sipola and others 2002). Fermented milk produced with *Lactobacillus delbrueckii* ssp. *bulgaricus* and *Lactobacillus lactis* spp. *cremoris* were also shown to contain ACE inhibitory peptides (Gobbetti and others 2000; Ashar and Chand 2004). Only a limited number of human studies have been performed on the antihypertensive activity of commercially available fermented milk products. In 1996, Hata and others (1996) designing a double-blinded placebo controlled study, demonstrated that ingestion of 95 mL per day of fermented sour milk (Calpis®) significantly reduced diastolyc and systolic blood pressure in mildly hypertensive human volunteers. Similar observations were made in other independent studies on the ingestion of fermented milk (150 mL per day) containing similar quantities of hypotensive tripeptides, Val-Pro-Pro and Ile-Pro-Pro, although the overall effect was modest (Seppo and others 2002, 2003; Tuomilehto and others 2004).

51.7 FUTURE TRENDS

It has become evident that fermented milk possesses a range of physiological activities beyond those provided by probiotics, prebiotics and symbiotics. The research is still

ongoing and it is expected to see more biogenic substances identified covering a broader range of activities than encountered today. However, this trend will ensue important questions that should resolve several scientific and regulatory as well as technological issues. The current technological methods may not be adequate to efficiently identify, extract, and concentrate bioactive components calling for innovative and novel techniques. The effect of processing parameters and/or their optimization for an improved functionality of bioactives is largely unknown. The safety of derived peptides and other compounds formed during fermentation needs to be assessed as well. More *in vitro* and *in vivo* animal and human studies are required to fully elucidate the effects of these compounds. The development of new molecular methods is needed to elaborate the mechanism(s) underlying the activity of a wide range of bioactives. Evidently, fermented milk proves to be an important component of diet not only providing for major nutrients but also minimizing risk associated with a range of chronic conditions and diseases.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

52.1 INTRODUCTION

Allergic disorders include a range of health problems including food and drug allergies, allergic rhinitis, allergic conjunctivitis, allergic dermatitis, allergic asthma, and systemic anaphylaxis. Allergies are also referred to as "atopic disorders" (atopy in Greek meaning "unusual"). This historical nomenclature of atopy as unusual conditions contrasts with the present global epidemic of allergies and asthma (ISAAC 1998; Bousquet and others 2004; Johansson and others 2004; Masoli and Beasley 2004).

Based on the time it takes for the clinical reaction to occur following exposure to the inciting agent, Coombs and Gell (1975) originally classified hypersensitivity diseases into four groups: Types I (immediate hypersensitivity), Type-II (cytotoxic reactions), Type-III (immune complex reactions), and Type- IV (delayed or cell mediated reactions). Accordingly, most allergies are generally regarded as Type-I diseases with some drug reactions being Type-II. Notably, although called "contact allergy", reactions to poison ivy or nickel are delayed reactions that belong to Type-IV category. Although allergies in general are regarded as Type-I hypersensitivities, recent advances reveal that atopic eczema, allergic asthma, and food allergies may involve both Type-I and Type-IV components (Johansson and others 2004; Sampson 2004).

Functional foods and nutraceuticals is a rapidly evolving biomedical area focused on finding diet related solutions to a variety of human diseases. Although there is not one universally acceptable definition of these terminologies, in this chapter we would like to use them to indicate the health effects of some foods and nutrients that are beyond their basic nutritive value. Most of the literature on functional foods has used these terms in a positive context of their impact on health. However, inclusion of foods with negative impacts in addition to foods with positive impact on health, in the definition of functional foods would be more holistic. For example, allergenic foods that cause food allergies might be argued as functional foods with negative impact on health.

In this chapter, the current literature on the potential of most commonly studied functional foods and nutraceuticals for use in allergic disorders has been reviewed.

52.2 CLASSIFICATION AND PREVALENCE OF ALLERGIC DISORDERS

In order to reduce the confusion on the actual meaning of various terminologies used in the allergy field, a revised nomenclature for allergy for global use has been recently proposed by the Nomenclature Review Committee of the World Allergy Organization (Johansson and others 2004). A summary of the proposed definitions for various allergy related terminologies including hypersensitivity, allergy, atopy, allergen, and anaphylaxis has been provided in Table 52.1.

The World Allergy Organization (WAO) Nomenclature Review Committee has classified allergic diseases into nine different clinical conditions: asthma, rhinitis, conjunctivitis, dermatitis, urticaria, food hypersensitivity, drug hypersensitivity, insect sting or bite hypersensitivity, and anaphylaxis (Johansson and others 2004).

Although the prevalence of allergic disorders is increasing globally, elevated prevalence has been reported primarily among the industrialized countries (ISAAC 1998). Accordingly, the overall prevalence of allergic rhinitis, asthma and atopic dermatitis in

TABLE 52.1 Newly Evolved Definitions of Allergy Related Terminologies.

Terminology	Definition and Comments
Hypersensitivity	Objectively reproducible symptoms or signs initiated by exposure to a defined stimulus at a dose tolerated by normal persons
Allergy	A hypersensitivity reaction initiated by specific immunologic mechanisms
Atopy	A personal and/or familial tendency, usually in childhood or adolescence, to become sensitized and produce IgE antibodies in response to ordinary exposures to allergens, usually proteins This definition establishes and reconfirms a central role for IgE antibodies as measured in the serum or by a positive skin prick test as key criteria for atopy
Allergen	Antigen causing allergic disease
Anaphylaxis	A severe, life-threatening generalized or systemic hypersensitivity reaction

Source: Johansson and others (2003).

developed countries (United States, United kingdom, Australia, and Canada) ranges from $\sim$10% up to 40%.

Food allergies are also becoming more common, especially in the developed countries. Recent data suggests a 100% rise in the prevalence of peanut allergy during the past decade in the United Kingdom and United States (Grundy and others 2002; Sicherer and others 2003; Sampson 2004). The overall prevalence of food allergies in general has been reported to be at 6% among children and at 3.7% among adults in the United States (Sampson 2004).

Scientific reasons for the dangerous trends of global allergy epidemic are unclear at present with a number of environmental factors being suspected as discussed later in this chapter.

52.3 ALLERGIC DISORDERS: MECHANISMS

Allergies in general are regarded as complex genetic diseases that are known to run in families (Hoffjan and Ober 2002). Several predisposing genes together with a variety of environmental factors appear to interact in many complex ways with the final clinical outcome as allergy or clinical tolerance to allergens.

Earlier observations that hayfever was rare among children born in larger sized family led to the "hygiene hypothesis" that has triggered an enormous amount of basic and applied research in the field with a focus on the role of the environment in allergy (Strachan 1989). Although it is controversial at present, this hypothesis appears to offer a unified framework to explain a number of environmental contributors to allergy development.

A number of environmental factors are suspected to play a role in the rising prevalence of allergies including: (1) environmental pollutants such as diesel exhaust particles, polychlorinated biphenyls, and tobacco smoke; (2) increased use of antibiotics especially during infancy/childhood; (3) reduced exposure to childhood infections; (4) growing up in nonfarming or urbanized environment during early childhood; and (5) alterations in the bowel microbiota due to reduced breast feeding, or use of antibiotics (Strachan 1989; Shirakawa and others 1997; Crane 2002; Diaz-Sanchez and others 2003; Kabesch and Lauener 2004; Kaiser 2004).

Allergic diseases are mediated by the immune system that normally plays a role in host defense. In this case, the immune system reacts to innocuous environmental agents (e.g., food, pollen, animal dander, insect feces/saliva, etc.) in such a way that the outcome is detrimental to the host rather than protection.

Extensive basic research in this area has identified key molecular and cellular factors in the pathogenesis of allergies. These include: IgE class of antibodies, Type-2 (or T-helper-2) cytokines such as IL-4, IL-5, IL-13, Type-2 associated chemokines such as eotaxin, TARC, MCP-4; B cells producing IgE antibodies, T-helper-2 cells, eosinophils, basophils, and mast cells (Gangur and Oppenheim 2000; Campbell and others 2002; Gangur and others 2003; Romagnani 2004).

52.4 FUNCTIONAL FOODS AND ALLERGIC DISEASES

In this section literature on fish oil, probiotics and breast milk as it relates to allergies has been reviewed.

52.4.1 Fish Oil and its Components

Arachidonic acid pathway of fatty acid metabolism plays a key role in the generation of mediators of inflammation such as prostaglandins, thrombaxanes, and leukotrienes. It is generally thought that the metabolic end products of the omega-6 pathway promote inflammation as opposed to the antiinflammatory nature of the end products of the omega-3 pathway of arachidonic acid metabolism. Consequently, in principle, promoting the omega-3 pathway may competitively inhibit the potential of omega-6 pathway mediated promotion of inflammation. One way of accomplishing this goal would be to use omega-3 (or n-3) fatty acids derived from dietary alpha-linolenic acid (18 : 3n-3) or from marine sources such as eicosapentaenoic acid (20 : 5n-3) (EPA) and docosahexaenoic acid (22 : 6n-3) (DHA). The latter fatty acids have been regarded as the active health promoting (or antiinflammatory) components of certain fish oils in particular.

There has been growing interest in the potential of fish oil use for treatment or prevention of allergic and other chronic inflammatory disorders. However, the outcomes from various studies have been controversial (Table 52.2).

In a prospective study examining the capacity of fish oil to prevent development of allergeies, the relation between introduction of fish in the diet during the first year of life, and risk of asthma and allergic rhinitis, was assessed in cohort study of 2531 Norwegian children. The introduction of fish in the diet during the first year of life resulted in the adjusted OR for allergic rhinitis of 0.45 (95% confidence interval [CI] = 0.28, 0.74) and for asthma 0.84 (95% CI = 0.57, 1.22) (Nafstad and others 2003).

A randomized control study examined the impact of dietary supplementation with fish oil for 10 months in 29 children with preexisting bronchial asthma (Nagakura and others 2000). To avoid exposure to pollen, the study was conducted in a long-term treatment hospital set-up. They used fish oil capsules containing EPA (84 mg) and DHA (36 mg), or control capsules containing 300 mg olive oil per day. They concluded that dietary supplementation with fish oil rich in EPA and DHA is beneficial for children with bronchial asthma based on decreased symptom scores and responsiveness to acetylcholine. However, mechanism of action was not studied.

TABLE 52.2 Fish Oil and Allergy: Summary of Major Studies.

Type of Disease	Type of Intervention	Subjects	Conclusion	Reference
Atopy	Level of n-3 PUFA in breast milk and risk of atopy in breast fed infants	Infants (up to 2 years)	Higher n-3 PUFA, DHA and DPA in colostrum associated with *increased* atopy	Stoney and others (2004)
	Plasma n-3 PUFA levels vs. atopy/asthma risk	Adults (~35 years)	Plasma n-3 PUFA are not associated with reduced asthma or atopy	Woods and others (2004)
	Maternal dietary supplements with n-3 PUFA during pregnancy vs. neonatal immune response to allergens	Infants (1 year)	3× less likely to be atopic to egg	Dunstan and others (2003)
	Dietary n-3 FA ± avoidance of HDM of pregnant mothers	Infants (up to 18 months)	No impact on readouts	Mihrshahi and others (2003)
Atopic Dermatitis	Maternal dietary supplements with n-3 PUFA during pregnancy vs. neonatal immune response to allergens	Infants (1 year)	No difference in frequency but less severe disease at 1 year age	Dunstan and others (2003)
	N-3 vs. n-6 PUFA lipid infusion iv	Adults (~23 years)	N-3 improved severity of AD	Mayser and others (2002)
Asthma	Plasma n-3 PUFA levels vs. atopy/asthma risk	Adults (~35 years)	Plasma n-3 PUFA are not associated with reduced BHR	Woods and others (2004)
	Fish oil consumption during first year of life	Children <1 year	Reduced risk of asthma in childhood	Nafstad and others (2003)
	Dietary n-3 FA ± avoidance of HDM by pregnant mothers	Infants (up to 18 months)	9.8% reduction	Mihrshahi and others (2003)
	Cochrane Database Review of Trials from 1986 to 2001	Children & adults	Little evidence in controlling asthma	Woods and others (2002)
	Dietary Supplementation with fish oil (EPA & DHA)	Children	Symptom scores decreased	Nagakura and others (2000)
	Asthma vs. dietary fish oil	Adults	Does not prevent asthma during pollen season	Thien and others (1993)
Hayfever	Fish oil consumption during first year of life	Children <1 year	Reduced risk of allergic rhinitis in childhood	Nafstad and others (2003)
	Dietary supplementation with fish oil in pollen allergic subjects	Adults	Does not prevent symptoms during pollen season	Thien and others (1993)

BHR, bronchial hyperresponsiveness; HDM, house dust mite; PUFA, polyunsaturated fatty acid; EIB, exercise induced bronchoconstriction; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid; AD, atopic dermatitis.

Another study tested the hypothesis that the incidence of asthma and allergy in high-risk children would be reduced by avoidance of HDM allergens, supplementation with omega-3 fatty acids, or the combination of these strategies (Mihrshahi and others 2003). They published the results of an interim analysis reporting outcomes assessed at 18 months. This study involved a total of 616 pregnant women who were randomized to an HDM avoidance intervention (accomplished by the use of impermeable mattress covers and an acaricide) or control and the use of an oil supplement, margarines, and cooking oils containing high levels of omega-3 fatty acids or control. Based on findings of 7.8% absolute reduction in the prevalence of wheeze ($p = 0.04$), they concluded that increasing dietary omega-3 fatty acids might have, beneficial effect. Notably, they found no major effects on serum IgE. Data from the follow-up study at five years is expected.

In contrast to above results, a community based cross-sectional study examining whether dietary n-3 PUFA intake differed between young adults with and without asthma concluded that neither plasma n-3 nor n-6 : n-3 ratio were consistently associated with asthma (as measured by BHR). (Woods and others 2004).

As opposed to numerous studies on asthma, relatively less has been studied in allergic rhinitis and atopic dermatitis or food allergies. One study reported that maternal dietary supplements with n-3 PUFA during pregnancy reduces the severity (but not frequency) of atopic dermatitis among infants born and that the infants are three times less likely to be atopic to egg (Dunstan and others 2003). Others reported that IV n-3-fatty acid administration is effective in acutely improving the severity of atopic dermatitis, paralleled by changes in plasma and membrane fatty acid composition and lipid mediator synthesis (Mayser and others 2002). They recommended further evaluation of long-term effects of this approach.

One study on allergic rhinitis (or hayfever) indicates that fish oil reduced the risk of disease among children (<1 year age) (Nafstad and others 2003). However, another study in adults during pollen season found no preventive effect of dietary fish oil (Thien and others 1993).

With the exception of one, studies examining atopy (i.e., allergen skin prick test positivity or serum IgE) as a readout conclude that n-3 PUFA has either had no impact on atopy (Mihrshahi and others 2003; Woods and others 2004) or higher n-3 PUFA (DHA and DPA) may increase the risk of atopy (Stoney and others 2004).

52.4.2 Probiotics and Allergy

Originally the term "probiotics" was coined to describe factors produced by protozoa that promote the growth of other protozoa (Lilly and Stillwell 1965). Later it was refined to refer to "a live feed supplement which beneficially affects the host animal by improving its microbial balance" (Fuller 1989).

Others have recently proposed a series of desirable criteria for probiotics to be useful in promoting health (Heyman and Menard 2002; Laiho and others 2002). These include: (1) resistance to acid and bile; (2) human origin; (3) ability to adhere to the intestinal epithelial cells; (4) ability to colonize and persist for long periods of time in the gut; (5) to produce antimicrobial substances; (6) to modulate immune responses; (7) desirable technological characteristics such as resist technological processes, good shelf life, etc.; (8) documented health benefits; and (9) safety. Notably, not every one in the field accepts whether all these criteria should constitute the definition of probiotics.

TABLE 52.3 Common Probiotic Bacteria for Potential Use in Functional Foods.

Genus	Species[a]
Bifidobacterium	*B. bifidum*
	B. longum
	B. adolescentis
	B. breve
	B. infantis
	B. lactis
Lactobacillus	*L.acidophilus*
	L. rhamnosus
	L. rhamnosus GG
	L. gasseri
	L. reuteri
	L. bulgaricus
	L. plantarum
	L. johnsonii
	L. lactis
	L. paracasei
	L. casei
	L. salivarius

[a]Boxed probiotic species have been tested in human allergic diseases.

Most frequently used probiotic microorganisms, typically in fermented dairy products, belong to the genuses *Lactobacillus*, *Bifidobacterium*, and *Steptococcus.* Common examples of species of probiotics are summarized in Table 52.3.

Potential application of probiotics in allergic diseases stems from the following two fundamental principles: (1) Population based studies (primarily epidemiological studies) suggest that increased exposure to bacteria early in life may have protective effects against allergies although the true nature of these bacterial species is unclear at present (Crane 2002; Prescott 2003; Kabesch and Lauener 2004). Probiotics are one set of candidate bacterial species implicated. (2) Certain probiotic bacteria have been shown to affect the immune response of the host in animal models and *in vitro* studies. For instance, some may modulate immune cell functions (Vaarala 2003) (Pestka and others 2001; Tejada-Simon and others 1999a,b). Since allergies are immune mediated diseases, probiotics offer promise in this context (Romagnani 2004).

These principles are supported by the following recent evidence: (1) Some clinical studies have shown that use of probiotics may help reduce the severity and frequency of atopic eczema in infants (Table 52.4) (Majamaa and Isolauri 1997; Isolauri and others 2000; Kalliomaki and others 2001, 2003); (2) use of antibiotics (presumably with consequent reduction or elimination of gut microflora) in infants is associated with increased allergies (Crane 2002; Wickens and others 1999); (3) some studies suggest that gut microflora of atopic vs. nonatopic subjects may differ in composition with the levels of *Clostridia* increased and the *Bifidobacterium* reduced among atopics (Kalliomaki and others 2001; Kirjavainen and others 2001; Ouwehand and others 2001; Laiho and others 2002).

Not all studies on the use of probiotics in allergy have revealed promise in treatment or prevention. Thus, one study found no significant changes in asthma during treatment with *Lactobacillus acidophilus* (Wheeler and others 1997). Another study found no

TABLE 52.4 Probiotics: Evidence for Potential Application in Atopic Eczema.

Type of Intervention	Outcome	Reference
Cow's milk formula fortified with *Lactobacillus rhamnosus* (strain GG)	Significant improvement in the clinical score of atopic eczema	Majamaa and Isolauri (1997)
Whey formula with *Bifidobacterium lactis* (Bb-12) or with *L. rhamnosus* (strain GG)	Significant improvement in the severity of atopic eczema	Isolauri and others (2000)
L. rhamnosus (strain GG) to infants or to mothers who breastfed their infants	Significant reduction in the incidence of atopic eczema during infancy (first two years of life)	Kalliomaki and others (2001)
L. rhamnosus (strain GG) to infants or to mothers who breastfed their infants	Preventive effect of the probiotic on atopic eczema extends beyond infancy (as assessed at four years of age)	Kalliomaki and others (2003)

major differences in symptomatic scores in allergic rhinitis/asthma when treated with *Lactobacillus rhamnosus* (Helin and others 2002).

While the reasons as to why probiotics were beneficial in some studies but not in others are not clear at present, there are a number of differences to consider: (1) age group of subjects (children vs. adults/adolescents); (2) species and strains of probiotic used (*Lactobacillus GG* vs. *L acidophilus*); and (3) the type of allergic disease readout tested (atopic eczema vs. allergic rhinitis/asthma). Clearly more studies are needed to replicate the above findings while addressing these potential variables.

52.4.3 Breast Milk: A Natural Functional Food Against Allergic Disorders?

Breast milk is the first wholesome food that the baby is expected to consume in a natural setting. Although breast milk is considered to be a food in general, available evidence in the literature would argue that it is a natural 'functional food' designed for the overall health and development of the baby. This is because, breast milk is enriched in not only food related components and nutrients but also a variety of immunoregulatory molecules as well as immune cells (Table 52.5) (Skansen-Saphir and others 1993; Kalliomaki and others 1999; Bottcher and others 2000, 2002; Hawkes and others 2002; Takahata and others 2003).

TABLE 52.5 Allergy Relevant Immunomodulators Present in Human Breast Milk.

Immunomodulator Group	Examples
Cytokines	IL-4, IL-5, IL-10, IL-13, IFN-γ, TGF-β1/β2,TNF-α
Chemokines[a]	CXCL8 (IL-8), CCL5 (RANTES), CCL11 (Eotaxin), CXCL10 (IP-10)
Lipid mediators	PGE2, LT
Antibodies	IgA1, IgA2

IL, interleukin; IFN, interferon; TGF, transforming growth factor; TNF, tumor necrosis factor; PG, prostaglandin; LT, leukotriene; IP, interferon inducible protein; RANTES, regulated upon activation naturally T cell expressed and secreted; Ig, immunoglobulin.

[a]Old names are indicated in parentheses.

The question of whether breast milk is protective against allergic disorders in particular has been addressed for more than two decades with equivocal evidence. There are several hypotheses related to breast milk and allergy that involve both protection as well as sensitization. One the major hypotheses in this area is that elevated levels of IgA antibodies bind to potential allergens in the infant's gut and facilitate their elimination, thereby preventing sensitization. This is supported by reports that low colostral IgA is associated with cow's milk allergy (Bottcher and others 2002; Savilahti and others 1991). Additional hypotheses implicate a role for immunomodulating molecules in breast milk such as cytokines in allergy (Skansen-Saphir and others 1993; Kalliomaki and others 1999; Bottcher and others 2000, 2002; Hawkes and others 2002; Takahata and others 2003) (Table 52.5).

There is evidence that exclusive breast feeding for four to six months is associated with reduced occurrence of eczema and asthma (Oddy and others 1999; Romieu and others 2000; Chandra 2002; Fiocchi and others 2003), although one study reports lack of such evidence (Rust and others 2001). Notably, this protection appears to be impaired by addition of cow's milk or soy formula to the diet (Chandra 2002a,b).

Food allergens such as peanut allergens can be passed on from the mother's circulation to the breast milk (Vadas and others 2001). Therefore, there is growing concern that breast milk may contain potentially hazardous sensitizing allergens that may pose a risk for the development of allergies among breast fed infants. Consequently, it may be prudent for pregnant/nursing mothers to avoid consumption of well established allergenic foods such as egg, peanut, tree-nuts, fish, and soy (Chandra 2002a,b; Fiocchi and others 2003).

There appears to be a general agreement that the late introduction of solid foods beyond six months after birth may delay/prevent development of allergies (Chandra 2002a,b; Fiocchi and others 2003). The mechanism of how this dietary method may prevent/delay allergies is unclear, but may be related to the immature gut physiology/immunology of the infants.

There has been enormous interest in developing hypoallergenic infant formulae. This approach is based on the principle that breaking-up of larger protein molecules into smaller pieces might eliminate the critical "epitope" structure required for immune recognition and allergy development. Accordingly, there is evidence that elemental or extensively hydrolyzed formulae may be of tremendous value in the management of food allergy (Agostoni and Haschke 2003).

52.5 NUTRACEUTICALS AND ALLERGY

The concept that certain nutrients may impact allergic disorders because of their antioxidant and/or immunomodulating properties continues to be explored. This is based on two underlying principles: (1) allergic disorders such as asthma and atopic dermatitis (AD) are associated with increased oxidative stress in the host (Kelly and others 1999; Antille and others 2002); and (2) allergic disorders result from overactive immune responses of particular types (e.g., T helper 2 dominated) (Gangur and Oppenheim 2000; Campbell and others 2002; Gangur and others 2003; Romagnani 2004).

These ideas have translated into a variety of investigations focused on three basic approaches: (1) to evaluate whether there is a fundamental *in vivo* deficiency of certain nutrients in asthma and AD; (2) to test the impact of dietary supplementation of such

nutrients on the disease; and (3) basic studies to evaluate the impact of selected nutrients on oxidative stress and immune functions using cell line and animal models. In this section we will restrict our discussions primarily to findings from human clinical studies.

52.5.1 Minerals

Common minerals examined in context of allergies and asthma includes: zinc, magnesium, and selenium. Certain minerals form part of the natural antioxidant defense mechanism of the body. Zinc, copper, and manganese are components of super oxide dismutase; and selenium is a component of glutathione peroxidase. Consequently much interest has been to evaluate the *in vivo* status of these minerals in allergy.

It is well known that the deficiency of zinc can result in dermatitis. Consequently, the role of zinc in atopic dermatitis has been studied. Zinc is often used in skin ointments and creams with clinical benefit. Although studies reveal reduced levels of zinc in the serum of children with atopic eczema (David and others 1984), others report no significant impact of oral zinc supplementation on atopic dermatitis (Ewing and others 1991).

Studies using a magnesium deficient mouse model revealed a role for this micronutrient on the host inflammatory and immune responses as well as apoptosis (Tam and others 2003). Fantidis and others (1995) have proposed that magnesium inhibits contraction of bronchial smooth muscle and histamine release – two key pathogenic functions involved in asthma (Fantidis and others 1995). Another study has shown that intravenous magnesium supplementation could alleviate symptoms in acute as well as chronic asthma (Monteleone and Sherman 1997). There is a study reporting that intracellular Mg decreases in leukocytes on the first day of asthma attack, but after five days of anti-asthma therapy (with salbutamol), these levels return to normal values (Mircetic and others 2001).

Inhaled magnesium has been shown to inhibit methacholine-induced bronchoconstriction (Rolla and others 1987). A large scale study of adults ($n = 2633$) in the United Kingdom found that increased intake of Mg (100 mg/day) resulted in decreased symptoms of asthma as reported by the patients (Britton and others 1994). In a small study, magnesium picolinate oral administration three times a day for one month to subjects with hayfever appeared to be beneficial, although a larger study is warranted to further evaluate this (Cipolla and others 1990).

The above results are in contrast to a recent negative outcome from a randomized, placebo-controlled, double-blind parallel group trial of 16 weeks supplementation with 450 mg/day magnesium chelate or matched placebo in 300 asthma patients aged 18–60 years with physician-diagnosed asthma (Fogarty and others 2003).

Examination of the blood of asthma patients has revealed reduced levels of selenium as opposed to controls (Stone and others 1989; Kadrabova and others 1996; Misso and others 1996). One study examining 100 mg of sodium selenite daily for 14 weeks revealed subjective improvement in asthma (Hasselmark and others 1993). However, another study showed no effect on the clinical severity of atopic dermatitis (Fairris and others 1989).

Thus, there is controversial evidence on the role of micronutritents as a therapeutic agent for allergies and asthma. Although there is some potential based on some studies with positive findings, more studies are needed to make a definitive conclusion on the utility of micronutrients in the treatment of allergies and asthma.

52.5.2 Vitamins

Vitamin C, vitamin E and alpha-carotene are implicated in allergies and asthma primarily because of their antioxidant activities. Many have examined the serum profile of antioxidants in patients with asthma or allergies. Thus, in one study asthma diagnosis was associated with lower levels of serum vitamin C, alpha-carotene, beta-carotene, and beta-cryptoxanthin (Harik-Khan and others 2004).

Studies examining the impact of vitamin C on exercise induced asthma, skin, and nasal allergy have all failed to reveal a significant impact on the disease (Britton and others 1995; Fortner and others 1982). Kaur and others (2001) performed a systematic review of literature on the role of vitamin C in asthma and concluded that evidence from randomized-controlled trials is insufficient to recommend a specific role for vitamin C in the treatment of asthma (Kaur and others 2001).

There has been more promising data on the impact of vitamin E on allergies and asthma. A large study (77,866 women) examined the incidence of asthma and intake of vitamin E via diet vs. supplements over a 10-year period. Women in the highest quintile of vitamin E intake from diet, but not from supplements, had a risk of 0.53 (95% confidence interval [CI] = 0.33–0.86) compared with women in the lowest quintile. This suggests of a modest protective effect of vitamin E from the diet (Troisi and others 1995).

More recent studies have revealed the following: (1) higher concentrations of vitamin E intake were inversely associated with serum IgE and lower frequency of atopy (Fogarty and others 2000); (2) Nagel and others (2003) reported that increasing intake of vitamin E had a protective effect on hay fever (OR: 0.38; n = 334 test vs. 1336 control subjects) especially among women and ex/current smokers (Nagel and others 2003); (3) another study concluded that the correlations between vitamin E intake (400 IU/day), IgE levels, and clinical symptoms indicates that vitamin E could be an excellent therapeutic tool for atopic dermatitis (Tsoureli-Nikita and others 2002); and (4) another study suggested that vitamin E intake may reduce adverse effects of air-pollutants such as ozone in subjects with asthma (Trenga and others 2001; Romieu and others 2002).

Thus, studies have revealed potential for the use of zinc, magnesium, selenium, and vitamin E in specific types of allergy phenotypes. It is also possible that other phytochemicals with antioxidant activities might be beneficial in these diseases. In this context, intake of 30 mg/day of lycopene for one week had significant protective effects against exercise induced asthma (Neuman and others 2000). Thus, there is wide scope for more research on the topic and more exciting discoveries are likely to be on the horizon.

52.6 SUMMARY, CHALLENGES, AND FUTURE DIRECTIONS

The current status of the field supports the concept that there is strong potential for certain probiotics, fish oil (specifically its constituents EPA and DHA), some minerals (zinc, magnesium), and vitamin E, to serve as components of novel anti-allergy functional foods with potential preventive and/or therapeutic applications (Fig. 52.1).

There are a number of challenges that this exciting research area faces including but not limited to the following: (1) Allergic disorders are a complex group of diseases; therefore, it is possible that specific nutraceutical/functional foods will not necessarily be applicable to all types of allergies. Consequently, studies need to be carefully designed, evaluated and interpreted so that the specific combination of nutraceuticals/functional foods could be used for appropriate types of allergies. For example, *Lactobacillus GG* may be useful in

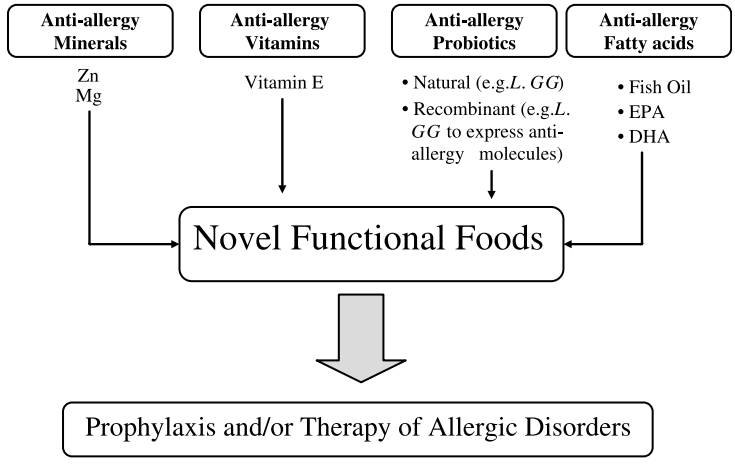

Figure 52.1 *An overview of the approach to develop novel functional foods for potential prophylaxis and/or therapy of allergic disorders.*

atopic dermatitis but unlikely to be useful in allergic rhinitis (Kalliomaki and others 2001, 2003). Similarly recent findings report that breast feeding was protective against some asthma phenotypes but not hay fever, atopic eczema or IgE (Karmaus and others 2003). (2) There is enormous amount of work ahead to establish variables including effective vs. toxic dose-ranges (for vitamins, minerals, EPA, DHA), effective combination of different nutraceuticals/functional foods, matrix effects, route of administration, impact of food processing, duration of intervention, and age and gender dependent differences. (3) It is unlikely that any novel preventive and therapeutic approach would be widely accepted unless underlying mechanisms of action (especially impact on relevant immune functions) is clearly demonstrable. Clearly, *in vitro*, animal model and human immune function studies should prove useful to address this issue.

Thus, despite several challenges, the area of functional foods and nutraceuticals vs. allergy is poised to make significant changes in the way we perceive food, diet, and human health in the 21st century.

ACKNOWLEDGEMENTS

The author's laboratory is supported by funding from the Michigan State University (MSU), MSU Foundation, Gerber Companies Foundation and the United States Environmental Protection Agency. Author would like to thank: Mr. Caleb James (Michigan State University) for assistance with manuscript preparation; Dr. Zey Ustunol (Michigan State University), Dr. Kent HayGlass and Ms. Sherry (University of Manitoba), and Dr. Hayu Ni (University of Toronto) for critical reading of this manuscript.

53.1 INTRODUCTION

In 1991, the Japanese Ministry of Health and Welfare first used the term "Foods for Specified Health Use" (FOSHU), a concept that was further coined by functional food in a Nature's article (Arai and others 2002). Functional food is considered any food able to enhance body functions improving health and decreasing disease risk. Detailed description regarding the concepts was done in Chapter 1.

Cognitive decline, cardiovascular disease, oxidative stress, inflammation, hypertension, and studies with health centenarians comprise important topics on aging research and practice (Pahor and Applegate 1997; Morley 2004).

A successful life span depends on many biological strategies to foster cell survival and preserve against many pathological stimuli. For useful purposes, biochemical and physiological protective pathways provided by functional foods can be separated in specific and nonspecific antiaging mechanisms.

53.2 SPECIFIC ANTIAGING MECHANISMS

As the study of functional foods is very recent, many controversial aspects could arise and the matter is far from a consensus. However, specific antiaging mechanisms of functional foods were recently suggested (Ferrari 2004) and are summarized in Table 53.1.

53.2.1 Antioxidant Activities

Antioxidant defense is essential to provide resistance against increased levels of oxidative stress biomarkers during the aging process (Ames and others 1993; Beckman and Ames 1997; Berllett and Stadtman 1997). Reinforcing the antioxidant-life span relationship, higher levels of vitamin A and E were found in human healthy centenarians (Mecocci and others 2000). Although some studies regarding antioxidant supplementation have reported positive effects on organisms' longevity, results are conflictive. Rather than increasing life span, antioxidants' benefits are related to the control of free radicals and mitochondrial stabilization that negatively influence healthy aging (Driver 2003; Le Bourg 2003).

Since oxidative stress induces both apoptosis (or programmed cell death) and necrosis (accidental cell death) leading to neuronal, cardiovascular, hepatic, ocular, renal, and other massive cell and tissue losses (Ferrari 2000a,b), antioxidant protection seems to be an essential protective antiaging strategy. Aging compromises mitochondrial membrane stability increasing cytochrome c releasing and reactive oxygen species (ROS) overload (Yan and Sohal 1998; Ferrari 2000a,b; Kokoszka and others 2001). Ishii and others

TABLE 53.1 Antiaging Specific Mechanisms Performed by Functional Foods.

Cellular and Molecular Activities	Cell Targets	Biomarkers
Antioxidation	Decreasing lipid peroxidation of cell membranes	Phospholipid bilayer; Mitochondrial external membrane (cytochrome c) and Bcl-2 protein
	Estimulation of the intracellular antioxidant defense systems	Antioxidant-response element (ARE), SOD, catalase, GSH, GPX, hemeoxygenase, GST, etc.
	Genome protection against reactive species (from oxygen, nitrogen, chlorine)	Oxidized DNA biomarkers
Antiapoptotic	Avoid membrane disruption and triggering of cell death machinery	Membrane death domains; Cytochrome c;
		Expression of Bcl-2 and other survival factors
Metal chelation	Chelation of iron, copper, and zinc excess to avoid mitochondrial damage and DNA oxidation	Cytochrome c; DNA oxidation products
Proapoptotic	Disruption of antioxidant defense and activation of apoptosis in oncogenic cells	Blockade of ARE; Cytochrome c releasing; Caspase activation
Mitochondrial stabilization	Protection of mitochondrial structures against damage	Apoptotic markers;
	Enhancement of mitochondrial function	ATP synthase activity, etc.

(2004) demonstrated that coenzyme Q_{10} and vitamin E, potent antioxidants, and mitochondrial stabilizers, had prolonged life span of *Caenorhabiditis elegans* worm by decreasing oxidative stress-induced apoptosis. The same protection is performed by melatonin (Reiter and Tan 2002).

Besides displaying an efficient control of cell death, antioxidants can provide two other protective mechanisms: (1) triggering expression of antioxidant genes (expression of superoxide dismutase enzyme, SOD); and (2) limiting LDL cholesterol oxidation in blood (Ferrari 2001).

53.2.2 Aging Impairs Cardiac and Vascular Functions

Health centenarians' studies have interestingly revealed that in successful aging cardiovascular control is essential, since they have higher HDL cholesterol levels and lower blood pressure than common elderly people (Morley 2004; Zyczkowska and others 2004), and their children have substantially reduced risks of diabetes, hypertension, and heart disease (Perls and Terry 2003).

Recently, it was observed that aging humans have increased levels of endothelin-1 (ET-1, a 21-residue vasoconstrictor peptide), a risk factor for high blood pressure, but execution of aerobic exercises programs reduced ET-1 and normalizes blood pressure (Maeda and others 2003). Corder and others (2001) reported that red wines strongly

inhibited ET-1 synthesis. Aging and hypertension have impairing effects on endothelial-dependent relaxing capacities, decreasing blood flow to important target organs, such as brain (Hongo and others 1998). Aged rats had lowered endothelial vasodilation capacity due to cycloxigenase (COX-2) activation and thromboxaneA_2 releasing (Heymes and others 2000). Reversion of vasodilation impairment is one important pharmacological effect of *G. biloba* and polyphenolics in neuroprotection.

53.2.3 Metal-Chelating Activities

In Alzheimer's disease (AD), massive iron loading is responsible for neuronal damage though Fenton-derived DNA oxidation and (β-amyloid formation (Smith and others 2000). Iron overload is also implicated in autoimmunity disorders and brain damage in autism, where lipoic acid supplementation seems to be beneficial (Padhye 2003). Clioquinol, a metal chelator that cross blood brain barrier, has been successfully used to treat AD (Barnham and others 2004). Natural polyphenolics are able to chelate metals. Quercetin, rutin, catechins, sesamol, caffeic, ferulic, and tannic acids present high antioxidant activities and metal-chelating properties (Chen and Ahn 1998; Lopes and others 1999). Myricetin and quercetin flavonoids are best copper and iron chelators (Mira and others 2002). However, iron deficiency, found in aging, anemia and vitamin B_6 deficiency, also seriously compromises mitochondrial functions contributing to neuronal death (Atamna and others 2002). Table 53.2, summarizes important antiaging functional foods.

53.3 NONSPECIFIC ANTIAGING MECHANISMS

53.3.1 Preventing Cataract and Eye Macular Degeneration (MD)

Macular pigment is constituted by vitamin A, lutein, and zeaxanthin, carotenoids that protect eye by means of ultraviolet light filtration, free radical scavenging, and protection of cell membrane lipids (Moeller and others 2000; Olson 1999). Other carotenoids such as lycopene and β-criptoxantine also quench ROS, especially singlet oxygen, decreasing the risk of MD (Olson 1999). Riboflavin, vitamins C and E can also lower cataract's risk, whereas iron has opposite effects (Bunce 1993; Garner and others 1999).

A case-control study in Burjassot (Spain) revealed that high plasma vitamin C levels ($>$49 μmol/L) were associated with 64% reduction of cataract risk, although intermediary tomato lycopene levels were also associated with decreased disease risk (Valero and others 2002).

The dietary intake of carotenoids, especially lutein and zeaxanthin found in spinach, broccoli, and eggs, was strongly related with lowered risk of cataract and MD (Moeller and others 2000); the *Nurses' Health Study* confirmed these results, although reported a lack of association regarding cataract and dietary intake of other carotenoids (α-carotene, β-carotene, lycopene, and β-criptoxantine) (Chasan-Taber and others 1999). However, Lyle and others (1999) did not find inverse association between carotenoids and risk of cataract, whereas tocopherol has been protective against cataract. Dietary intake of three or more portions of fruit was inversely associated with MD risk (relative risk = 0.64) in comparison to the low consumption group (Cho and others 2004).

TABLE 53.2 Antiaging Biological Mechanisms and Representative Classes of Functional Food Bioactive Compounds.

Mechanisms	Bioactive Compounds	Food Source
Antioxidants	Flavonoids (apigenin, kaempferol, luteolin, myricetin, quercetin, lycopene)	Onion, garlic, tomato, fruits, and vegetables
	Polyphenols	Grapes (juices), wines, berries, apples, cocoa and chocolate, eggplant, teas, etc.
	Curcuminoids	Turmeric
	Monounsaturated fatty acids	Oils and seeds
	Phytosterols (genistein & daidzein)	Soybean
	Tocopherols	Oils and seeds
Antiapoptotic agents	Ascorbic acid	Citrus and other fruits *Ginkgo biloba*
	Egb761 extract (quercetin, kaempferol, isorhamnetin, and bilobalide, a terpene lactone)	Polyphenol rich foods
	Gallic acid	
Metal chelators	Phenols, polyphenols, and their acids (quercetin, rutin, catechins, sesamol, caffeic, ferulic, and tannic acids)	Grapes and wine
Proapoptotic agents	Artellipin C	Brazilian propolis
	Butyrate	Vegetable fibers
	Catechins	Tea polyphenols
	Genistein	Soy
	Indol-3-carbinol	Cruciferae vegetables (broccoli)
	Isoprenoids, terpenoids, and tocotrienols	Vegetable oils (olive oil), nuts (Brazil nuts, cashew nuts, almonds, etc.), and seeds
	Isothiocyanates	Cruciferae
	Fish oils	Fish oil
	Retinoids (vitamin A-related)	Vitamin A rich foods (oils, dark green leaf vegetables, and fruits)
	Polyphenols	Persimmon (*Diospyros kaki*), green teas, wine, berries, and purple fruit
	Protopanaxadiol	Metabolites from ginsenosides (Rb1/Rb2/Rc)
	Organosulfur compounds	Garlic and onion
Mitochondrial stabilizers	Carnosine (β-alanyl-L-histidine)	Muscle foods
	Coenzyme Q_{10} (ubiquinone)	Soy oil, colza seed oil, mackarel fish, sesame seed oil, meat, peanut, pork meat, fish filet, chicken, and nuts
	Melatonin	*Scutellaria biacalensis* (Huang-qin), *Hypericum perfuratum* (St. John's wort), fever few, mustard, and fenugreek seeds
	Lipoic acid	Meat, liver, and heart
	Nicotinamide	Meats, grains, beans, fish, milk, eggs, seeds, vegetables
	n-3 fatty acids	Fish (tuna, mackerel, salmon), canola (rapeseed) and flax-seed oils, flaxseed, and nuts.
	Tocopherol	Oils (olive) and seeds

53.3.2 Cardiovascular Protection

Scavenging free radicals produced during ischemic conditions constitute one of the most important cardiovascular benefits of antioxidant phytochemicals, vitamins, and minerals in foods (Hu and others 1998; Ferrari 1998; Chopra and others 1999; Block and others 2001; Cui and others 2002; Couture 2002; Ferrari 2004).

Blood cholesterol lowering effects represent another important mechanism to protect against cardiovascular diseases. Vegetable and fruit fibers (with pectin), and garlic have hypocholesterolemic effects in humans through partially inhibition of absorption than suppression of hepatic cholesterol synthesis by blocking of hydroxymethylglutaryl-CoA reductase enzyme (Lampe 1999).

Antioxidant vitamins, whole grains, and phytochemicals also protect vascular systems in heart and brain against homocysteine, and independent vascular risk factor (Broekmans and others 2000; McKeown and Jacques 2001; Matson 2003).

Intake of flavonoids, from apples and onion, has been associated with decreased cardiovascular mortality (Knekt and others 1996). Within the cardiovascular protective mechanisms of flavonoids, inhibition of platelet aggregation, increasing of nitric oxide synthesis, and lowering of superoxide production seems to be important (Freedman and others 2001). Ginseng increases antioxidant SOD expression in vitro (Kim and others 1996), induces vascular relaxation and hypotensive effects (Li and others 2001; Couture 2002), which can benefit both cardiac and neurovascular domains. Cardiovascular protective functional foods are summarized in Table 53.3.

TABLE 53.3 Protective Cardiovascular Mechanisms of Functional Foods.

Biological Mechanism	Bioactive Compound(s)	Food Sources
Decreasing of blood cholesterol	Tocopherols, n-3 fatty acids, phytosterols and others	Almonds and nuts (cashew, Brazil)
	Organosulfur compounds	Garlic
	Phytosterols	Margarine
	Omega-3	Fish oil
	Fiber and phytochemicals	Oat cereal
	Genistein and daidzein	Soy
	Eritadenine	Shiitake mushrooms
Inhibition of LDL cholesterol oxidation	Carotenoids	Green leafy vegetables, fruits, and palm oils
	Lycopene-rich foods	Tomato, tomato juice, spaghetti sauce, and tomato oleoresin
	Polyphenolics and monounsaturated fatty acids	Extra-virgin olive oil
	Tea polyphenolics	Green tea
Decreasing blood pressure	Ascorbic acid	Citrus fruits
	Ginsenosides	*Panax Ginseng*
	Quercetin	Onion and garlic
	Tea polyphenols (theaflavins)	Green and black teas
	Unknown (polyphenolics?)	*Psidium guajava* (guava leaves)
Avoiding ischemic-hypoxic myocardial injuries	Curcumin	*Curcuma longa* (turmeric)
	Unknown (polyphenolics?)	Grapes and propolis
Decreasing homocystein	Folate	Fruits, grains, and vegetables
	Vitamin C	Citrus fruits and vegetables
	Vitamin E	Nuts, seeds, and oils

53.3.3 Neuroprotection by Herbs and Functional Foods

Considerable evidence has pointed out that higher intake of vegetables, fruits, and seeds rich in vitamin C, carotenoids and vitamin E are positively associated with better cognitive function and decreased risk of dementia in the elderly (Bates and others 2002; Berr 2000; Youdim and Joseph 2001). An important contribution from the Rotterdam study is that people with higher intake of vitamin C, vitamin E, beta-carotene, and flavonoids had diminished the risk of AD (Engelhart and others 2002).

The pharmacological properties *G. biloba* comprise blood flow enhancing, scavenging of ROS, inhibition of platelet aggregation, protection of striatal dopaminergic system, and inhibition of monoamine oxidase (Bastianetto and others 2000; Louajri and others 2001; Youdim and Joseph 2001). Efective and commonly used in Germany (Wagner 1999; Ernst 2002), *G. biloba* can induce brain hemorrhage as side effect (Vale 1998). Bilobalide a *G. biloba* compound, protected against both ischemic-induced and glutamate-induced neuronal cell deaths (Chandrasekaran and others 2003). Although ginseng has improved memory performance in animals (Youdim and Joseph 2001), it did not enhance brain performance in humans (Ernst 2002). Omega-3 fatty acids (Song and Horrobin 2004) can improve multiple sclerosis pathogenesis (Mayer 1999). Vitamin E (Ortega and Horrobin 2002), carnosine (Hipkiss 2000; Holliday and McFarland 2000), tea polyphenols (Skrzydlewska and others 2002), broccoli isothiocyanates, lipoic acid (Drukarch and others 2001), and tomato (Suganuma and others 2002) can also protect against neurodegeneration. By preventing homocysteine overload, slowing down its oxidative potential, folate can efficiently repair DNA and maintain neuronal integrity, which means decreased risk of neurodegeneration (Mattson 2003; Morley 2004).

53.3.4 Anticancer Activities

Anticancer functional foods can induce (Ferrari and Torres 2003; Kelloff and others 2000): (1) apoptosis of cancer cells; (2) antioxidant protection of DNA; (3) decreasing of oxidative stress and inflammation; and (4) antiangiogenesis.

Anticancer foods and their protective mechanisms are listed in Table 53.2 and above-mentioned.

53.4 FUNCTIONAL FOODS AND HERBS: TOWARDS A HEALTHY DIET

53.4.1 Fish, Fish Oil, and Olive Oil

Fish and fish oils can be beneficial to decrease cancer's risk. In a rat model of azoxymethane-induced colon carcinogenesis, intake of fish oil increased cell proliferation, and apoptosis of colon cells, mechanisms that could avoid colon carcinogenesis (Chang and others 1998). Fish oil, rich in n-3 fatty acids, is responsible for lower degree of cellular rectal proliferation (Biasco and Paganelli 1999). Myocardial infarction was partially reversed by fish oil intake, which improved mitochondrial respiratory functions, partially abrogating lipid peroxidation, lactate production, calcium release, and phospholipase activities (Padma and Devi 2002).

In azoxymethane-induced colon carcinogenesis, rats fed an olive oil rich diet had less aberrant crypt foci and prostaglandin E_2 levels than carcinogen-treated group (Bártoli and others 2000). Olive oil also increases nitric oxide production and decreases prostaglandin synthase-2 in resident macrophages (Moreno and others 2001). Higher dietary intake of olive oil and olive oil cooked vegetables strongly decreased the risk for rheumatoid arthritis in a Greek population (Linos and others 1999). However, Pedersen and others (2000) reported that olive oil increased LDL cholesterol in humans. Notwithstanding, fish oil intake has adverse health effects. Its consumption can increase the risk of bleeding disorders and worsen *Listeria monocytogenes* liver and spleen infections (Irons and others 2003).

53.4.2 Soy Foods: A Look to the Orient

In a mice model of carcinogenesis, dietary intake of soy foods reduced tumor cell proliferation, increased apoptosis, and reduced microvessel density, effects associated with decreased levels of insulin-like growth factor-I, an angiogenic protein (Zhou and others 1999). Soy food and phytoestrogens consumption is associated with many beneficial actions such as antioxidant activities (Wiseman 1996), induction of breast cancer cells apoptosis (Katdare and others 1999), and decreased toxicity of xenobiotic metabolites (Kelloff and others 2000; Xu and others 2000). High intake of soy foods during adolescence was inversely associated with breast cancer risk with a lowering of 65% in risk of this cancer (Shu and others 2001). Unfortunately, soy genistein appears to favor *C. albicans* growth (Yazdanyar and others 2001), a fact that deserves more research and attention from doctors and nutritionists.

53.4.3 Cocoa and Chocolate

Cocoa and dark chocolate have high antioxidant activity, protects LDL from oxidation and decrease platelet aggregation, protecting against heart and vascular diseases (Kondo and others 1996; Rein and others 2000; Richelle and others 2001; Wan and others 2001). These foods can protect genome against mutations (Yamagishi and others 2001).

53.4.4 Calcium and Vitamin A: New Functions for "Old" Nutrients?

Calcium is currently being tested as antineoplastic drug, once it diminishes hyperproliferation of colon cancer cells, decreasing cancer (Lipkin 1999; Kelloff and others 2000). Calcium inhibits ornithine decarboxilase activity, decreases the mutation rate of *ras* (a gene involved in proliferative responses), and promotes the formation of insoluble complexes with bile and fatty acids, decreasing proliferative and irritative effects on intestine (Lipkin 1999; Ferrari and Torres 2002).

Originary from vitamin A or synthesized by human body, retinoids can modulate cell proliferation, differentiation, and apoptosis, decreasing carcinogenesis, effects controlled by six different human nuclear retinoid receptors, grouped as retinoic acid receptors (RAR) and retinoid X receptors (RXR) (Lippman and Lotan 2000). In a rat experimental model of hepatocarcinogenesis, vitamin A and *all trans* and *9-cis* retinoic acids inhibit cell proliferation and oncogenesis (Silveira and others 2001), confirming the anticarcinogenic role of carotenoids and vitamin A in human breast cancer (Zhang and others 1999).

53.4.5 Curcumin (Diferuloylmethane)

Curcumin from turmeric (*Curcuma longa*), an Indian spice very used in oriental culinary, is able to inhibit nuclear factor-kappa-beta (NFκB) activation (Singh and Aggarwall 1995), which is associated with suppression of cell proliferation including inflammatory processes. Curcumin induced apoptosis of promyelocity leukemia HL-60 cells, an effect mediated by increasing intracellular ROS and partial inhibition of Bcl-2 protein (Kuo and others 1996). Antiinflammatory effects (mediated by inhibition of cycloxigenase-2, which is involved in prostaglandin synthesis), xenobiotic detoxifying mechanisms and induction of colon cancer cells apoptosis also constitutes biological properties of curcumin (Manson and others 2000). It also helps to metabolize carcinogens by activation of quinone reductase, an enzyme from cytochrome P450 complex (Dinkova-Kostova and Talalay 1999), and induces expression of the potent antioxidant enzyme heme-oxygenase (Scapagnini and others 2002).

53.4.6 Propolis: An Aid from Bees?

Propolis was used by ancient Egyptians to embalm mummies and has many bioactive compounds, such as flavonoids (flavones, flavonols, flavonones), caffeic acid phenetyl ester (CAPE), terpenoids, and other aromatics, fatty acids, phenols, aminoacids, vitamins (A, B1, B2, B6, C, and E), and minerals (Mn, Cu, Ca, Al, Si, Ni, Zn, and Cr), which explains its antibiotic, antitrypanosomal, antiviral, antimutagenic, and immunomodulatory properties, justifying its widespread and current use in dermatological and periodontal products (Pereira and others 2002). Brazilian propolis at low concentrations inhibited growth and survival of *C. albicans* and *C. tropicalis* (Sforcin and others 2001). CAPE is a potent inhibitor of NFκB and is able to induce apoptosis in HL-60 cells, an effect mediated by increasing intracellular ROS and decreasing glutathione (GSH) (Natarajan and others 1996; Chen and others 1998). In an experimental model of ferric nitrilotriacetate-induced lung carcinogenesis, Kimoto and others (1998) reported that Brazilian propolis extract and artepillin C decreased lipid and DNA peroxidation, blocking cancer progression. Propolis block COX-2 synthesis (Michaluart and others 1999) and increase SOD synthesis (Sforcin and others 1995), performing antiinflammatory and antioxidant effects, respectively.

53.4.7 Intake of Fruit and Vegetable Fibers Protects Against Gastrointestinal Cancers

Dietary fiber decreases intestinal time bulk transit, detoxify bile acids, and has other beneficial effects, protecting not only intestine, but also decreasing the risk of esophageal and gastric cardia adenocarcinomas (Roth and Mobarhan 2001).

Butyrate, a short-chain fatty acid from vegetable fibers, induces apoptosis and decreases cell proliferation, inhibiting colon cancer cells (Biasco and Paganelli 1999; Chapkin and others 2000; Kelloff and others 2000). Found in fibers and milk fat, butyric acid and tributyrin were able to induce apoptosis of human liver cancer cells (Watkins and others 1999).

53.4.8 Eat Tomato, Broccolis, and Garlic . . . Daily!

Lycopene, a tomato carotenoid, was not a potent growth inhibitor of human prostate carcinoma cells, but in association with α-tocopherol both decreased viability of tumor

cells by 90% (Pastori and others 1998). Dietary intake of tomato is very important to decrease risk of prostate cancer and possibly other tumors (Weisburger 1999).

Garlic, an ancient popular "medicinal food", is constituted by many sulfur-rich biomolecules, which confers high antioxidant activity (Borek 2001). In spite of a slight effect on platelet aggregation, garlic extracts can potently affect platelet adhesion to fibrinogen, collagen, and von Willebrand factor (Steiner and Li 2001). Oil-soluble garlic has potent antiproliferative and anticarcinogenic effects modulated by inhibitory effect on protein kinase involved in cell cycle progression and induction of apoptosis (Knowles and Millner 2001). In dimethylbenz[a]anthracene (DMBA)-induced carcinogenesis, administration of S-allyl-cysteine, a water-soluble garlic compound, prevented carcinogenesis and significantly increased GSH, glutathione peroxidase (GPx) and glutathione-S-transferase (GST) levels (Balasenthil and Nagini 2002). In a rat model of streptozotocin-induced diabetes, Campos and others (2003) observed that onion feeding lowered both hyperglycemia and SOD levels, without increase lipid peroxidation, whereas HDL cholesterol levels consistently increased. Unfortunately, garlic is not exempt from side effects. It enhances effectiveness of anticoagulant warfarin, increasing bleeding occurrence (DasGupta 2003).

When glucosinolates from broccoli suffer hydrolysis in human gut they yield isothiocyanates, indol-3-carbinol and sulphoraphane, a group of bioactive compounds able to increase hepatic cytochrome P_{450} xenobiotic detoxification, induce antioxidant response-element cytoprotection, decrease the risk of hormone-dependent cancers, and trigger growth inhibition and apoptosis of breast, colon, prostate cancer cells (Chen and others 1998; Kelloff and others 2000; Ferrari and Torres 2002; Xiao and Singh 2002; Keck and Finley 2004). It is important to note that many glucosinolates are also environmental carcinogens (Ames 2004).

53.4.9 Grapes and Wine

Dietary intake of grapes and wine polyphenols results in potent antioxidant and antiinflammatory cell activities, affording strong neuroprotection (Youdim and Joseph 2001). Wine has many anticarcinogenic effects mediated by suppression of tumor growth and inhibition of transformed cell proliferation and induction of apoptosis, actions attributed to quercetin (Wei and others 1994), cathechin (Stavric 1994), and resveratrol (Soleas and others 2000). Resveratrol was associated with inhibition of androgen-receptor activity for hormones in prostatic tumor cells (Mitchell and others 1999). Potent antioxidant activities, suppressive actions on phase I xenobiotic enzymes and triggering of phase II metabolism, inhibition of prostaglandin synthesis and NFκB pathway, induction of cell cycle arrest, estrogen-receptor mediated activities, and antiangiogenic activities constitute other pharmacological mechanisms of resveratrol (Brakenhielm and others 2001; Savouret and Quesne 2002).

53.4.10 Neuroprotective Effects of Teas (*Camellia sinensis*) and Coffees (*Coffea arabica*)

Antioxidant activity of coffee can prevent oxidative DNA damage (Vieira and others 1999). Coffee has also higher antioxidant activity in vitro, measured as lag-time to LDL oxidation, as compared to cocoa, green tea, black tea, and herbal tea (Richelle and others 2001). Several epidemiological studies had reported that coffee intake is inversely associated with risk for Parkinson's disease and AD (Ross and others 2000; Maia 2001).

Blocking A_2A receptors from nigrostriatal dopaminergic neurons by caffeine is the suggested protective mechanism of coffee (Schwarzschild and others 2003). Beyond the recognized negative effects of caffeine on blood pressure, heavy coffee consumption seems to increase plasmatic levels of homocysteine (Urgert and others 2000). Testing if coffee drinking can perform neuroprotection is an important achievement, once its daily consumption is very common around the world.

Tea polyphenols (epicatechins, catechins, and thearubigin) are potent antioxidants and decrease the risk of oral and gastrointestinal cancers (Yang and others 1998; Weisburger 1999; Ferrari and Torres 2003). Administration of green tea polyphenols (5 g/L) to interleukin-2-deficient rats (a model of autoimmunity) decreased inflammatory biomarkers (IFN-γ e TNF-α) and severity of colitis (Varilek and others 2001). Green tea consumption is also associated with low incidence of cardiovascular disease in the Orient by means of decreasing cholesterol oxidation and atherosclerosis (Miura and others 2001). Tea also blocked angiogenesis slowing down the metastatic capacity of tumors (Cao and Cao 1999).

53.5 CONCLUSION

Regular daily intakes of functional foods and adoption of a healthy lifestyle, which incorporates regular practice of physical activities (Maeda and others 2003; Mahoney and others 2002) improves health and reduces the burden of aging.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

54.1 INTRODUCTION

Gastroenterologists seldom think about food consumption outside the context of excesses (obesity) and deficits (malabsorption and malnutrition). However, the clinical perception of food quality and quantity is changing as physicians must contend with emerging evidence for functional foods. Functional foods and food supplements are operationally defined as foods with health benefits beyond their nutritional content (Shanahan and McCarthy 2000). Consumers are increasingly aware of food labels and economists have predicted that the consumer will soon demand that all foods have a functional content (McCarthy and others 2004). Terms such as pharmafood, vitafood, medical food, nutraceutical, and designer food are now commonplace as the distinction between a food and a drug becomes blurred. Although some clinicians dismiss the notion of functional foods as being in the realm of alternative medicine or food faddism, there is sound scientific evidence in support of a direct health benefit from certain food supplements. Examples include the supplementation of drinking water with fluoride to prevent dental caries, the use of folate to prevent neural tube defects and cancer and the exploitation of oral tolerance within the gastrointestinal tract to treat or prevent autoimmunity by feeding putative self-antigens. Perhaps the most impressive evidence for functional foods in treating or preventing intestinal disease is in the area of therapeutic manipulation of the gut flora with probiotics and our focus in this chapter is on mechanisms of probiotic action in gastrointestinal disorders.

54.2 HISTORICAL CONTEXT

In 1907 the Russian Nobel Prize Laureate Elie Metchnikoff first hypothesized that a high concentration of lactobacilli in intestinal flora were important for health and longevity in humans (Metchnikoff 1907). The term "probiotic" dates to 1954 when Ferdinand Vergin compared the harmful effects of antibiotics on the flora and the beneficial effects of certain bacteria (Vergin 1954). In 1965, the term probiotic was used to describe any substance or organism that contributes to intestinal microbial balance (Lilly and Stillwell 1965). Fuller subsequently stressed the benefits of a live microbial feed supplement in treating human disease (Fuller 1991). Probiotics are defined as live microorganisms which, when administered in adequate amounts, confer a health benefit on the host (Isolauri and others 2002). For the purpose of this chapter probiotics are operationally defined as commensal organisms that can be harnassed for health benefit.

Most probiotics belong to a large group of bacteria empirically designated as lactic acid bacteria (*lactobacilli*, *streptococci*, *bifidobacteria*). These are important components of the human gastrointestinal microflora where they exist as harmless commensals. Lactic acid is the principal end product of metabolism for all these species. Other probiotics include microbes such as yeast (e.g., *Saccharomyces boulardii*) and entirely unrelated bacteria (e.g., *E. coli nissle*). While some probiotics may be species specific it remains to be clarified if probiotics must be of human origin. They must be both acid and bile resistant and have the ability to sustain metabolic activity within the luminal flora, where ideally they should survive, if not persist for the long term.

54.3 MECHANISMS OF ACTION OF PROBIOTICS

Many diverse theories have been proposed for the mechanisms of action of probiotics. However a definitive understanding of the exact mechanisms eludes us. It is likely however that these mechanisms are multifactorial and both strain and host specific. It would be simplistic to assume that probiotics are generic, behaving the same way and that one strain is suitable for all patients.

54.3.1 Defense Against Infection and Inflammation

The role of probiotics in enteric infections is summarized in the Cochrane review (Allen and others 2003). Activities of probiotics appear to take place at least three levels, which are not necessarily mutually exclusive, the luminal environment, the epithelial surface and the mucosal immune system, as shown in Figure 54.1.

54.3.1.1 Activities Within the Lumen

Competition for Substrates. Probiotics may affect the growth and function of pathogenic bacteria by competing with them for nutrients in the gut. *Bifidobacterium longum* has several high-affinity oligosaccharide transporters, including those for more than 80 oligosaccharides in breast milk. This could be the mechanism which would favor its presence and competition for substrates in the breastfeeding infant (Schnell and others 2002). However, *in vivo* evidence is lacking and this theory might not be true due to the abundance of nutrients in the gut.

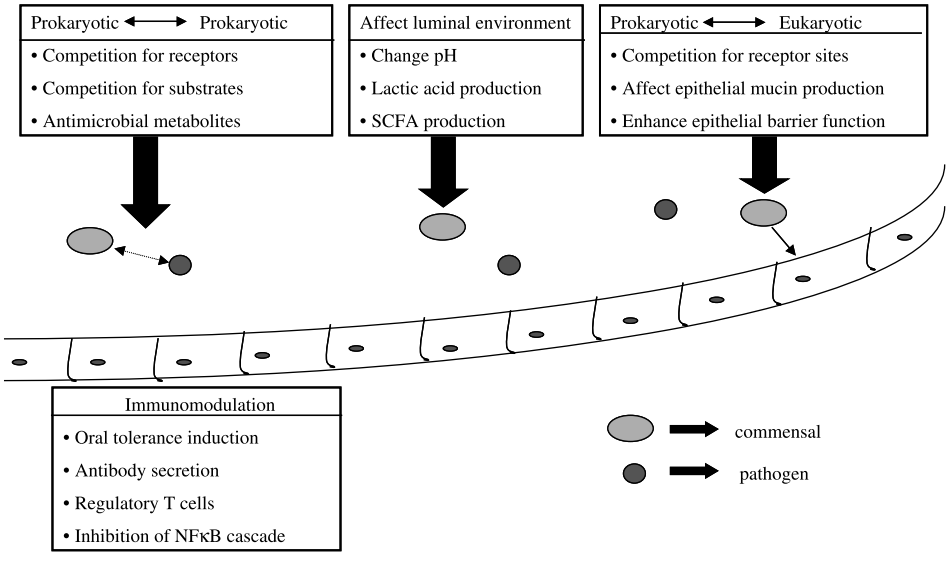

Figure 54.1 *Conceptual overview of examples of potential mechanisms of actions of probiotics in the Gastrointestinal tract.*

Generation of a Restrictive Environment. Probiotics may also affect the colonic environment making it less conducive to growth of certain pathogenic components of the flora. *Lactobacillus* in particular has been shown to reduce colonic lumen pH through production of short-chain fatty acids (Johansson 1993) and lactic acid. This is the major mechanism used by lactic acid bacteria to inhibit growth of several anaerobes. Production of hydrogen sulfide and effects on the oxidation-reduction potential by certain species of the flora have also been suggested as possible mechanisms.

Production of Antimicrobial Metabolites. Another important quality of probiotics in enhancing host defense is their ability to secrete antimicrobial substances that inhibit the growth of other organisms for example, *E. coli*, *C. difficile*, and *salmonella* (Aiba 1998; Fekety and Shah 1993; McFarland and others 1989). Other antimicrobial factors such as lactic acid and bacteriocins are produced mainly by lactic-acid bacteria (Flynn and others 2002). Bacteriocins are ribosomally synthesized proteins (Moll and others 1999). They show bacteriocidal activity against species that are closely related to the bacteria that produce them (Tagg and others 1976). Biochemical and genetic characteristics divide bacteriocins into three different classes: (1) lantibiotics, (2) nonlantibiotics, which are both small, membrane-active and heat-stable, and (3) large heat-labile proteins (Moll and others 1999). A number of *lactobacillus* bacteriocins and their genetic determinants have been described. Their inhibitory spectrum varies greatly most inhibit other *lactobacilli* or related Gram-positive bacteria, whereas some are active against a wide range of Gram-positive or Gram-negative bacteria as well as yeasts and moulds (Nemcova 1997). It is likely that production of these proteins plays a role in the survival and persistence of these organisms in the gastrointestinal tract.

The production of lactic acid has been implicated in the ability of certain probiotics to overcome pathogenic bacteria and thus exert a beneficial effect on the host. This has been most notable in studies looking at the effect of probiotics on *Helicobacter pylori* infection. Probiotics were able to inhibit the growth of *H. pylori in vitro* and in human and murine models (Aiba 1998; Michetti and others 1999). Both studies established that this effect is due to the production of large quantities of lactic acid as the inhibitory effect could be reproduced after incubation of *H. pylori* with lactic acid. They found that lactic acid has bacteriocidal activity and also prevents *H. pylori* adherence to gastric mucosa cells. The outer membrane of Gram-negative bacteria becomes permeable rendering it susceptible to other antimicrobial substances. A further study of the effect of a *L. acidophilus* strain on *H. pylori* activity *in vitro* showed that an autolytic process occurs that is linked to a proteinaceous compound released after cell lysis (Lorca and others 2001).

54.3.1.2 Activities at the Epithelial Surface. Activities of probiotics probably mimic the normal gut flora. Probiotics influence the mucosal epithelium mainly by competing for receptor sites and adherence.

Competition for Receptor Sites. Some commensal bacteria prevent adhesion of pathogens to receptor sites mostly by spatial hindrance due to their size and number and by blocking specific receptors. One study showed that probiotics have effects on pathogenic bacterial binding in the colon. IL-10 deficient mice exhibit increased mucosal adherence or invasion of aerobic bacteria in the colon that precedes the development of colitis. This is coupled with a decrease in colonic luminal lactobacillus species. However restoration

of lactobacillus species levels to normal reduces the concentration of adherent and translocated bacteria and thus attenuates the colitis (Madsen and others 1999).

It has also been proposed that probiotics release pathogen-inhibitory substances that inhibit bacterial translocation. *Lactobacillus GG* was found to have a direct effect on enterocytes that results in diminished passage of pathogens across the epithelial monolayer by upregulating the epithelial barrier mechanism (Mattar and others 2001). *L. GG* also binds to cell surface receptors on enterocytes and thus competes with pathogenic bacteria enterocyte attachment.

Steric hindrance of pathogen receptors was demonstrated after several heat inactivated strains of *lactobacillus* species were able to adhere to Caco-2 (a human colon cancer epithelial cell line) cell cultures and inhibit the adhesion of pathogenic *E. coli* and *S. typhimurium (*Chauviere and others 1992).

Competition for Adherence. Probiotics have been shown to directly and indirectly inhibit adherence of organisms to intestinal epithelial cells. Their effects on intestinal mucins play an important part. Mucins are high molecular weight glycoproteins synthesized and secreted by epithelial cells. They diminish the ability of enteric bacteria to bind to mucosal epithelial cells. In fact they are a component of the epithelial cell's innate immune response to invasive bacteria; MUC2 and MUC3 being the predominant ileocolonic mucin genes.

A study on the *in vitro* effects of probiotics on epithelial cell function showed that probiotic agents, such as *L. plantarum 299v*, which are able to bind to epithelial cells *in vitro* and colonize the intestinal tract *in vivo* (Johansson 1993), induce epithelial cells to secrete mucins that diminish enteric pathogens binding to mucosal epithelial cells (Mack and others 1999).

Mucins isolated from intestinal tracts of animals have been shown to inhibit *in vitro* adherence of pathogenic bacteria such as *E. coli* (Mack and Sherman 1991; Forstner 1994; Smith 1995). This interruption of the enteropathogen adherence to intestinal epithelial cells could provide therapeutic benefit to the host. However the mechanism by which *Lactobacilli* may cause increased mucin gene transcription remains to be determined.

Other research has shown how certain microorganisms are able to modify the cellular carbohydrate pattern thereby promoting colonization of specific beneficial bacteria. *Bacteroides thetaiotaomicron strain VPI-5482* changes a specific galactosylation pathway in HT-29-MTX intestinal epithelial cell line through a heat labile soluble factor (Freitas and others 2001). The probiotic compound *VSL#3* has a direct effect in enhancing barrier integrity in the IL-10 K.O. mouse. This is likely to be secondary to a proteinaceous soluble factor that is secreted by the bacteria found in *VSL#3*. There is a similar effect on human epithelial barrier function (Madsen and others 2001).

54.3.1.3 Activities at the Mucosal Immune System

Immunomodulation. The gut immune response to microorganisms relies on both innate and acquired components of immunity. The innate response is a primitive but highly conserved immune response which discriminates between pathogens and commensals using preformed receptors known as toll-like receptors. This allows immediate recognition of bacteria and the host can respond accordingly by activating innate immune cells. The more specific component of the immune system is the adaptive response. This is responsible for formation of memory. Cells of the adaptive immune response recognize and

recall antigens using antigen specific receptors (T-cell receptors and immunoglobulins). The complex interaction between the innate and adaptive immune systems protects the host against pathogens, which preserves intestinal mucosal function. Precise regulatory mechanisms exist that ensure appropriate inflammatory reactions and that nonpathogenic commensals are tolerated at local and systemic levels. It has been suggested that probiotics may mimic normal flora through modulation of this host immune response. They educate and prime the immune response.

Probiotics have been shown to increase the synthesis of antibodies to microbial pathogens, especially secretory IgA (Kaila and others 1992). Certain probiotic bacteria induce specific immune responses and hyporesponsiveness to commensals. This tolerance induction matures the gastrointestinal associated lymphoid tissue such that it is ready to produce IgA in response to pathogen antigenic stimulus. In support of this, defective oral tolerance to commensals and ingested antigens has been shown in germ-free animal models (Faria and Weiner 1999).

Probiotics may also exert their effects at the level of regulatory T-cells. Many animal models have been used to investigate the balance between effector and regulatory T-cells in the inflammatory processes of the gut. Some groups have demonstrated that regulatory T-cells exist that control mucosal immunity to the enteric flora (Kronenberg and Cheroutre 2000; Shanahan 2000). It has been demonstrated in murine models that the mucosal response to enteric antigens is linked with a predominance of T helper cells of the Th2 and Th3 types. The Th2 response produces anti-inflammatory cytokines (IL-4, IL-10), which promote the secretion of IgA and Th3 produces TGF-β. Both of these responses are critical for the development of oral tolerance. Probiotics may also influence the development and activity of these regulatory T-cells. This mechanism may account for their apparent clinical efficacy in disorders involving Th1 immunological processes, such as inflammatory bowel disease.

The mechanisms used by the immune system to recognize pathogens and commensals are still not well understood. Dendritic cells are involved in antigen presentation to the mucosal immune system and it may be at this level that the bacteria are differentiated. Commensals presented by dendritic cells to mesenteric lymph nodes do not elicit a systemic immune reaction. Dendritic cells can imprison live commensals for days and produce specific IgAs which then prevent these commensals from penetrating the gut mucosa (Macpherson and Uhr 2004).

There is increasing evidence that some of the probiotic effects encountered may not require a whole live bacterium. Bacterial DNA has been successfully used to attenuate murine models of colitis by their potent immunostimulatory effects. It is thought that this attenuation could be due to antiapoptotic mechanisms. These DNA sequences or immunostimulatory sequences (ISS) or CpG motifs are under extensive study (Rachmilewitz and others 2002).

Signaling. The transcription factor NFκB is pivotal to the inflammatory immune response to invasive pathogens (Elewaut 1999). It has been postulated that probiotics could exert an antiinflammatory effect through the inhibition of this pathway.

Certain probiotics exert antiinflammatory actions on epithelial cells by inhibition of NFκB. It has been shown that probiotic DNA downregulated proinflammatory cytokine secretion by attenuation of NFκB pathway in intestinal epithelial cells (Madsen 2002). The counter-regulatory factor to NFκB is IκB and some nonpathogenic bacteria may attenuate proinflammatory responses by delaying its degradation (Neish and others 2000). Recently *Bacteroides thetaiotaomicron*, a nonpathogenic commensal,

TABLE 54.1 Summary of Human Trials of UC.

Probiotic Used	No. of Subjects	Study Type	Results	Reference
E. coli strain Nissle 1917	120	Randomized controlled trial	Patients with active colitis had similar relapse rates compared to patients on mesalazine	Kruis and others 1997
E. coli strain Nissle 1917	116	Randomized controlled trial	As above	Rembacken and others 1999
E. coli strain Nissle 1917	327	Randomized controlled trial	*E. coli* as effective as mesalazine in maintaining remission	Kruis and others 2004
VSL#3	20	Open labeled trial	Maintained remission in 75% of patients	Venturi and others 1999
Saccharomyces boulardii	25	Open labeled trial	68% of patients with a relapse of UC achieved remission when treated with a combination of probiotic and mesalazine	Guslandi and others 2003
Bifidobacterium longum with prebiotic inulin-oligofructose	18	Randomized controlled trial	Short term treatment of active UC resulted in improvement of the full clinical appearance of chronic inflammation	Furrie and others 2005
Balsalazide (5-amino salicylate derivative) with VSL#3	90	Randomized controlled trial	Low-dose balsalazide with a high dose of VSL#3 is more effective than balsalazide alone or mesalazine in the treatment of acute mild-to-moderate ulcerative colitis	Tursi and others 2004
BIFICO – probitic mix	30	Randomized controlled trial	20% in the *BIFICO* group had relapses during 2-month follow-up period, compared with 93.3% in placebo group	Hai-Hong Cui and others 2004

TABLE 54.2 Summary of Trials in CD.

Probiotic Used	No. of Subjects	Study Type	Results	Reference
Saccharomyces boulardii	20	Randomized controlled trial	Decrease in CDAI in probiotic group	Plein and Hotz 1993
Saccharomyces boulardii	32	Randomized controlled trial	Maintenance of remission in treatment group superior as relapse observed in 6.25% of patients receiving probiotic plus mesalazine compared to 37.5% on mesalazine alone	Guslandi and others 2000
Lactobacillus GG	14	Open labeled trial	Increase in gut IgA response	Malin and others 1996
Lactobacillus GG	4	Open labeled trial	Improved intestinal permeability and CDAI	Gupta and others 2000
Lactobacillus GG	45	Randomized controlled trial	No difference seen in rate of recurrence 1 year after surgery between group given probiotic or control	Prantera and others 2002
Lactobacillus GG	5	Randomized controlled trial	No benefit in inducing or maintaining medically induced remission in CD	Schultz and others 2004
E. coli strain Nissle 1917	28	Randomized controlled trial	Remission achieved in patients on probiotics and steroids greater than with steroids alone	Malchow 1997
VSL#3 with antibiotic	40	Randomized controlled trial	Patients with CD had 20% remission when given antibiotic and *VSL#3* compared to 40% in mesalazine treated group	Campieri and others 2000
Lactobacillus salivarius 118	25	Open labeled trial	Reduction of mean CDAI and induction of IgA in patients with relapse	McCarthy and others 2001; 2004

was demonstrated to target the transcriptionally active NFκB subunit RelA and enhance its nuclear export thereby preventing an inflammatory response in colonic epithelial cell lines (Kelly and others 2004). This group also showed how this bacterium exerts the above effect through a PPAR-γ dependent pathway. Peroxisome proliferator activated receptors (PPAR) activation by PPAR ligands not only result in the transcription of antiinflammatory genes but also inhibit NFκB directly. Nonpathogenic bacteria also exert antiinflammatory effects by inhibiting IκB ubiquitination (Neish and others 2000) This would preserve IκB (inhibitory κB) so that NFκB pathway is not activated.

There is evidence from murine studies to suggest that IL-10 is an essential modulator of the regulatory T-cells that control inflammatory responses to intestinal antigens. It suppresses the inflammatory immune response in the gut mucosa by promoting the activity of regulatory T-cells that hold effector Th1 cells in check. Murine models with targeted disruption of the IL-10 gene develop enterocolitis. Administration of IL-10 has provided therapeutic benefit in a human study of inflammatory bowel disease (Van Deventer and others 1997). Experiments have shown that IL-10 can restore tolerance of T-cells to resident intestinal bacteria. A genetically-engineered bacteria to synthesize IL-10 within the intestinal lumen of murine models was administered with good antiinflammatory results (Steidler and others 2000). Other murine studies have looked at the effect of probiotics on enterocolitis and the immune response in IL-10 knockout mice. Our group found that specific strains of both *lactobacillus* and *bifidobacterium* significantly attenuate colitis in this model. They showed that this attenuation of colitis was associated with a reduced ability to produce Th1-type proinflammatory cytokines (TNF-α, IL12) at a mucosal and systemic level whereas TGF-β levels were maintained (McCarthy and others 2003). A summary of human trials of probiotics in inflammatory bowel disease can be seen in Tables 54.1 and 54.2.

54.3.2 Metabolic Effects of Probiotics

Probiotics may exert beneficial effects on the host through their effects on metabolism of dietary elements such as polysaccharides affecting energy intake, absorption, and storage. A seminal study of the effect of recolonising germ-free mice with normal microflora showed that the gut microflora regulates fat storage through promotion of monosaccharide absorption from the gut lumen leading to induction of hepatic lipogenesis, and deposition of triglycerides in adipocytes (Backhed and others 2004).

Probiotics also enhance gut-associated lymphoid tissue responses directly or indirectly through the production of short-chain fatty acids (Bornet 2002*)*. Short-chain fatty acids are the end products of anaerobic bacteria breakdown of carbohydrates in the large bowel. They are readily absorbed by the intestinal mucosa, are relatively high in caloric content, are metabolized by colonocytes, stimulate sodium and water absorption in the colon, and are trophic to the intestinal mucosa. There is increased interest recently in their role in the treatment of inflammatory bowel disease. Their effects have been attributed to the oxidation of these fatty acids in colonocytes and to the ability of butyrate (a SCFA) to induce enzymes promoting mucosal restitution (D'Argenio and Mazzacca 1999). The significance of these acids in immunomodulation needs further consideration.

The ability of probiotics to synthesize beneficial vitamins is speculative at best. However one study found that folate was produced by *bifidobacterium* and *streptococcus thermophilus* and depleted by *lactobacillus* (Crittenden and others 2003). Vitamin K is

TABLE 54.3 Summary of Trials in Cancer.

Bacterial Species	Action	Mechanism of Action	Reference
L. acidophilus, L. gasseri, L. confuses, Streptococcus thermophilus, Bifidobacterium breve, B. longum	Inhibits N′-nitro-N-nitrosoguanidide (MNNG) and 1,2-dimethylhydrazine (DMH)-induced genotoxicity in rat colons	Reduction of DNA damage induced by chemical carcinogens	Pool-Zobel and others 1996
Bifidobacterium longum	Inhibits liver, colon, and mammary tumors induced by food mutagen 2-amino-3-methyl-3H-imidazo (4,5-f) quinoline (IQ) in rats	Inhibition of potential carcrinogens	Reddy and Rivenson 1993
L. acidophilus NCFM and *N-2*	Decrease in bacterial enzyme activity: B-glucuronidase, nitroreductase, azoreductase, in healthy volunteers	Alteration of metabolic activities of intestinal microflora	Goldin and Gorbach 1984
L. acidophilus, B. bifidum	Decreases fecal pH and decrease in proliferative activity in colonic crypts in patients with colonic adenomas	Alteration of physicochemical conditions in the colon	Biasco and others 1991
Lactic acid bacteria	Reduces growth and viability of HT-29 human colon cancer cell line	Production of antitumorigenic compounds	Baricault and others 1995
L. casei Shirota	Inhibits tumor growth and increases survival in mice	Enhancing the immune response by producing cytokines	Matsuzaki 1998
L. casei YIT 9018	Potentiates systemic immune responses that modify T-cell functions in tumor-bearing mice	Enhancing the immune response	Kato and others 1994
B. Longum	Suppresses azoxymethane (AOM)-induced colonic tumor development, effect which is associated with a decrease in the activities of colonic mucosal and tumor ornithine decarboxylase and ras-p21	Effect on host physiology	Reddy 1998

produced by a wide variety of bacteria including *bacteroides*, *bifidobacterium*, *lactobacillus*, *clostridium*, *enterococcus*, and *streptococcus* (Hill 1997). In other studies looking for production of vitamins, no increased production of B complex vitamins was detected. The role of probiotics in the synthesis of vitamins is unlikely to be significant. However they may alter the microflora environment making the absorption of vitamin substances more efficient.

54.3.3 Anticarcinogenic Effects

The anticarcinogenic effects of probiotics are putative, few epidemiological studies exist to support this however there is some indirect evidence in the literature, largely from laboratory studies. In recent years several good animal models have been established to investigate the link between colon cancer and dietary factors, which may be protective, such as lactic acid probiotics (Hirayama 2000; Lee 2000). The precise mechanisms by which lactic acid bacteria may exert an anticarcinogenic effect are unknown but suggestions include: altering the metabolic activities of the intestinal microflora, by changing physicochemical conditions in the colon and host physiology, by binding and degrading potential carcinogens, and by the production of antitumerogenic compounds (Rafter 2003). A summary of trials investigating probiotics in cancer, adapted from work published by Rafter can be seen in Table 54.3.

54.4 EFFECTS OF PROBIOTICS IN OTHER DISORDERS

54.4.1 Effects of Probiotics in Gastrointestinal Disorders

54.4.1.1 Irritable Bowel Syndrome. This is characterized by abdominal cramps or bloating, alternating bowel habit, or excessive flatus without an organic cause. A disruption of the normal flora could result in these symptoms. Low numbers of *lactobacilli* and *bifidobacteria* have been isolated from the faeces of patients with this disorder. It has been suggested that probiotics may restructure the intestinal microflora or its activity (Madden and Hunter 2002). In a recent randomized placebo-controlled trial our group demonstrated the effects of *Bifidobacterium infantis 35624* and *Lactobacillus salivarius UCC4331* on symptom response and cytokine ratio in IBS patients (O'Mahony and others 2001). For all symptoms, with the exception of bowel movement frequency and consistency, those randomized to *B. infantis 35624* experienced a greater reduction in symptom scores. At baseline, patients with IBS demonstrated an abnormal IL-10 to IL-12 ratio, indicative of a proinflammatory, Th-1 state. This ratio was normalized by *B. infantis 35624* feeding alone. It was therefore concluded that *B. infantis 35624* alleviates symptoms in IBS and this is associated with normalization of the ratio of an antiinflammatory to a proinflammatory cytokine response, suggesting an immunomodulatory role for this organism. A review of the literature shows only eight trials in 29 years, six of which show improvement in various symptoms. Most of the trials used *L. plantarum*, solely or in combination. A summary of the trials of probiotics in irritable bowel disease can be seen in Table 54.4.

54.4.1.2 Clostridium Difficile-Associated Intestinal Disease. The role of the probiotic organism in C difficile infection is to restore the colonization resistance of the

TABLE 54.4 Summary of Human Trials of IBS.

Probiotic Used	No. of Subjects	Study Type	Results	Reference
Streptococcus faecium	54	Randomized controlled trial	Improvement of overall condition in 81% compared to 41% in controls	Gade and Thorn 1989
L. plantarum (DSM 9840)	60	Randomized controlled trial	Decrease in pain and flatulence but no effect on bloating	Nobaek and others 2000
Lactobacillus GG	25	Randomized controlled trial	No effect on pain, urgency or bloating. A trend towards more formed bowel motions noticed in patients with diarrhea in those on probiotic	O'Sullivan and O'Morain 2000
L. plantarum 299V (L299V)	40	Randomized controlled trial	All patients (20) on the probiotic reported resolution of their abdominal pain compared to 11 out of 20 in placebo group. 95% on *L299V* reported improvement of all symptoms compared to 15% in placebo group	Niedzielin and others 2001
L. plantarum 299V (L299V)	12	Double-blind, crossover trial	No improvement in symptoms found	Sen and others 2002

VSL#3	25	Randomized controlled trial	No effect on abdominal pain, urgency and gas but decrease in bloating in diarrhea-predominant IBS. No effect in gastrointestinal transit	Kim and others 2003
L. plantarum LP 01 with *B. Breve BR 03*. *Lactobacillus plantarum LP 01* with *Lactobacillus acidophilus LA 02*	70	Randomized controlled trial	Decrease in pain score and symptom severity score in both groups as compared to placebo	Saggioro 2004
Bifidobacterium infantis 35624, *Lactobacillus salivarius UCC4331*	77	Randomized controlled trial	*B. infantis 35624* alleviates symptoms in IBS except for bowel movement frequency and consistency and is associated with normalization of the ratio of an antiinflammatory to a proinflammatory cytokine. *L. salivarius UCC4331* was no better than placebo	O'Mahony and others 2005
Lactobacillus acidophilus	18	Randomized controlled crossover trial	Reduction of symptoms in 50% on probiotic	Halpern and others 1996
Encapsulated Bifidobacterium infantis 35624	291	Randomized controlled crossover trial	Relief of all cardinal symptoms using lower daily encapsulated dose	Whorwell and others 2005 (at press)

normal flora, which has been disrupted by antibiotic therapy (Kyne and Kelly 2001). A number of studies on human subjects have shown promising results (Elmer 2001). The probiotic agents that have been used include *lactobacillus GG*, *bifidobacterium infantis*, and *saccharomyces boulardii* (McFarland and others 1994). Uncontrolled studies showed that small numbers of children and adults with *C. difficile* responded well to treatment with probiotics (Gorbach and others 1987; Biller and others 1995). A prospective randomized placebo-controlled trial of *lactobacillus GG* in combination with standard antibiotics showed that this probiotic was effective in reducing recurrence rates of *C. difficile* and there was subjective improvement in patient symptoms (Pochapin 2000).

The antimicrobial activity of *bifidobacterium infantis* and *lactobacillus salivarius* against *C. difficile* was identified by a Korean group using PCR methods. The probiotic species they used were isolated from healthy infant faeces (Lee and others 2003).

Saccharomyces boulardii is a nonpathogenic yeast that has been shown to protect against antibiotic-associated diarrhoea and recurrent *C. difficile* colitis (Elmer and McFarland 1987; Castagliuolo and others 1996; McFarland and others 1994). This yeast stimulates intestinal immunoglobulin A immune response to *C. difficile* toxin A in mice and enhancing host intestinal immune responses may be an important mechanism for *S. boulardii*-mediated protection against diarrhoeal illnesses (Qamar and others 2001). It has also been postulated that *S. boulardii* protects animals against *C. difficile* intestinal disease through a protease degradation of the toxin receptor on the intestinal mucosa (Castagliuolo and others 1999). Further work to elucidate the exact mechanism of action of probiotics in modifying *C. difficile* inflammatory response is needed.

54.4.1.3 Pouchitis. Probiotics also demonstrate some benefit in pouchitis, a complication occurring in up to 20% of patients with inflammatory bowel disease (IBD) who have undergone pouch formation after bowel resection. VSL#3, a probiotic cocktail of four lactobacilli strains (*L. plantarum*, *L. casei*, *L. acidophilus*, *L. delbrueckii* ssp. *bulgaricus*), three bifidobacteria strains (*B. infantis*, *B. breve*, *B. longum*) and one strain of *Streptococcus salivarius* ssp. has been used in clinical trials of pouchitis with some success, as summarized in Table 54.5. A possible explanation could be that these bacteria do not demonstrate mucus degradation properties, which is likely what occurs secondary to bacterial overgrowth in pouchitis. The role of probiotics in pouchitis in the future is likely to be as an adjunct to conventional therapy as this is an aggressive condition. Examples of probiotics used in the treatment of pouchitis are summarized in Table 54.5.

54.4.1.4 Lactose Intolerance. This is a common enzyme deficiency disorder resulting from a congenital deficiency of β-galactosidase, which helps digest lactose. It presents with symptoms such as diarrhoea, abdominal cramps, and bloating. Lactase-positive bacterial strains such as *Lactobacillus*, *Bifidobacterium*, and *Streptococcus* added to milk products help to digest lactose (Marteau and others 1990). This is perhaps secondary to a reduction of lactose in the dairy product through fermentation and the release of lactase in the gastrointestinal tract by the probiotics.

54.4.2 Effects of Probiotics in Extraintestinal Disorders

54.4.2.1 Allergies. Atopic eczema due to milk allergy in infants was shown to improve following administration of probiotics. The proposed mechanism is that probiotics promote the endogenous barrier mechanism and reduce intestinal inflammation (Majama and Isolauri 1997). Other studies have shown significant differences in the

TABLE 54.5 Summary of Human Trials in Pouchitis.

Probiotic Used	No. of Subjects	Study Type	Results	Reference
VSL#3	40	Randomized controlled trial	Maintenance of remission in chronic pouchitis after antibiotic induced remission. 15% relapse rate compared with 100% in control group	Gionchetti and others 2000
VSL#3	40	Randomized controlled trial	Prevention of acute pouchitis in patients after ileo-anal pouch surgery. 10% pouchitis rate in probiotic group compared with 40% in control group	Gionchetti and others 2003
Lactobacillus rhamnosus GG	20	Randomized controlled trial	No differences were observed between the groups with regard to the mean pouchitis disease activity index	Kuisma and others 2003
VSL#3 (high dose)	36	Randomized controlled trial	Maintenance of remission in recurrent or refractory pouchitis after antibiotic induced remission. 85% remained in remission at one year, compared with 6% in placebo group	Mimura and others 2004

ratio of *bifidobacterium* to *clostridium* species in children who later develop atopy. A randomized double-blind placebo-controlled study demonstrated how perinatal administration of *L. rhamnosus strain GG* halved the incidence of atopic eczema in at-risk children during the first two years of life and this preventive effect extends to the age of four years (Kalliomaki and others 2003). Hence probiotics could have a role in the maturation of human immunity to a nonatopic state. Early priming of the immune system by commensal flora, resulting in a Th1 response rather than the more atopic Th2 response, could confer protection against allergy (Bjorksten and others 2001; Kalliomaki and others 2001).

54.4.2.2 Old Age. Elie Metchnikoff first hypothesized that a high concentration of lactobacilli in intestinal flora were important for longevity in humans (Metchnikoff 1907). In health the adult gut microflora stays stable in species composition within individuals over time (Zoetendal and others 1998). In old age there are changes in both species composition and amount. The elderly have lower amounts of *bifidobacteria* and higher amounts of yeasts, *enterobacteria*, *clostridia*, *lactobacilli*, *streptococci*, and *enterobacteria*. Restoring the gut microflora with probiotics may help restore gastrointestinal health in the elderly. Probiotics have been shown to increase transit times in human feeding studies, thereby improving nutrient absorption (Marteau and Buotron-Ruault 2002). As mentioned previously probiotics may interfere with the *in vivo* growth of *H. pylori*. This gastrointestinal infection is a common cause of morbidity in the elderly. They also showed promise in the treatment of *C. difficile* and antibiotic associated diarrhoea in clinical trials.

Immunosenescence, causing reduction in T cell population, occurs in the elderly. Phagocytes and natural killer cells are also reduced leading to increased susceptibility to infections. Immunomodulation by probiotics may help counter this effect. A clinical trial showed how probiotics were associated with a reduction in duration of illness caused by "winter" infections (Turchet and others 2003).

54.4.2.3 Hepatic Encephalopathy. In this disorder, the liver fails to break down the ammonia, among other products, produced by urease activity of intestinal bacteria so that it reaches a toxic level causing mental impairment. Lactic acid bacteria used as an add-on to treatment has shown a decrease in faecal urease activity and thus shows promise for future use (Scevola and others 1989).

54.4.2.4 Sucrase-Isomaltase Deficiency. This is not an uncommon primary disaccharidase deficiency where sucrose malabsorption occurs leading to hydrogen-producing bacterial fermentation causing bloating, cramps, and diarrhea. Symptoms disappear on sucrose-free diet. In one study *Saccharomyces cerevisiae* was used with some success to treat this condition. The authors postulate that the probiotic organism supplies the missing enzyme (Harms and others 1987).

54.4.2.5 Hypercholesterolaemia. Several lactic acid bacteria have been shown to produce bile salt hydrolase, which deconjugates bile salts in the enterohepatic circulation. This effect may reduce cholesterol (De Smet and others 1998). This mechanism of action could be similar to that of bile binding resins (e.g., cholestyramine) which bind bile acids so that the liver has to use cholesterol to produce more bile acids. It was also shown that deconjugated bile salts do not function as well as conjugated forms, which would result in less absorption of cholesterol (Reynier and others 1981). *In vitro*, lactic acid bacilli *Streptococcus HJS-1*, *Lactobacillus HJL-37*, and *Bifidobacterium HJB-4* isolated from the human intestinal tract had the ability to reduce cholesterol. One group suggests that *Lactobacillus acidophilus* reduces blood cholesterol by direct breakdown of cholesterol and deconjugation of bile salts (Gilliland and others 1985).

Herbal remedies and diabetes mellitus have a long shared history. Both were first described in historical accounts of several ancient cultures over 2000 years. Symptoms of diabetes that included polyuria and polydypsia were described in the Egyptian Ebers papyri, Greek Epidemics Book III of Hippocrates, the Chinese Nei Ching, and Ayurvedic writings (Cheng 2000; Sanders 2001). The treatments for these disorders were described largely as being plant based herbal remedies (Cheng 2000; Sanders 2001). Ethnopharmacological investigations have since implicated thousands of plant derived herbs in the treatment of diabetes mellitus. A comprehensive review of data for 1000 of these herbs reported that >80% have demonstrated some antidiabetic activity (Oubre and others 1997). There is, nevertheless, only one example of an approved antidiabetic drug that was developed from a herb with a long history of use for diabetes: the biguanide Metformin from French lilac (*Galega officinalis*) (Marles and Farnsworth 1995). Numerous other herbs remain candidates for antidiabetic drug development. This chapter addresses the evidence supporting the use of herbs in the management of diabetes. It starts with a discussion of the problem of diabetes, the opportunity that exists for herbs in the management of diabetes, and the state of the evidence for their clinical antidiabetic efficacy. It then proceeds to a discussion of the evidence for one of the best studied herbs, ginseng, with an emphasis on data from in vitro, animal and human studies. Finally, the limitations of the evidence supporting the clinical antidiabetic efficacy of herbs are discussed using ginseng as an example to illustrate the challenges in achieving reproducible clinical efficacy.

55.1 PROBLEM OF DIABETES MELLITUS

Diabetes mellitus is comprised of a heterogeneous group of metabolic diseases, characterized by hyperglycemia. There are two main types: type 1 and type 2 diabetes. The former is caused by the complete absence of endogenous insulin production owing to the autoimmune destruction of pancreatic β-cells. The latter is caused a combination of insulin resistance and an insulin secretory defect. Type 2 diabetes is more prevalent than type 1 diabetes, representing 90% of the cases (American Diabetes Association 2006). In >80% of people, type 2 diabetes also clusters with obesity, dyslipidemia (low HDL-cholesterol and high triglycerides), elevated blood pressure, and impaired fibrinolysis (Haffner and others 2000) This constellation of features defines the dysbolism of insulin resistance and is

termed the metabolic syndrome (Alberti and others 1998; Adult Treatment Panel III 2001; Grundy and others 2005). Because of this clustering of risk factors and the increased CVD burden that accompanies it, diabetes is now treated as a risk equivalent to established CVD in therapeutic guidelines for the Word Health Organization (Alberti and others 1998), American Heart Association (Grundy and others 2005) and National Cholesterol Education Program (Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001). Guidelines for the pharmacological and nutritional medical therapy of diabetes aggressively target the features of the metabolic syndrome, in addition to the insulin resistance and/or insulin secretory defect underlying the hyperglycemia that characterize diabetes (Alberti and others 1998; Wolever and others 2000; Grundy and others 2005; Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001).

Despite the numerous preventative strategies and armories of medication, the management of type 2 diabetes remains grossly unsatisfactory. Diabetes is emerging as a pandemic. From 1995 to 2025 the prevalence of diabetes in adults is predicted to increase by 27% in developed countries and 48% in developing countries (Gu and others 1999). In the US, the trends may already be outpacing the predictions. Data from the Centers for Disease Control show that from 1991 to 2001 diabetes increased by 61% and obesity, one of its most important precipitating factors, increased by 74% (Mokdad and others 2003). The progression of the disease has been no better attenuated. Men with diabetes have benefited far less from declines in CHD mortality, while women with diabetes have experienced an increase in risk compared with their nondiabetic counterparts (Gu and others 1999). Glycemic control targets for monotherapy also continue to go unmet in those with the disease (Turner and others 1999). With the reliance on multiple patented pharmacological agents to attain glycemic control targets, the cost of treatment has also become a real concern. Even with the use of generic drugs, the escalation of costs with multiple-therapy treatment is high. There is a 30-fold cost differential among approved diabetes treatments (Leiter and others 2002). The World Health Organization (1993) acknowledges that the ability of developing countries to afford this level of treatment is dubious. These concerns point to the need for cheaper and more effective prevention and treatment modalities.

55.2 OPPORTUNITY FOR HERBS IN DIABETES

Complementary and alternative medicine (CAM) approaches that include herbs may hold promise in diabetes. A compelling argument has been made that the random in vitro "high-throughput" screening for new drug therapies preferred by pharmaceutical companies has less practical merit than an ethnopharmacological approach that involves ethnobotany and screening of traditional systems of medicine for candidate therapies (Marles and Farnsworth 1995). This is especially true for diseases such as diabetes that are complex metabolic disorders, as certain metabolic targets of these approaches may be unrelated or secondary to effects on more proximal defects (Marles and Farnsworth 1995). The implication is that herbal treatments not identified by conventional in vitro screening systems might still be proven to have clinical efficacy and potential for development.

The public in their actions already endorse the use of herbs. Driven by the insufficiency of treatment and anecdotal evidence, paraherbalism and pseudoscience, the use of CAM

increased by 68% from 1990 to 1997 in the US (Eisenberg and others 1998). The most recent estimates suggest that 75% of general medical patients in the U.S. are now using CAM therapies (Winslow and others 2002). One of the strongest independent determinants of this behavior is the use of CAM to treat diabetes (Wolsko and others 2002). Among Canadians with diabetes, it has been reported that 37% use CAM (Ryan and others 2001). This increasingly high demand has occurred in the absence of safety and efficacy evidence, adequate regulatory standards, patient disclosures to physicians, and physician education. This has prompted a unified call from the medical community in the form of editorials, letters, and commentaries for randomized controlled clinical trials (RCTs) to evaluate CAM treatments and provide a basis for legitimate health claims (Goldbeck-Wood and others 1996; Levin and others 1997; Angell and Kassirer 1998; Hershfield 1998; Hoey 1998; Dalen 1998; Oppel 1998; Anonymous 2000; Ernst 2000).

55.3 EVIDENCE FOR THE EFFICACY OF HERBS IN DIABETES

The call for more rigorous clinical assessments of CAMs is being answered by a segment of the literature. There is a growing database of clinical trials investigating the effects of several herbs in diabetes. The efficacy, safety, and mechanisms of these herbs in diabetes have been well described in a recent systematic review of 42 randomized and 16 non-randomized clinical trials (Yeh and others 2003). The herbs with supporting clinical data in diabetes were shown to include ginseng (*Panax* spp.), ivy gourd (*Coccinia Indica*), garlic (*Allium sativum* and *Allium cepa*), holy basil (*Ocimum sanctum*), fenugreek (*Trigonella foenum graecum*), prickly pear cactus or nopal (*Opuntia streptacantha*), milk thistle (*Silibum marianum*), fig leaf (*Ficus carica*), gurmar (*Gymnema sylvestre*), bitter melon (*Momordica charantia*), Aloe vera, Gingko biloba, and various herb combinations in Traditional Chinese Medicine, Native American medicine, and Tibetan medicine. Various hypoglycemic mechanisms have been suggested for these herbs from animal and in vitro models. These include delayed glucose absorption in the gut (Aloe vera, prickly pear cactus), increased glucose uptake/disposal (fig leaf, ivy gourd), glucose stimulated insulin secretion (garlic, holy basil, gurmar), the first two (fenugreek), the last two (bitter melon), or all three (ginseng) (Yeh and others 2003; Vuksan and others 2001a, b).

The antihyperglycemic efficacy remains inconclusive for the majority of these herbs. Although determined to be safe, there is insufficient evidence to make conclusions about their efficacy (Yeh and others 2003). This is despite the direction of the evidence for a positive effect being strong. Greater than 75% of studies show improved indices of glycemic control (Yeh and others 2003). The main limitation is that individual herbs have only a small number of clinical trials, the majority of which suffer from poor quality owing to under-powering or small sample size, lack of randomization, absence of blinding, and inadequate reporting of dropouts. But strong evidence is mounting to support the use of selected herbs in diabetes. Ivy gourd and American ginseng (*Panax quinquefolius* L.) were determined to have the best evidence from adequately designed RCTs to support clinical efficacy in diabetes (Yeh and others 2003). This conclusion, as it relates to ginseng, is further supported by the position of American Diabetes Association in their evidence based nutrition recommendations (Franz and others 2002).

55.4 EVIDENCE FOR THE EFFICACY OF GINSENG IN DIABETES

The state of the evidence for ginseng serves as an example of the quantity and quality of evidence that is available to support antidiabetes claims for herbs. A detailed discussion of the in vitro, animal, and human evidence for the antidiabetic efficacy of ginseng and its components follows.

55.4.1 Ginseng and Its Components

Ginseng is an herb derived from several species of the plant family Araliaceae and genus *Panax*. It is usually consumed as dried powder in capsules, but is also available as a gel, tea, or tincture (World Health Organization 1999). Thirteen distinct species of ginseng have been identified with numerous different cultivars (British Columbia Ministry of Agriculture 1999) (Fig. 55.1). The two most popular species of ginseng are American and Asian ginsengs. Other commercial species include Korean red (steamed *Panax ginseng* C.A. Meyer), Japanese (*Panax japonicus* C.A. Meyer), Sanchi, Vietnamese (*Panax vietnamensis*), and the nonpanax species Siberian ginseng. American ginseng is indigenous to Ontario, Quebec, BC, and Wisconsin, while the other species are indigenous to Asia (World Health Organization 1999). All are genetically distinct (Mihalov 2000).

Various components of ginseng have been shown to have pharmacological activity. These include ginsenosides (dammarane-, oleanane-, and octillilol-type triterpene glycoside saponins) (NG and Yeung 1985; Attele and others 1999), ginsenans (polysaccharide), panaxans, quinquefolans, and eleuthernas (peptidoglycans) (Konno and others 1984; 1985; NG and Yeung 1985; Hikino and others 1986; Oshima and others 1987; Tomoda and others 1993, 1994), and peptide fractions (Kajiwara and others 1995). Most pharmacological action of ginseng is attributed to ginsenosides. The most common ginsenosides are the dammarane-type triterpene glycosides. These share similarities with the classical steroid hormones (Fig. 55.1).

55.4.2 Antidiabetic Efficacy of Ginseng and Its Components in Animals

55.4.2.1 Antihyperglycemic Effects of Ginseng in Animals. A substantial database of animal studies has reported improvements in longterm glycemic control with feeding of various ginseng sources. Aqueous extracts of Asian ginseng root body and rootlets each administered orally at a dose of 500 mg/kg/d body weight for 28d decreased fasting blood glucose by ~40% and ~37% with a concomitant decrease in insulin of ~76% and 52% in KKAy diabetic mice (Cheung and others 2001). Both results were comparable to reductions (37% for glucose and 67% for insulin) observed for the thiazolidinedione, rosiglitazone, administered at a dose of 0.33 mg/kg (Cheung and others 2001). Asian ginseng fed at 1000 mg/kg/d for 15–16 d reduced fasting glycemia by ~35% in streptozotocin-induced diabetic rats (Xie and others 1993). Asian ginseng root extract at 150 mg/kg significantly improved glucose tolerance by ~10% in ob/ob mice (Dey and others 2003). Asian ginseng berry extract at 150 mg/kg significantly improved glucose tolerance by ~30% in both ob/ob mice (Dey and others 2003) and db/db mice (Xie and others 2002a) after 12 d. It also improved fasting insulin and insulin sensitivity in ob/ob mice after 12 d (Attele and others 2002). Finally, 150 mg/kg American ginseng berry (Xie and others 2002b) and 50 and 150 mg/kg American ginseng leaf (Xie and others 2004) extracts were

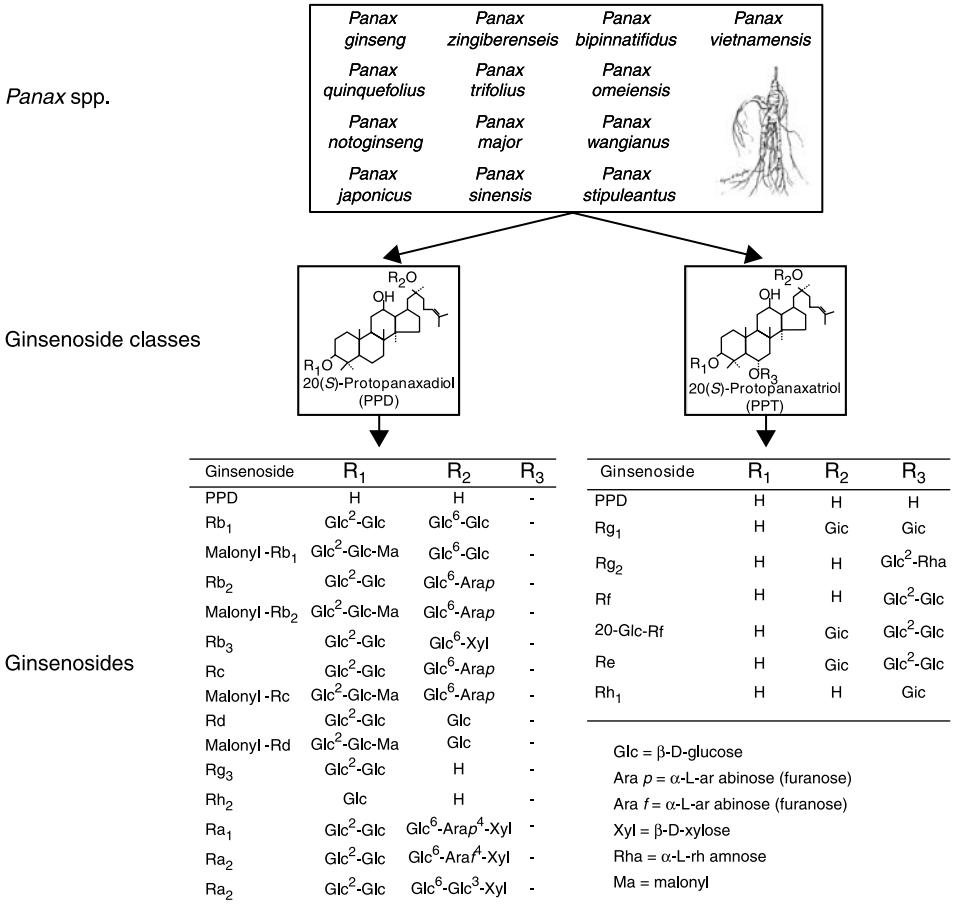

Figure 55.1 *Schematic depicting the 13 known species of ginseng and the structures of the two dammarane-type triterpene glycoside classes of ginsenosides derived from them with examples of the most common individual ginsenosides derived from each class. The individual ginsenosides and the composition of their glycosidic side chains are tabulated below each structure. Adapted from British Columbia Ministry of Agriculture (1999), NG and Yeung (1985), and Attele and others (1999).*

able to replicate the improvements in glucose, insulin, and body-weight control in ob/ob mice after 12 d.

Acute reductions in glycemia have also been reported following various ginseng sources. A water extract of Asian ginseng injected intravenously at 100 mg/kg with glucose decreased glycemia significantly compared with glucose alone in diabetic mice (Kimuru and Suzuki 1991). An oral injection of a water extract of Asian ginseng decreased glycemia at doses of 200 and 400 mg/kg by ~18 and 28% in normal mice and by ~23 and 36% in epinephrine induced hyperglycemic mice (Ohnishi and others 1996). Methanol extracts of Chinese, Korean red, Ontario grown American, and Sanchi ginsengs administered by stomach intubation decreased glycemia in resting mice from ~5–15% compared with placebo (Martinez and Staba 1984). And established extracts of Asian ginseng administered intraperintoneally reduced resting glycemia, epinephrine induced hyperglycemia,

and intravenous glucose tolerance: *DPG-1* at 360 mg/kg (Kimura and others 1981), *DPG-3-2* from 3 to 100 mg/kg (Morita and others 1985), *EPG-3-2* at 50 mg/kg (Kimura and others 1981; Hitonobu and others 1982), and *Fraction 4* at 10 mg (Yokozawa and others 1975). Taken together, these data suggest that ginseng possesses acute hypoglycemic effects.

55.4.2.2 Antihyperglycemic Effects of Ginsenoside in Animals. Specific ginsenosides may play a role in the effects observed with whole ginseng and its extracts. Various ginsenosides and their classes have been shown to decrease glycemia directly in various animal models. For example, the most prevalent PPT ginsenoside, Rg_1, was shown to decrease glycemia in resting mice by 17% compared with placebo when administered by stomach intubation at 50 mg/kg (Martinez and Staba 1984). Rb_2, a PPD ginsenoside, was also noticed to decrease glycemia in streptozotocin induced diabetic rats after 6 d at 10 mg/kg by intraperintoneal injection (Yokozawa and others 1985a). An Asian ginseng extract high in Re significantly reduced glycemia in alloxan diabetic mice (Kimura and others 1981). Finally, Re decreased fasting glycemia in ob/ob mice after 12 d at 20 mg/kg by intraperintoneal injection (Attele and others 2002).

55.4.2.3 Antihyperglycemic Effects of Panaxans, Quinquefolans, Eleutherans, and Ginsenans in Animals. The role of non-ginsenoside components in the antihyperglycemic effects of ginseng cannot be precluded, although their effects have only been observed following intraperintoneal injection. Panaxans A-U from Asian ginseng (Konno and others 1984; Konno and others 1985; Ng and Yeung 1985), quinquefolans A-C from American ginseng (Oshima and others 1987), and eleutherans A-G from Siberian ginseng (Hikino and others 1986) have all shown marked yet differential hypoglycemic effects when administered as intraperintoneal injections at doses from 10 to 300 mg/kg in both normal and alloxan induced hyperglycemic mice. No studies investigating the effects of ginsenans on glycemia could be found in the literature.

55.4.3 Antidiabetic Mechanisms of Ginseng and Its Components

How ginseng through its various fractions has its effect on glycemic regulation is not clear. In vitro and animal data support four possibilities: modulation of (A) glucose absorption, (B) insulin secretion, (C) glucose transport, and/or (D) glucose disposal (Fig. 55.2). A discussion of each follows.

55.4.3.1 Modulation of Glucose Absorption. There is indirect in vitro and animal evidence to suggest that ginseng may affect the rate of digestion. An inhibition of neuronal discharge frequency from the gastric compartment of the brain stem in rats by American ginseng has been observed (Yuan and others 1998). Inhibition of gastric secretion by Chinese ginseng has also been observed in rats (Suzuki and others 1991). The result of both may be to slow the digestion of food, decreasing the rate of carbohydrate absorption into portal hepatic circulation. This suggestion is supported by more direct evidence. More recent data showed that the addition of Asian ginseng inhibited both glucose and maltose stimulated duodenal muscle movement, as assessed by short circuit current in isolated rat and human duodenal mucosa (Onomura and others 1999).

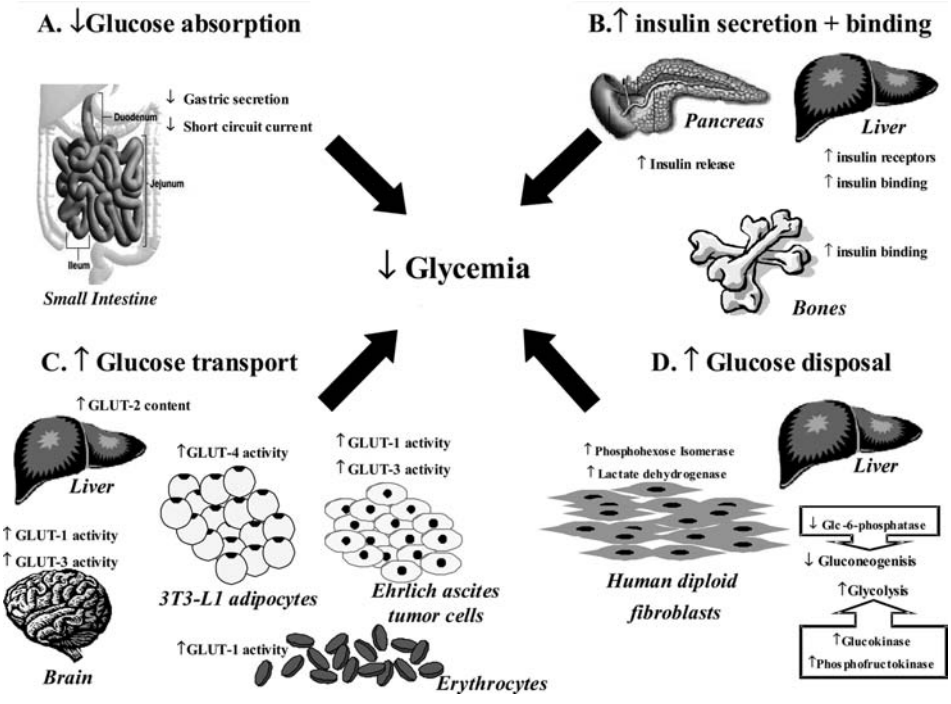

Figure 55.2 *Schematic depicting the four possible antihyperglycemic mechanisms of action of ginseng and its components: (a) modulation of glucose absorption, (b) modulation of insulin secretion and binding, (c) modulation of glucose transport, and (d) modulation of glucose disposal. The site of action and specific observations at that site are shown for each mechanism. Please refer to the accompanying text for greater detail and references. GLUT denotes glucose transporter.*

55.4.3.2 Modulation of Insulin Secretion and Binding. Both in vitro and animal data indicate that various ginseng extracts and ginsenosides increase insulin secretion and binding. DPG-3-2 stimulated insulin biosynthesis in mice islets and rat pancreas at concentrations from 0.5 to 1.0 mg/ml (Kimura and others 1981b; Hitonobu and others 1982). EPG-3-2 increased glucose stimulated insulin secretion in alloxan diabetic mice at doses from 10 to 50 mg/kg after intraperintoneal injection (Waki and others 1982). Total ginsenosides from Asian ginseng increased glucose and nonglucose stimulated insulin release from rat islets in a dose dependent manner at doses from 0.10 to 0.25 mg/ml (Li and Lu 1987). Rg_1 increased insulin binding with a ~2-fold increase in the total number of binding sites in rat liver and brain 3 d and 5 d after three consecutive days of intraperintoneal injections at 10 mg/kg/d (Tchilian and others 1991). An Asian ginseng extract with 40% total ginsenosides/saponins increased insulin binding by ~4-fold in the bone marrow of older rats at an intra-gastric dose of 100 mg/kg/d for 12 d (Yushu and Yuzhen 1988). Finally, panaxan B increased glucose stimulated insulin secretion in a dose-dependent manner at doses from 0 to 10 mg/kg with a maximal increase that was 6-fold higher than control and increased insulin binding 5 h after intraperintoneal injection in normal mice (Suzuki and Hikino 1989).

55.4.3.3 Modulation of Glucose Transport. A growing database of in vitro studies suggests that ginseng and some of its components may increase glucose transport in

various cell lines. A water extract of Chinese ginseng increased GLUT-2 protein in the livers of normal and hyperglycemic mice (Ohnishi and others 1996). PPT, (20R)-PPD, Rg_1, Rc, Rd, Re, Rf, Rg_2, Rh_1, Rb_1, and Rb_2 increased 2-deoxy-D-[2-^{3}H]-glucose uptake in isolated sheep erythrocytes by GLUT-1 in a dose dependent manner at doses from 0.01 to 10 μM (Hasegawa and others 1994). The standardized Asian ginseng extract G115®, which has a high ratio of PPD:PPT (Cui 1995), increased 2-deoxy-D-[2-^{3}H]-glucose uptake in a dose dependent manner in rabbit brain at doses from 23 to 46 μg/ml (Samira and others 1985) and Ehrlich ascites tumour cells at doses from 0.5 to 10 μg/ml (Yamasaki and others 1993). Presumably these increases in uptake were mediated principally by GLUT-1 and/or GLUT-3, as neither tissue expresses SGLT-1, GLUT-2, or GLUT-4 (Au and others 1997) and the GLUT-5 in brain has only low affinity for glucose (Sheppard and Kahn 1999). A water extract of Asian ginseng increased basal (non-insulin stimulated) 2-deoxy-D-[2-^{3}H]-glucose uptake in 3T3-L1 adipocytes at a dose of 100 μg/ml, presumably through GLUT-4 (Hong and others 2000). Finally, panaxan B increased glucose disappearance during an insulin suppression test at an intraperintoneal dose of 10 mg/kg after 5 h in normal mice (Yushu and Yuzhen 1988).

These direct effects on glucose transport are further supported by primary effects of ginseng on related intracellular signaling systems. An effect on the peroxisome proliferator activated receptor-γ (PPAR-γ), the target of the thiazolidinediones, has been observed. The aqueous extract of Asian ginseng rootlets increased PPAR-γ protein comparably with rosiglitazone in KKAy mice (Chung and others 2001). Ginsenosides Rh1 and Rh2 also decreased PKC activity at concentrations from 10 to 100 (M, via a concomitant decrease in its allosteric activator diaclyglycerol (DAG), in NIH 3T3 fibroblasts (Byun and others 1997). Other effects included decreasing effects of ginsenosides Rb1, Rb2, and Rc on tumor necrosis fator-α (TNF-α) in human macrophages at concentrations from 10 to 100 M (Cho and others 2001). Similar changes have been related to improvements in insulin sensitivity (Itani and others 2002; Ruan and others 2002).

55.4.3.4 Modulation of Glucose Disposal. Data from various animal models of diabetes suggest that different ginseng extracts and ginsenosides may increase glucose disposal. The saponin fraction from G115® at a dose of 200 μg/ml in human diploid fibroblasts increased the glycolytic enzyme, phosphohexose isomerase, and several isozymes of the pyruvate lactate shunt enzyme, lactate dehydrogenase, although no changes in intracellular or extracellular glucose concentrations or glucose uptake accompanied these changes (Shia and others 1982). Oral administration of aqueous extracts of Asian ginseng root body and rootlets at a dose of 500 mg/kg for 28 d decreased the activity of the rate limiting gluconeogenic enzyme glucose-6-phophatase (G6Pase) in liver preparations of KKAy diabetic mice by 46% and 20% (Chung and others 2001). Asian ginseng berry extract at 150 mg/kg and American ginseng leaf at 50 and 150 mg/kg significantly increased glucose disappearance in ob/ob mice after 12 d (Attele and others 2002; Xie and others 2004). Finally, Rb_2 increased the activity of the rate limiting glycolytic enzymes phosphofructokinase and pyruvate kinase, while decreasing the activity of the rate limiting gluconeogenic enzyme G6Pase in liver from normal rats after a single 10 mg intraperintoneal injection (Yokazawa and others 1984b) and increased the activity of glucokinase while decreasing the activity of G6Pase in liver from streptozotocin diabetic rats after intraperintoneal injection at 10 mg/d for 6 d (Yokozawa and others 1985a). These mechanisms are also supported by the same primary cellular signaling mechanisms described above for improvements in glucose transport.

55.4.4 Effect of Ginseng and Its Components on Features of the Metabolic Syndrome in Animals and In Vitro

Ginseng and its components been shown to have effects on several features of the metabolic syndrome in animal and in vitro models. First, an extract of Asian ginseng berries with high Re improved obesity, inducing weight loss in db/db (Xie and others 2002a) and ob/ob mice (Attele and others 2002).

Second, Korean red ginseng and its total ginsenosides (Yamamoto and others 1983a; Inoue and others 1999), fractions 3 and 4 (Yamamoto and others 1983b, c), a lipophillic ginseng fraction (Park and others 1996), Rb_1 (Park and others 2002), and Rb_2 (Yokazawa and others 1984a, 1985b) improved the dyslipidemia that characterizes the syndrome, decreasing serum triglycerides while increasing serum HDL-cholesterol in the rat. This is in addition to related effects that included decreasing serum cholesterol (Sakakibara and others 1975; Ikehara and others 1978; Yamamoto and others 1983b, c; Yokazawa and others 1984a, 1985b), plasma free fatty acids (Yamamoto and others 1983c), and liver total cholesterol (Sakakibara and others 1975; Ikehara and others 1978; Park and others 2002) and increasing clearance of ^{14}C-labeled cholesterol from plasma and excretion of C^{14}-labeled cholesterol and its metabolites (bile acids, saponifiable material, sterols) from the liver (Yamamoto and others 1983c).

Third, different ginseng species and their fractions improved hypertension. Sanchi ginseng decreased both systolic and diastolic blood pressure (Lei and Chiou 1986) and total ginsenosides from Asian ginseng decreased mean blood pressure in a dose dependent manner in the rat (Kang and others 1995a). An aqueous Asian ginseng extract (Toda and others 2001), Korean red ginseng preparations with increasing concentrations of Rg_3 (Kim and others 2001), total ginsenosides (Kang and others 1995b), PPTs, Rg_1, Rg_3 (Kim and others 1999a, b), Re (Kang and others 1995a; Scott and others 2001), and Rb_1 (Scott and others 2001) also produced related increases in endothelium-dependent relaxation mediated by nitric oxide and cGMP (Kim and others 1983b; Kang and others 1995a, b; Kim and others 2000; Scott and others 2001; Toda and others 2001) and endothelium-independent relaxation mediated by potassium channels (Kim and others 1983a) in studies in animal aorta, cerebral arteries, and ventricular myocytes.

Fourth, various ginseng species and their fractions improved impaired fibrinolysis. Japanese ginseng (*Panax japonicus* C.A. Meyer) (Matsuda and others 1989), notoginsenoside-R1 (Zang and others 1997), Rg_1 (Ushio 1992; Matsuda and others 1986b), Rg_2, Rg_3, Re, Rb_1, Rb_2, Rc (Matsuda and others 1986a), and Ro (Matsuda and others 1986a, b) increased fibrinolysis mediated by increases in tissue plasminogen activator (tPA) (Ushio 1992; Zhang and others 1997) and urokinase (Matsuda and others 1986b, 1989) and decreases in plasminogen activator inhibitor-1 (PAI-1) (Zhang and others 1997). An Asian ginseng extract (Cui and others 1999), Korean red ginseng (Yun and others 2001), the lipophilic fraction of Asian ginseng (Park and others 1996, 2002), Rb_1, Rb_2, Rc, Re, Rg_1, Rg_2, Ro (Matsuda and others 1986b), and Rg_3 (Jung and others 1998) have also produced related inhibitory effects on platelet aggregation and adhesion in rabbit, rat, and human platelets (Matsuda and others 1986b; Park and others 1995; Jung and others 1998; Cui and others 1999) and coagulation, assessed by increased activated partial prothrombin time (APPT), prothrombin time (PT), and thrombin time (TT) in platelet-poor rat plasma (Yun and others 1987; Park and others 1996; Jung and others 1998).

Taken together, various ginseng sources and ginsenosides have been shown to improve features of the metabolic syndrome in animal models that include obesity, dyslipidemia, hypertension, and impaired fibrinolysis. These effects are in addition to the observed

antihyperglycemic effects of ginseng and its components and can be considered complementary in reducing diabetes and cardiovascular disease risk in animal models.

55.4.5 Antidiabetic Efficacy of Ginseng and Its Components in Humans

Until recently, there was very limited data in humans to support the traditional use of ginseng in diabetes and confirm the hypoglycemic effect of ginseng observed in animal and in vitro models. Only a small group of flawed published studies were accessible. Sotaniemi and coworkers (1995) reported that 8 weeks of treatment with 100 and 200 mg/d of an unspecified ginseng improved fasting glycemia and longterm glycemic control, assessed by HbA1c, respectively in 36 type 2 diabetic subjects. But the results were ambiguous due to significant weight loss differences between the treatment groups and poorly described statistics. In another study, Tetsutani and coworkers (2000) reported that 24 months of treatment with a Korean red ginseng extract at doses from 3 to 4.5 g decreased HbA1c in 34 people with type 2 diabetes compared with controls. But the subject selection, allocation to treatment, statistics, and follow-up of the study were very poorly described. Secondary sources also reported glycemic benefits of Korean red ginseng in diabetes (Anonymous 2005). But control groups were not reported and primary sources could not be retrieved for verification.

55.4.5.1 Antihyperglycemic Effects of American Ginseng in Humans. The need for good human data prompted us to initiate a clinical testing program to explore the acute and chronic effects of American ginseng in humans. We conducted a series of five randomized placebo controlled acute clinical studies (Table 55.1) to evaluate the efficacy of American ginseng (*Chai-Na-Ta Corp.*, BC) in lowering postprandial glycemia and its dosing and timing effects in subjects with and without diabetes using a 25 g-OGTT protocol. The principal goal was to identify an efficacious dosing and timing schedule for of a single batch of American ginseng for a longterm study. The main findings were 4-fold: (1) American ginseng reduced postprandial glycemia from 9.1 to 38.5%; (2) doses from 1 to 9 g were equally efficacious; (3) times from 0 to 120 min before the glucose challenge were equally efficacious in diabetic subjects without interaction with their usual antiihyperglycemic therapy; and (4) only AG >40 min before the OGTT reduced glycemia in nondiabetic subjects. We concluded that the selected batch of American ginseng at a dose of 1 g, administered as an oral agent 40-min before each meal was sufficient to reduce acute postprandial glycemia (Vuksan and others 2000a–d, 2001c).

Although this acute clinical testing program identified an efficacious treatment protocol, it was unclear which part of American ginseng's profile gave rise to the acute antihyperglycemic effects. To address this issue, we measured the ginsenoside composition of the American ginseng used in all of the above acute studies (Table 55.2). It was noticed that it had a high proportion of PPD (Rb_1, Rb_2, Rc, and Rd) relative to PPT (Rg_1, Re, Rf) ginsenosides, a ratio smaller than one for the ratios Rg_1/Re and Rb_2/Rc, and Rf was absent. All of these features of its composition indicated that ginseng was of the genus and species selected (Ma and others 1996; Wang and others 1999; Awang 2000). Although it was tempting to suggest that these features might be responsible for its effects, without a basis for comparison we concluded that they were interpretable only for authentication (Vuksan and others 2000a–d, 2001c). Other unmeasured components could have played an independent or interactive role. These include >25 different ginsenosides, >10 peptidoglycans (quinquefolans for American ginseng), various ginsenans, numerous peptides and fatty acids, and countless other organic compounds. It was

TABLE 55.1 Summary of Five Acute Clinical Studies Assessing the Dosing and Timing Effects of a Single American Ginseng (AG) Source on Postprandial Glycemia.

Study	Sample	OGTT Dose	AG Dosing	AG Timing	% AUC Reductions	*P*-value

concluded that replication of the findings with an American ginseng designed to have a similar profile was the most viable way to offer evidence for the efficacy of this ginsenoside profile.

The ginsenoside profile and treatment protocol identified in our acute clinical testing program were applied to a longterm study. We designed an American ginseng extract (*Chai-Na-Ta Corp.*, Langley, BC) to have a ginsenoside profile similar to that of the American ginseng used in the 5 acute studies (Table 55.2; Vuksan and others 2000a–d, 2001c): total ginsenosides of 3.54 and a PPD:PPT ratio of 2.4. An 8-week double-blind, placebo-controlled crossover trial was then undertaken in which the designed American ginseng extract or placebo at a dose of 1 g was administered as an oral agent 40 min before each meal (3 g/day) in 24 subjects with type 2 diabetes (Vuksan and others 2000e). The primary outcomes were markers of glycemic control. Fasting glucose and HbA_{1c} were decreased on the American ginseng extract compared with placebo after 8 weeks. There was also an observable but insignificant increase in insulin suggesting a possible improvement in β-cell function. These benefits occurred without increasing adverse events or altering hepatic, renal, haemostatic, or blood pressure function. Taken together, the data represented proof of two concepts. First, standardization of key features of the ginsenoside profile may lead to reproducible effects. But whether the standardized ginsenoside component is driving this reproducibility is unclear. It may only be acting only as a proxy for other non-measured ginsenosides or nonsaponin components such as the peptidoglycan fraction (quinquefolans). Second, our acute postprandial testing model used to select the most efficacious ginsenoside profile, dose, and time of

administration successfully predicted longterm safety and efficacy of a source of American ginseng in type 2 diabetes. The ~15–20% glycemic lowering efficacy seen acutely (Vuksan and others 2000a–d, 2001c) was sustained in this longterm investigation.

55.4.5.2 Antihyperglycemic Effects of Korean Red Ginseng in Humans. To test whether the batch, preparation, dosing, and timing of another species of ginseng could be selected to have longterm efficacy using the same acute postprandial testing program, a similar approach was applied to Korean red ginseng (steam treated *Panax ginseng* C.A. Meyer) (Sievenpiper and others 2002). We conducted a preparation-finding study of different Korean red ginseng root fractions followed by a dose-finding study of the most efficacious fraction. Double-blind, randomized, within-subject designs were used in both studies. In the batch-finding study, seven healthy subjects received 6 g placebo and Korean red ginseng preparations of rootlets, root-body, and whole root H_2O extract 40 min before a 50 g-OGTT. In the dose-finding study, 12 healthy subjects received 0 g (placebo), 2 g, 4 g, and 6 g of the most efficacious root fraction following the same protocol. The studies were successful in identifying efficacious preparation and dose of Korean red ginseng. In the preparation-finding study, a wide variation in the ginsenoside profiles was achieved across the three root fractions. This variation coincided with differential effects, although the PPD:PPT ratio was unrelated. Rootlets decreased AUC by 29% compared with placebo, while neither the H_2O extract nor root-body affected glycemia. In the dose-finding study, the rootlets were tested as the most efficacious fraction. A significant effect of rootlets treatment (mean of three doses) but not dose was found. The mean of three doses decreased AUC by 17% compared with placebo. Taken together the studies indicated that rootlets given at a dose of 2 g, 40-min before a meal was sufficient to achieve reproducible reductions in postprandial glycemia. This Korean red ginseng treatment protocol was indicated for longterm study (Sievenpiper and others 2006).

The most efficacious preparation (Korean red ginseng rootlets), dose (2 g), and mode of administration (oral preprandial agent at −40-min) selected from the sequential acute preparation- and dose-finding studies were subjected to longterm testing. A double-blind, randomized, placebo-controlled, crossover trial was conducted. Nineteen type 2 diabetic subjects received 2 g placebo or Korean red ginseng rootlets 40 min before each meal (6 g/d) for 12 weeks, while maintained on their conventional diabetes treatment. Fasting plasma insulin and 75 g-OGTT derived AUC plasma insulin were significantly decreased on the selected Korean red ginseng treatment compared with placebo. This occurred while fasting plasma glucose was unchanged and 75 g-OGTT derived AUC plasma glucose was significantly decreased. The combination was reflected in an identical 33% increase in both the homeostasis model assessment (HOMA) and the 75 g-OGTT derived insulin sensitivity indices on the selected Korean red ginseng treatment compared with placebo. These benefits occurred without increasing adverse events or altering hepatic, renal, haemostatic, or blood pressure function. We concluded that our acute testing program identified a Korean red ginseng preparation, dose, and mode of administration that improved longterm glucose and insulin regulation safely beyond conventional treatment in type 2 diabetes (Vuksan and others 2006).

55.4.6 Effect of Ginseng on Features of the Metabolic Syndrome in Humans

Additional effects of various ginseng sources on features of metabolic syndrome have been observed in humans. First, weight-controlling effects of ginseng have been reported.

In the clinical diabetes trial of Sotaniemi and coworkers (1995), 100 and 200 mg/d of the unspecified ginseng improved obesity, decreasing weight after 8 weeks of treatment compared with baseline.

Second, lipid and lipoproteinemia improving effects have been observed. Korean red ginseng at a dose of 4.5 g/d (1.5 g before each meal TID) improved dyslipidemia, decreasing triglycerides and increasing HDL cholesterol after 7 days in an uncontrolled pilot study of five normal and six hyperlipidemic men (Yamamoto and others 1983). In our longterm randomized, double-blind, crossover study with the American ginseng extract, total-cholesterol, LDL-cholesterol, and the total-/HDL-cholesterol ratio were reduced compared with placebo, with an observable but insignificant increase in HDL cholesterol in subjects with type 2 diabetes (Vuksan and others 2001d).

Third, antihypertensive effects have been observed in different cohorts. Different ginseng preparations improved various indices of blood pressure function. Korean red ginseng at a dose of 4.5 g/d (1.5 g before each meal TID) decreased 24 h mean systolic blood pressure compared with placebo after 8 weeks in 26 subjects with essential hypertension in a nonrandomized, unblinded, crossover study with a shortened placebo phase (4 vs. 8 weeks) (Han and others 1998). The Asian ginseng (*Panax ginseng* C.A. Meyer) extract *Ginsana G115* (Pharmaton, Ridgefield, CT, USA) significantly decreased acute blood pressure 2 h after ingestion compared with baseline (Caron and others 2002). Korean red ginseng significantly increased forearm blood flow responses, consistent with mediation by nitric oxide, in seven hypertensive test subjects compared with 10 untreated hypertensive control subjects (Sung and others 2000). In our longterm study with the American ginseng extract, both systolic and diastolic blood pressures were significantly reduced compared with placebo in subjects with type 2 diabetes (Stavro and others 2000). But two follow-up studies from our clinic with various American ginseng preparations showed null effects in hypertensive subjects (Stavro and others 2005, 2006).

Finally, improvements in haemostatic parameters have been observed with ginseng in subjects with type 2 diabetes. In our longterm study with the American ginseng extract, a significant reduction in plasminogen activator inhibitor-1 (PAI-1) was observed from baseline. But the comparison with placebo was only approaching significance (Vuksan and others 2001e).

Taken together, various sources of ginseng, especially Korean red and American ginseng, have been observed to improve different metabolic disorders related to diabetes in various human cohorts. In addition to impaired glycemia, these include prominent features of the metabolic syndrome: obesity, dyslipidemia, hypertension, and impaired fibrinoloysis. As these additional metabolic effects have been observed across different ginseng preparations, doses, disease models, and investigator groups, they offer robust support for the efficacy of American and Korean ginseng sources in reducing diabetes and cardiovascular disease risk in humans.

55.5 LIMITATIONS OF THE EVIDENCE FOR HERBS AND DIABETES

55.5.1 Variability in the Composition of Herbs

The evidence for the antidiabetic efficacy of herbs comes with serious limitations. Our experience with ginseng serves as an example. To quantify the extent of the variability in the active components found in ginseng, we undertook a meta-analysis of the coefficient-of-variation (CV) in ginsenosides across ginseng type (batch, preparation, variety, species), assay-technique, and ginsenoside-type. Thirty-two articles met the inclusion criteria. Together these articles reported ginsenoside concentrations for 317

batches of ginseng. Ginseng-type comprised 10 levels of *Panax* species, their preparations, and their varieties: 121 Asian (cultivated) (*Panax ginseng* C.A. Meyer (cultivated)), 36 Asian (red) (*Panax ginseng* C.A. Meyer (red)), three Asian (wild) (*Panax ginseng* C.A. Meyer (wild)), 35 Asian (extract) (*Panax ginseng* C.A. Meyer (extract)), 74 American (cultivated) (*Panax quinquefolius* L. (cultivated)), four American (wild) (*Panax quinquefolius* L. (wild)), seven American (extract) (*Panax quinquefolius* L. (extract)), 12 Japanese (*Panax japonicus* C.A. Meyer), 10 Pseudo (*Panax pseudoginseng* WALL.), and 10 Sanchi (*Panax notoginseng* (Burk.) F.H. Chen) ginseng batches. Assay technique comprised six levels of different assay techniques: 213 HPLC-UV, 43 GC-MS, 33 HPLC-MS, 12 DCC, nine HPLC-differential refractometry [DR], and four HPLC-ELSD. Ginsenoside-type comprised 21 levels of ginsenoside indices: the protopanaxadiol (PPD) ginsenosides (207 Rb_1, 197 Rb_2, 199 Rc, 202 Rd, 34 Rg_3), protopanaxatriol (PPT) ginsenosides (202 Rg_1, 230 Rf, 208 Re, 105 Rg_2) their sums (228 PPD, 229 PPT, 252 Total) and ratios (239 PPD:PPT, 255 Rb_1:Rg_1, 197 Rb_2:Rc, 261 Re:Rb_1, 262 Rc:Rb_1, 258 Rd:Rb_1, 259 Rb_2:Rb_1, 254 Rf:Rb_1, 207 Rg_1:Re). This meta-analysis demonstrated a high CV in ginsenosides across the three main factors: 26–103% for ginseng-type, 31 to 81% for assay-technique, and 36 to 112% for ginsenoside-type (Fig. 55.3) with the differences in ginseng-type dependent on the assay-technique used. This analysis demonstrated that the ginsenoside composition of ginseng is highly variable across different ginseng source parameters (Sievenpiper and others 2004a).

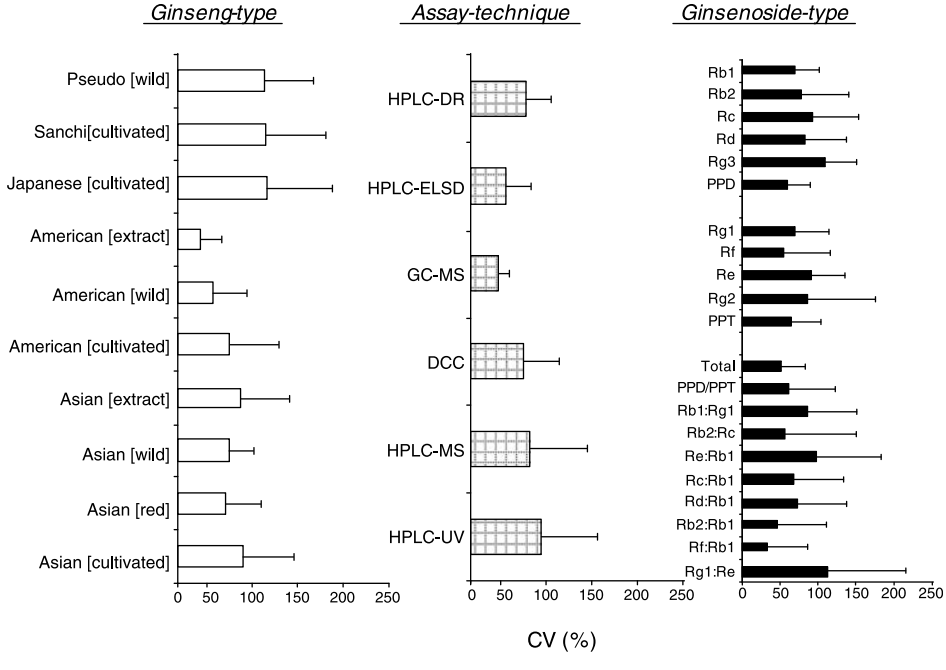

Figure 55.3 *Coefficient-of-variation (CV) of ginsenoside concentrations for the main effects species, assay-technique, and ginsenoside-type. CV of ginsenoside concentrations were calculated as CV = SD/mean x 100% in a three-factor block design. A blocking principle was applied to the data such that each level of each factor (10 levels of species, six levels of assay-technique, and two levels of ginsenoside-type) was crossed with each level of the other factors for the calculation of CV. The CV data calculated for each possible combination were pooled and meaned for each level of each factor. As a result, CV data are mean ± SD. Adapted from Sievenpiper and others (2004a).*

55.5.2 Variability in the Efficacy of Herbs

There is evidence that this high variability in composition may contribute to equally high variability in efficacy. Variable pharmacological effects appear secondary to differences in composition. We conducted a series of acute, blinded, placebo-controlled clinical studies, to assess the effect of increasing ginsenoside variability across similar ginseng source parameters of progressively greater ginsenoside variability (batch, preparation, variety, and species) on postprandial glycemia. A 75 g-oral-glucose-tolerance-test (75 g-OGTT) protocol was followed with ginseng administered 40 min before the start of each test. The ginsenoside variability we were able to achieve experimentally across the ginseng source parameters was equal to the actual variability seen across similar parameters in the meta-analysis. This coincided with highly variable glycemic effects. In the first study, while our original efficacious batch of American ginseng again demonstrated acute postprandial glycemic lowering efficacy, a second batch with a depressed ginsenoside profile including a low PPD:PPT ratio was ineffective (Sievenpiper and others 2003a). In the next two studies, another species, Asian ginseng, with marked inversions in its ginsenoside profile (PPD:PPT < 1) had null and opposing effects on plasma glucose indices (Sievenpiper and others 2003b). Finally, in the most recent study, in which eight of the most common ginseng types with distinct ginsenoside profiles were compared head-to-head, decreasing, null, and increasing effects was observed. A third batch of American ginseng lowered plasma glucose, while Japanese-rhizome (*Panax japonicus* C.A. Meyer), Sanchi (*Panax notoginseng*), Vietnamese-wild (*Panax vietnamensis*), and Korean red ginsengs had null effects and Asian (Sievenpiper and others 2004b), Siberian (*Eleutherococcus senticosus*), and American-wild ginsengs significantly raised acute postprandial plasma glucose (Fig. 55.4). The PPD:PPT ratio was implicated as the sole independent predictor of four of seven plasma glucose and insulin outcomes in this study (Sievenpiper and others 2004b). But the variance explained by this ginsenoside ratio was $<7\%$, bringing into question its utility as a marker for standardization. Again other unmeasured saponin or nonsaponin components could have played independent or interactive roles. Taken together, the high variability in acute postprandial glycemia appeared secondary to the variability in the ginseng source (batch, preparaprtion, variety, and species) and its composition, as represented by the measured ginsenoside profile, specifically the PPD:PPT ratio.

The implications of this high variability is that the evidence for efficacy and safety reported for specific herbal products may not be generalizable to other over-the-counter species, varieties, preparations, and batches of the herb. Although this concern makes a compelling argument for better regulatory standards, there are mitigating factors. One limitation is that no basis for standardization exists. For example, it is not clear which of the >30 ginsenosides and their ratios should be standardized in ginseng. The independent and interactive roles of other principles such as panaxans (peptidoglycans) and ginsenans (polysaccharides) are also unknown. The implication is that even with standardized products, uncertainty remains. Another important limitation is the assay. No universal assay exists for most compositional factors. The observed interaction between ginseng-type and assay-type seen in the meta-analysis of the CV in ginsenoside concentrations may produce biases in comparisons among ginseng samples. The same set of concerns is applicable to all herbal treatements.

Taken together, these limitations indicate the need to tie reference components to efficacy and establish specific assay criteria. Positive steps in this direction are being taken. In the case of ginseng, we reviewed above a growing database of rigorously conducted animal and in vitro studies that are pointing to different ginsenosides for

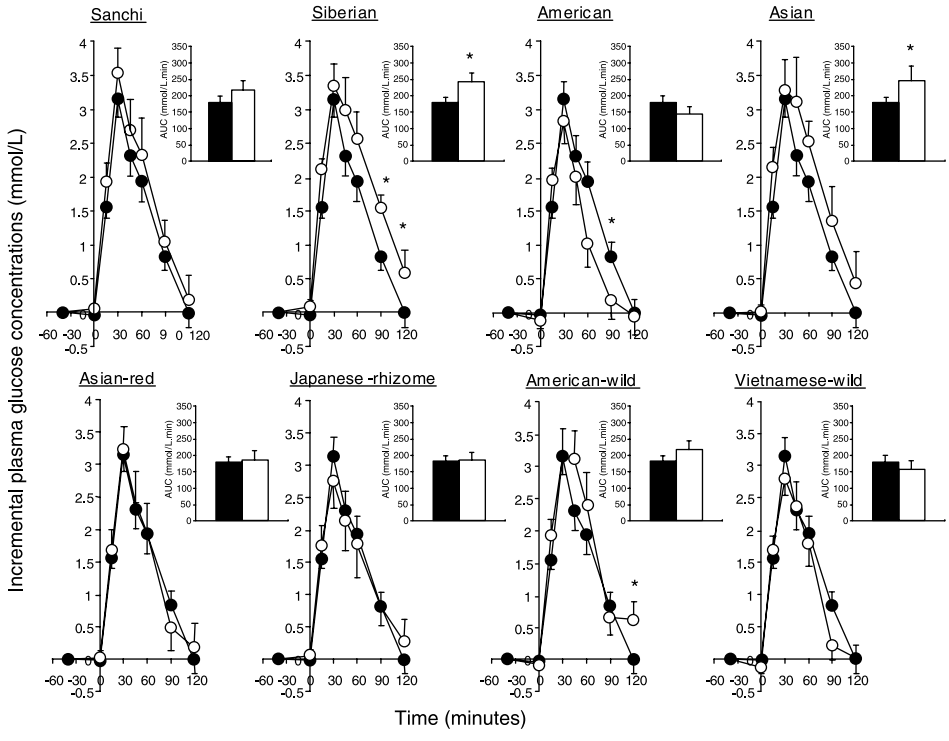

Figure 55.4 *Decreasing, null, and increasing effects of eight common types of ginseng on postprandial plasma glucose. The line plots and bars in the array represent the incremental change and area under the curve (AUC) for the mean of 2 identical placebos (•) or one of eight of the most popular ginseng types, Sanchi, Siberian, American, Asian, Asian-red, Japanese, American-wild, or Vietnamese-wild ginseng, (o) administered at a dose of 3 g 40 min before a 75 g-OGTT in 12 nondiabetic subjects (sex: 6 m:6 f, age: 34 ± 3y, BMI: 25.8 ± 1.2 kg/m^2). Asterisks indicate that points or bars for ginseng are significantly different from placebo ($P < 0.05$, one-way repeated measures ANOVA with non-orthogonal contrasts). Data are mean ± SEM. Adapted from Sievenpiper and others (2004b).*

antihyperglycemic indications. Some of the most promising isolated components, for which there is consistent data across different models, species, doses, and investigator groups include Re (Spinas and others 1998; Attele and others 2002), Rb2 (Yokozawa and others 1984b, 1985a; Hasegawa and others 1994), and panaxan B (Yushu and Yuzhen 1988; Suzuki and Hikino 1989). The American Botanical council (2006) has also initiated the largest ginseng evaluation program with the development of a common HPLC-UV assay. Finally, our clinic is presently undertaking a stepwise assessment of the effect of progressively smaller ginseng fractions on acute postprandial glycemia in nondiabetic subjects.

55.6 CONCLUSIONS

In conclusion, although the evidence from traditional systems of medicine through to randomized controlled clinical studies is largely aligned in supporting a diabetes indication for selected herbs, such as Ivy gourd and American and Korean red ginsengs, the reproducibility of their safety and efficacy remains questionable. The extensive evidence reviewed for ginseng illustrates this point. There is a large database of animal and in vitro studies that support the effect of various ginseng sources and ginsenosides and non-ginsenosides

components (panaxans, quinquefolans, eleutherans, and ginsenans) on glycemic regulation, effector mechanisms, and features of the metabolic syndrome. Added to this scientific foundation is a growing database of clinical studies that has twice shown that a ginseng source can be selected using an acute postprandial screening model to have long-term efficacy and safety in people with type 2 diabetes. Despite these advances, further clinical investigations have revealed compelling caveats. Not all ginseng sources exhibit the same magnitude or direction of effects in humans. Highly variable acute glycemic effects have been observed secondary to the ginsenoside profile, as it varies across ginseng batch, preparation, variety, and species. Variability across other unmeasured saponin and nonsaponin compositional factors also cannot be ruled out. The clinical consequences of this compositional variability may be that its efficacy and safety in diabetes will be equally highly variable. This situation necessitates that compositional markers of its antihyperglycemic effects be identified. Without these data the consumer cannot be assured of the safety and efficacy of ginseng products and the call from the medical community for randomized controlled trials and standardization of ginseng are moot. Although some leads have emerged, it remains unclear which species, varieties, batches, and preparations of ginseng have antihyperglycemic efficacy and which saponin or nonsaponin components confer this efficacy. The implication is that a basis for standardization for ginseng or other less well studied herbs is premature. One alternative may be to conduct batch-to-batch efficacy screening to identify efficacious batches using the same stepwise acute postprandial clinical screening model we have developed. But this alternative seems practically and financially untenable on an industrial scale. Future research directed at the identification of active components becomes the only viable means of supporting efficacy claims for herbs. In the absence of such standardization, consumers should remain cautiously optimistic about the use of herbs in diabetes.

ACKNOWLEDGMENT

This work was supported by grants from the Canadian Diabetes Association, Canadian Institutes of Health Research (CIHR), Korean Ministry of Agriculture and Forestry, Ontario ginseng growers Association, and Ontario ministry of Agriculture and rural affairs. We are grateful to Cyril WC Kendall, PhD, Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Canada and Marcella Garsetti, PhD, Danone Research, Palaiseau, France for expert peer review of the manuscript.

56.1 INTRODUCTION

The designation of "functional food" applies to foods that have a naturally occurring bioactive ingredient, that is, nutrient or phytochemical molecule, with major benefits to health beyond basic nutrition. Each bioactive ingredient exists in sufficient amounts in one serving of a functional food to either promote health, prevent disease, or both.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

These functional foods almost invariably carry a health claim if they are processed and packaged. Many examples of functional foods exist, but this chapter focuses on dairy products that provide calcium, or calcium plus vitamin D. Calcium-rich functional foods may have beneficial effects in decreasing the risks of a few tissue-specific cancers, they may also contribute to weight loss and to reduction of blood pressure, and they may lower the risk of skeletal fractures. Most human studies showing health benefits of calcium from dairy foods or from foods plus supplements of calcium have been population-based or epidemiologic, but others have been experimentally or clinically based. The highest value placed on any type of study is now accepted to be prospective randomized clinical trials (RCTs) because they have well defined end-points and they essentially link cause (etiologic risk factors) and effect. The major strength of RCTs is the randomization of subjects in human experiments to a treatment or control group. Even though other types of human studies, especially observational ones, may help investigators by generating hypotheses for the design of RCTs, they have lower scientific value because they do not meet these two criteria. This conservative approach to basing clinical decisions on the findings of RCTs is now commonly accepted as the scientific basis for medical therapy. Furthermore, meta-analyses of RCTs on the same diet-disease linkage are quite powerful in influencing medical decision-making for prevention or treatment of specific diseases.

The health effects of other macronutrients, especially magnesium and potassium that are found in rich supply in plant foods, have not been investigated to any considerable degree as calcium has. So, little information is available for review of research on these minerals at this time. The emphasis on calcium in this review, therefore, reflects the extensive investigation of this single mineral, either by itself or with vitamin D, on several health or disease endpoints.

56.2 DEFINITIONS

Functional foods, in the context of the definition of the term, include one or more ingredients that have a positive impact on bone mass or density, and that may help reduce skeletal fractures. New lines of investigation have been attempting to pinpoint benefits of calcium on the risk reduction of cancers and the loss of body weight resulting from adequate intakes of calcium on long-term basis. Only a few foods providing sufficient calcium fit this rather stringent definition. These are dairy foods, that is, milks, cheeses, yogurts, and related derivative products of milk. Soy milks, while important sources of calcium consumed by strict vegetarians and others, are not reviewed here because so little research has examined the roles of calcium from soy milk in health promotion and disease prevention. For the same reason, calcium-fortified foods per se are not reviewed.

Calcium is a mineral on the Generally Recognized as Safe (GRAS) list of the Food and Drug Administration that has multiple functions as a fortificant, in addition to its role as a basic nutrient. Because the upper limit (UL) of safety for calcium has long been established as 2500 mg/day, calcium fortification of suitable food vehicles has been generally considered safe. Concerns arise, however, regarding the potential, especially in conjunction with high intakes of vitamin D, of soft tissue calcifications, including those of arterial walls, and renal stones.

This review focuses on the health effects of calcium derived from foods obtained from cows' milk, from fortified foods, and calcium provided by daily supplements (pills).

Although other mammalian species provide milks rich in calcium, relatively few human studies have examined the calcium-health/disease linkages of milks other than those from cows.

56.3 MACROMINERALS: CALCIUM

The major macromineral with a rich literature on health/disease relationships is calcium, and so review of recent reports of calcium and its potential benefits on cancer, weight control, osteoporosis, and hypertension is offered. In several published reports calcium has been administered to experimental subjects along with vitamin D. So, unraveling the effects of one or another or both nutrients has not been easy; further comment on the results of research investigations involving both calcium and vitamin D are provided in this review.

The most positive data relating calcium intake to risk reduction of cancer applies to colon cancer for which a number of reports have found declines in colon or colorectal cancer when consumption patterns were adequate in calcium or when calcium supplements were taken. (By far, most of the studies have investigated colon cancer; only a few have examined rectal cancer, so that this review will cover only colon cancer.) Less positive support exists for an adverse role of calcium on prostate cancer risk reduction. The effects of calcium on bone health and osteoporosis prevention are weakly positive, and, therefore, less robust than often portrayed. The linkage of calcium to hypertension is weak, despite numerous reports attempting to show a major reduction of blood pressure following lengthy periods of calcium supplementation. The highlights of these reports are covered next.

56.3.1 Calcium and Cancer

Reports on this broad topic of calcium and cancer are numerous; so emphasis is on reports that have been published in the last few years. Most of the literature cited has focused on colon cancer, and much less on prostate and other cancers. Often calcium intake is closely related to vitamin D intake, but these two nutrients may have differing effects relating to cancer development or its prevention. For example, calcium and vitamin D may both may be considered protective against colon cancer, but they may have opposite effects regarding prostate cancer. Nutrients in dairy foods other than calcium that may also exert anticancer roles, including conjugated linoleic acids, but they are not reviewed herein.

56.3.1.1 Colon Cancer. The first major research report on the postulated linkage between vitamin D/calcium and lower risk of colon cancer was published in 1980 (Garland and Garland 1980). Several case-control studies have also supported the beneficial effects of calcium on colon cancer, but, because prospective trials provide more acceptable study methodology, they serve as the basis of the review of the calcium-colon cancer relationship.

A meta-analysis on this linkage published in 1996 concluded that calcium did not protect against colorectal cancer, but more recent prospective investigations have essentially reversed this earlier meta-analysis (Bergsma-Kadijk and others 1996). Why has this switch in perspective occurred? An accumulation of new evidence from more carefully designed studies has resulted in better understandings of the mechanisms through

which calcium ions may be influencing the carcinogenic process in colonic epithelial cells. Vitamin D has also been speculated to have a role in the benefit accrued from calcium, but too little research has been conducted on this vitamin alone for review here.

Colonic cancer development is a multiple-step process that begins with the formation of adenomatous polyps as the initial part of the adenoma–carcinoma sequence. Adenomas (polyps) may grow in size and develop increasing levels of disorganization or dysplasia. A small proportion of adenomas develop into carcinomas (cancer). Several genes are involved in the different stages, but the local colonic environment, including intraluminal nutrients, modifies cellular functions either favorably or unfavorably. Many of the clinically based investigations have studied patients with recurrent adenomas in order to demonstrate benefits of calcium, typically calcium supplements which increase total calcium intake to within the range of 1200–2000 mg per day, in reducing new polyp formation. These investigations, published in the last several years, have strongly supported a protective effect of calcium in reducing the risk of colon cancer. A few of these reports are noted.

Baron and others (1999) demonstrated that calcium supplements (1200 mg per day) given subjects with an increased risk for cancer because of a history of prior adenomas in treated subjects versus control subjects given a placebo. This was the first carefully designed randomized clinical trial on this relationship, and it essentially overruled the earlier studies that found no effect of calcium, including the meta-analysis (Bergsma-Kadijk and others 1996). Two other published reports of randomized clinical trials by Hofstad and others (1998) and Bonithon-Kopp and others (2000) arrived at a similar conclusion, namely calcium supplementation over several years significantly reduced colonic adenomas. Grau and others (2003) who used a supplement of both calcium and vitamin D found a significant reduction in adenomas and, based on their results, they suggested that sufficient dietary calcium was necessary for a beneficial effect of vitamin D.

A U.S. Cancer Prevention Study (not a trial) generated results from dietary intakes obtained from over 120,000 men and women that support a modest lowering of the risk of colorectal cancer with higher calcium intakes (those in the upper quintiles). The investigators reported a benefit of vitamin D only for men (McCullough and others 2003).

Peters and others (2004a) reported on almost 3700 patients with histologically verified adenomas of the distal colon and compared them to almost 35,000 subjects with no adenomas. Calcium intakes from foods and supplements were assessed in all subjects and then the subjects were split into quintiles according to total calcium intake. Colonic adenoma risk declined by 27% in subjects who consumed 1200 mg of calcium or more per day than for control subjects (low- or non-users of supplements) whose total calcium intake was less than $\sim$1000 mg. The significant decline in risk of adenomas was attributed by the authors to their supplement use that raised their total calcium intake to greater than 1200 mg a day (Peters and others 2004a).

The Women's Health Initiative (Wactawski-Wende and others 2006) found no reduction in colorectal cancer in postmenopausal women administered supplements of calcium plus vitamin D compared to women given placebo. This study has been criticized because the dose of vitamin D, 400 IU per day, is now considered too low to be effective. Other aspects of this study have also come under attack. Further investigations are needed, while addressing these deficiencies, to determine if calcium plus vitamin D, at a dosage of 800–1000 IU per day, is effective in reducing colon cancer. Both an adequate intake of calcium, 1000 mg per or so, and of vitamin D are now considered important for reducing the risk of colon cancer (Fleet 2006). Dietary or biosynthesized vitamin D may be critical

for mucosal cell maintenance of the active D metabolite, calcitriol, in colonic tissue, according to speculation based on results of a study of mice (Cross and others 2006).

Two major mechanisms of action of calcium in reducing colon cancer risk have been put forth, and they are not exclusive of each other. The first is that calcium ions, not absorbed by the small bowel, are able to bind to organic acids, such as free fatty acids and bile acids, within the lumen, thereby removing these potentially carcinogenic acids for elimination in stools. The other major mechanism has been newly proposed: calcium ions act with a calcium-sensing receptor (CaSR) found on the luminal membrane surface of epithelial cells of the colonic mucosa (Lamprecht and Lipkin 2003), and thereby modify intracellular signaling that is associated with the risk of advanced adenomas (Peters and others 2004a,b). It is presumed that both mechanisms may operate simultaneously to reduce the carcinogenic effects of bile acids on the colonic cells and also to improve intracellular calcium ion pathways that reduce cell proliferation but promote cell differentiation, depending on stage of cell differentiation (Buras and others 1995). Intracellular calcium may also help to regulate apoptosis in healthy cells. Finally, new understandings from animal studies suggest that colonic cells themselves help to maintain concentrations of the vitamin D hormone, calcitriol (also known as 1,25-dihydroxyvitamin D), which in turn keeps calcium ion concentrations up within these cells (Buras and others 1995). Folate may also be required in maintaining cell calcitriol levels by serving as methyl donors.

56.3.1.2 Prostate Cancer. The hypothesized positive linkage between calcium (and vitamin D) and prostate cancer remains rather tenuous after more than a decade of research. Yet, the idea that calcium ions may reduce prostate proliferation and inhibit carcinogenesis remains intriguing. Some reports, however, suggest that vitamin D may be the beneficial factor in preventing prostate cancer (Giovannucci 2005). Two reports of large prospective cohorts even concluded that high calcium intakes increased the risk for prostate cancer (Rodriguez and others 2003; Giovannucci and others 2006). A leading idea about the adverse effect of calcium on prostate cancer relates to the intracellular suppression by calcium of the metabolic conversion of vitamin D to its final hormonal form, calcitriol, which is considered beneficial for the prevention of prostate cancer (Giovannucci 2005). A recent report by Giovannucci and others (2006) issued a warning about the consumption of too much calcium by middle-aged men who may be at increased risk of prostate cancer. This cautious view is also supported by a meta-analysis (Gao and others 2005). Thus, the potentially different roles of these two dietary nutrients in reducing the risk of prostate cancer make it critically important that better understandings of their functions within prostate cells be obtained. If calcium is beneficial in colonic mucosa cells, why should it not also be beneficial, either alone or along with vitamin D, in prostate cells? Does vitamin D have a beneficial effect independent of calcium in colonic cells but not in prostate cells? Do these two nutrients regulate cell proliferation in a differential way? These and other questions regarding prostate caner etiology need answers.

The mechanisms of action of calcium ions and vitamin D, in the hormonal form, on prostate cells appear to be different than for colonic mucosal cells. Calcium ions apparently do not have effects on the CaSR on membrane surfaces of prostate cells because of the absence or low numbers of CaSR, as colonic epithelial cells do, but it remains possible that an intraluminal role of calcium ions exists for slowing proliferation and/or normalizing differentiation and apoptosis in prostate cells (Cross and others 2006). The

hormonal form of vitamin D acts on its nuclear receptors and activates vitamin D response elements of DNA, thereby promoting normal cell proliferation and differentiation, as well as supporting normal rates of apoptosis. The vitamin D hormonal receptor exists in practically all cell types of the body, not just in cells of the intestinal epithelium or bone. Understandings of the molecular biology of this receptor are still unfolding.

Observational and case-control studies have not provided such useful information that can help ferret out mechanistic understandings. No randomized clinical trials have been reported, but one recent report of an epidemiological cohort suggests that dairy sources of calcium and vitamin D may even increase the risk of prostate cancer (Tseng and others 2005). So, the postulated effects of calcium and vitamin D require further investigation using well-designed RCTs that can sort out the different effects of calcium and vitamin D on prostate cancer.

56.3.1.3 Other Cancers. Although other cancers, such as breast and ovarian cancers, may respond to dietary calcium or vitamin D in a positive way, too few investigations have been reported to generate a meaningful review. Vitamin D, without calcium, has been proposed to have potentially significant risk lowering effects for these reproductive cancers. The benefit of vitamin D, although promising, is supported by limited studies, none being a RCT.

56.3.1.4 Summary. The reports on colon cancer strongly support a beneficial effect of calcium or calcium plus vitamin D on the reduction of risk for colon cancer, but the same cannot be stated for prostate cancer at this time, since RCTs are lacking. Table 56.1 includes the findings of the more critical RCTs linking calcium intake and risk reduction of colon cancer. The mechanism of action by which calcium exerts its beneficial effects has not been fully established, but investigators suggest that, for colon cancer, unabsorbed calcium ions may combine with bile acids and other organic molecules with acidic groups within the lumen of the large bowel, thus preventing their uptake of these potentially carcinogenic acids by colonic epithelial cells. Mechanisms for a role of calcium ions in prostate cancer have not been elucidated. The concern that too high an intake of calcium may actually induce prostate cancer puts a dampener on supplementation of middle-aged men with calcium and vitamin D.

TABLE 56.1 Recent Findings of Randomized Clinical Trials Linking Supplemental Calcium Intake and the Reduction of Risk of Colon or Colorectal Cancer.

Reference	Treatment (Supp.) Daily[a]	Duration	Significant Outcome
Baron and others (1999)	Calcium (1200 mg)	12 months +48 months	Decreased recurrent adenomas (moderate)
Hofstad and others (1998)	Calcium (1600 mg)	36 months	Decreased adenoma formation
Bonnithon-Kopp and others (2000)	Calcium (2000 mg)	36 months	Modest reduction in adenomas (not signif.)
Grau and others (2003)	Calcium (1200 mg) & adequate vit. D status	48 months	Decreased recurrent adenomas

[a]Placebo used for control groups. Vit. = vitamin. Signif. = significant.

TABLE 56.2 Summary of Two Randomized Clinical Trials that Support the Relationship Between Calcium and Weight Reduction.

Reference	Treatment Daily[a]	Duration	Significant Outcome
Zemel and others (2004)	Ca supplement (500, 800, or 1200 mg)	6 months	6, 9, or 11% weight decrease; similar fat losses
Zemel and others (2005)	Dairy foods (milk or yogurt)	12 months	Weight reduction

[a]Placebo used for control groups.

56.3.2 Calcium and Weight Control or Weight Loss

Reports by researchers suggest that weight reduction in regular consumers of dairy products results from the large amounts of calcium consumed in these foods on a daily basis. This emerging area of investigation has stimulated great interest because of the current epidemic of overweight and obesity in the United States. Nevertheless, no randomized clinical trials have been performed on the calcium-weight relationship and the proposed mechanism through which calcium or vitamin D exerts its weight-lowering or appetite suppressing effect(s) have not been satisfactorily established.

In two recent publications examining women (Lin and others 2000; Zemel and others 2004), data suggest that increased intake of calcium-rich foods, either milk or yogurt, resulted in modest, though, significant weight loss over periods of 12 weeks or longer. The weight reduction in young healthy women may help prevent overweight (Lin and others 2000), but the study of weight loss in obese older women supports the benefits of dairy foods in helping these subjects lose weight (Zemel and others 2004). A recent abstract of a multicenter study which showed that, as a result of high dairy food consumption, the lean compartment of body composition may be increased along with a decline in the fat compartment (Zemel and others 2005). Other reports have generated similar conclusions.

Several possible mechanisms have been propounded to explain loss primarily in the fat compartment of the body, but evidence in support of a role for calcium or calcium plus vitamin D is limited.

In summary, these few reports support a very modest beneficial effect of calcium on the reduction of body weight. Complete data from RCTs are needed before the promise of the calcium-induced weight loss can be scientifically assessed. Table 56.2 includes a summary of the one RCT that has examined the relationship between calcium and weight reduction. In addition, the postulated mechanisms of action of calcium in contributing to weight reduction which remain elusive need further documentation.

56.3.3 Calcium and Osteoporosis

The long-held view that calcium intakes at or approximating the amounts recommended prevent or delay osteoporosis and related fractures. This generalization is only weakly supported by a scientifically more rigorous meta-analysis of randomized clinical trials that used calcium supplementation of postmenopausal women to try to improve bone density (Shea and others 2002). In the conclusion of this meta-analysis, the authors stated: “Calcium supplementation alone has a small positive effect on bone density. The data show a trend toward reduction in vertebral fractures, but do not meaningfully address the possible effect of calcium on reducing the incidence of nonvertebral fractures”

(Shea and others 2002). As developed next, skeletal gains from adequate calcium intakes are most robust in pre- and postpubertal boys and girls, especially when the calcium is provided by foods, rather than during late life. Calcium supplements of boys and girls have also been shown to increase bone mass and density, but once indistinguishable from those of control subjects within 6–12 months (Johnston and others 1992). So, adequate amounts of calcium provided by foods are more likely able to sustain optimal measurements of bone tissue than calcium supplements.

The most critical need for calcium intakes that help meet the recommended intakes of the Food and Nutrition Board of the Institute of Medicine (IOM 1997) relates to the development of peak bone mass during the prepubertal and postpubertal years of both boys and girls, that is, the span of years from approximately 8–18 years for girls and 10–20 years for boys. During this decade of early life, the accrual of bone mineral mass reaches almost 95% of total mass (sometimes referred to as optimal mass) of an individual during a lifetime (Matkovic and others 2005). Therefore, only about 5% of additional mass is gained during the decade of the 20s or slightly longer (Tylavsky and others 1989). This so-called consolidation may be enhanced by lengthy lactations of 6 months or longer by adult women, because of the large increase of "new" bone formation if calcium intake is adequate (Anderson and Rodano 1996). Bone mass typically begins to decline, though only slightly, during the latter part of the decade of the 1930s, especially in females. Although the strongest positive results of adequate calcium intakes have been shown for the growing skeleton, most of the calcium studies using supplements have involved postmenopausal women in efforts to reduce the risk of osteoporotic fractures.

A large literature exists on the relationship between calcium and bone, but only a few prospective RCTs using calcium supplementation compared to placebo have been reported for postmenopausal women. Data from studies of early postmenopausal women (less than 10 years since the menopause) suggest that calcium has practically no benefit to vertebral bone mineral density (BMD) and presumably to other skeletal sites (Dawson-Hughes and others 1990). On the other hand, later postmenopausal women (10 years or longer since the menopause) did receive some benefit, especially in modestly improved BMD of the lumbar vertebrae, but little or no benefit at other skeletal sites such as the proximal femur (hip) (Dawson-Hughes and others 1990; Elders and others 1994) (Table 56.3).

TABLE 56.3 Summary of Randomized Clinical Trials on the Relationship Between Calcium and Reduction of Osteoporotic Fractures of the Hip and Nonvertebrae or of All Skeletal Sites.

Reference	Treatment (Daily)[a]	Duration	Significant Outcome Fracture Reduction(s)
Dawson-Hughes and others (1990)	Ca supplement (1000 mg)	6 months	Vertebrae of women: >5 years postmenopause
Elders and others (1994)	Ca supplement (1000 or 2000 mg)	24 months	Vertebrae of women (perimenopausal)
Chapuy and others (1992)	Ca (1200 mg) and vitamin D (800 IU)	18 months	Hip & nonvertebral sites of women
Dawson-Hughes and others (1997)	Ca (500 mg) and vitamin D (700 IU)	36 months	Nonvertebral sites; only men significant
Larsen and others (2004)	Ca (1000 mg) and vitamin D (400 IU)	41 months	All sites of men and women

[a]Placebo used for control groups.

No studies of postmenopausal women using calcium-rich foods have been reported, but the dairy foods might have additional skeletal benefits because of the other nutrients they contain, including phosphate. The calcium: phosphate ratio of dairy foods is near 1 : 1, which provides less of a perturbation on calcium homeostasis than a supplement containing only calcium. These calcium-rich foods with phosphates may actually improve bone through short term increases in PTH that stimulate the bone formation activities of osteoblasts in bone tissue. This short-term effect of PTH has only been recognized in the last few years as contributing to bone-building. Studies of such foods in elderly subjects, especially postmenopausal women, are needed to verify the hormonal changes and increments in BMD. Vitamin D-fortified foods may possibly have an added boost in improving bone measurements. Supplements alone may not be as effective in stimulating PTH-mediated bone formation.

The proposed mechanisms for any skeletal benefit of calcium supplements in elderly women are two-fold. A slight increase in serum calcium ions resulting from intestinal absorption has an inhibitory effect on the secretion of parathyroid hormone (PTH) that works through the CaSR on cell membranes. The reduction in serum PTH in turn leads to a lower rate of skeletal resorption operating via osteoclasts and other osteolytic cells. The second mechanism, which implies an increase in intestinal calcium absorption mediated by the active hormonal form of vitamin D, that is, $1,25(OH)_2$vitamin D, provides more calcium ions for movement into bone and an increase in bone mass and BMD. Other mechanisms could also be operating to improve bone.

Another approach used by a few investigators to reduce skeletal fractures has been the combination of calcium plus vitamin D supplements. A few recent reports showing significant benefits of this combination treatment used in RCTs suggest that both calcium and vitamin D, at least in the northern latitudes of North America and Europe when vitamin D skin biosynthesis is low or zero, are needed to reduce the risks of osteoporotic fractures (Chapuy and others 1992; Dawson-Hughes and others 1997; Larsen and others 2004) (Table 56.3). When coupled with vitamin D, calcium supplements have helped to reduce significantly hip and other non-vertebral fractures (Chapuy and others 1992).

Still another approach has been the supplementation with vitamin D alone, but this preventive strategy works well only when calcium intake from foods is near recommended intake levels. Studies of vitamin D supplementation alone, though not all investigations have had significantly positive outcomes, have generally resulted in modest skeletal improvements in late postmenopausal women and older men. One vitamin D investigation in particular showed improved serum 25-hydroxyvitamin D and reduced parathyroid hormone concentrations in 50-year-old men and women administered 100 μg per day over a period of 6 months (Veith and others 2004). The investigators found this dosage level was also safe.

Because almost all of these studies have used calcium supplements at doses typically of 1000 mg per day or more, the abrupt initial perturbations in calcium regulation must be adjusted to by skeletal changes, that is, increases in bone formation and reductions in bone resorption, in order to obtain long-term gains in bone mass and density. In addition, the gains in bone mass and density following calcium supplementation, as considered in a meta-analysis, have been shown to be small or possibly nonmeasurable (Shea and others 2002). The long-term adaptations clearly lead to very modest increases in the bone measurements, as long as the supplements are continued. When they are stopped, bone measurements revert almost 100% of the time to presupplementation bone values (or worse). No comparable studies of postmenopausal women have been performed using

calcium-rich foods like milk, cheese, and yogurt. Also, only a few studies have been performed in elderly men so that conclusions cannot be made for this gender.

To sum up, although calcium supplementation results in only small gains in bone mass and density at almost every stage of the life cycle, it may be beneficial for many individuals because calcium exerts an inhibitory effect on the secretion of parathyroid hormone and, hence, on osteoclastic bone resorption. A tolerable upper limit of safety (UL) of 2400 mg exists and individuals who approach or exceed this amount from dietary sources and supplements may be at increased risks of soft-tissue calcification. So, consumption at or above the UL is of concern now in the United States because of the increasing prevalence of arterial calcification, such as of the aorta, and of potentially more serious calcifications of the kidneys and other organs.

56.3.4 Calcium and Blood Pressure

The relationship between calcium and blood pressure has been examined in many studies using adult men and women, but the findings have been controversial because so many other factors – both dietary and lifestyle – also affect blood pressure. Also, very few RCTs have been reported. The recent Dietary Approaches to Stopping Hypertension (DASH) studies which use a modified dietary approach to reduce blood pressure, including low-fat dairy foods, have shown modest lowering of both systolic and diastolic pressures in compliant subjects (Appel and others 1997; Sacks and others 2001). These two major DASH reports of RCTs have been widely cited for their beneficial effects, but the dietary changes have included, in addition to increased calcium, extra servings of fruits and vegetables that provide potassium, and little or no processed foods that typically contain sodium. So, a direct role for calcium alone in lowering blood pressure, if one exists, must be so small that it is difficult to measure in a consistent way to provide scientific validity.

56.4 SUMMARY OF THE RELATIONSHIPS BETWEEN CALCIUM-RICH FOODS AND REDUCTION OF DISEASE

The established benefits of calcium-rich functional foods on health are largely limited to bone and the reduction of osteoporotic fractures, but information about cancer, hypertension, and body weight/fat is being generated by new research investigations. The benefits of calcium from foods or supplements in RCTs have been limited to small gains (or incremental improvements in treatment groups compared to placebo or no treatment in control groups) in bone mass or density of adults over extended periods ranging from a year to several years, but the benefits are generally small, that is, 0.5–1.0%, even though these benefits are statistically significant (Shea and others 2002). Such statistically significant improvements have not been found for calcium alone (or calcium plus vitamin D) in other prospective studies, and results of too few RCTs have been reported for any solid conclusions about the calcium–disease relationships.

Potentially adverse effects of high consumption patterns of calcium or calcium plus vitamin D are of some concern in populations that are physically inactive and have high rates of adults with the metabolic syndrome. Such adult individuals are now known to be more likely to have calcified (mineralized) plaque in major arteries and potentially in kidney tissue, besides renal stones. Any site of calcification has serious effects, but

renal calcification may have deadly consequences. So, the question arises if nutritionists and other health professionals may be "pushing" too much calcium and vitamin D on the sub-population that already has adequate consumption of both calcium and vitamin D. Individuals who truly need greater amounts of these nutrients, as determined by U.S. dietary surveys such as NHANES and Canadian surveys, are generally the poor and less well educated. U.S. subpopulations include migrants and minorities, especially those with darker skin color who generate less vitamin D by skin synthesis. This issue of who benefits the most from functional foods containing calcium and possibly vitamin D needs further investigation and research support by federal agencies because the problem of low consumption of these nutrients may have broader consequences for a variety of chronic diseases than previously recognized. Nevertheless, calcium and vitamin D-enriched functional foods can be appropriately used to help prevent and to treat several diet-related chronic diseases in the developed nations of the world and help reduce deficiencies of calcium and/or vitamin D in the less developed world.

A further note of caution about calcium and vitamin D supplementation is raised by recent studies demonstrating a potential increase in arterial calcification in adults who already have significant plaque formation in their vessels rather than entry of the calcium ions into bone. How serious this shunting of calcium is for health remains uncertain now.

56.5 IMPLICATIONS FOR THE CONSUMPTION OF CALCIUM-RICH FUNCTIONAL FOODS

At this time, no FDA-approved health claims exist for (1) calcium and the reduction of risk of site-specific cancers, (2) calcium and the reduction of body weight, and (3) calcium and the reduction of blood pressure. A claim does exist, however, for calcium and the reduction of risk of osteoporosis. A logical progression would be the eventual approval of the additional claims for calcium, as reviewed herein. Yet, the scientific basis for each potential claim must be established first. Although the data for cancer, weight reduction, and hypertension are of considerable suggestive value, the cumulative research is not yet sufficiently strong to warrant approval of health claims for these. New trials and supportive findings on the calcium-rich functional foods are necessary before advanced scientific understandings of prevention of cancer or high blood pressure or weight reduction can be accepted by a consensus of the scientific community. Until new claims become established, the consumption of calcium according to the recommendations of the Food and Nutrition Board of the IOM (IOM 1997) remains the best guide for U.S. and Canadian populations. Functional foods containing both calcium and vitamin D may make the best combination of fortification because of the long-established dietary deficits of calcium and the newly recognized deficits of vitamin D among North American populations (Hanley and Davison 2005).

Several public health implications result from this review, as follows:

1. Calcium intakes that approximate the recommended intake levels for adults (IOM 1997) may have several physiologic benefits on cells and tissues that help maintain health and reduce the risks of several diseases or conditions. These benefits exist throughout life. Getting calcium from foods rather than supplements may be preferable because excessive intake may be better avoided.

2. Vitamin D intakes at recommended levels for adults (IOM 1997) are now considered to have been set too low, so that new guidelines are needed to attempt to overcome widespread insufficiency, if not frank deficiency.
3. The addition of vitamin D to calcium-rich foods may not only help maintain bone and reduce the risk of osteoporotic factures, but it may also help lower the risks of several cancers and a few other diseases or conditions. Because the recommended intakes for vitamin D of the IOM are now considered to be too low, populations living in northern (or southern) latitudes away from the equator may be at higher risk because of insufficient skin biosynthesis and may be consuming inadequate intakes of this fat-soluble vitamin, even though it is typically fortified in milk and a few other dairy products.
4. Emphasis on the consumption of foods rich in calcium and vitamin D, whether fortified with either nutrient or not, means that animal products must be a major contributor of these nutrients because plant foods typically are low in calcium, except for calcium-fortified soy milk. Strict vegetarians or vegans living at northern or southern latitudes are not likely to be able to synthesize enough vitamin D in their skin for more than six months each year throughout their lives.
5. Concern about excessive calcium intake from all sources, foods and supplements, remains when the UL of intake is set at 2400 mg per day because some individuals are close to or exceeding the UL in the United States. Calcium overload has potentially adverse effects on several organs because of the likelihood soft tissue calcifications.
6. For colonic cell health, adequate calcium and vitamin D intakes may need to be assured along with adequate folate for helping maintain the vitamin D hormone in colonic mucosal cells.

ACKNOWLEDGMENTS

Appreciation for help in this review process is expressed to Boyd R. Switzer, Ph.D., and Robert S. Sandler, M.D., for critical comments on the manuscript. Thanks are also offered to Agna Boass, Ph.D., for helping with resources and other aspects for this manuscript.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

57.1 INTRODUCTION

Thermal processing has been applied to foods as a traditional method to achieve several objectives, such as sanitation, preservation, palatability, and improved digestibility. From the sanitation point of view, heat processing is still the cheapest and most efficient method to ensure pathogen-free foods. Preservation is achieved by the destruction of spoilage microorganisms and enzyme inactivation that otherwise lead to food deterioration. Depending on the expected shelf life, a given treatment severity will be applied. Therefore, heat treatment varies from cooking, a relatively mild treatment, to commercial sterilization, a drastic process ensuring that practically all microorganisms are destroyed. Under certain circumstances, toxins produced by some microorganisms are also destroyed. Palatability, considered as consumers' acceptance, is also improved in cases such as meat and fish cooking, vegetable steaming, or bread baking. However, it is important to note that while heat processing improves food chemical and physical characteristics, it frequently, has a deteriorating effect.

57.2 CONSIDERATION FOR THERMAL PROCESS CALCULATIONS

Thermal process calculations derive from basic information: thermal resistance of a given microorganism, where destruction is taken as a basis for calculation, the temperature history of the food, the way it has been handled, and the expected shelf life under given storage conditions. However, other parameters must be considered such as physical and chemical properties of the food; temperature gradient between the food and the heating medium; heat transfer coefficients of food and container; and physical changes in the food during the process (gelling, viscosity reduction or increase, emulsion stability, etc.).

57.2.1 Food Heterogeneity

Microbiologically, to obtain a safe product is to reduce microbial-initiated reactions. To reach this objective, two important considerations are: minimize initial microbial populations and potential microbial colonization.

Physical structure determines the rate and extension of microbial colonization and, therefore, the required severity of any thermal process. Although microorganisms frequently cause spoilage in the food surface, migration to inner parts of the food depends on the food structure. Therefore, knowledge of food microbial ecology is necessary to design an efficient process. Food heterogeneity promotes diversity of habitats, and in consequence, of microbial populations. Macroscopic gradients are common in foods; for instance, lactic acid concentration in Emmenthal cheese (60 μmol/g in the surface and 0–10 μmol/g at the center), is related to the presence of propionibacteria in the center but is absent in the surface, whereas oxygen and pH gradients in Brie cheese determine bacterial population type: the center is anaerobic and highly acidic, and the surface is alkaline and aerobic (Board and others 1992). In tomatoes or tomato paste, if infected by *Alternaria*, *Rhizoctonia*, or *Fusarium*, surface pH is close to 8, but drops to 4.5–4.6 in the inner parts, where healthy tissue is located (Gould 1992).

57.2.2 pH

Foods can be classified, according to their pH, into highly acidic (pH $<$ 3.7), acidic (pH 3.7–4.5) and moderate acidic or neutral (pH $>$ 4.5). pH 4.5 is the grow limit

for *Clostridium botulinum*, a strict anaerobe widely distributed in nature and able to colonize almost any canned food. In low acidic foods, *C. botulinum* can grow, and produce toxins and thermo resistant spores, but cannot grow nor produce toxins in highly acidic foods; destruction of this microorganism is often the calculation basis of thermal processes of foods. Therefore, moderate acidic foods require more severe treatments due to possible pathogen presence (Peck 1997). Thermal process calculations at this pH are also based on inactivation of a facultative anaerobe, *Bacillus stearothermophilus*, its spores are 20 times more resistant than *C. botulinum* spores. Germination of *B. stearothermophilus* spores produce acid flavor due to acid and gas production, its optimum grow temperature is between 49 and 55°C, but cannot survive below 38°C.

A process calculation in acid foods is based on destruction of facultative anaerobes such as *Bacillus coagulans* (*B. thermoacidurans*), *B. macerans*, and *B. polymyxa*. Several thermoresistant spores can survive thermal processing, but if low pH is also a barrier, they do not represent a sanitation problem. Spore forming bacteria do not grow at $pH < 3.7$ (International Commission on Microbiological Specifications for Foods 1998); thermal processing of highly acidic foods is based mainly in yeast and fungi destruction.

57.2.3 Water Activity (a_w)

The food system becomes more or less susceptible to deterioration, dependent on two important factors:

- Amount of available water it contains.
- Amount of water necessary for microbial metabolism and chemical or enzymatic reactions.

Bacteria in general need more than $a_w = 0.90$ to grow; yeast can grow at $a_w > 0.88$ and fungi at $a_w > 0.75$. However, certain bacteria such as the pathogen *Staphylococcus aureus* can grow at $a_w = 0.86$ (Masana and Rodríguez 2006). *C. botulinum* grows at water activity as low as 0.95. Dry products do not need thermal processing, although yeast and fungi tolerate environments with low water activity (International Commission on Microbiological Specifications for Foods 1980).

57.2.4 Redox Potential (Eh)

Redox potential (Eh) is the oxidation–reduction balance, resulting from the concentration of chemical compounds promoting oxidation or reduction in a system. It is directly related to the type of microorganisms present. Strict aerobes, such as *Pseudomonas* can only grow at positive/oxidized Eh (+500 to +100 mv), whereas facultative such as *S. aureus* can grow in a wider range (+30 to −200 mv), and strict anaerobes at negative-reduced Eh, since they do not produce catalase or peroxidase necessary to eliminate preoxidized toxic substances. Chemicals such as proteins and S-containing amino acids are also efficient in promoting a reducing environment (Masana and Rodríguez 2006).

57.2.5 Thermal Conductivity

Heat penetration in foods depends on factors such as chemical composition, physical structure and physicochemical characteristics. Thermal conductivity (Cp), the thermal

flow rate within the product, largely depends on food composition. Carbohydrates, fats, and protein protect microorganisms against heating due to the low heat transfer coefficients of these chemical compounds. Meats, for instance, have very low coefficients (1.89 kJ/h m°K) (Stiebing 1992); if compared to stainless steel coefficient (59.47 kJ/h m°K) (Green and Maloney 1997). It is also important to note that food structure plays an important role in thermal conductivity. If a thermal flow is applied perpendicular to the meat fibers, Cp = 1.72 kJ/h m°K with 78% relative humidity at 0°C. If a thermal flow is applied parallel to the meat fibers, Cp = 1.76 kJ/h m°K at the same relative humidity and temperature conditions (Pérez and Calvelo 1984).

57.2.6 Antimicrobial Agents

Addition of antimicrobial agents is another method to increases sanitation and shelf life in several foods (Leistner 2000). Added benzoates or sorbates as well as chemicals naturally present in the food such as organic acids, essential oils, medium length chain fatty acid, alkaloids, and fitoalexins acts as antimicrobials (Deng and others 1999). Gram-positive bacteria, micrococcus, and *Bacillus* sp. are sensitive to egg conalbumin. Essential oils of cinnamon, garlic, onion, rosemary, and oregano inhibit various yeast species as well a mycelia of several fungi (Draughon 2004).

57.3 ENZYME INACTIVATION AND NUTRIENT DESTRUCTION

Another heat processing objective, in addition to producing foods free from pathogens and spoilage microorganisms, is enzyme inactivation since many spoilage processes are basically of enzymatic nature. Enzyme inactivation depends upon mechanisms similar to those affecting microbial inactivation rates; in fact, microbial destruction is based on inactivation of, at least, one enzyme involved in metabolic pathways (Ashie 2003). However, some isoenzymes are heat resistant and can cause deleterious changes in certain foods; for instance, peroxidases can promote off-odors in peas (Whitaker and others 2003). When thermal processes are calculated for enzyme inhibition, inactivation of the most heat stable enzyme is taken as the calculation basis. At low temperatures, destruction of heat resistant spores is higher than spore inactivation; the opposite is true at high temperatures (Brown 1982). As a result, the food can undergo spoilage due to enzymes that are still active after spore destruction; therefore, the process must be calculated on the basis of enzyme inactivation, not spore destruction. In general, enzyme inactivation and spore destruction take place at the same time: between 130 and 145°C (Dziezak 1991).

57.4 HEAT TRANSFER MECHANISMS

Inactivation of either pathogen or spoilage-causing microorganisms is calculated by heat penetration. Vegetative cells are destroyed at temperature slightly higher than optimum growth temperatures, whereas spores can survive at higher temperatures (Zamudio 2006). As heat application involves the destruction of at least one microbial enzyme,

vegetative cells and spores are inhibited according to a first order reaction rate equation (Baranyi and Roberts 1995):

$$-\frac{\mathrm{dc}}{\mathrm{dt}} = \mathrm{kc}$$

That is, cell concentration (dc) decreases (hence, negative) with time (dt) in a direct proportion of viable cell concentration. However, this is a logarithmic reduction; it decreases in log cycles (for instance, 10^3 to 10^2) as time linearly increases. Using this equation it is possible to compare death rate of several given microbial populations due to the fact that all microorganisms follow the same logarithmic destruction rate (Han 1975).

Thermal processing is basically an operation where heat flows from a hot body (the heating medium) to a cold body (the food). A dynamic process, it is a mechanism where heat flows in proportion to the causing force, and inverse to flow resistance (Karlekar and Desmond 1985). From the thermodynamic point of view, thermal processes are lead by at least one of the following heat transfer mechanisms: conduction, convection, and radiation.

57.4.1 Conduction

Heat is transmitted within a body due to vibration of adjacent molecules following the Fourier law:

$$q = k(A\Delta T/L)$$

where:

A = area
ΔT = temperature difference
L = material thickness
k = material thermal conductivity.

This mechanism occurs is solids, such as pieces of canned food, or material gelling in the can (luncheon meats, desserts, baby foods, etc.) (Mittal and Blaisdel 1984).

57.4.2 Convection

This mechanism takes place in fluid foods due to movement of different parts of the stream having different densities: changes in density occur during heating or cooling. This mechanism follows the Newton law:

$$q = hA\Delta T$$

where:

A = area
ΔT = temperature difference
h = depends on flow properties surface type and flow velocity of the heating medium.

The coefficient, h, varies widely, for instance: gases (natural convection): $h = 2.5-25$ kcal/h m$^{2\circ}$K; water (forced convection): $h = 500 - 5000$ kcal/h m$^{2\circ}$K; condensing steam: $h = 5000 - 15{,}000$ kcal/h m$^{2\circ}$K (Green and Maloney 1997).

Heat transfer during canning of foods such as soup, sauces and brines occurs by this mechanisms; the heat flow direction is from the heating medium (hot water or steam) through a barrier (the can) to a cold fluid within the can (the food) (Welti-Chanes and others 2003). Heat diffusion is faster if an external force is applied, such as can rotation, decreasing temperature difference to a minimum (Valiente 1997).

57.4.3 Radiation

Heat is transmitted by electromagnetic waves from a hot body and absorbed by a cold body. Infrared waves ($\lambda = 0.8 - 400$ μm) are used as a heating medium as they are easily absorbed and transformed into heat (Hanson 1990). This mechanism is seldom used in food processing, but it is commonly used in food preparation just before consumption at home and in hotels, restaurants, and so on.

57.5 HEAT AND MASS TRANSFER

As foods are complex systems, more than the above described mechanism frequently takes place. In addition, simultaneous heat and mass transfer often happens. This occurs in processes such as meat smoking or oven cooking. In meat products such as smoked sausages, moisture permeable casing acts as a barrier between the heating medium and the meat batter; heat is transferred from the hot air in the smokehouse together with chemicals in the smoke to the casing surface; from there, smoke components diffuse though the casing and into the meat batter (Müller 1990). Since the flow rate depends on the temperature difference between the gas environment in the smokehouse and the meat batter, the flow rate increases with the temperature difference, hence increasing the heating rate. Of the three heat transfer mechanisms, conduction and convection are predominant in foods. As conduction occurs by direct contact from particle to particle, this mechanism dominates inside the product from the surface inwards, in a transient state; that is, temperature in any one part of the product will change with time (Valiente 1997). From the heating medium (hot smoke) to the sausage surface, there is a convection mechanism caused by temperature gradients that promote free convection due to density gradients. Heating is more efficient in forced convection systems; this is the reason why industrial smokehouses are fitted with fans. Free convection in air (2.5–25 kcal/h m$^{2\circ}$K), such as oven cooking, if the heat transfer coefficient in the food surface is very small, the limiting factor is convection from the heating medium to the food surface. Conversely, when a very high heat transfer coefficient such as condensing steam (5000–15,000 kcal/h m$^{2\circ}$K) is applied; in this case the limiting factor of conduction rate inside the product (Hanson 1990).

In canning operations, it is assumed that in convection-heated foods all solid pieces immersed in a liquid have the same treatment as the brine. However, this assumption is only valid with solid pieces with high heat transfer coefficients. Since in most cases, heat transfer coefficients are low, process calculation is the same for conduction and convection regimes (Barbosa-Canovas 2003). In cases of a fluid product with severe mixing, such as HTST pasteurization, the same lethality takes place in every point of the food, although conduction cannot be considered.

The extent of heat penetration depends on the dominant mechanism; more intense penetration occurs in low viscosity foods or those with small particles because the main mechanism is by convection. In canned foods penetration can be increased by rotation, generally applied in continuous autoclaves. Very viscous or solid foods are heated by conduction, a slower mechanism occurring in vegetable puree, canned beans, baby foods, or canned sausages (Guerrero Legarreta 2001).

Heat transfer mechanisms may change certain foods during processing. For example, foods containing large amounts of starch or protein that gel within the can, such as dairy desserts, soups, or luncheon meats. During gelling, macromolecules such as proteins or carbohydrates interlink trapping water in the formed network. Due to the high molecular weight of proteins and carbohydrates, they behave as particles in suspension (Li-Chan and others 1985). At initial heating stages, the dominant mechanism is convection caused by density gradient; as particles interlink, heat is transferred by vibration between molecules changing the mechanisms to conduction (Himmelblau 1997). The practical aspect of phase changing is that heating rate also changes. Therefore, in food materials where this gelling is expected to occur heating time should be calculated to avoid overheating.

57.6 TIME–TEMPERATURE CALCULATIONS

Thermal processing calculations are based on the destruction of pathogens, spoilage microorganisms and enzymes. Chemical, physicochemical, and structural food characteristics of the food are taken into consideration, as well as expected shelf life, further storage conditions, packaging material, and quality deterioration. However, the main calculation basis is a given food microorganism. It was already discussed that, in general the strict anaerobe *C. botulinum* is taken as the target microorganism due to its pathogenicity; however, other target microorganisms are *B. stearothermophilus* as the facultative anaerobe. *B. thermoacidurans*, *B. macerans*, and *B. polymyxa* destruction is considered for acid foods, whereas *Coxiella burnetti* is the target microorganism for milk pasteurization (Guerrero Legarreta 2004).

In all thermal processes, as destruction follows a logarithmic model microbial population decrease is asymptotic to the x-axis. The concept of commercial sterility is then applied. Because commercial sterility must be achieved in every part of the food, process evaluation is based on the point taking the longest time to reach process temperature, that is, the "cold point." In conduction mechanisms, the geometric center is at the same time, the cold point. In convection mechanisms, it is located along a vertical axis, around one-third of the distance from the container's bottom end (Guerrero Legarreta 2001). Calculating thermal processes for a new product must include the cold point localization by placing thermocouples in several parts of the container. Several calculated parameters help to control the process efficiency, these parameters are described below.

57.6.1 D-value

Microbial destruction is logarithmic, 90% of the microorganisms are destroyed in a given time at constant temperature. This interval, different for each microorganism, is called decimal reduction time or D-value, it represents the number of minutes necessary to destroy 90% of a given microbial species at a given temperature. The temperature at

which D-value is calculated is written as $D_{70^\circ C}$; D-values are expressed in minutes. For instance, $D_{110^\circ C}$ for *Clostridum sporogenes* (i.e., to reduce 10^5 to 10^4 cells if heated at 110°C) is 10 min ($D_{110^\circ C} = 10$ min) (International Commission on Microbiological Specifications for Foods 1980).

57.6.2 z-value

z-value is the temperature increase necessary to obtain 1 by 10 reduction in D values. For instance, z-value for *C. botulinum* type A is z = 10°C, and $D_{121^\circ C} = 0.2$ min; this means that the same destruction is achieved at 131°C in 0.02 min and at 111°C in 2 min (International Commission on Microbiological Specifications for foods 1996). z-values increase with microbial heat resistance; for yeast, fungi, and bacterial vegetative cells values range from 1.1 to 5.5°C, and between 5.5 and 14°C for spores (International Commission on Microbiological Specifications for Foods 1980).

57.6.3 F-value

Adding up all destruction effects acting upon a microbial population, gives the F-value of the overall process. F-values allow comparing thermal treatments among different foods. F = 1 means the total lethal effects acting during 1 min at 121.1°C (250°F). Known Z-values are used to compare heating times at temperatures above or below 121.1°C. If Z-value is 10°C, it means that the process must be carried out at 111.1°C for 10 min to achieve the same lethal effect, or at 131.1°C for 0.1 min. The relationship between D and F, taking into consideration the initial and final microbial cell concentrations is:

$$F = D(\log a - \log b)$$

where:

a = initial microbial cell concentration

b = final microbial cell concentration.

It is assumed that a moderate acid food (pH > 4.5), is heated to a temperature that ensures that the food is safe from *C. botulinum* contamination. In this case, spore counts must be reduced from 10^{12} to $1 \times 10^{\circ}$, that is, a 12-log cycle reduction, or 12D. In other words, a contamination of one *C. botulinum* spores per gram of food, or $1/10^{12}$. Population of *C. botulinum* type A and B are the calculation basis for D-values at 121.1°C and 0.21 min. Under the 12D concept, foods should be heat treated at F = 2.5, which is called "botulinum heating," to ensure that *C. botulinum* is practically absent (Mathlouthi 1986).

As F-value is the effect of every part of the process, a simple but precise method to calculate the lethal effect during the heating and cooling operations is to record with thermocouples the temperature in the "cold point" of a food or food container, and to calculate the corresponding F-value. The addition of all F-values will be the total F-value for the process.

In the food industry, specific F-values used are defined and calculated, according to specific conditions:

F_s: addition of all lethal effects in an infinite number of points in the container. This is a calculated value, obtained as a result of F-values from all parts of food in the container.

F_c: addition of lethal effects (F) in the geometric center of a food container; that is the coldest point of the food container. F_c is lower than its corresponding F_s because

the heating effect in the containers geometrical center is lower that the total of every part of the container.

57.7 THERMAL PROCESSING IN THE FOOD INDUSTRY

Conversely with microorganisms and enzymes, the aim of a given thermal process is minimal nutrient destruction; since the same factors inhibiting microbial populations also affect nutrients. In some cases, such as HTST processing, temperature increase may cause microbial inhibition but not nutrient deterioration (Mathlouthi 1986).

Heat transfer principles are applied to all thermal processes in foods. However, every process type has a specific objective; process severity depends on this objective. There are basically four types of thermal processes in foods, depending on the applied temperature: scalding, cooking, pasteurization, and sterilization.

57.7.1 Scalding

Scalding is generally applied to fruits and vegetables before freezing, drying, or further processing; therefore scalding objectives depend on the following process. If it is applied before freezing or dehydration, the main objective is enzyme inactivation. Non-scalded frozen or dried food material undergoes changes in color, flavor, and nutritional value as a consequence of enzymatic activity. Peroxidase and catalase, widely distributed in plant material, are highly resistant heat resistant. Activity of these enzymes is taken as an indicator of scalding efficiency; if both are inactivated it is assumed that all other enzymes are also inactive (Quirasco and López Murguía 2006). Scalding time to destroy peroxidase and catalase depends on the fruit or vegetable, heating method, and size of the material. For instance, if scalded in boiling water, small beans require 1–1.5 min to inactivate peroxidase and catalase, whereas large beans 3–4 min; broccoli will need 2–3 min, and spinach 1.5 min (Collins and Marangoni 2000). In some cases, enzyme activation is also achieved during scalding. This is the case of pectinmethylstearase in green beans, its activity provides more firmness to the tissue. Fruits are scalded in calcium containing brines, to achieve more firmness by formation of calcium pectinate (Camire 2000).

In addition to enzyme inactivation, scalding has other advantages such as gas removal from the tissue, increase in tissue temperature and material cleaning. If the material is intended for canning, gas removal to reduce oxygen content in the can; provides better vacuum conditions. Most scalding operations are carried out by food contact with hot water or steam for a given time. Scalding can be a batch operation, although generally is continuous; the food on a conveyor is transported through a steam tunnel. Water scalding can also be a batch and a continuous operation; in batch, the food is immersed in hot water (90–100°C) for a given time. In continuous scalding the food is transported in several ways. If conveyor is used, the residence time depends on the velocity of the moving conveyor. The main problem of this scalding method is the need to renew large water volumes to avoid excessive solids in suspension that may cause off-flavors (Watson and Harper 1988).

57.7.2 Cooking

The main objective of cooking is to improve food sensory characteristics and digestibility. The term "cooking" is applied to different processes: oven cooking, grilling, roasting,

frying, boiling, and steam cooking; the way heat is applied depends on cooking type. Dry heat at more than 100°C is applied in oven cooking, grilling and roasting; boiling and steaming is carried out by placing the food in water; frying involves treatments at more than 200°C (Hanson 1990). Whether the process is carried out at high relative humidity, as well as process temperature, several changes can occur. Dry heat is less efficient than humid heat in inactivating vegetative cells or spores (Mathlouathi 1986). Presence of water also modifies the type of reaction taking place among flavor components (Bailey and Eining 1989).

Cooking is an efficient preservation process, if recontamination is prevented. Toxin destruction is also achieved during cooking, such as hemagglutinins in soybeans or enzyme inhibitors in wheat, as they are protein compounds and can be denaturalized during heating (Iwaoha and Brewer 2000). However, loss of nutrients also takes place. For instance, up to 56% folic acid. Thirty-six percent vitamin B6 and 20% vitamin B1 is lost in corn after 8 min (Collins and Marangoni 2000) of cooking.

57.7.3 Pasteurization

Pasteurization and commercial sterilization are basically the same process. They differ in the severity of heat treatment, and therefore the extent of microbial destruction. Whereas pasteurization was originally aimed at destruction of *Mycobacterium tuberculosis*, the bacteria causing tuberculosis, other bacteria having similar D-values, are also destroyed. However, at industrial level, milk pasteurization parameters are based on destruction of *Coxiella burnetti* (20 min at 60°C) a more heat resistant microorganism than *Mycobacterium tuberculosis* (Masana and Rodríguez 2006).

Heat process optimization is fundamental in pasteurization and commercial sterilization, as temperature-dependent processes such as microbial inactivation and enzyme inactivation proceed in a completely different way. In fluid foods such as milk, HTST process result in a maximum nutrient retention; this is because microbial destruction rate is higher than nutrient degradation (Karlekar and Desmond 1985).

Pasteurization kills part, not all, viable cells in foods, therefore it is applied to foods that will receive additional preservation methods to minimize microbial growth. In most cases, the aim of pasteurization is to destroy pathogens, but spoilage microorganisms can survive, making it necessary to apply other, less severe preservation methods such as refrigeration, addition of chemical preservatives (carbohydrates, acids, salts, etc.), packaging, and so on. Several processing conditions can be applied: high temperature short time pasteurization carried out at 71°C for 15 s in fluid milk produced a good quality and sanitary safe product; a low temperature longer process time is also applied (62°C for 30 s) to fluid milk (Ray 1996). Optimization of this process depends on relative microbial destruction rate and quality factors.

Pasteurization of acid foods is based on the destruction of yeast and fungi; in fermented beverages such as wine or beer pasteurization is calculated to destroy native yeasts, preventing fermentation to proceed before a given limit (Zamudio 2006). Since pasteurization is carried out below 100°C it can be applied to solid foods using the same equipment used in scalding. Acid foods or meat products can be easily pasteurized in a water bath; the packaged product is placed in tanks and heated with water; cooling with water is applied at the end of process. In continuous pasteurization packaged products are moved through a heating tunnel by a conveyor (Hanson 1990).

Continuous pasteurization is also carried out using a spray system, especially for beer and bottled fruit juices. In this method, bottled products are transported in a conveyor through heating and cooling zones in a tunnel; these zones are: primary preheating, secondary preheating, pasteurization, precooling, and final cooling. Tunnels are designed on the basis of temperature gradients, controlled by mixing water and vapor, water used in primary preheating is also further used in precooling; finally, cooling is carried our by water spraying or immersion (Mathlouthi 1986). Pasteurization using steam is applied in metal containers, never in glass; when glass bottles are used care must be taken to prevent thermal shock; this can be achieved by keeping pasteurization-preheating temperature gradients around 20°C, and pasteurization-cooling around 10°C (Müller 1990).

Pasteurization of nonpacked liquids is carried out in direct or indirect heat exchangers, parallel plates, or pipe and shell types, although parallel plates are more commonly used. In parallel plate heat exchangers the product is transported in one side of a wall and a heating medium (vapor or water) in the other side. It is a common process to pasteurize milk, beer, and fruit juice. The plates are generally dented to promote a turbulent flow, increasing heat transfer coefficients up to 4000–9000 kcal/h $m^{2\circ}$K in nonviscous fluid such as milk (Valiente 1997). Energy saving is achieved by using the hot pasteurized fluid as preheating medium for the incoming fluid food.

57.7.4 Sterilization

A sterile product is defined as that in which no microorganism is present. Temperatures above those for microbial growth give result in the death of vegetative cells, but spores can survive. Therefore, sterilization processes are calculated based on spore survival. However, "sterilization" is not an accurate term for food heat treatment, since the sterility criteria cannot be applied in a food product, that is, pathogens are destroyed but nonpathogens may be present but inactive; storage conditions do not allow them to grow. In this situation, foods are "commercially sterile," "microbiologically inactive," or "partially sterile" (Guerrero Legarreta 2006). Commercially sterile foods are merchandised in hermetic containers to prevent recontamination; therefore strict aerobes vegetative cells cannot grow.

However, strict aerobes spores are less resistant to heat than spores of facultative or anaerobes. In foods such as canned cured meat, if oxygen is not completely evacuated and a mild heat treatment is applied together with other preservation methods (curing, refrigeration), aerobes such as *Bacillus subtilis* or *Bacillus mycoides* can be present and promote spoilage (Masana and Rodríguez 2006).

There are two methods of commercial sterilization: heating the food after placing it in a container, or heating and cooling the food then aseptically packaging and sealing. The first method is a conventional canning operation, developed by Nicholas Appert in the 18th century; the second method is known as aseptic packaging. Both processes have the same basic principles.

57.7.4.1 Canning. The objective of canning is to destroy certain microbial populations (vegetative cells and spores) and/or enzymes promoting spoilage or harmful to human health. Problems solved by canning, from a sanitation point of view, are prevention of vegetative cells, and spores, ability to grow and produce toxins, and to eliminate or inhibit microbial development.

The canning process basically consists of four operations: food preparation (cleaning, selection, size reduction, scalding, etc.), can filling, air exhaustion from the can, sealing and thermal process (heating and cooling).

The can is filled with a food at relatively low temperature and placed in a retort, air is then exhausted and the retort filled with condensing steam; latent vaporization heat is transferred through the can into the food; under these circumstances, heat transfer at the surface is very high, therefore the only resistance to heat flow is in the product itself (Watson and Harper 1988).

In addition to preventing quality deterioration by food reaction with oxygen, air exhaustion from the headspace also improves heat penetration. When large food pieces are canned, exhaustion during filling and sealing is generally enough to remove the air (Foottit and Lewis 1999). Conversely, pastes tend to incorporate gas during every filling step; it is not carried out under vacuum. In many cases, cooking is carried out during the sterilization phase of canning; therefore, if small gas bubbles are trapped, adequate sterilization may not be reached (Lan and others 1995). Air exhaustion from the headspace also reduces risks of excessive internal pressure increase during heating, resulting in can blowing or deformation. Risks of anaerobe growth is also reduced (Institute of Food Technologists 2000).

Exhaustion is carried out by heating or by steam injection. Heating (75–95°C) induces steam to replace air in the headspace; cans are immediately closed and sealed. Once cooled down, vacuum is promoted by vapor condensation. However, if the headspace is too large there is incomplete vacuum formation. Alternatively, cans are transported in a conveyor where they are heated at 85–95°C, 90% or more of the air is removed from the headspace, depending on the residence time and temperature of the exhaustion tunnel (Mathlouthi 1986).

Thermal processing during canning operations has two cycles: heating and cooling. Time–temperature relationships are calculated according to microbial destruction and enzyme inactivation criteria, as described before. In general, temperatures applied are 60–90°C for fungi destruction; 60–75°C for enzyme inactivation; 115–121°C for bacterial spore destruction (Foottit and Lewis 1999).

Heat penetration depends on a solid–liquid relationship, and of food distribution within the can. In solid foods in brine, such as canned sausages placed along the vertical axis, a convection–conduction mechanism is established; solid material loosely packed is heated faster than a tightly packed material (Guerrero Legarreta 2001). In general, 30% of the can volume should be a fluid (brine or syrup) in order to get good heat transfer. The can is filled with the liquid after placing the solid food; pastes are almost always handed with dispensers, in this case care must be taken to avoid gas bubbles. For heat transferee calculations, a headspace of approximately 0.5% of the can volume must be considered. In addition, efficiency of air exhaustion from the can depends of the headspace volume (Welti-Chanes and others 2003).

Heat treatment is applied in two main equipment types: autoclave or still retort, used in small plants handling all types of containers (metal, glass, flexible pouches) or large operations handling metal or glass containers; and continuous autoclaves. In a still retort, the cans or glass containers are placed inside, the retort is closed and air is exhausted by steam injection (Manev 1983). Temperature is controlled along the processing time, in order to achieve a given heat transfer rate to the containers.

Cooling is carried out by closing the steam injection and feeding in cold water. Pressure difference is controlled to avoid deformation or lid blowing in large format cans. In

continuous retorts, processing rate is higher, and costs are reduced. In addition, as cans are rotated, heat transfer rate is increased, mainly when a convection mechanisms is dominant. In this operation type, cans are conveyed through a pressure seal to retort parts where processing temperature is applied (Guerrero Legarreta 2001).

57.7.4.2 Food Alterations During Canning. Although canning is a very efficient operation, and foods subjected to this process have considerable shelf life extension, some alterations can occur if processing is not carefully controlled. In delays of more than 20 min between filling and sealing, or before processing, microbial growth can take place; the subsequent heat process can inactivate the microorganisms, but gas or other metabolites may be present in the can (Masana and Rodríguez 2006). Microbial alteration can be also be caused by insufficient heat treatment, as a consequence gas production by surviving microorganism metabolism blows or deforms the can, or the food becomes sour. These alterations are indicative of contamination by sporulated bacteria (Zamudio 2006). In this case, time–temperature process conditions must be checked, as well as food initial microbial load and sanitation of water, equipment, handling, and so on. If similar alterations occur in the same place of the retort, it could be due to operation or equipment failure, such as pipes and valves causing insufficient heating or air in the retort (Hanson 1990). However, it can be also due to inadequate can distribution in the retort, probably packed too tightly, causing heating deficiency as steam or water does not reach every part of the can surface (Thumel 1995). Insufficient or slow cooling may promote thermophile growth. If cans are stored in large blocks, cooling is too slow; therefore, cans must be stored in small well ventilated blocks, particularly in tropical areas when relative humidity and temperature are high (Guerrero Legarreta 2006). Microbial contamination also occurs through seals, if cooling water is not of adequate sanitary quality. Recontamination by cocci, sporulated and nonsporulated bacilli after heat treatment (Brown 1982) is one of the main problems, causing can blowing, meaning sealing failure (Manev 1983).

Although can blowing is generally due to microbial contamination, it can be also due to chemical reactions of the food components to packaging materials producing hydrogen or sulfur compounds. The reaction also promotes bluish black spots, drastically altering flavor and odor. One other very common reaction in canned fruits and vegetables, and dairy products is nonenzymatic browning (Mathlouthi 1986).

Finally, physical alterations in cans occur by equipment mishandling such as fast pressure increase, not enough vacuum or excessive filling. Cans, mainly large formats are distorted and seals can break. Blowing of the bottom end is due to insufficient exhaustion. If cans are transported to high altitudes, blowing is likely to occur; every 300 m increase in altitude, 2.5 cm vacuum is lost. Conversely, excessive exhaustion can cause can collapse (Hanson 1990). Excessive filling causes deformation during heating due to food expansion, mainly in foods that undergo cooking in the can such as luncheon meats, or foods containing several ingredients as meat, beans, corn, rice, and so on that notably increase in size during cooking (Watson and Harper 1988).

57.7.4.3 Aseptic Processing. Food sterilization before packaging involves the same principles as pasteurization; differences are in process severity and applied temperatures. Due to the fact that very high temperature is applied in aseptic commercial processing (132–175°C); it can be considered as a HTST condition process (Welti-Chanes and others 2003). Heat exchangers include rough surface, parallel plates, pipe and shell, and

direct steam injection types (Valiente 1997). Other systems have been developed for fluid containing small particles in suspension; however operation efficiency is considerably reduced when larger particles, such as peas in brine, are processed, mainly due to pumping. Direct seam injection has been used for milk sterilization in a process known as uperization; it is efficient only if further refrigeration is applied (Thumel 1995).

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

58.1 INTRODUCTION

There are two important types of hams which mainly depend on the different processing technology. Dry-cured ham involves the use of a dry cure that is rubbed on the external surface followed by a mild drying. On the other hand, wet-cured ham or cooked ham involves the use of brine that is either injected or soaked followed by the application of thermal treatment. The production of both types of hams are described in this chapter.

Dry-cured ham was originally produced for preservation purposes and as a food reservoir for times of scarcity. The expanded use of refrigeration during the last century reduced this need but increased the need for better consumer acceptance. So, the processing technology was slightly modified in order to obtain better sensory acceptance even though it remained largely empirical, following the experience transmitted by manufacturers from generation to generation (Toldrá and others 1997). Scientific knowledge on chemical and biochemical mechanisms related with flavor and texture development in curing processes experienced a rapid increase during the last decades of the 20th century and prompted some technological evolution. In-depth knowledge on numerous biochemical reactions, mainly affecting proteins and lipids, were thus available. These reactions take place in postmortem meat and are especially significant during the dry-curing process, mainly along the ripening period and have a decisive contribution to the development of an adequate texture and a characteristic flavor (Parolari 1996; Toldrá 1998; Toldrá and Flores 1998). The adequate control of these reactions is essential for quality standardization (Toldrá 2004a; Toldrá and others 2004). Today, there are different technologies depending on the raw materials and the processing conditions. The processing technologies for the production of both types, dry-cured ham and cooked ham, are discussed in this chapter.

58.2 TRADITIONAL PROCESSING OF DRY-CURED HAM

The traditional processing of hams was more usual in old times but today is limited in production and restricted to rural areas located near the mountains where cool and dry winds are available most of the year. Basically, it consists in rearing pigs at home for about 1 year. These pigs are slaughtered by the end of November to coincide with the beginning of the coldest months. Hams are then salted by rubbing salt on their surface and left for a few weeks. Once the salt is diffused through the whole ham, they are hung in big rooms on the top of the house for the ripening and drying processes which coincide with the spring and summer. More or less aeration is achieved by manual opening of windows. The decision is based on subjective evaluation of the hams status. Total processing time takes near 1 year, the hams being ready for the consumption by early autumn.

58.3 DRY-CURED HAM: MODERN PROCESSING TECHNOLOGY

The processing of dry-cured hams is apparently simple but requires a minimum length for the muscle enzymes to develop the characteristic flavor. Main stages are the reception of hams, salting, postsalting, ripening, and drying as shown in Figure 58.1.

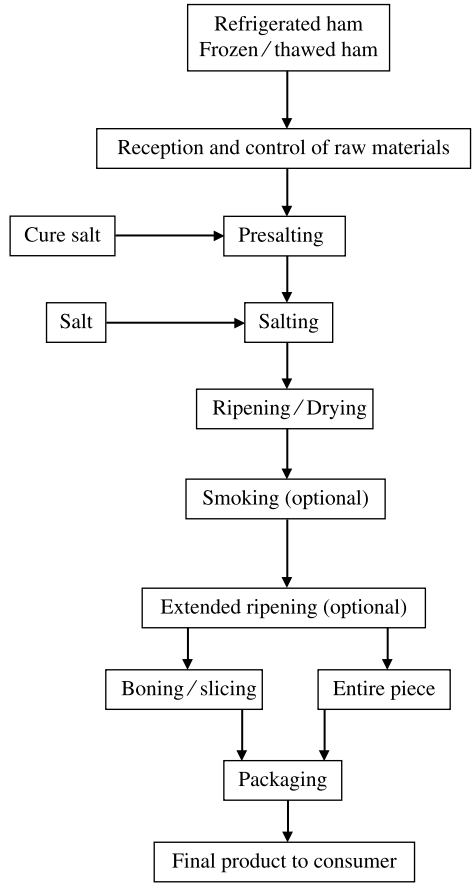

Figure 58.1 *Process flow diagram for the processing of dry-cured hams.*

58.3.1 Reception

This step is crucial because all the process depends on the quality of raw hams. It is important to discriminate DFD (dark, firm, and dry) hams because its high pH can prompt the development of undesirable microorganisms. DFD hams must be used for other types of products. On the other hand, PSE (pale, soft, and exudative) hams create some difficulties to processors because of an excessive rapid water loss due to their lower water-binding capacity (Arnau and others 1995) and an unpleasant salty taste due to an excess of salt intake. Selection by weight facilitates the control of time during the salting stage as will be described later. The control of fat is important for correct flavor development. Fat composition in fatty acids depends on the feed given to pigs (Toldrá 2005; Jiménez-Colmenero and others 2006), and the crossbreed used (Armero and others 2002). The detection of any undesirable oxidation and/or development of rancid off-flavors is essential at this stage. Easy controls for unsaturation and freshness consist in the measurement of the iodine index and the acid index, respectively (Toldrá 2002).

In general, hams from heavy pigs give better quality (reddish color, intramuscular fat, marbling, etc.) than industrial standard pigs. Main reasons are related with chemical and biochemical characteristics of respective muscles (i.e., different enzyme profile) (Toldrá and others 1996).

Frozen hams are allowed to thaw till they reach an internal temperature about 2–4°C. The skin is partially removed, leaving an area where salt will penetrate and water will evaporate. Hams are registered on its surface to facilitate traceability and subjected to pressing rollers for bleeding. Just before salting, part of the skin is removed in order to allow salt penetration and water evaporation. The size of this area depends on the different types of ham.

58.3.2 Presalting

Refrigerated hams or frozen/thawed hams are stored for 1–2 days at 2–4°C to reach a uniform temperature. Then, hams are bled to extract any remaining blood inside and rubbed on the external surface with the curing salt (a mixture of sodium chloride and potassium nitrate) to get a final nitrate concentration of 150 mg/kg inside the ham. In some cases, the curing salt may be directly applied in the salting stage (i.e., for French and country-style hams). Nitrate, that is added as a protective agent against botulism, is slowly reduced to nitrite by the action of nitrate reductase (Cassens 1995), a bacterial enzyme present in the natural flora (i.e., Micrococcaceae) of ham. The European Union allows a maximum amount of 150 ppm potassium nitrate or 300 ppm for the combination of potassium nitrate + sodium nitrite, while the United States allows 156 ppm sodium nitrite ($\frac{1}{4}$ ounce per 100 pounds of meat).

58.3.3 Salting

This stage corresponds to the introduction of salt into the ham. There are several important roles for salt like reduction of a_w and inhibition of the growth of spoilage microorganisms, imparting a characteristic salty taste and increase of the solubility of myofibrillar proteins. Salt is added to the external surface of the hams in an exact proportion, hand-rubbed and left for penetration into the ham. For instance, 20–30 g medium-grain salt per kg on the lean surface and 10–20 g of wet salt per kg on the skin during 14–20 days for Parma hams (Parolari 1996). In other cases, like in Spain, hams are surrounded by dry salt (rough sea salt or refined mineral salt) and time of salting is strictly controlled to 1.1 day per kg

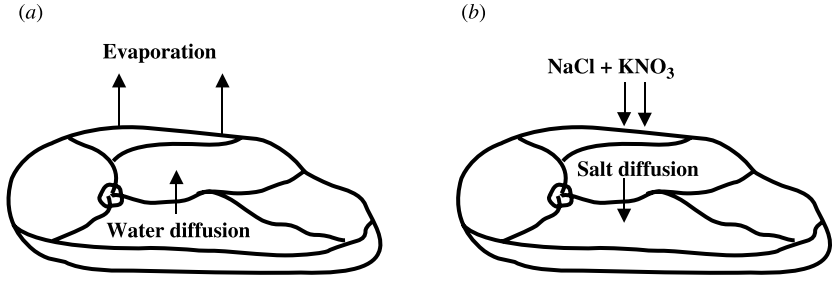

Figure 58.2 *Scheme showing the uptake of salt and nitrate during the salting and then its diffusion during the postsalting stage.*

(Toldrá 2002). Weight losses are about 3–4% and the excess of salt is removed by rinsing and brushing at the end of this stage.

58.3.4 Postsalting

Salt that has penetrated into the ham slowly diffuses to the inner area (see Fig. 58.2*a*). This takes 40–60 days, depending on the size of the ham, pH, amount of intramuscular fat, and temperature. Weight losses may reach around 4–6%.

58.3.5 Smoking

The use of smoke is used in short processes like American country-style or German Westphalia ham. Smoking is more typical in areas where drying was originally more difficult. Consumers are used to the smoked flavor. Furthermore, smoke compounds constitute a means of preservation due to its bactericidal effects (Ellis 2001).

58.3.6 Ripening–Drying

This stage is very important in order to reach the final desired quality. There are many combinations of air speed, temperature, and relative humidity which are typical for each type of ham. This is achieved through the use of computer-controlled drying chambers. Relative humidity must be carefully controlled to avoid excessive evaporation of eater on the surface of the ham (see Fig. 58.2*b*). Ripening and drying are very specific for each type of ham. One of the targets consists in achieving a final weight loss around 32–36% in relation to the initial weight. Then, the length of the drying will depend on when this goal is reached. Usually, at least 6–9 months are necessary. High quality hams are further ripened to allow for more intense enzyme action and flavor development. These hams are covered with a layer of lard to prevent further dehydration. The quality of hams (texture, appearance, color, and flavor) is monitored and evaluated by experts. A sniffing test, consisting in the insertion of a small probe till the bones junction and rapid sniffing for any off-flavor, allows the detection of any spoilage inside the ham (Parolari 1996).

58.3.7 Extended Ripening

Hams of excellent quality, like Iberian hams, may experience further ripening cellars at mild temperatures for long periods of time up to 24–30 months. These hams exhibit exquisite and intense flavors generated through further chemical and enzymatic reactions. Sometimes, the proteolysis is so intense that produces large amounts of free amino acids. Tyrosine, that is quite insoluble, produces small crystals visible as white spots on the cut surface (see Fig. 58.3).

58.3.8 Final Product

The commercial distribution of hams may be as an entire piece, as a boned piece or as slices. Boned hams can also be sliced by retailers or directly by consumers at home. A cross section of a ham where intense marbling can be appreciated is shown in Figure 58.3. Sliced ham may be vacuum-packaged or kept under controlled atmosphere

Figure 58.3 *Section of a typical dry-cured ham. Some small white crystal spots of tyrosine, proving intense proteolysis, can be observed.*

(Toldrá and others 2004). The typical consumption of dry-cured ham is as an entire piece (see Fig. 58.4).

58.4 PHYSICAL AND (BIO)CHEMICAL CHANGES DURING THE PROCESSING OF DRY-CURED HAM

There are two important diffusion phenomena in dry-cured ham affecting water and salt. Water must diffuse through the piece of ham towards the external surface. Then, water is

Figure 58.4 *A typical ham ready for slicing.*

evaporated to the environment depending on the relative humidity existing in the drying chamber (see Fig. 58.2*a*). The equilibrium is difficult to reach but is extremely important to get an optimal quality. A slow diffusion would accumulate water into the ham and would give poor weight loss and soft texture. However, an excess of evaporation results in excessively dried hams and tough textures (Toldrá 2005).

Diffusion of salt is a very slow process that depends on many variables like the size of the ham, its temperature, pH, water content, and intramuscular fat. Once salt penetrates into the ham, there is an equalization through the full piece that may take up to 3–4 months (see Fig. 58.2*b*).

The pH range is quite limited for the full process, starting at pH about 5.6 at the beginning to values near 6.4 for the final product. PSE hams have a pH evolution similar to normal ones even though they take more salt due to their initial lower pH and excessive moisture (Arnau and others 1995). All the enzymes and chemical reactions operate within this narrow range (Toldrá 1998) even though more intense proteolysis has been reported in low-pH hams (Buscailhon and others 1994a).

Most of the biochemical changes in dry-cured ham are a consequence of enzymatic reactions (Toldrá 1992). Proteolysis and lipolysis constitute two of the most important enzymatic phenomena, responsible for the generation of compounds with direct influence on taste and aroma.

Proteolysis consists in the generation of peptides and free amino acids from the progressive enzymatic degradation of major sarcoplasmic and myofibrillar proteins. This chain of reactions constitute the basis for important biochemical changes in the ham (Toldrá 2006a). Main muscle proteases are cathepsins B, D, H, and L; calpains I and II; tripeptidylpeptidases I and II; dipeptidylpeptidases I, II, III, and IV, and alanyl, arginyl, leucyl, and methyl aminopeptidases (Toldrá 2005). The activity of these endogenous muscle enzymes depends on the original crossbreeds (Armero and others 1999a,b; Soriano and others 2005) and the age of the pigs (Toldrá and others 1996; Rosell and Toldrá 1998). These enzymes have shown very good stability in long dry-curing processes (Toldrá and Etherington 1988; Toldrá and others 1993; Toldrá and others 2004). Temperature, time of drying, and ripening determine the action of these enzymes and, thus, the final sensory quality. The amount of salt exerts an important inhibitory effect on cathepsins (Rico and others 1990, 1991; Toldrá and others 1992a,b) and peptidases (Sentandreu and Toldrá 2001). In fact, hams with high cathepsin B activity and low salt content may result in soft hams (Parolari and others 1994). A good number of peptides generated as a consequence of peptidases action (Aristoy and Toldrá 1995). Finally, dry-cured hams are characterized by important amounts of free amino acids which are generated by endogenous muscle aminopeptidases (Toldrá and others 1995). The generation of free amino acids is extremely large in dry-cured ham and is somehow affected by levels of salt (Toldrá and others 2000). For instance, lysine and tyrosine are well correlated to an improvement in the aged taste of Parma ham (Careri and others 1993). The levels of salt also affect salty taste and texture of hams (Andrés and others 2004, 2005).

Lipolysis consists in the enzymatic generation of free fatty acids from the breakdown of triacylglycerols and phospholipids. Main lipolytic enzymes are lysosomal acid lipase and acid phospholipase that are located in muscle and neutral lipase located in adipose tissue (Toldrá 2005) and have also shown good stability through the entire process (Motilva and others 1992; Toldrá and Navarro 2002). The activity of these enzymes also depends on the type of breeding (Armero and others 2002; Cava and others 2004) and age (Toldrá and

others 1996). The generation rate for the release of free fatty acids during the process increases for up to 10 months in the muscle (Motilva and others 2003a; Vestergaard and others 2000) and up to 6 months in adipose tissue (Motilva and others 2003b; Buscailhon and others 1994b).

The generated free fatty acids with one or more double bonds are susceptible to further oxidative reactions that will generate volatile compounds with particular aroma characteristics (Berdagué and others 1991; Buscailhon and others 1993). Muscle oxidative enzymes, like peroxidases and cyclooxygenases, the content in moisture and metallic cations, and other external factors like light and heating, catalyze the generation of free radicals which are very reactive (Coutron-Gambotti and Gandemer 1999). Secondary oxidation products are formed and contribute to flavor (Flores and others 1998). Many volatile compounds with different contribution to ham flavor are generated. For instance, aldehydes and ketones are related to the aroma of French-type hams (Buscailhon and others 1994c) and Spanish hams (Flores and others 1997; Sabio and others 1998) while esters are well correlated with Parma ham aged odor (Careri and others 1993; Bolzoni and others 1996). Alkanes and alkenes as major volatile compounds and branched aldehydes and sulphur compounds have been found in Chinese Jinhua ham (Du and Ahn 2001). Due to the particular generation of volatile compounds according to the type of process, a method based on solid phase extraction of volatile compounds followed by its injection into a gas chromatograph has been recently proposed to characterize aromas (Pérez-Juan and others 2006) or differentiate among types of hams (Luna and others 2006; Pérez-Juan and others 2006). Main sensory characteristics are described in the chapter on sensory quality of meat products.

58.5 TYPES OF DRY-CURED HAMS

There are many varieties of dry-cured hams depending on the raw materials, the region or country of origin, the type of process, the additional smoking, and so on. So, different types of hams are produced throughout Europe. Iberian hams are produced in southwestern areas of Spain through a very long process that may reach up to 2 years or longer. Raw hams are selected from autochthonous Iberian heavy pigs which are bred extensively and fed with acorn and grass, essential for the final characteristic flavor of the product (Toldrá and others 1997; Carrapiso and others 2003; Cava and others 2004). Corsican hams are also produced in Corsica (France) from autochthonous heavy pigs bred in extensive system and fattened with chestnuts. Its processing may take up to 18 months even though the total production is very low. Known hams are produced from certain crossbreeds of white pigs which are slaughtered at about 110 kg live weight or even higher weights like 150 kg for Parma ham. There is a careful selection of the raw materials and processing conditions. Processing time is usually above 12 months. Some of the most well-known are Spanish Serrano, Italian San Danielle, and French Bayonne dry-cured hams. The European Union (EU) gives different labels to protect these hams like Protected Designation of Origin, Protected Geographical Indication, or Traditional Speciality Guaranteed. Hams are then controlled by consortiums (i.e., the Parma Consortium or the Serrano Foundation) that inspect the compliance of all the specific requirements. Hams produced in the Mediterranean area are eaten without further smoking or

cooking (Toldrá 2004b). A picture of an entire piece of ham, ready for consumption, is shown in Figure 58.4.

Traditional hams in northern Europe are usually processed for shorter times and smoked and cooked before consumption. This is the case of the traditional German Westphalian ham, the German Katenschinken (cold smoked ham) and the Finnish "sauna" hams (Puolanne 1982). American hams, known as country-style hams, are also smoked and cooked. Some of the most well-known are produced in Kentucky and Virginia. Hams produced in other areas of the world are also growing significantly in recent years. Good examples are those hams like Ying Hua or Yunnan produced in China (Campbell-Platt 1995; Du and Ahn 2001).

58.6 ACCELERATED PROCESSING

Dry-curing constitutes a long time-requiring process. This is the main reason for the different attemps to accelerate the process. Some strategies are focused on the salting process in order to facilitate the penetration and diffusion of salt into the hams (Marriott and others 1987, 1992). So, some researchers have assayed boning and skinning of hams (Montgomery and others 1976; Kemp and others 1980; Marriott and others 1983), tumbling of hams in rotative drums (Leak and others 1984) or mechanical tenderization through blade penetration prior to dry cure. Other strategies are centered on membrane disruption that can be easily achieved by freezing and thawing of hams (Kemp and others 1982; Motilva and others 1994). More recent attemps have consisted in the substitution of the salting stage by using simultaneous brine salting method while frozen hams are thawed. This process can be further accelerated using simultaneous vacuum impregnation (Barat and others 2006). It gives a substantial reduction in the time needed for thawing and salting without affecting the biochemical reactions taking place during the processing (Flores and others 2006a) nor the sensory quality of the final product (Flores and others 2006b).

58.7 COOKED HAM: PROCESSING TECHNOLOGY

Cooked ham is also known as canned ham. Main stages are the reception of hams, the brine injection, tumbling and massaging, cooking, and cooling as shown in Figure 58.5.

58.7.1 Reception

Refrigerated hams or frozen/thawed hams must be controlled before its processing. In this type of process where hams are cooked but not dried, DFD (dry, firm and dry) hams are not rejected. Its high pH is not a problem because these hams are heat-treated avoiding any risk for microbial growth. Furthermore, the high pH facilitates water retention. As mentioned for dry-cured hams, the fat is very important for flavor development. The composition in fatty acids, that depends on the feed given to pigs (Toldrá 2005; Jiménez-Colmenero and others 2006) and the crossbreed used (Armero and others 2002), will affect the final aroma profile. Any undesirable aroma (i.e., rancidity) or oxidative development must be detected before processing. In most cases, hams are boned to facilitate the brine injection and diffusion.

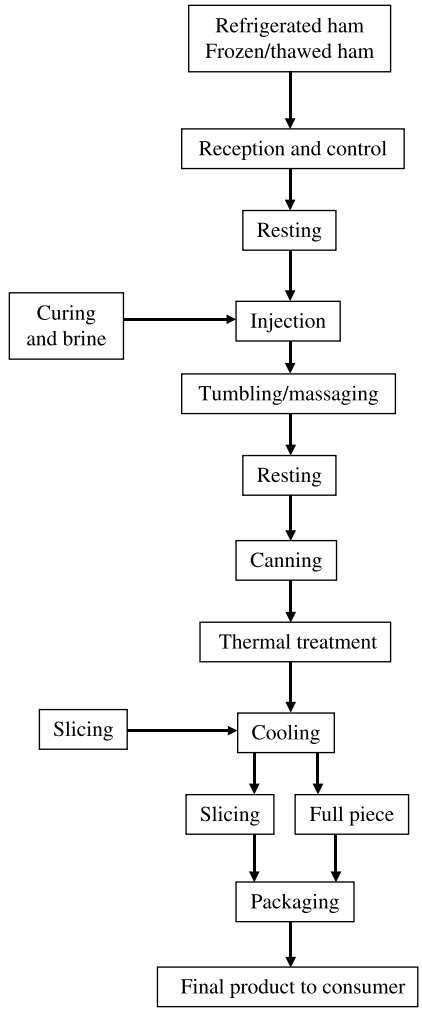

Figure 58.5 *Process flow diagram for the processing of cooked hams.*

58.7.2 Brine Injection

Salt is the main ingredient of brines and its amount varies depending on the type of product. It can be accompanied by sugars like sucrose, dextrose, or corn syrup, to give a pleasant mild taste. It is important that salt has a reduced content of impurities in order to reduce lipid oxidation. Nitrite is added to assure the generation of nitric oxide for preservation and color formation. Sodium ascorbate or sodium erythorbate are added to assure rapid nitrite disappearance and protection against the generation of nitrosamines. Other additives may be added to the brine but this is only used for the production of low quality hams. This is the case of phosphates, polyphosphates, or pyrophosphates that increase the pH of the ham far from the isoelectric point of muscle proteins, which is around 4.5, and thus increase the amount of retained water. Phosphates also increase the ionic strength and contribute to protein solubilization.

Figure 58.6 *Picture of a typical brine injection machine with multineedle.*

The brine is injected into the ham through a multi-needle system (see Fig. 58.6). Pumping speed and volume of injection may be controlled. The injection machines may pump brine into boneless hams or also into bone-in-hams. The brine favors the binding of muscles, the solubilization of protein and gives a better yield and a higher final weight.

After the brine injection it is a current practice to hold the hams for resting during a brief period of time to help the diffusion of salt and additives through the entire piece.

58.7.3 Massaging and/or Tumbling

This stage is also operated under refrigeration conditions. Hams can be massaged for a few hours in mixers under mild agitation to avoid physical disruptions or damages. The paddles of the mixer exert minimal damage under these low speed conditions and preserve the full muscle's appearance. In the case of tumbling, hams are moved in rotary tumblers operating under vacuum to avoid air bubbles and further undesired oxidations. There are many designs for tumblers but, in general, they consist in rotary drums with inner baffles to ensure maximum homogenization of the brine inside the hams. This operation also facilitates improved tenderness and juiciness.

58.7.4 Cooking

Cooking of hams is a delicate stage that requires a rigorous control of time and temperature to achieve the final desired effect and ensure the wholesomeness of the product (Ponce-Alquicira 2005). Heat treatment aims microbial destruction and enzyme inactivation. The heat treatment is calculated to inactivate pathogen and spoilage microorganisms for extended shelf-life of the product with minor effect on sensory characteristics (Guerrero-Legarreta 2001). Hams are canned in special molds that will give the final shape. They can optionally be packaged in special plastic (zero water loss). Cooking can be considered as pasteurization since internal temperature into the ham reaches around 72°C for 30–60 min. Cooking, that can be achieved with either steam or hot

water baths, needs a precise control of temperature. The speed of temperature increase during cooking is important. There are two heat transfer mechanisms: Convection which is the transfer from the heating medium to the ham surface and conduction which is the main heat transfer mechanism from the ham surface to the inner areas (Guerrero-Legarreta 2005). Cooking can be operated in three ways: (1) heating at a fixed temperature but this process may give some problems of excess or lack of heating; (2) heating until reaching a determined temperature inside the ham (usually 68°C), and (3) heating by stages that consist to increase the temperature of the ham through steps, not exceeding 25–30°C each time. This process avoids excessive heating. The cooking process contributes to the final development of sensory characteristics typical of these hams. Several reactions, like enzymatic reactions, oxidations, Maillard reactions, and so on, take place into the hams during this stage (Toldrá 2006b).

58.7.5 Cooling

Cooling is also a delicate stage to ensure the wholesomeness of the hams and complete food safety. Cooling is achieved by inmersion in cold water or with cold water showers. The target is to achieve temperatures of the ham down to 5°C. However, the most hazardous period is the transit between 50° down to 12° where bacteria might grow, especially under slow cooling conditions. Total time to decrease temperature to 5°C should not exceed 10 h. The rate for the cooling process depends on the number of spores forming bacteria.

58.7.6 Final Product

Once hams are cooled, they are taken out of the molds and packaged. At this stage, hams can be given a surface heat treatment to avoid any recontamination before packaging. In some cases (smoked hams), hams can be smoked to acquire a typical color and smoke flavor (Ellis 2001). Cooked hams are usually commercialized in slices ready to be consumed. A wide variety of vacuum packages containing different numbers of slices are typically found in supermarkets. More recently, other types of packages like those using modified atmosphere are available. Hams can also be sold to retailers as a full piece for direct slicing to consumers under request.

58.8 PHYSICAL AND (BIO)CHEMICAL CHANGES DURING THE PROCESSING OF COOKED HAM

58.8.1 Color

The color of ham mainly depends on the concentration of its natural pigment myoglobin. Its content depends on the type of muscle and the age of the animal, being higher in older animals and in muscles with oxidative pattern (Laborde and others 1985; Aristoy and Toldrá 1998).

The typical color of cooked ham changes from red to pink during the heating process, especially at temperatures above 65°C. This is due to the transformation of nitrosylmyoglobin, a compound formed after reaction of nitric oxide with myoglobin, into nitrosylhemocrome which has a typical light pink cured meat color. Upon heating, globin denatures and detaches

itself from the iron atom, and surrounds the heme moiety. This color is also known as cooked cured-meat pigment (Pegg and Shahidi 2000). Some darker surface colors on smoked hams may result from the pyrolytic decomposition of wood.

58.8.2 Texture

The texture of cooked hams depends on several factors, such as the extent of heating (structure breakdown), the moisture content, the extent of proteolysis (degree of myofibrillar protein breakdown), and the content of connective tissue. The content of intramuscular fat also exerts a positive influence on some texture and appearance traits. Starches added to ham help to enhance texture and bind water as well as improve the mouth feel. There are different types of starches and each one will impart different texture and sensory properties to the cooked product. So, starches may be extracted either from cereals (i.e., wheat or corn) or roots and tubers (i.e., potato). Commercial starches are usually modified to pregelatinization to be cold water swellable, cross-linking to impart stability for cooked ham processing, and stabilization to increase the water holding capacity (Martin 2001).

58.8.3 Biochemical Changes

Cooked ham experiences some biochemical changes as a consequence of enzymatic reactions, mainly through proteolysis and lipolysis. Muscle proteases and lipases contribute to the generation of free amino acids and fatty acids with influence on taste and aroma even though these enzymes have a reduced time for action. A comparison of main reactions in cooked ham to those in dry-cured ham is shown in Table 58.1.

The conditions into the hams (high water activity, low salt content) favor the proteolysis but these enzymes get rapidly inactivated during cooking because they are sensitive to temperatures above 50°C where their stability decreases rapidly (Toldrá and others 1992a, b). In any case, there is generation of free amino acids by muscle aminopeptidases that contribute to taste (Flores and others 1998) but the amount of released amino acids depends on the extent of resting before cooking.

TABLE 58.1 Main Groups of (Bio)chemical Reactions Affecting Sensory Properties of Dry-Cured and Cooked Hams.

Groups of Reactions	Dry-Cured Ham	Cooked Ham
Protein degradation	Intense by enzymatic proteolysis	Intense by heat denaturation
Generation of small peptides and free amino acids by proteolysis	Large	Poor
Lipid degradation	Intense by enzymatic lipolysis	Medium by heat damage
Generation of free fatty acids by lipolysis	Large	Poor
Oxidation of free fatty acids	Intense	Medium
Generation of volatile compounds	Intense	Medium
Strecker degradation of amino acids	Intense	Scarce
Maillard reactions	Medium	Intense
Cured color generation	Nitrosomyoglobin	Nitrosohemocrome

Lipolysis is also favored by conditions previous to cooking, especially the pH near neutral conditions. Fatty acids are released during resting and initial cooking of hams (Toldrá 2006b). One or two days of resting, previous to cooking, allows longer enzymatic action and larger amounts of released amino acids and fatty acids that will act as substrates for further chemical reactions (i.e., Strecker reactions) responsible for the generation of volatile compounds. As in the case of proteases, lipases are also inactivated during cooking. The composition in fatty acids is a key aspect in flavor generation. An excess of linoleic acid may impart some off-flavor during cooking. Further chemical reactions (i.e., Maillard reactions) are accelerated during cooking and contribute to the generation of aroma volatile compounds. The extent and characteristics of flavor will depend on the time and intensity of heating.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

59.1 INTRODUCTION

The production and consumption of sausages, in particular those produced through drying, probably originated around the Mediterranean area, as its particular climate allowed a natural drying and ripening process, and these were intense commercial exchanges. On the other hand, the use of smoke was applied in northern and colder areas where the climate did not allow a natural drying.

There are many historical references to pork and its products. Pork was described as an important food source in Sumer, several times, in numerous Sumerian tablets, written in the cuneiform language around the year 2000 B.C. (Kramer 1965). In ancient Egypt, Seth was introduced into the the eye of Horus in the form of a black pig, blinding him (Max Müller 1996). Ancient Romans and Greeks also produced and consumed numerous pig products, coinciding with the great expansion of the pig throughout Europe. Specific details of pig slaughtering and the cooking of its products were described ca. 900 B.C. in the famous Odyssey (Homero 1993). In the first century, Petronio described in his book "El satiricón" the famous banquet of Trimalción, where one of the main dishes consisted of products from wild pig (Petronio 1965). Romans found that salted meats were easy to store and/or transport, assuring a food supply at distances from home. It is not surprising that some expressions like the Spanish "salchichón" or the French "saucisson" were probably derived from the latin word "salsicia" or the Italian "Salami" from the latin word "salumen". On the other hand, the word salami has also been attributed to the city of Salamis in Cyprus (Zeuthen 1995). Recipes of salted meat products, which are still consumed in certain Mediterranean areas, were described by Catón in his "De Re Agricola" (Pineda 1989). Roman coins adorned with the shape of a pig leg are to be found in museums. In the fifth century, the French butchers known as "charcutiers" already prepared different pork derivatives. The Saint Antoine l'Abbaye practiced innovative medicine in the twelfth century using pork meat and lard. Pork meat products were widespread in consumption during the Middle Ages. A good number of pork meat products were described in the famous book "El Quijote" written by Miguel de Cervantes in 1604. As an example, Dulcinea del Toboso was described to have better hands for pork salting. Chinese cooked sausages like lup cheong have been known in China for more than 2500 years.

The modern dry-fermented sausage was apparently invented around 1730 in Italy, being later adopted around 1780 by the German countries after the stay in Italy of a German butcher named Butleb (Leistner 1992). Manufacturing procedures had to be adapted to the climatic conditions of the production area. As an example, the summer sausage was produced in the summer and was heated for safety reasons (Zeuthen 1995). Manufacturing practices were brought to America by settlers and many typical European sausages may still be found in Northern States like Wisconsin.

59.2 CLASSIFICATION OF SAUSAGES

The term "sausage" is used for a great number of meat products, although its meaning may vary depending on the kind of product and country of origin. Traditionally, this term means a product consisting of a mince of ground meat and fat, which is stuffed into a casing. It also involves the use of a curing salt (sodium chloride + nitrate/nitrite) that contributes to its characteristic color and flavor. Thus, it is a broad term applied to many different meat

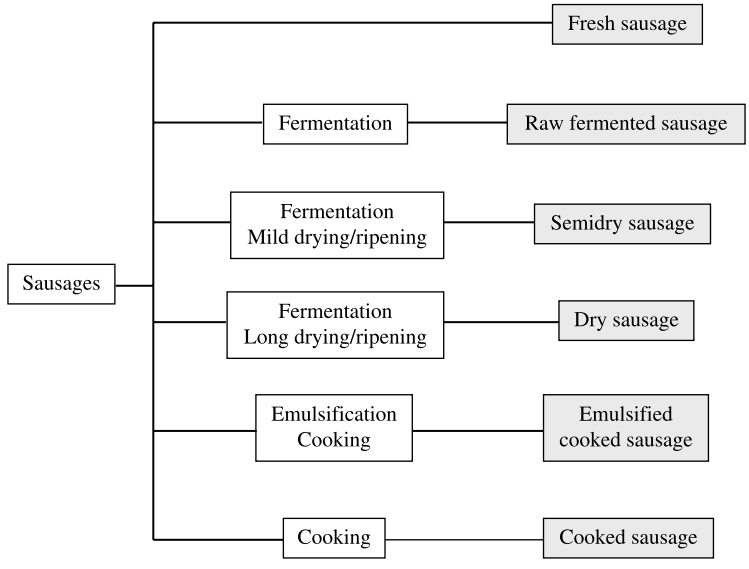

Figure 59.1 *Scheme for classification of sausages.*

products. Basically, sausages can be arranged into several groups based on the main preservation practices of fermentation, drying, or cooking (Flores and Toldrá 1993). A general scheme for this classification is shown in Figure 59.1. Depending on the conditions used for fermentation, the sausages can be low-acid or high-acid (Incze 2004). In the case of drying, there are further classifications depending on the fermentation, time for ripening, and extent of drying. So, taking into account the effect of drying and the remaining moisture content, sausages may be classified as semidry when the weight loss is lower than 20% or dry when the weight loss exceeds 30%. The length of the ripening period depends on the kind of product (size and diameter) as well as the desired final quality. The process can be considered as rapid when it takes less than 7 days, regular when it takes around 3 weeks, or slow when it exceeds 90–120 days (Toldrá 2002).

59.3 TYPES OF SAUSAGES

59.3.1 Fresh Sausages

Fresh sausage may also be known as moist sausage, because its moisture content is high, at between 50 and 60%. These sausages are stored for a few days under refrigeration and are cooked before eating. Fresh sausages can differ in texture, seasoning, type of casings, and meat content (Ockerman and Basu 2004). Some of the most well known are mettwurst and bockwurst, which were originally fresh, but more recently are cooked (see Table 59.1). Others, like country-style sausages, may be smoked.

59.3.2 Raw Fermented Sausages

These sausages are fermented at high temperatures so that lactic acid bacteria may grow and drop the pH towards acid values. Merguez-type sausages are produced in North

TABLE 59.1 Examples of Different Types of Sausages.

Product Type	Moisture	Treatment	Denomination
Fresh sausages	Moist	May be cooked	Mettwurst
Fresh sausages	Moist	May be cooked	Bockwurst
Fresh sausages	Moist	May be smoked	Country-style
Fresh sausages	Moist	No treatment	Hog sausage
Raw fermented sausages	Moist	Fermented	Fresh Thuringer
Raw fermented sausages	Moist	Fermented/smoked	Lebanon Bologna
Raw fermented sausages	Moist	Fermented	Merguez-type
Semi dry sausages	Semidried	Fermented, smoked	Summer sausage
Semi dry sausages	Semidried	Fermented, smoked	Thuringer
Semi dry sausages	Semidried	Fermented/short drying	Saucisson d'Alsace
Semi dry sausages	Semidried	Fermented/short drying	Laap Ch'eung
Semi dry sausages	Semidried	Fermented/short drying	Xun Chang
Semi dry sausages	Semidried	Fermented/short drying	Longaniza
Dry sausages	Dried	Fermented, long drying/ripening	Salami
Dry sausages	Dried	Fermented, long drying/ripening	Salchichón/saucisson
Dry sausages	Dried	Fermented, long drying/ripening	Chorizo
Dry sausages	Dried	Fermented, long drying/ripening	Pepperoni
Dry sausages	Dried	Fermented, long drying/ripening	Fjellmorr gilde
Dry sausages	Dried	Fermented, long drying/ripening	Turkish-style saudjouk
Cooked sausages	Moist	Cooking	Bologna
Cooked sausages	Moist	Cooking	Hot dogs
Cooked sausages	Moist	Cooking	Frankfurters
Cooked sausages	Moist	Cooking	Wieners
Cooked sausages	Moist	Cooking	Knockwurst
Cooked sausages	Moist	Cooking	Paté
Cooked sausages	Moist	Cooking	Bratwurst
Cooked sausages	Moist	Cooking	Mortadela
Cooked sausages	Moist	Cooking	Cotto salami

African countries and Southern European countries and can be briefly dried after fermentation. Raw fermented sausages can be smoked (e.g., Lebanon Bologna) or cooked (Table 59.1). They are preserved under refrigeration and are cooked before eating.

59.3.3 Semidry Sausages

There are many varieties of semidry sausages. As their denomination indicates, their moisture content is intermediate, between 35 and 50%, as a result of a mild drying and short ripening step. The water activity is above 0.86 and pH near 5.0. These sausages are fermented rapidly for a few hours in the United States or more slowly in Europe. They are smoked and can be cooked for pasteurization. The summer sausage is quite popular in the United States. Longaniza is typical in Spain and France. Semidry sausages are preserved under refrigeration unless the combination of low pH (below 5.0), and a moisture to protein ratio of less than 3.1:1 are achieved to guarantee the shelf-life (Sebranek 2004).

59.3.4 Dry Sausages

There are many dry types of sausage. In general, they have a moisture content below 35%. The denominations may vary according to the geographical area where they are produced. In other cases, the names may be applied depending on the physical or chemical

Figure 59.2 *Typical view of sliced salchichón.*

characteristics of the sausages like form, diameter, size of fat particles, application of smoking, addition of specific spices, presence of molds on the external surface, and so on. Examples of typical dry sausages are compiled in Table 59.1. Some of the most popular are salamis, which may have different diameters. There are salamis of 55–60 mm diameter and a ripening time of 28–32 days, like French Ménage, 14–21 days of ripening like the Italian Turista, or 14–18 days of ripening as for the Spanish Salchichón. A typical view of sliced salchichón is shown in Figure 59.2. Other salamis may have larger diameters such as 90–100 mm. In this case, ripening times are longer, up to 60–70 days as in the French Varzi and Italian Crespone Milano (Baldini and others 2000). Milanese salami is seasoned with garlic, white wine, peppercorns and sugar. Typical Mediterranean sausages are French saucisson, Spanish chorizo (Fig. 59.3) or Italian salami, while typical North-European products are German- or Hungarian-style salamis. Pepperoni and summer sausages constitute typical sausages in the USA (Toldrá 2004a).

Figure 59.3 *Slices of typical Spanish chorizo.*

59.3.4 Cooked Sausages

There are also many types of cooked sausages, including garlic sausages, frankfurters, mortadella, and so on. Italian mortadella, or Bologna sausage, is fermented at 30–38°C for 2–7 days. Then, it is cooked until it reaches an internal temperature of 65–70°C, cooled, and dried for maturation. German Bruhwurst is smoked and scalded. Kochwurst is also scalded and may contain large chunks of meat; it is eaten either sliced or spread (Fisher and Palmer 1995). Frankfurters, wieners, and hot dogs are coarsely minced or finely chopped (Knipe 2004). Cotto salami is cooked, contains peppercorns, and may be smoked. This type of cooked salami is refrigerated before eating.

59.4 INGREDIENTS AND ADDITIVES

59.4.1 Meat and Fat

Pork meat, either alone or in combination with beef, is the main ingredient of sausages. In other products like poultry sausages, the main ingredient is poultry. It is important to control the characteristics of all these raw meats, in particular hygienic quality (Roca and Incze 1990). Beef meat contributes to a better red color of the product. The same applies to the use of meat from older animals, which are richer in myoglobin (Toldrá 2006a).

The other main ingredient is fat which must be fresh or stored under frozen storage. It is convenient to avoid long frozen storages because endogenous lipases are active at low temperatures and can generate free fatty acids that are prone to oxidation and development of rancidity (Toldrá 2006b). Firm pork back fats with high melting point are the most adequate for sausage production (Lücke 1985). Soft fats can produce smearing during chopping. Fat unsaturation control through the iodine index and the amount of free fatty acids through the acid index (as an indicator of freshness) are recommended.

59.4.2 Salt

Salt is an essential ingredient of sausages, usually added at 2–3%. It contributes to the technological and sensory quality through

1. Selection of the microbial flora by inhibition of the growth of undesirable microorganisms;
2. A characteristic salty taste of the sausage;
3. An increase of myofibrillar protein (actin and myosin) solubility; and
4. Control of enzyme activity (Toldrá 2004b).

59.4.3 Nitrite and Nitrate

Nitrite constitutes an essential additive for sausage preservation. Sodium nitrite is formulated in a curing salt. In some cases, potassium nitrate can also be added in the formulation when sausages are ripened for a long time. In this case, nitrate acts as a reservoir of nitrite. Nitrate is reduced to nitrite by nitrate reductase activity from bacteria either naturally present in the mix or added as starter cultures (such as *Micrococcaceae*). Nitrite is very reactive and interacts rapidly with proteins, such as myoglobin, and inhibits the growth of

undesirable microorganisms, in particular *Clostridium botulinum* (Cassens 1997). Despite its effectivity against pathogens, the amounts of nitrate and/or nitrite added to the initial mixture are kept at a low level to keep residues as low as possible in the finished product. The reason for this is that nitrites can react with secondary amines, producing nitrosamines, which can exert toxic (i.e., cancerigen) effects (Cassens 1995). Ascorbic and erythorbic acids or their sodium salts are used to accelerate the reduction of nitrite to nitric oxide, assuring the absence of residual nitrite in the products and thus avoiding the risk of nitrosamine formation.

59.4.4 Carbohydrates

Carbohydrates are added as the substrate for microbial fermentation. Lactic acid is the main compound resulting from fermentation by lactic acid bacteria. Depending on the type and amount of carbohydrates, more or less lactic acid will be generated and pH will drop accordingly (Lücke 1985). Glucose or saccharose favor a faster pH drop. If an excessive amount of carbohydrates is added, pH can drop to values below 4.7 and most of the enzymes responsible for the generation of flavor compounds can be inhibited and the sensory quality seriously affected. However, the addition of low amounts or long-chain carbohydrates may result in a deficient pH reduction that will allow the growth of undesirable microorganisms (Toldrá 2006c).

59.4.5 Spices and Flavorings

There is a wide variety of spices and flavorings that can be used for seasoning the sausages. Spices can also contribute to a specific flavor or color. There is a great variety of seasoning formulations for different types of sausages (Coggins 2001). This includes mustard, oregano, rosemary, garlic, onion, pepper, or paprika. Spices can be used either in a natural form (whole or ground) or as flavoring extracts (essential oils and oleoresins). Flavoring agents and flavor enhancers may be used to accentuate a specific flavor. Smoke flavoring may be applied on the surface as an oil or water solution to give a smoke flavor (Ellis 2001).

59.4.6 Starter Cultures

The use of starter cultures for sausage production has expanded in recent years. The use and properties of starter cultures are fully described in the chapter on fermented meat production.

59.5 PROCESSING TECHNOLOGY

There are some essential stages in the processing of sausages. Outlines of the main unit operations in the processing of semidry and dry sausages, cooked sausages, and emulsified sausages are shown in Figures 59.4 and 59.5, respectively. Several operations are common for the different processes but others are specific for each type of product. There are some differences as follows:

1. Dry and semidry sausages are stuffed into porous casings that allow water evaporation, and cooked sausages are stuffed into nonpermeable casings to guarantee water retention during cooking;

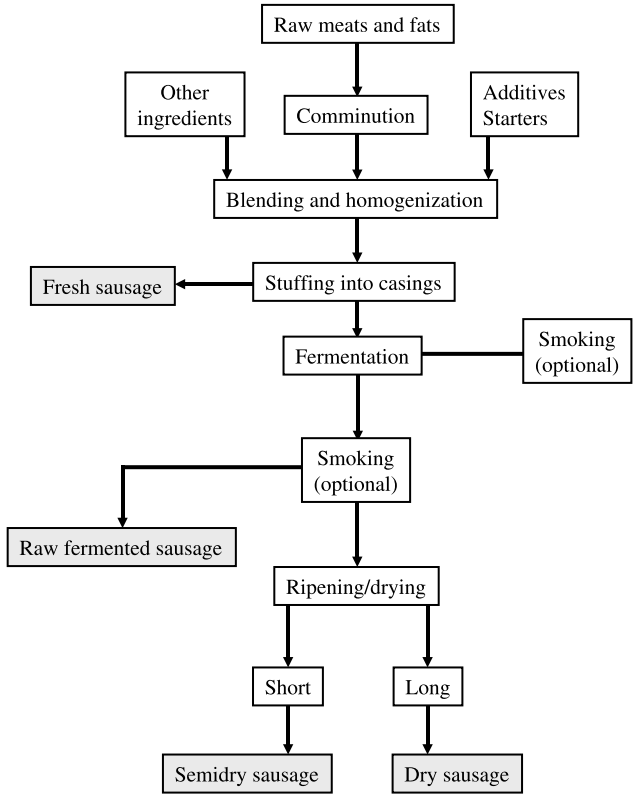

Figure 59.4 *Process flow diagram for the processing of fresh raw fermented, semidry and dry sausages.*

2. Dry and semidry sausages are usually fermented and afterwards submitted to ripening and drying, but cooked sausages are cooked just after stuffing and chilled;
3. The shelf-lives of these types of products are also different because dry sausages are stable at room temperature, but the others must be preserved in cold temperatures. The basic operations are described in the following.

59.5.1 Comminution and Stuffing

Raw meats and fats are chopped and comminuted in a grinder under cold temperatures. The size of lean and fat particles will depend on the plate size during grinding (Roca and Incze 1990). The pieces of a grinder are shown in Figure 59.6. The rest of the ingredients and additives, including microbial starters, are added to the resulting ground mass. Homogenization of the ground mass is a very important step in obtaining a good distribution of the additives through the mass. The batter is homogenized under cold temperatures by mixing under vacuum for removing as much oxygen as possible. An example of the homogenized batter is shown in Figure 59.7. In the case of cooked sausages, the comminution is performed in a cutter machine. The batter is stuffed into natural (mostly for traditional products) or man-made (collagen or synthetic) casings by using vacuum filling machines. In the case of dry or semidry sausages, casings must be porous

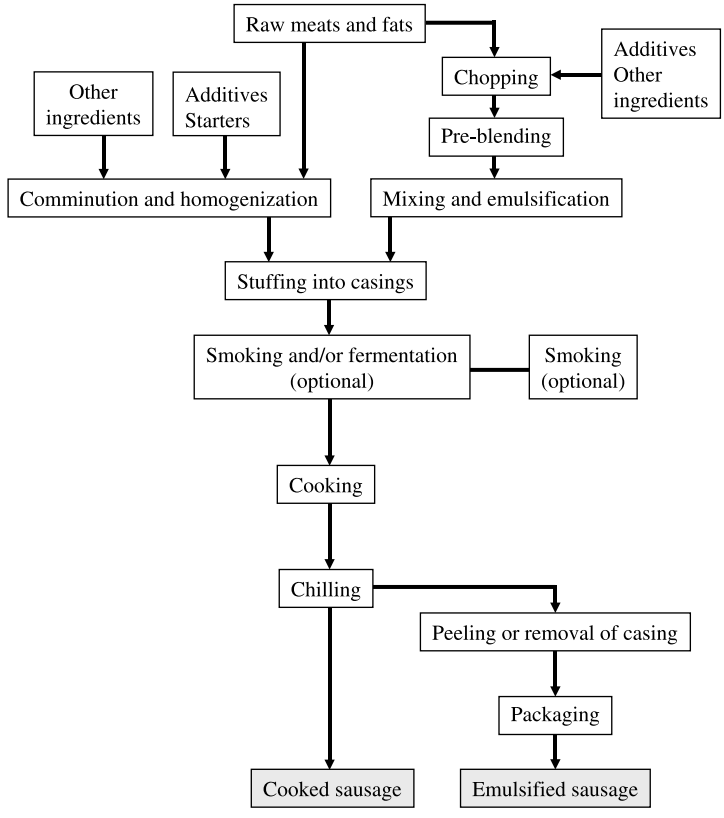

Figure 59.5 *Process flow diagram for the processing of cooked sausages.*

Figure 59.6 *Main process of a grinder.*

Figure 59.7 *View of the batter after homogenization.*

and the pore size of the casings must allow evaporation of water during fermentation/ripening/drying (Acton 1977). In the case of cooked sausages, casings made with co-extruded collagen, alginate, or plastic are usual (Rust 2004).

59.5.2 Emulsification

In the case of emulsified cooked sausages, emulsification procedures must be followed. The mixer–emulsifier process consists of a mixing step and an emulsifying step. Preblended lean meat and fat mixtures including spices, binders, and so on, are combined in a mixer and the mixing continues until the temperature reaches 5–7°C, which is below the emulsion temperature that depends on the predominant source of fat. The mixture is then passed through the emulsifier several times depending on the temperature rise and is stuffed into the casing (Knipe 2004).

59.5.3 Fermentation

This stage is fully described in the chapter on fermented meat production. The main objective is to activate microorganisms, added in the starter cultures, and achieve a good microbial development. Fermentation temperatures are lower in Europe, around 22–26°C, for *L. sakei* or *L. plantarum* to produce lactic acid and reach the desired pH drop. Fermentation temperatures are higher in the United States, around 30–37°C, to allow typical starters like *L. plantarum* or *P. acidilactici* to produce high amounts of lactic acid and achieve pH values below 5.0 to 4.6. Rapid acidification ensures the inhibition of spoilage microorganisms (Toldrá 2006d).

59.5.4 Smoking

Smoking constitutes a traditional technology, especially in Northern countries, used for the preservation of food stuffs. Its application depends on the type of product and the

country. The smoke flavoring can be sprayed or atomized on the surface of the sausage. This flavoring is a liquid produced by distillation and subsequent condensation of volatile compounds from smoke (Ellis 2001). It can be applied at different stages of the processes: during fermentation, ripening, or even at the end of the process. In the case of cooked sausages, smoking may be applied during cooking or afterwards.

Smoking imparts a characteristic flavor and gives a darker external color to the product. It also exerts antioxidant properties due to the phenolic portion of the smoke and contributes to preservation due to the antimicrobial properties of smoke. However, some undesirable effects of smoking are related to formaldehyde and other possible carcinogenic substances contained in the smoke process (Bem and others 1995).

59.5.5 Ripening/Drying

This stage is applied to semidry and dry fermented sausages. Its main objective is to reduce water content and favor the development of characteristic flavor. Sausages are hung in racks and placed in drying chambers. The conditions for ripening and drying (time, temperature, and relative humidity) depend on the size and type of product. Temperature is milder for long processing times and higher for short processes. Air velocity is fixed at mild speed, around 0.05–0.1 m/s, and helps to homogenize the humidity in the chamber environment. Relative humidity is decreased progressively to avoid excessive dehydration of the sausages. Drying is a delicate stage where water must diffuse from inside the sausage to the outer surface and then is evaporated from the outer surface to the environment. However, both processes, diffusion and evaporation, must proceed at similar rates to have the correct drying. If evaporation is too intense and rapid, sausages may develop case hardening, an usual defect consisting in an excessively dry and hard outer layer (Toldrá 2002).

59.5.6 Cooking

Cooking ensures microbial destruction of microorganisms and inactivation of a good number of enzymes. It also helps to develop characteristic color and flavor of the product. Cooking is carried out in forced convection ovens either in batch or continuous operation. Smoking may be simultaneously applied during heating. The heat treatment is calculated to inactivate pathogen and spoilage microorganisms for extended shelf-life of the product with minor effect on sensory characteristics (Guerrero-Legarreta 2006). Cooking can be considered as pasteurization because the temperature in the sausages reaches around 72°C for 30–60 min. Chilling is also a delicate stage to ensure the wholesomeness of the sausages and complete food safety.

59.5.7 Packaging

Typical consumption of sausages occurs once they are sliced. Sliced sausage constitutes a common commercial presentation for its sale in supermarkets. However once the sausage is sliced, it is not protected by the casing and is thus exposed to rehydration or dehydration, oxidation, recontamination, and so on. The basic requirements for these packages, in addition to extreme hygienic conditions for packaging, are a high water vapor barrier, high barrier to oxygen, and reduced headspace or headspace with low oxygen levels (Toldrá and others 2004). Vacuum packaging and modified atmosphere packaging

(MAP) have been widely used for the preservation of sliced sausages. Both systems are effective for preserving color, suppressing microbial spoilage, and extending shelf-life. However, slices are firmly adhered in the vacuum packaging and the unpleasant separation of slices can be avoided with MAP (Sebranek and Houser 2006). More recently, active and intelligent packagings are being developed to retain the maximum quality of the product.

59.6 SENSORY CHARACTERISTICS

The color of sausages mainly depends on the concentration of its natural pigment myoglobin. Its content depends on the type of muscle and the age of the animal, being higher in older animals and in muscles with oxidative pattern (Aristoy and Toldrá 1998). The typical color of semidry and dry sausages is due to the formation of nitrosylmyoglobin by reaction of nitric oxide, generated from nitrite, with myoglobin. In the case of cooked sausages, the color changes from red to pink during the heating process, especially at temperatures above 65°C. This is due to the transformation of nitrosylmyoglobin into nitrosylhemochrome, which has a typical light pink cured-meat color. Upon heating, globin denatures and detaches itself from the iron atom, and surrounds the heme moiety. This color is also known as cooked cured-meat pigment (Pegg and Shahidi 2000).

The texture of semidry and dry sausages depends on the degree of drying and pH drop as low pH coagulates proteins and makes the texture harder. The content of fat and its composition also affects texture. In the case of cooked sausages, texture depends on several factors, such as the extent of heating (structure breakdown), the moisture content, the extent of proteolysis (degree of myofibrillar protein breakdown), and the content of connective tissue. The content of intramuscular fat also exerts a positive influence on some texture and appearance traits. Starches and vegetable proteins added to the formulation help to enhance texture and bind water as well as improve the mouthfeel.

As in the case of ham, proteolysis and lipolysis contribute to the generation of free amino acids, and fatty acids, which will contribute to the generation of taste and aroma. The flavor of sausages is described in the chapter on processed pork meat flavors.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

60.1 INTRODUCTION

The consumption of fermented food products is one of the oldest known practices. Traditionally, meat fermentation was based on the development of desirable indigenous flora. However, it is evident that not all species constituing the microbial flora present in the product contribute desirably to fermentation. So, there is a positive flora contributing to the specific characteristics of the meat product and a negative flora that can inhibit the growth and/or development of the positive flora and, what is worse, produce undesirable transformations of the substrate, resulting in important sensory and safety problems. Thus, the composition of the microbial flora may change at the site of production depending on many parameters and, if the positive flora is substantially decreased, the fermented meat products may lack adequate organoleptic characteristics. The need for a consistent quality and regular production suggests a need for flora reinforcement. In some cases, natural flora has been reinforced by back-slopping which, consists of the addition of small amounts of previously fermented meat having good sensory properties (Toldrá 2002). This practice was used for decades but gave heterogeneous quality.

Microbial starters, initiated in the United States in the 1950s and in Europe in the 1960s, revolutionized the processing of fermented foods in general and also in fermented meats. Today, fermented meats are generally produced with microbial starters. The microbiology of meat fermentation and the use of microbial starters are described in this chapter.

60.2 MICROBIOLOGY OF MEAT FERMENTATION

For many decades, meat fermentation was based on the development of the indigenous flora, in particular the positive flora. This flora has been studied and, more recently, these microorganisms have been isolated and biochemically identified through molecular methods applied to extracted DNA and RNA (Rantsiou and Cocolin 2006). Examples of bacteria identified through these modern methods are shown in Table 60.1, including a general description of the main groups of natural flora typical of fermented meat.

60.2.1 Lactic Acid Bacteria (LAB)

These bacteria metabolize glucose or other carbohydrates through either homo or hetero-fermentative pathways and generate lactic acid. This acid is accumulated into the product and drops the pH towards acid values. In some cases, where there is a heterofermentative pathway, some undesirable secondary products such as acetic acid, hydrogen peroxide, acetoin, and so on may be generated. Growing temperatures differ depending on the species. So, *L. sakei* and *L. curvatus* grow at mild temperatures, and are mainly used in European sausages where mild fermentation temperatures are typically used. On the other hand, *L. plantarum* and *P. acidilactici* grow well at higher temperatures (30–35°C) and are used in the United States where fermentation temperature is higher (Toldrá 2006a). Lactic acid bacteria have a proteolytic system (described later), and are also able to generate different types of bacteriocins with antimicrobial properties.

60.2.2 Micrococceae

This group of microorganisms is mainly composed of *Staphylococcus* and *Kocuria* (formerly *Micrococcus*). These microorganisms have proteolytic and lipolytic activity,

TABLE 60.1 Examples of the Main Microorganisms Isolated from Different Typical and Naturally Fermented Meat Products.

Microorganism	Product	Country	Reference
L. sakei	Salame friulano	Italy	Rantsiou and others (2005)
	Soppressata	Italy	Andrigetto and others (2001)
	Fuet	Spain	Aymerich and others (2003)
	Chorizo	Spain	Aymerich and others (2003)
L. curvatus	Salame friulano	Italy	Cocolin and others (2000)
	Sausage	Hungary	Rantsiou and others (2005)
	Fuet	Spain	Aymerich and others (2003)
	Chorizo	Spain	Aymerich and others (2003)
L. plantarum	Sausage	Greece	Rantsiou and others (2005)
	Salame friulano	Italy	Comi and others (2005)
	Salame tradizionale	Italy	Andrigetto and others (2001)
	Fuet	Spain	Aymerich and others (2003)
	Chorizo	Spain	Aymerich and others (2003)
L. curvatus *S. xylosus*	Salame friulano	Italy	Rantsiou and others (2004)
	Salsiccia	Italy	Rossi and others (2001)
	Fuet	Spain	Aymerich and others (2003)
	Chorizo	Spain	Aymerich and others (2003)
K. varians	Salame friulano	Italy	Cocolin and others (2001a)
S. carnosus	Salame friulano	Italy	Cocolin and others (2001b)

and contribute to flavor and to nitrate reductase activity, which reduces nitrate to nitrite and contributes to the typical color formation and safety. These microorganisms grow little at the onset of fermentation unless they are already present in high amounts. The species from this family also have catalase activity, which helps to prevent lipid oxidation and contributes to color stability.

60.2.3 Yeasts

Debaryomyces hansenii is the predominat yeast in fermented meats. This yeast grows preferentially in the outer area of the sausage due to its aerobic metabolism. *D. hansenii* has a good lipolytic activity and is able to degrade lactic acid. In addition, it contributes to the generation of volatile compounds from branched-chain amino acids (Durá and others

2004a). This yeast has an important deaminase/deamidase activity able to act on certain free amino acids and generate ammonia as a byproduct, which raises the pH in the sausage (Durá and others 2002).

60.2.4 Molds

The presence of molds on the outer surface of sausages is typical in certain areas, for example in Mediterranean dry fermented sausages. These molds give a characteristic white coating on the surface. The most usual molds identified are *Penicillium nalgiovense* and *P. chrysogenum*, which grow in the sausages from the indigenous flora, or houseflora, of the processing plant (Sunesen and Stahnke 2003). These molds contribute to flavor through their proteolytic and lipolytic activity and can also generate ammonia through deaminase and deamidase activity.

60.3 MICROBIAL STARTERS

Microorganisms used as starter cultures must have good stability under the processing conditions. This means that they must resist acid pH and tolerate the presence of salt and low water activity. These microorganisms must also be able to grow at fermentation temperatures (i.e., 18–25°C in Europe or 35–40°C in the United States). They must also have a good enzyme profile for the generation of the desired products (lactic acid for pH drop, volatile compounds for aroma, nitrate reduction, secretion of bacteriocins, and so on) and a lack of undesirable enzymes like decarboxylases that generate amines. Thus, the selection of strains is extremely delicate. The most important microorganisms used as starters belong to the lactic acid group of bacteria, *Micrococacceae*, yeasts, and molds (Leistner 1992). More specifically, the most important are *Lactobacillus sakei*, *L. curvatus*, *L. carnosus*, *L. plantarum*, *P. pentosaceus*, *Lactococcus lactis*, *Kocuria varians*, *Staphylococcus xylosus*, the yeast *Debaryomices hansenii*, and the molds *Penicillium*

TABLE 60.2 Main Enzyme Activities of Microorganisms and Their Effects in Fermented Meats.

Microorganisms	Enzyme Activity	Effects
Lactic acid bacteria	Glucohydrolase	Lactic acid generation
	Endoprotease	Protein breakdown
	Exoprotease	Generation of free amino acids
Micrococacceae	Nitrate reductase	Nitrate reduction to nitrite
	Lipase	Generation of free fatty acids
	Exoprotease	Generation of free amino acids
	Catalase	Degradation of hydrogen peroxide
Yeasts	Lipase	Generation of free fatty acids
	Transaminase	Transformation of amino acids
	Deaminase/deamidase	Lactic acid consumption and generation of ammonia
Molds	Lipase	Generation of free fatty acids, ready for oxidation
	Exoprotease	Generation of free amino acids
	Transaminase	Transformation of amino acids
	Deaminase/deamidase	Generation of ammonia

nalgiovense, and *P. chrysogenum* (Toldrá 2004, 2006b). The main enzymes and their effects for each group of microorganisms are shown in Table 60.2. The use of bacterial starter cultures with protective effects, also known as protective cultures, has the main advantages of safety enhancement and prevention of potential food-borne microbial hazard (Hugas and others 2002; Talon and Leroy 2006).

60.4 THE MICROBIAL PROTEOLYTICAL SYSTEM

The proteolytic system in microorganisms is essential for a large number of cellular processes involved in the use of proteins to supply free amino acids as nutrients and gene regulation (Pritchard and Coolbear 1993). This system is composed of endo-peptidases or proteinases, which are predominantly extracellular and bound either to the cell wall or to the cell membrane (Visser 1993), and peptidases, which are located inside the cell. The mode of action can vary if using cell-free extracts where all the enzymes will be in contact with the substrates. However, when using whole cells, which is the normal situation, the amino acid and peptide transport system will regulate the supply of the amino acids required for growth (Tan and others 1993). The cell wall proteinase is the first enzyme to degrade proteins approaching the cell. Once the generated large peptides are transported into the cell, they are further degraded to small peptides and free amino acids by different peptidases and amino-peptidases (Bockelman 1995).

60.4.1 Endo-Peptidases

The proteolytic activity of several lactic acid bacteria like *L. sakei*, *L. curvatus*, *L. plantarum*, and *L. carnosus* has been assayed, as either whole cells or cell-free extracts, against meat proteins (Fadda and others 1999a,b; Sanz and others 1999a,b). Lactic acid bacteria have some proteinases associated with the cell membrane that are responsible for initial protein breakdown. These proteinases have shown poor effectivity in hydrolyzing myofibrillar proteins, but are able to hydrolyze sarcoplasmic proteins, especially *L. plantarum* and *L. casei* (Sanz and others 1999a). The peptide profiles resulting from these hydrolyses have also been studied. A large number of hydrophilic peptides, correlated to desirable cured-meat flavors, have been detected. Other hydrophobic peptides, correlated to bitterness, have also been detected (Aristoy and Toldrá 1995; Henriksen and Stahnke 1997). Yeasts have also shown proteolytic activity. *D. hansenii* has a protease B that is active at neutral–basic pH (Bolumar and others 2005, 2006). This protease has been able to hydrolyze sarcoplasmic proteins. This activity has been observed when using either whole cells or cell-free extracts (Santos and others 2001). However, this enzyme is inactivated at acid pH, reducing its expectatives in fermentation of pH levels of 5.0 or even lower.

60.4.2 Exo-Peptidases

Lactic acid bacteria contain several important exo-peptidases that contribute to the generation of small peptides and free amino acids during fermentation. These enzymes are located inside the cell so that cell-free extracts from *L. sakei*, *L. curvatus*, and *L. casei* of myofibrillar and sarcoplasmic proteins give a net increase in the content of free amino acids. These extracts give particularly significant increases in glutamic acid, alanine, and leucine for *L. sakei*, glutamic acid and alanine for *L. curvatus*, and arginine

and glutamic acid for *L. casei* (Fadda and others 1999a; Sanz and others 1999a,b). In the case of *L. plantarum*, there was a decrease, probably due to lower exo-peptidase activity or higher intracellular metabolic activity for amino acid degradation (Fadda and others 1999b). There are a wide variety of exo-peptidases in lactic acid bacteria. For instance, the following exo-peptidases have been purified and characterized from a typical meat lactobacillus like *Lactobacillus sakei*:

- A general aminopeptidase, with optimal neutral pH, and a broad range of activity against amino acids, especially alanine and leucine (Sanz and Toldrá 1997);
- An arginine aminopeptidase, with optimal acid pH, and preference for basic residues such as arginine and lysine (Sanz and Toldrá 2002);
- A dipeptidase with optimal basic pH and a broad specificity against dipeptides except those containing Pro or Gly at the N-terminus (Montel and others 1995);
- A tripeptidase with optimal neutral pH and able to hydrolyze a wide spectrum of tri-peptides except those with Pro in the second position (Sanz and others 1998); and
- A X-prolyl-dipeptidylpeptidase, with optimal neutral pH and able to hydrolyze X-Pro dipeptides from the amino terminus from different peptides (Sanz and Toldrá 2001).

The yeasts (*Debaryomices hansenii*) also have several exo-peptidases such as a prolyl aminopeptidase, with an optimal neutral pH, and restricted to the hydrolysis of Pro at the amino terminus of peptides (Bolumar and others 2003a), and an arginyl aminopeptidase, with an optimal neutral pH and maximum specificity for basic residues like arginine and lysine (Bolumar and others 2003b). Incubations with whole cells and cell-free extracts of *Debaryomices hansenii* have shown a good hydrolysis rate of sarcoplasmic proteins with the generation of hydrophilic and hydrophobic peptides and free amino acids (Santos and others 2001).

60.4.3 Transformation of Amino Acids

Microorganisms have further enzymes (decarboxylases, deaminases, and so on) able to transform amino acids and affect the sensory characteristics of the final product (Ordoñez and others 1999; Toldrá and others 2001). These enzymes use free amino acids, generated from proteolysis, as substrate. Decarboxylation of amino acids may produce biogenic amines from respective amino acids (see Table 60.3). Transamination

TABLE 60.3 List of Amines (and Their Origins) that can be Generated in Fermented Meats.

Compounds	Origin
Tyramine	Tyrosine
Tryptamine	Trytophane
Phenylethylamine	Phenylalanine
Cadaverine	Lysine
Histamine	Histidine
Putrescine	Ornithine
Spermine/spermidine	Methionine

consists in the transference of the α-amino group of the first amino acid to the α carbon atom from an α-keto acid, generating a keto acid from the first amino acid and a new amino acid. Dehydrogenases transform the amino acid in the corresponding keto acid and ammonia. Deamidation and deamination also generates ammonia (Durá and others 2002). The microbial degradation of the amino acid side chain of tyrosine and tryptophan by liases may lead to phenol and indole formation, respectively (Molinard and Spinnler 1996). The Strecker degradation of amino acids produces branched aldehydes, like 3-methylbutanal, 2-methylbutanal and phenylacetaldehyde from leucine, isoleucine, and phenylalanine, respectively (Ordoñez and others 1999). Strecker degradation can produce sulfur compounds with high negative aroma impact when affecting sulfur-containing amino acids like methionine, cysteine, and cystine, which have low threshold values and a high aromatic impact (Flores and others 1998).

60.5 BIOCHEMICAL CHANGES DURING FERMENTED MEAT PRODUCTION

60.5.1 Glycolysis in Fermented Meat

Lactic acid is the main product resulting from carbohydrate fermentation. The generation rate and the final amount will depend on the type of lactic acid bacteria used as starter, the type and amount of added carbohydrates (glucose is easily fermented), the fermentation temperature (higher in the United States and lower in Europe), and other processing parameters (such as amount of salt and time of ripening). Added carbohydrates (glucose, sucrose, and so on) are transported into the cell and start the glycolytic or Embden–Meyerhof pathway. Key enzymes in this pathway are aldolases, which generates glyceraldehyde-3-phosphate, pyruvate kinase, which generates pyruvate from phosphoethanol pyruvate, and lactate dehydrogenase, which generates lactic acid from pyruvate (Demeyer 1992). When the pathway is heterofermentative, some additional end products such as acetate, formate, ethanol, and acetoin may be generated in trace amounts and can affect the sensory quality of the sausage (Demeyer and Stahnke 2002). The generated lactic acid may be either the D(−) or L(+) configuration, or a mixture of both, depending on the species of lactic acid bacteria used as starter. The ratio between the L and D enantiomers will depend on the actions of L and D lactate dehydrogenase, respectively, and the presence of lactate racemase (Demeyer and Toldrá 2004).

The generation of lactic acid is important because it lowers the pH towards acid values. Acid pH favors protein coagulation as it approaches the isoelectric point of myofibrillar proteins, and thus also favors water release (Toldrá 2004). Furthermore, safety is improved because of the inhibition of undesirable, pathogen, or spoilage bacteria. The pH drop favors initial proteolysis (by stimulating the activity of muscle cathepsin D) and lipolysis (by stimulating lysosomal acid lipase), both active at acid pH. However, excessive acidity may inhibit other enzymatic reactions related to the generation of flavor compounds (Toldrá and Verplaetse 1995).

60.5.2 Proteolysis in Fermented Meat

Muscle and microbial proteases have a combined action during meat fermentation. The relative contribution of each group of enzymes depends on the type of meat and the microorganisms used as starter cultures. The enzyme activity also depends on the applied

temperature and extent of the process. To evaluate these contributions, some studies have been carried out using antibiotics and other protease inhibitors. Muscle cathepsin D, which is very active at pH 4.5, appears to be the protease that initiates the degradation of myosin and actin, and other muscle proteases, like cathepsins B and L, are limited to a few proteins like actin and its degradation products (Molly and others 1997). Myofibrillar proteins, in particular myosin, α-actinin, and actin, have been reported to be degraded (García and Fox 1991). Lactobacilli have shown a good ability to degrade sarcoplasmic proteins (Fadda and others 1999a,b; Sanz and others 1999a,b).

Once proteins are broken down, muscle and microbial peptidases generate a good number of peptides that are further degraded to small peptides and amino acids, but there are large variations in the amounts generated. The highest nonprotein nitrogen value has been reported in sausages with pH value below 4.7 (Flores and others 1997). Some of these peptides have been sequenced and the parent protein identified by comparison of homologies. So, five peptides originating from myoglobin, creatin kinase, troponin T, troponin I, and myosin light chain 2, have been derived (Hughes and others 2002). Muscle and microbial tri- and dipeptidylpeptidases are responsible for the generation of small tri- and dipeptides, but their activity depends on the pH and the level of salt that inhibits this type of enzymes (Sentandreu and Toldrá 2001). The generation of small peptides may be depressed by the level of salt that inhibits muscle peptidases (Sanz and Toldrá 1999; Sanz and others 2002; Toldrá 2004), although intense levels of nonprotein nitrogen, up to 20% of the total nitrogen content, may be reached. This is the reason for wide variations in increases in nonprotein nitrogen, from 2- to 12-fold. The final step consists in the generation of free amino acids by aminopeptidases, especially muscle alanyl and methionyl aminopeptidases, together with major aminopeptidase from *L. sakei*. Basic amino acids, such as arginine and lysine, would be generated by muscle and microbial arginyl aminopeptidases (Toldrá 2006c). Some amino acids have been correlated with taste descriptors like spicy, beefy, sweet, bitter, and astringent (Talon and others 2004). Microbial metabolism of leucine, valine, and isoleucine may be responsible for the generation of branched-chain aldehydes and secondary products such as acids, alcohols, and esters (Toldrá 2006b). This metabolism is found in the *Micrococcaceae* family (Staphylococcus and Kocuria) and *Debaryomices hansenii*, and to a less extent in Lactobacilli (Demeyer and others 2000). The incubation of leucine with *Staphylococcus xylosus* and *S. carnosus* generates other volatile compounds such as 3-methylbutanoic acid and α-hydroxy isocaproic acid (Olesen and others 2004a), although curing salts have a pronounced effect on the level of volatile compounds (Olesen and others 2004b).

60.5.3 Lipolysis in Fermented Meat

Lipolysis consists of the generation of free fatty acids through the breakdown of triacylglycerols by lipases and phospholipids by phospholipases. The released fatty acids exert a direct effect on taste (sourness) and an indirect effect on aroma through generation of volatile compounds via oxidative reactions. Lipolysis in fermented meat is the result of the action of muscle and microbial enzymes (Hierro and others 1997). The percentage contribution of muscle lipolytic enzymes to total fat hydrolysis is estimated to be around 60–80%, the rest being due to microbial lipases (Molly and others 1997). Lysosomal acid lipase and acid phospholipase are the main muscle lipases, and the hormone-sensitive lipase and the monoacylglycerol lipase are the most important in adipose tissue (Toldrá 1992, 1998). These enzymes have shown good stability throughout the full process (Motilva and others 1992, 1993a,b), and their activity will vary depending

on the conditions found in the sausages (pH, salt concentration, temperature, and water activity) (Motilva and Toldrá 1993). Oleic, linoleic, estearic, and palmitic acids constitute the free fatty acids generated at a faster rate and most of them proceed from phospholipid degradation (Toldrá 2002). Rapid rates are also observed in adipose tissue fat, although they proceed from triacylglycerols. Those fatty acids with double bonds are prone to further oxidative reactions and generate volatile compounds (Buscailhon and others 1994). Starter cultures have a definitive effect on the formation of flavor in dry sausages (Berdagué and others 1993).

60.5.4 Oxidation in Fermented Meat

Fatty acids with double bonds (mono- and polyunsaturated fatty acids) are susceptible to further oxidative reactions. These reactions may generate volatile compounds with desirable aroma or some compounds with unpleasant aroma. Off-flavor development is typical of excessive oxidation (Skibsted and others 1998). Oxidation can be initiated by muscle oxidative enzymes, such as peroxydases and cyclooxygenases, which catalyze the formation of free radicals. Other catalyzers are external light, heating, and the presence of moisture and/or metallic cations (Toldrá and others 2001). Peroxide radicals propagate the reaction of free radicals with oxygen. Hydroxyperoxides (primary oxidation products) are formed, but are very reactive and generate secondary oxidation products that contribute to flavor. Numerous volatile compounds with aroma properties are generated by oxidation (Stahnke 2002). The main products from lipid oxidation are aliphatic hydrocarbons (poor contribution to flavor), alcohols (high odor threshold), aldehydes (low odor threshold), and ketones. Alcohols may interact with free carboxylic fatty acids, giving esters, especially when nitrate is not used (Toldrá 2006b).

60.5.5 Generation of Undesirable Substances

The generation of undesirable compounds depends on several factors, but the most important is the hygienic quality of the raw materials. The most important amines that can be generated during meat fermentation are listed in Table 60.3. Microorganisms with decarboxylase activity contribute to the generation of biogenic amines. For instance, certain lactic acid bacteria may produce tyramine through decarboxylation of tyrosine (Eerola and others 1996). Even though tyramine releases noradrenaline from the sympathetic nervous system and the peripheral vasoconstriction and increase in cardiac output result in higher blood pressure and risk for hypertensive crisis (Shalaby 1996), its tolerance level is relatively high, between 100 and 800 mg kg^{-1} (Nout 1994). Other microorganisms in the contaminating flora may be generating cadaverine and/or putrescine. Starter cultures decrease the levels of putrescine considerably (Kalac 2006). Phenylethylamine may cause migraine and increases in the blood pressure, and histamine may excite the smooth muscles of the uterus, the intestine, and the respiratory tract. The levels of amines in fermented sausages are very variable (Hernández-Jover and others 1997). This variability is a result of several factors, such as the quali–quantitative composition of microbial flora, the chemical–physical variables, the hygienic conditions of raw meats, as well as the procedure adopted during production and the availability of precursors (Suzzi and Gardini 2003). Therefore, it is necessary to control the hygienic conditions of the raw materials, use microorganisms lacking decarboxylase activity, and apply good manufacturing practices (Talon and others 2002).

Finally, the generation of nitrosamines in fermented meat is usually very low or even negligible because there is a limited amount of nitrite remaining in the product able to react and produce nitrosamines (Cassens 1997). Some oxides of cholesterol may be generated during meat fermentation. Oxides like 7-ketocholesterol and 5,6α-5,6-epoxycholesterol have been linked to cardiovascular-related diseases, but analysis in European sausages has revealed very low levels, less than 1.5 μg/g, for exerting any toxic effect (Demeyer and others 2000). Other studies in Brazilian salamis have not found cholesterol oxides (Baggio and Bragagnolo 2006).

60.6 TRENDS FOR IMPROVED FERMENTED MEAT

60.6.1 Enzyme Addition for the Improvement of Sensory Quality

Different enzymes have been added to fermented meat in order to accelerate the process and improve flavor development. Some examples include a lactobacillus serine proteinase (Naes and others 1995), a proteinase (alcalase) from *Bacillus licheniformis*, and a proteinase from *L. paracasei* subsp. *paracasei* (Hagen and others 1996), neutral proteinase (neutrase) from *Bacillus subtilis* (Zapelena and others 1998), neutrase, alcalase, HT proteolytic from *B. subtilis* var. *amiloliquefaciens* and fungal protease from *Aspergillus oryzae* (Zapelena and others 1997), and pronase E from *Streptomyces griseus* (Díaz and others 1993). Other strategies have comprised the addition of cell-free extracts from *D. hansenii* and *L. sakei* (Bolumar and others 2006c). Some have improved sensory scores and overall acceptability of the sausages. In other cases, like the addition of papain and bromelain, the result was an undesirable flavor and texture (Ansorena and others 2002). Another important inconvenience of proteinases is the risk of introducing excessive texture softening. Other assayed alternatives have consisted of the addition of whole cells or cell-free extracts in an attempt to accelerate and improve the sensory quality of the sausages (Durá and others 2004a–c).

60.6.2 Probiotic Addition for the Improvement of Nutritional Quality

The possibility of using probiotics in fermented meats has been studied recently. Strategies are based on using existing commercial starter cultures or studying the survival in a meat environment of lactic acid bacteria of intestinal origin. In all cases, these bacteria must grow to numbers that may have health-promoting benefits (Leroy and others 2006). Sensory and technological properties must not be negatively affected. Some bioprotective lactic acid bacteria, selected to produce bacteriocins and low-molecular-mass antimicrobial compounds, have been found useful in the small intestine against food pathogens (Työpponen and others 2003). Other authors have investigated potential probiotic properties of several Lactobacillus strains (Pennacchia and others 2006). These authors found that the analyzed strains had good adhesion capability to human intestinal Caco-2 cell lines and good growth behavior in the presence of prebiotic carbohydrates, but further *in vivo* assays are necessary to fully demonstrate the probiotic properties. This field will no doubt experience rapid development in the next few years.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

61.1 INTRODUCTION

Most of the meat products produced today are based on traditional practices. These products are attractive to consumers because they offer a wide variety of colors, flavors, and textures. There are many factors affecting the sensory characteristics of meat products such as the meats used as raw materials (genetic type, feed, age, sex, and rearing system), microorganisms selected as microbial starters for the fermentation and type of processing technologies (cooking, drying, ripening, smoking, etc.). There are many different cured meat products although they could be grouped into two major groups: dry-curing and wet-curing. Manufacturing processes for the most representative products in both groups are briefly schematized in Figure 61.1. Dry-cured ham and dry-fermented sausages are the main representative of dry-curing. In these meat products a dry cure (salt plus nitrate and/or nitrite) without any added water is applied either on the surface of the ham or mixed with the mince for the sausage. In both cases, the products are dried and ripened for a relatively long period of time for dehydration and, simultaneously, for the enzymatic development of flavor (Toldrá 2002). Cooked ham and frankfurters are good representative of wet-curing. In these cases, as schematized in Figure 61.1, a pickle injection or brine soaking is used as vehicle for cure penetration into the product or, in the case of sausages, by mixing with the mince (Flores and Toldrá 1993). These products are generally cooked, optionally smoked, and are shorter in processing time. Flavor may be also modulated through the use of spices and/or condiments. All these types of foods will be considered in this chapter, with special attention to taste and aroma compounds.

61.2 ENZYMATIC GENERATION OF TASTE NONVOLATILE COMPOUNDS IN MEAT PRODUCTS

A great research effort on the biochemical changes and enzymes involved during meat ageing were performed during the 1970s and 1980s. However, scarce information on

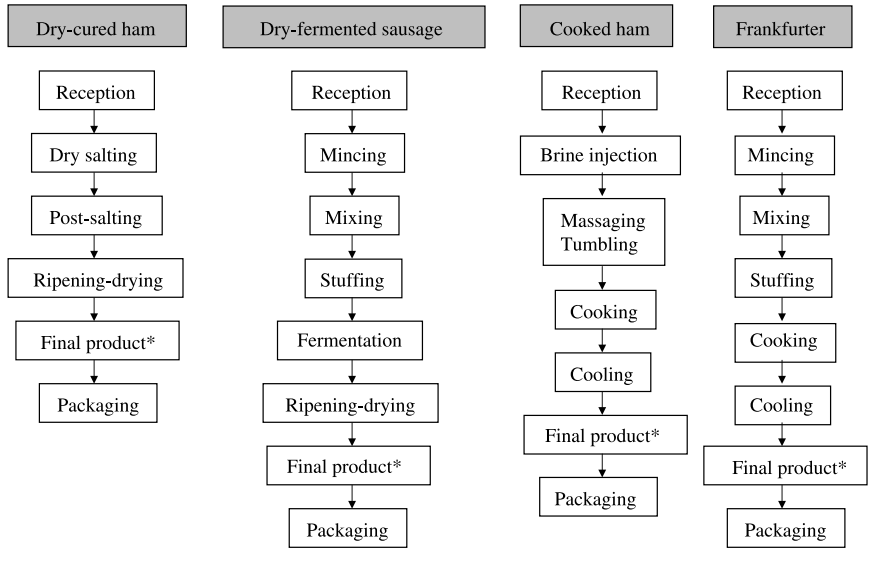

Figure 61.1 *Brief scheme of the manufacturing processes for representative products in dry-curing (dry-cured ham and dry-fermented sausage) and wet-curing (cooked ham and frankfurter). * The product may be optionally smoked.*

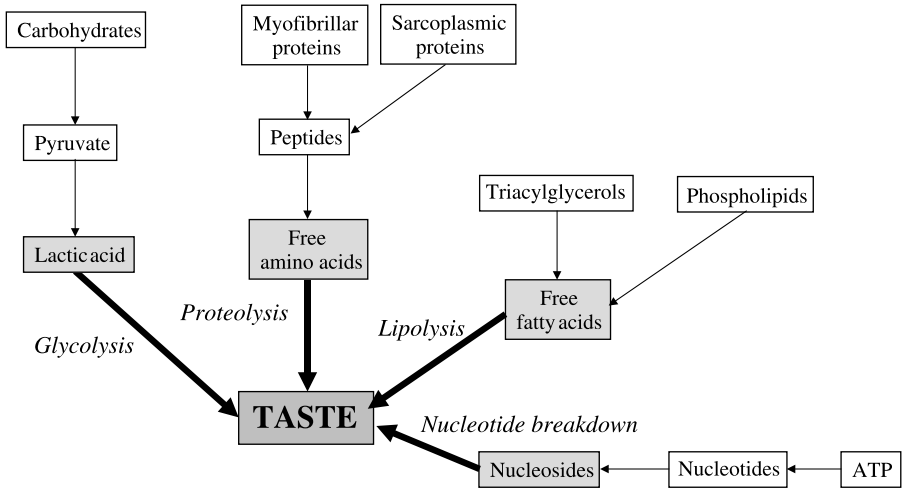

Figure 61.2 *Scheme of main biochemical mechanisms involved in taste development.*

biochemical changes was available in other products like cooked, dry-fermented and dry-cured meats. The endogenous and microbial enzyme systems were deeply studied in the 1990s, with special focus on its role in the processing and quality of these meat products (Toldrá 2002). The main enzymatic processes that take place during the processing of meat products, and are directly involved on flavor development, are briefly schematized in Figure 61.2 and described below.

61.2.1 Proteolysis

Proteolysis consists in the enzymatic hydrolysis of myofibrillar and sarcoplasmic proteins. This hydrolysis is brought about by the combined action of muscle proteinases (cathepsins and calpains) and exopeptidases. In fermented meat products, like dry fermented sausages, starter proteases also play an important role on proteolysis. Proteolysis contributes to the consistency of the product by the degradation of the myofibrillar structure and to its taste through the accumulation of small peptides and free amino acids. These amino acids directly contribute to flavor or indirectly as precursors of flavor compounds through amino acid degradation reactions (Toldrá and Flores 1998). The extent of proteolysis is variable and mainly depends on the raw materials and processing conditions and, in the case of fermented meats, the type of starters added (Toldrá 2002).

61.2.2 Lypolysis

Lipolysis consists in the enzymatic hydrolysis of triacylglycerols and phospholipids. Muscle and adipose tissue lipases as well as muscle phospholipases, respectively, are responsible for these hydrolysis (Toldrá and Navarro 2002). In fermented meat products, like dry fermented sausages, lipases from microbial starters also play an important role on lypolysis. The generation of free fatty acids as final products is very important for flavor because they will act as substrates for further oxidative reactions for the formation of volatile compounds with aroma properties (Flores and others 1998).

61.2.3 Nucleotides Breakdown

The original ATP present in living muscle is degraded very rapidly, reaching negligible values in just a few hours. This degradation is complex and involves numerous enzymes. Main changes are observed during the first days postmortem. In this way, intermediate degradation compounds, like ADP and AMP, disappear within 24 h postmortem. Other nucleotides, like IMP (inosin monophosphate), shows maximum levels at 1 day postmortem and then slightly decrease. Inosine and hypoxanthine, which are final products of the nucleotides breakdown, increase up to 7 days postmortem (Batlle and others 2001).

61.2.4 Glycolysis

Living muscle contains certain amounts of glycogen and glucose. These carbohydrates are rapidly hydrolyzed in postmortem muscle producing lactic acid as end product. The accumulation of lactic acid in the muscle produces a pH drop towards acid values around 5.3–5.8. The contribution of glycolysis is restricted to few hours in postmortem meat but is very important in fermented meats where sugar is added for microorganisms to grow. In this case, glycolysis is mainly due to the enzymatic system of lactic acid bacteria that produces high amounts of lactic acid as end product (Demeyer and Toldrá 2004).

61.3 TASTE CONTRIBUTION OF NONVOLATILE COMPOUNDS

Nonvolatile compounds are formed during meat processing. Mechanisms like glycolysis, proteolysis, and lipolysis produce a good number of nonvolatile compounds with important flavor properties that play an important role in the taste impression of the product (Toldrá and Flores 2004). Endogenous muscle enzymes are responsible for most of these reactions and their extent will depend on the type of process as reflected in Table 61.1. In the case of cooked products, the processing time is short but the increase of temperature during cooking accelerates the enzymatic action although for a few hours. On the other hand, a good number of nonvolatile compounds are generated in dry-cured ham because of its long ripening time, sometimes longer than 1 or even 2 years.

TABLE 61.1 Relative Importance of Taste Contributor Substances Present and/or Generated During the Processing of Different Meat Products.[a]

Substances	Cooked Ham	Dry-Cured Ham	Dry-Fermented Sausage
Free amino acids	+	+++	++
Peptides	+	+++	++
Nucleotides	++	+	+
Lactic acid	+	−	+++
Long-chain free fatty acids	+	+++	++
Short-chain free fatty acids	−	+	++
Carbohydrates	++	−	+
Inorganic salts	+	+++	++
Spices/condiments	+	−	+++

[a]Relative intensity: no intensity (−), poor (+), medium (++), high (+++).

TABLE 61.2 Taste Contribution of Compounds Present and/or Generated During the Processing of Cured Meat Products.

Sour	Sweet	Bitter	Salty	Umami
Lactic acid	Carbohydrates	Phenylalanine, tryptophane, tyrosine	Inorganic salts (NaCl)	Nucleotides, nucleosides
Dipeptides containing glutamic or aspartic acids	Glycine, alanine	Peptides with hydrophobic amino acid side chain		Glutamate, aspartate
Short and long-chain free fatty acids				

In the case of fermented meat products, there is a combined action between muscle and microbial enzymes and the accumulation of end products depending on the type of product, especially the pH drop rate and length of the process.

The main products resulting from glycolysis are organic acids, being the major products lactate and acetate, that contribute to the sour taste of the product (see Table 61.2). This pH drop is usual in fermented meats when starters are used, mainly lactic acid bacteria. It positively affects color development, texture, and homogeneity of drying. However, an excessive production of these acids may impart unpleasant flavors due to the partial masking of global aroma by the sourness. Some sweetness may be appreciated if some nonhydrolyzed carbohydrates are remaining. Lipolysis, either from endogenous meat enzymes or from starter cultures, generates free fatty acids and di- and monoacylglycerols. The contribution of free fatty acids to the sour taste is rather poor because of the low concentration of these compounds for effective perception. It would be only significant in dry-cured ham, where the generation of long chain fatty acids is quite important (see Table 61.2). The further oxidation of the free fatty acids generates many different compounds responsible of the aroma of the product as will be later described. While lipolysis is mainly due to endogenous enzymes present in the muscle and adipose tissue, the lipid oxidation process is due to either microbial or chemical action and thus they should be considered as different processes.

Many yeasts and molds, usually found in fermented sausages, may contribute to the fermented flavor. They contain lypolytic enzymes that contribute to flavor through the generation of carbonyl compounds. Molds and yeast are also able to oxidize lactic acid in the presence of oxygen. In addition, a mold layer on the surface of the sausage contributes to air drying by reducing available oxygen in the sausage.

Polypeptides, peptides, and free amino acids are the main products from proteolysis. They have shown an improvement in meat taste during storage (Nishimura and others 1988; Spanier and Miller 1993) and are also very important for taste development in meat products (Nishimura and others 1988; Kato and others 1989). The extend and profile of proteolysis depends on the type of product and its pH. So, cathepsin D is very important in acid products, like dry-fermented sausages, and some important proteins as myosin and actin are broken down to fragments with 135 and 38 kDa, respectively (Demeyer and Toldrá 2004). In products with mild pH values, like dry-cured ham, initial proteolysis is exerted by calpains and cathepsins B and L. Major myofibrillar proteins are also broken down to oligopeptides, small tri- and dipeptides and free amino acids (Toldrá and others 2000). A tripeptide containing Glu, Val, and Asp and some dipeptides like Ile-Val, Leu-Glu, Ile-Asp, Ala-Met, Gly-Glu, Glu-Arg, Pro-Leu, Gly-Ser, Asp-Val,

and Ser-Lys have been isolated and identified at the end of the process (Sentandreu and others 2003). When hydrophobic peptides and/or hydrophobic amino acids are predominant, a bitter taste and off-flavors are typically perceived (Aristoy and Toldrá 1995). In fact, free amino acids are very important for taste (see Table 61.2). Hydrophobic amino acids have a bitter taste while other amino acids like alanine and glycine may elicit sweet taste (Nishimura and Kato 1988). Sodium glutamate and aspartate contribute to the umami taste but also to sour taste when they are in dissociated state (Kato and others 1989). An example of free amino acids generation for different meat products is shown in Table 61.3 where noticeable differences may be observed due to the different processes. Large amounts are produced in dry-cured ham due to the longer processing time while few amounts are produced in cooked ham where processing is very short. Dry fermented sausages show intermediate amounts. Some unpleasant tastes such as bitter-like or metal aftertaste have been reported as a consequence of an excessive protein hydrolysis, when the proteolysis index is higher than 29–30% (Careri and others 1993; Virgili and others 1995).

The activity of hydrolytic enzymes may be altered by heating in cooked meat products. In fact, heating causes structural and functional changes in meat proteins that generate additional peptides and amino acids, that may have their own flavor, and also react with reducing carbohydrates to originate new taste and aroma compounds via Maillard reaction and Strecker degradation (Spanier and others 2004).

Amino acids and their degradation products may contribute to the taste of the meat product. In the case of fermented meats, free amino acids could be further decarboxylated, deaminated, or even further metabolized depending on the type of microbial flora developed in the product (Toldrá and others 2001). So, some rise of pH may be expected if ammonia is formed and thus, sausage taste would be milder in sourness. In addition,

TABLE 61.3 Generation of Free Amino Acids (Expressed in mg/100 g) in Cooked Ham, Dry-Cured Ham and Dry-Fermented Sausage.

Amino Acids	Cooked Ham	Dry-Cured Ham	Dry-Fermented Sausage
Aspartic acid	14.6	300.4	43.4
Glutamic acid	36.9	493.2	180.6
Serine	8.0	247.9	49.4
Asparagine	1.2	26.1	22.5
Glycine	6.5	208.8	71.9
Glutamine	0	0	32.5
Tyrosine	5.4	169.7	4.4
Proline	4.1	285.4	47.8
Alanine	12.8	374.8	137.7
Arginine	10.4	226.9	64.4
Threonine	5.8	276.6	50.1
Valine	4.2	312.1	94.0
Methionine	3.0	132.3	54.2
Isoleucine	4.1	216.5	75.1
Leucine	4.0	339.8	138.9
Phenylalanine	4.9	207.1	83.3
Tryptophan	0	30.7	13.3
Histidine	7.8	94.8	28.9
Lysine	9.5	731.4	58.1

Source: Data from Toldrá and others (1995), Flores and others (1998).

aminopeptidases would be less inhibited by acid pH values and would generate higher levels of free amino acids. Therefore, an equilibrium between acid production and taste is required in fermented meat products, taking into account that ammonia production by certain yeasts like *Debaryomyces hansenii* may neutralize final acidity and enhance sausage taste (Durá and others 2004). Some umami taste may be due to nondegraded nucleotides, like 5′-inosin monophosphate and 5′-guanosin monophosphate which is specially important in cooked meats (see Table 61.2). Finally, just mention that salty taste is due to the added inorganic salts, usually sodium chloride, that is a typical curing agent in meat products. The contribution of spices and condiments is very important in dry fermented sausages where they are typically added.

61.4 MECHANISM OF GENERATION OF VOLATILE COMPOUNDS AND CONTRIBUTION TO THE AROMA OF MEAT PRODUCTS

The compounds that act as precursors of meat flavor have been classified into two categories; water soluble compounds and lipids. However, as indicated above, the generation of these compounds depends on the processing conditions. In this sense, the effect of heating, smoking, and spices added to meat products, are responsible of many flavor differences among cured meat products through reactions that lead to meat aroma volatiles. The main reactions that occur during the processing of meat products are: carbohydrate degradation, amino acid degradation reactions (decarboxylation, deamination, transamination), Maillard reactions, Strecker degradation, degradation of ribonucleotides, thiamin degradation, and lipid degradation. The contribution of these reactions to aroma formation depends on the specific processing technology for each meat product (see Table 61.4). In general, these reactions are quite more complex due to secondary reactions that can occur between the products resulting from the initial reactions giving a high number of aromatic compounds.

61.4.1 Carbohydrate Degradation

The degradation of carbohydrates takes place by heating or fermentation. The heating process produces caramelized flavors due to the formation of high odor compounds such as furan derivatives, carbonyls, alcohols, and aliphatic and aromatic hydrocarbons

TABLE 61.4 Relative Importance of Mechanism of Aroma Formation During the Processing of Different Meat Products.[a]

Mechanisms	Frankfurter	Cooked Ham	Dry-Cured Ham	Dry-Fermented Sausage
Carbohydrate degradation (heating or fermentation)	+	+	−	+++
Microbial amino acid degradation reactions	−	−	−	++
Maillard reactions	+++	+++	+	+
Strecker degradation	+++	+++	++	+
Degradation of ribonucleotides	+++	+++	++	++
Thiamin degradation	++	++	++	++
Lipid degradation	+++	+++	+++	+++

[a]Relative intensity: no effect (−), poor (+), medium (++), high (+++).

(Mottram 1991). These sugar caramelization reactions are mainly produced in small surface areas of roast and grilled meat that have been dehydrated. Therefore, the contribution of the sugar degradation reaction in meat products such as frankfurters and cooked ham will depend on the further heating treatment applied. However, the concentration of sugars in meat products is low except in fermented products were they constitute the substrate for the fermentation process being the second route for carbohydrate degradation. In this sense, the fermentation process release compounds of low molecular weight such as diacetyl, acetoin, butanediol, acetaldehyde, ethanol, and acetic acid. The generation of the specific volatile compounds during the carbohydrate fermentation depends on the starter used in the processing of dry fermented sausages. The generation of compounds such as diacetyl, acetoin, or butanediol impart a butter and yogurt aroma in fermented sausages. Sugar degradation is an important source of di- and tricarbonyls which may react subsequently with amino acids in Strecker reactions (MacLeod and Seyyedain-Ardebili 1981).

61.4.2 Amino Acid Degradation Reactions

The degradation of amino acids can be produced by the enzymatic activity present in the meat products. This is the case of fermented meat products where the microbial population is responsible of reactions such as the degradation of amino acid side chain, decarboxylation, oxidative deamination, and transamination (Toldrá and others 2001). The side chain degradation for tyrosine and tryptophane leads to phenol and indole formation (Molimard and Spinnler 1996) producing compounds such as 3-methylindole (skatole) responsible of unpleasant odors in meat products. On the other hand, the microbial decarboxylation of amino acids produce biogenic amines (Ordoñez and others 1999) that can affect negatively the flavor and safety of the meat product. The oxidative and nonoxidative deamination of amino acids produce keto acids that can be also transformed to aldehyde by descarboxylation and then, this aldehyde can be either reduced to the corresponding primary alcohol or oxidized to an acid. The generation of aromatic compounds from methyl branched amino acids in dry fermented sausages is mainly due to the action of staphylococci and lactic acid bacteria (Berdagué and others 1993; Stahnke 1995, 1999; Schmidt and Berger 1998). The catabolism of branched amino acids such as valine, leucine, and isoleucine generates 2- and 3-methylbutanal, 2- and 3-methylbutanol, 2- and 3-methylpentanoic acids, respectively. Dimethyldisulfide is catabolyzed from cysteine and benzeneacetaldehyde from phenylalanine. These sulfur compounds are important contributors to meat flavor because of their low threshold values.

61.4.3 Maillard Reactions

These reactions between reducing sugars and amino compounds are responsible of many flavor compounds in cooked foods (Mottram 1991). The reaction rate increases with temperature and is associated with low moisture levels. The flavor compounds are mainly generated at the temperature usual of cooking processes. The first step of the reaction is the addition of the carbonyl group of the open chain form of a reducing sugar and the amino group of an amino acid, peptide, or other compound with a primary amino group, to give a glycosylamine. The further elimination of water gives a Schiff's base that with subsequent rearrangement forms Amadori and Heyns intermediates that by themselves do not contribute to flavor although they are precursors of flavor

compounds (furanones derivatives, furfurals, dicarbonyl compounds, and others). All these Maillard products can experience further reactions with other reactive compounds; amines, amino acids, hydrogen sulfide, thiols, ammonia, acetaldehyde, and other aldehydes, leading to many important flavor compounds including heterocycles (pyrazines, oxazoles, thiophenes, thiazoles, and others). Furfurals and furanones, generally impart caramel-like, sweet, fruity characteristics to foods. Probably, they are minor contributors to meat-like flavors however they are important intermediates to other flavor compounds.

61.4.4 Strecker Degradation

The Strecker degradation of amino acids consists in the oxidative deamination and decarboxylation of an α-amino acid in the presence of a dicarbonyl compound. The dicarbonyl compounds arise from sugar degradations or Maillard reactions. The reaction produces an aldehyde containing one fewer carbon atom than the original amino acid and an α-aminoketone. Thus, acetaldehyde is formed from alanine, propanal from α-aminobutyric acid, 3-methylbutanal from leucine, 2-methylbutanal from isoleucine, 2-methylpropanal from valine, phenylacetaldehyde from phenylalanine, and methional from methionine (MacLeod and Seyyedain-Ardebili 1981). Furthermore, the Strecker degradation of sulfur containing amino acids such as methionine, cysteine, and cystine leads to the production of hydrogen sulfide, ammonia, and acetaldehyde. These compounds are important as reactive intermediates for the formation of sulfur compounds characterized by low threshold values and therefore, a high aromatic impact in meat products (Shahidi and others 1986).

61.4.5 Degradation of Ribonucleotides

The contribution of this reaction to the generation of flavor compounds in meat is by the production of ribose from inosine monophosphate and other ribonuclotides. This ribose takes part in the Maillard reaction generating important flavor compounds. The reaction of 4-hydroxy-5-methyl-3(2H)furanone that comes from the degradation of ribose, with hydrogen sulfide produces a complex mixture of compounds possessing roasted meat odors. These compounds are identified as mercapto-substituted furan and mercapto-substituted thiophen derivatives (MacLeod and Seyyedain-Ardebili 1981).

61.4.6 Degradation of Thiamin

The degradation of thiamin during the cooking process produces a number of aromatic compounds including furans, furanthiols, thiophenes, thiazoles, and aliphatic sulfur compounds (Mottram 1991). These compounds have been reported to possess roasted meat odors and have been found in cooked meats (MacLeod and Seyyedain-Ardebili 1981).

61.4.7 Lipid Degradation

The oxidation of unsaturated fatty acids is responsible for the generation of flavor compounds. The oxidation process can be due to the effect of temperature during meat cooking, autoxidation, and autoxidation during dry-curing. The thermally induced oxidation is an important route to aroma volatiles during cooking (Mottram 1998), the autoxidation during storage of fatty foods produce undesirable flavors associated with

rancidity (Gray and others 1996; StAngelo 1996) and the drying process during dry-curing produce many volatile compounds responsible for the cured flavor (Toldrá and Flores 1998; Gandemer 1999, 2002). The mechanism of autoxidation is free radical in nature and the reaction has been widely studied (Frankel 1980). Phospholipids contain higher amounts of polyunsaturated fatty acids than triacylglycerols, making them more susceptible to oxidation. The contribution of phospholipids to cooked meat aroma has been demonstrated (Mottram and Salter 1989; Mottram and Whitfield 1995) also their contribution to the development of the characteristic aroma in the processing of dry-cured ham (Flores and others 1985, 1987). Lipid oxidation accounts for the generation of nonbranched aliphatic compounds such as alkanes, alkenes, ketones, aldehydes, alcohols, carboxylic acids, esters, and several furanic cycles. The contribution of alkanes to flavor is almost irrelevant due to their high thresholds. The flavor of alcohols was considered unimportant in comparison to other carbonyl compounds. The straight chain primary alcohols are relatively flavorless but as the carbon chain increases, the flavor becomes stronger (Shahidi and others 1986) giving greenish, woody, and fatty floral notes. C3 and C4 aldehydes exert sharp and irritating flavor, intermediate (C5–C9) have green, oily, and fatty flavors and the higher (C10–C12) exert citrus flavor (Forss 1972).

61.5 CONTRIBUTION OF SPICES TO THE AROMA OF MEAT PRODUCTS

Although not a mechanism of formation of flavor compounds, spices constitute a source of many volatile compounds that will impart a specific characteristic to the meat product. In this sense, the spices and condiments added in the manufacture of meat products contribute to a particular flavor, depending on local traditions. In fact, there are many specific flavors due to the high number of available aromatic plants such as pepper, paprika, mustard, nutmeg, cloves, oregano, rosemary, thyme, garlic, onion, and so on. These compounds have a high impact on the aroma of fermented products (Ordoñez and others 1999). For instance, the high content of terpene hydrocarbons or sulfur compounds found in the headspace of dry fermented sausages, comes from pepper or garlic, respectively. Dry-cured ham is not normally condimented with spices and only salt and nitrate are added in its formulation.

61.6 CONTRIBUTION OF SMOKING TO THE FLAVOR OF SMOKED MEAT PRODUCTS

The practice of smoking of meat and meat products produces a drying effect, imparts desirable flavor and color of the meat and protects the meat product from rancidity and spoilage (Ellis 2001). Nowadays, meat smoking consist on the addition of vaporous or liquid smoke to meat or meat products (Fessmann 1995). The major contribution of liquid smoke to the headspace of meat products are phenols, cyclopentenones and furans (Knowles and others 1975; Guillen and others 1995). Phenol and methoxyphenol derivatives are originated mainly from the pyrolysis of lignin which accounts for 25% of the composition of wood. Cyclopentanones are produced from dicarboxylic acids by decarboxylation and ring formation, while furans probably come from the degradation of glucose, a thermal degradation product of cellulose (Toth and Potthast 1984). The characteristic smoke flavor has been attributed to phenols (Fiddler and others 1970).

61.7 IDENTIFICATION AND RELEVANCE OF VOLATILE COMPOUNDS TO THE FLAVOR OF MEAT PRODUCTS

Many volatile compounds have been identified in cooked ham (Baloga and others 1990; De Winne and Dirinck 1997; Guillard and others 1997), frankfurters (Chevance and Farmer 1999a,b; Chevance and others 2000; Estevez and others 2005), dry-cured ham (Berdague and others 1991; Buscalhion and others 1994; Bolzoni and others 1996; Flores and others 1997; Ruiz and others 1998, 1999; Andres and others 2002; Timon and others 2002; Carrapiso and others 2003; Garcia-Esteban and others 2004; Sanchez-Peña and others 2005) and fermented products (Berdagué and others 1993; Stahnke 1994, 1995; Viallon and others 1996; Ansorena and others 2001; Stahnke and others 2002; Muguerza and others 2003; Benito and others 2004; Olesen and others 2004; Tjener and others 2004a,b; Flores and others 2004, 2005; Herranz and others 2005; Hierro and others 2005; Bolumar and others 2006). The volatile compounds identified in these meat products belong to the following classes: alkanes, alkenes, aldehydes, ketones, alcohols, aromatic hydrocarbons, carboxylic acids, esters, terpenes, sulfur compounds, furans, pyrazines, amines, and chloride compounds. Although many compounds are found in the four meat products, its flavor is completely different depending on its processing. Different pathways in the processing technology are responsible for the formation of these volatile compounds. However, the impact of an odor component on the total aroma depends on a number of factors, such as odor threshold, concentration, solubility in water or fat, and temperature as reported for dry-cured ham flavor (Flores and others 1998).

Solid-phase micro-extraction (SPME) is a recent extraction technique very useful for the study of aroma compounds in foods (Steffen and Pawliszyn 1996) and specially, in meat products (Ruiz and others 1998; Gianelli and others 2002; García-Esteban and others 2004; Marco and others 2004). Typical SPME gas chromatograms of cooked ham and frankfurter is shown in Figures 61.3*a* and 61.3*b*, respectively. It is remarkable the high number of volatile compounds detected, for example compounds 1 to 9 were detected in both cured meat products (see Table 61.5). However, compounds C to F were only detected in frankfurter, typical compounds from the smoking treatment. On the other hand, typical SPME gas chromatograms of dry-fermented sausages and dry-cured ham are shown in Figures 61.4*a* and 61.4*b*, respectively. Several of the most abundant compounds are indicated in Table 61.6 being two compounds, three (acetic acid) and six (hexanal) detected in high proportion in both meat products however, the chromatograms were completely different.

In many cases, the study of volatile compounds in meat products has been focused on the most abundant compounds without taking into consideration their contribution to the overall aroma. The study of odor impact compounds in meat products has been done through olfactometry techniques (Toldrá and Flores 2004).

The odor-active compounds detected in dry meat products including their odor description and possible origin are shown in Table 61.7. In dry-cured ham, several sulfur compounds have been detected and contribute to dry-cured aroma (Carrapiso and others 2002a,b; Carrapiso and García 2004). It is remarkable that these sulfur compounds are in very low proportions in dry-cured ham but its effect is due to their low thresholds (Shahidi and others 1986). On the other hand, aldehydes that result from amino acid degradation and lipid oxidation are contributing to the aroma of dry-cured ham as several ketones that also come from lipid oxidation. Only one ester compound has been described

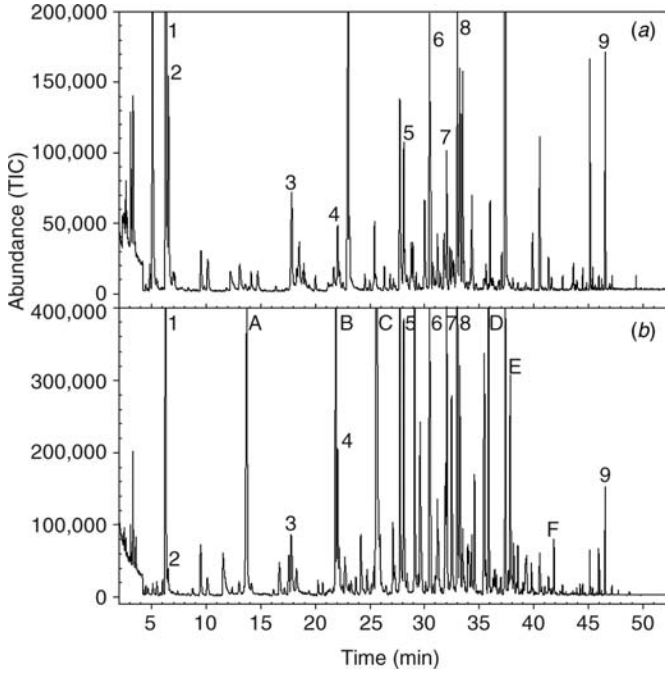

Figure 61.3 *Typical gas chromatogram of the volatile compounds of cooked ham (a) and frankfurter (b). Chromatograms obtained by GC-MS using the SPME fiber (75 μm Carboxen/PDMS) after sampling the headspace for 2 h at 30° C. The numbers and letters represent compounds identified and listed in Table 5.*

as contributor to the aroma of dry-cured ham. However, the presence of ester compounds in dry-cured ham depends on the processing conditions (Toldrá and Flores 1998) because they have been isolated in higher proportions in Parma (Italian) than in Iberian or Serrano (Spanish) dry-cured hams.

On the other hand, many ester compounds have been detected as odor active compounds in dry fermented sausages (Stahnke 1994; Meynier and others 1999) followed by several aldehydes, one ketone, one carboxylic acid, one sulfur compound, one pyrrol, and one alcohol (Table 61.7). The contribution of esters compounds to the aroma of fermented sausages is very important even though their concentrations are

very low; they are easily detected by sniffing adding fruity notes and masking rancid odors (Stahnke 1994). It is important to remark the diverse pathways originating the same volatile compound. Sulfur compounds such as methional, dimethyl disulfide, and methylpropyl disulfide have been found in the headspace of fermented sausages and they can arise from the Strecker degradation of cysteine and methionine, or from the garlic added as a spice (Viallon and others 1996). On the other hand, compounds such as acetic acid and ethanol detected in high proportions (peaks 1 and 3 in Fig. 61.3*a*), can also be produced in the catabolism of lipids or amino acids and some methyl compounds also generated in the degradation of branched amino acids by Strecker degradations. Blank and others (2001) indicated that pyrrol compounds seems to play an important role in fermented meat products by contributing to a strong roasty note. However, its formation is not clear as they can be producuced by the Strecker degradation of proline or also by sugar degradation and microbial origin. The content in volatile compounds depends on the dry fermented sausage process. In the case of Italian and Spanish sausages, they mainly contain the following dominant compounds: terpenes (from spices), ketones and aldehydes (from lipolysis and lipid oxidation), and esters. However, certain low acid sausages contain aldehydes, ketones, alcohols and esters, and low quantities of N-containing volatiles, indicating a low proteolysis in the product. On the other hand, sausages of medium acidity (pH = 5.1–5.3) contain aldehydes and ketones (constituents of the 60% of total volatile), furans, sulfur compounds, pyrazines, and amines, indicating a high proteolysis in the product (Ordoñez and others 1999).

The differences in volatile composition of uncured and cured cooked pork has been studied by several reports (Ramarathnam and others 1991, 1993) in order to establish the effect of curing in the development of cured cooked flavor. Different reports have studied the volatile composition of cooked ham (Baloga and others 1990) and the effect of refrigerated storage on the volatile compounds (De Winne and Dirinck 1997). However, few reports have studied the odor active compounds in cooked cured meat products (Table 61.8) (Guillard and others 1997; Chevance and Farmer 1999a,b). Many volatile compounds identified in these products are originated from smoke and seasonings while others come from reactions occurring in the meat as described above. Therefore, it is necessary to know the processing conditions and additives added to the meat product. In the study of odor active compounds in cooked cured meat products, several terpenes were identified from cooked ham and frankfurters (Table 61.8). Moreover, several compounds derived from liquid smoke played a major contribution to the aroma of frankfurter (Chevance and Farmer 1999) being phenols the most important group of compounds. On the other hand, the compounds responsible of many meaty, roasted and grilled notes in frankfurters were sulfur-containing compounds. However, different structures of sulfur compounds have been detected in frankfurters that can be due to different cooking procedures applied (Chevance and Farmer 1999a). This is the case of oven cooking that can produce higher temperatures and lower moisture levels on the surface favoring the Maillard reaction in comparison to cooking in a water bath. On the other hand, few compounds have been described as odor active compounds in cooked ham, apart from terpenes from the spices added, the sulfur-compounds are contributing to the aroma of cooked ham and a branched acid originated from the Strecker degradation of amino acids (Guillard and others 1997) (Table 61.8). It is important to remark that the refrigerated storage of cooked cured products can modify the volatile composition due to the presence of lipid oxidation and fermentation phenomenon that will generate typical fermentation products such as methyl branched alcohols and aldehydes, and oxidation products such as unsaturated aldehydes (De Winne and Dirinck 1997) that are not present in the fresh cooked ham.

62.1 INTRODUCTION

There is a trend in the last decades towards an increased demand of meat products due to many factors including changes in consumer lifestyles, such as the demand for easy-to-prepare products with convenient and smaller portions. There is a wide variety of processed meat products and, in fact, its quality varies according to the ingredients and additives used in the formulation as well as the type of processing (Flores and Toldrá 1993). So, the sensory characteristics vary according to the type of product but, even for a given product, particular

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

characteristics may change depending on the geographical area (i.e., addition of certain spices), physical appearance (form, diameter of cross-section, size of fat particles, specific color), extent of drying and/or ripening, application of smoking, presence of external molds, and so on (Toldrá 2002, 2004a). The contribution of volatile compounds to the aroma of meat products has been deeply studied. In fact, the contribution of volatile compounds to flavor depends on many factors such as particular odor characteristics (i.e., odor threshold), concentration in the product, solubility in water or fat and temperature (Toldrá and Flores 2004). Something similar happens with the relation between nonvolatile components such as peptides amino acids and nucleotides and product flavor (Spanier and Miller 1993). Many studies have related the volatile and nonvolatile compounds with the sensory charactersitics of the meat products by using multivariate statistical methods.

The sensory attributes of meat products may differ depending on the type of product, specially due to important processing differences. In this chapter, the main sensory characteristics of some selected beef and pork meat products will be presented and its evaluation discussed.

62.2 EFFECTS OF PROCESSING TECHNOLOGY ON SENSORY ATTRIBUTES

There are many types of meat products, most of them treated with salt and sodium nitrite and subjected to either cooking, smoking, or drying. In general, there are several important groups: wet-curing, pickle-curing, and dry-curing (Flores and Toldrá 1993). In wet-curing the additives are mixed with the minced meat and fat, and ice to cool the meat paste and then stuffed into casings. In pickle-curing the additives are dissolved in water forming a brine that penetrates into the meat by either soaking or injection. In both cases, the meat products are cooked and, optionally, smoked. In dry-curing, the curing additives can be either rubbed onto the outer surface of the ham and left for ripening and drying, as is the case for dry-cured ham (Toldrá 2004b), or mixed with the minced meat and fat, stuffed into casings and left to ferment and dry, that is the case for dry-fermented sausages. These products can also be optionally smoked (Demeyer and Toldrá 2004).

The acceptability of cured meat is largely dependent upon its flavor: however, very little is known about the chemical mechanisms involved in the reactions leading to the formation of cured meat flavor and furthermore, there are certain difficulties in the elucidation of the compounds responsible for this flavor (Ramarathnam 1998). In fact, many volatile compounds have been isolated and identified from cured pork meats although no compound has been identified yet as responsible of cured meat flavor (Shahidi and others 1986; Flores and others 1998; Ramarathnam 1998).

Curing additives have several roles, some of them closely related with sensory characteristics, as briefly described here. The main functions of salt are its contribution to taste and preservation as well as the enhancement of the functional properties of meat proteins. Sugar produces an enhancement of the flavor of the cured product and constitutes a substrate for fermentation while the reducing agents (ascorbates and erythorbates) accelerate the development of the characteristic pink color of cured meat. Nitrite exerts an antimicrobial effect by preventing the growth of *Clostrodium botulinum*, imparts the characteristic pink color to the cured meat, prevents lipid oxidation providing meat stability (Pegg and Shahidi 2000).

Meat flavor is primarily developed through the cooking process where several reactions take place and many aromas and tastes are generated (Cheng and Ho 1998). The reactions involved are very complex and include the thermal degradation of individual muscle

components, thermal oxidation of lipids, reactions between amino acids and carbohydrates and further interactions between these compounds. The characteristic flavor can not be adscribed to any single compound although it is generally accepted that meaty notes are mainly originated from sulfur-containing compounds generated from water soluble precursors in lean meat (Spanier and others 2004), while fat substances mainly contribute to flavor species differences (Shahidi and others 1986).

Flavor research characterizes and measures overall meat flavor quality and individual attributes by studying the influence of processing conditions. In sensory descriptive methods, the purpose is to identify and measure the presence or intensity of a particular characteristic (Piggott and others 1998). Flavor lexicons constitute a widely used tool for documenting and describing sensory perception. They are used to record and define a product flavor, compare products and determine storage stability, as well as consumer apreciation and acceptability and chemical flavor data (Drake and Civille 2002). The aromatics, tastes and feeling factors are the basis for the lexicon and these lexicons have been used for meat products such as roast beef, frankfurters, bacon, cooked ham, dry-fermented sausages and dry-cured ham as described in this chapter. Sensory descriptive attributes and different evaluation techniques including the methodology (i.e., training, scales, etc.) are summarized at the beginning of each table.

62.3 PROCESSED MEAT PRODUCTS

62.3.1 Roast Beef

Currently, only a small proportion of beef cuts from carcass is used for further processing in comparison to pork and chicken (Boles and Swan 2001). The major reasons for not using beef for further processing are basically related to its the cost and variability of the raw material. So, few different meat cuts may be used in the processing of roast beef. The roast cuts are injected or immersed in a brine containing salt, sugar, polyphosphates, and occasionally, other additives like nitrite, garlic powder, and others. After injection, the roast can be tumbled, vacuum-packaged, and cooked. The sensory characteristics of the roast beef will be developed during the cooking process but the sensory quality will depend on the additives added in the brine. The flavor of raw meat is almost negligible but a desirable flavor is developed during cooking as a result of multiple reactions such as lipid oxidation/degradation and thermal degradation of proteins, peptides, amino acids, sugars, ribonucleotides, and thermal degradation of thiamine (McLeod 1998). In the new preparation procedures of beef roasts several problems have appeared such as warmed-over flavor, reduced juiciness and yield loss due to cooking (Stites and others 1989). The main sensory characteristics studied in roast beef are shown in Table 62.1. One of the main studied characteristics is the warmed-over flavor that consists in an undesirable flavor developed during refrigerated storage of cooked meat due to oxidation of lipids, particularly phospholipids. In this case, the addition of nitrite in the brine contributes to delay the lipid oxidation phenomenon and off-flavor development (Cheng and Ockerman 1998). Other important quality attributes are beef flavor intensity and juiciness and tenderness for texture. For instance, different additives, like polyphosphates, are added during processing affecting the juiciness and tenderness but also acting as an antioxidant although its effect depends on the application of the brine (either surface or injected) (Cheng and Ockerman 1998). Recently, the most important factors underlying beef steak purchase were color, price, visible fat, and cut, while tenderness, flavor, and juiciness were the most related with eating satisfaction

TABLE 62.1 Sensory Descriptive Terms for Evaluating Sensory Characteristics of Roast Beef.

Technique	Aroma	Flavor	Taste	Texture	Others	Reference
Trained panel 15 cm anchored unstructured line		Beef flavor intensity Off-flavor intensity		Juiciness Tenderness		Stites and others (1989)

Consumer descriptive sensory panel. Six point structured hedonic scale		Beef flavor intensity Off flavor		Tenderness Toughness Juiciness Dryness	Buying the product Overall acceptability	Boles and Swan (2002)
Consumer descriptive sensory panel. Nine point hedonic scale		Beef flavor	Saltiness	Juiciness Tenderness	Overall acceptability	Robbins and others (2003)
Trained panel		Overall flavor		Tenderness Chewiness Juiciness Binding	Overall acceptability Color acceptability	Lennon and others (2006)

(Robbins and others 2003). In the same study, roast beef produced from cattle supplemented with vitamin E was more acceptable than nonsupplemented controls.

62.3.2 Bacon

Pork bellies are pumped with a curing pickle containing salt, sugar, sodium nitrite, and sodium erythorbate. These pumped bellies are vacuum-tumbled and then, smoked and heat processed. Then, the bellies are chilled, sliced and packaged as an usual format for this product.

The sensory attributes evaluated in bacon are summarized in Table 62.2. In general, characteristic flavor notes of the product like cured pork flavor, smoke, boar, fatty, browned, and others have been evaluated. The four taste attributes and the texture of the bacon have also been described. In this case, texture attributes with importance for the quality of bacon are juiciness and hardness (Berry and Blumer 1981; Sheard and others 2000) as reflected in Table 62.2. However, other evaluated descriptors are crispness and greasiness that are more related with the cooking procedure (frying) applied to the product before consumption (Heymann and others 1996; Maw and others 2001).

The sensory characteristics can be highly affected by processing, addition of different additives (nitrite, salt), and levels of addition, muscle quality, genotype, animal feeding, and sex. The effect of additives on sensory quality of bacon was studied in order to reduce nitrite levels in bacon. The effect of various sodium nitrite and potassium sorbate levels on sensory and chemical properties of bacon was studied (Berry and Blumer 1981). These authors found that the percentage and distribution of lean exert more influence on textural, physical, and cooking properties of bacon than sodium

TABLE 62.2 Sensory Descriptive Terms for Evaluating Sensory Characteristics of Processed Bacon.

Technique	Aroma	Flavor	Taste	Texture	Others	Reference

nitrite and potassium sorbate levels. However, they detected that the partial replacement of nitrite by potassium sorbate results in different chemical-like aromas during frying. They also found that sodium nitrite prevent or delay the onset of strange aromas in vacuum-packaged bacon.

The effect of the feeding system like the increased use of fishmeal in the diet was associated with increased levels of fishy flavor in the bacon (Maw and others 2001). Recently, the addition of n-3 polyunsaturated fatty acids to the feeds in order to improve the fatty acids profile and, thus, the nutritional quality of pig meat, increases the susceptibility of this meat to further oxidation that can be easily detected as off-flavors (Sheard and others 2000).

Animal sex affected the sensory quality of bacon (Heymann and others 1996) as gilts produced less backfat compared to barrows and resulted in bellies that gave a cooked bacon with more protein, less fat, and more cholesterol. The consumer acceptance of bacon is highly dependent on the leanness of pork belly (Heymann and others 1996). This leanness produces better appearance, better palatability, and lower cooking losses. However, Maw and others (2001) did not find differences in bacon between sexes for tenderness, juiciness, saltiness, bacon flavor, and odor although they also detected differences between sexes for abnormal odor and boar odor. The boar taint odor is a urine-like odor being the hormone androstenone one of the major contributors. Those factors that affect androstenone levels such as genotype and environmental factors affect boar taint odor and therefore, the final sensory quality of bacon. Maw and others (2001) also found that boar taint and fishy aromas were competing with the bacon taste. Moreover, these authors also studied the effect of other factors on sensory quality of bacon such as genotype and farming. In this sense, genotype affected the eating quality of bacon specially the saltiness and pinkness. They also found that bacon from straw-court pigs tended to be darker, tender, and more intense in positive flavors than those from slatted and concrete-floored housing. Finally, through the study of the eating characteristics of bacon, Maw and others (2001) suggested a link between intramuscular fat and meat flavor, and between intramuscular fat and texture.

62.3.3 Frankfurters

The standard manufacturing practices in frankfurter processing consist on the preparation of a batter that mostly contains meat (beef, pork, others) and fat, with water, salt, sodium nitrite, sodium ascorbate, polyphosphates, thickeners (starch, milk proteins, others), and spice mix. Initially, meat (beef, pork, others) with half the ice, salt, sodium polyphosphate, sodium nitrite, and sodium ascorbate, are chopped in a vacuum cutter at medium speed. Then, the fat, spice mix, and half the ice, are added to the bowl cutter and mixed. Finally, the thickeners are added and the batter is chopped at high speed to an end-point temperature of around 11°C. Once fully mixed, the batter is stuffed and cooked so that, optionally, can be performed in a smokehouse and vacuum-packaged.

This comminuted meat product is a complex food system where water absorption, gelation, and emulsion formation influence the stability and texture of the product. In addition, the development of the characteristic pink color of this product is due to the formation of nitrosomyoglobin that is stabilized by the cooking treatment. The final structure of the product is achieved during the initial processing stages by the formation of the batter, as a result of coagulation of meat proteins during cooking and gel formation by the added thickeners.

Therefore, the sensory attributes described for frankfurters have been summarized in Table 62.3. Many texture attributes such us hardness, juiciness, cohesiveness, gumminess, chewiness, greasiness, graininess, and others are described in that table. The reason for so many attributes is that all the additives added to the batter can affect them in different ways. The addition of nonmeat proteins (i.e., milk proteins) in these meat products decrease the ingredient cost and increase yield but can affect the sensory quality of the meat product (Ellekjaer and others 1996). Milk proteins act as emulsifiers and therefore, can affect the emulsion formation and thus, the texture. But texture can change from springy at lower protein concentrations to cakey and dry at higher concentrations (Lyons and others 1999). Moreover, these nonmeat protein agents have been added to reduce the fat content of sausages and improve its unhealthy image for the high fat levels (20–50%). However, the reduction of the fat content in final comminuted meat products to less than 20% can produce unacceptable texture, flavor, and appearance. For example, the overall palatability of low-fat frankfurters has been directly related to firmness and inversely related to juiciness and spice and foreign flavor of the product (Yang and others 2001). Soy protein concentrates and isolates have also been used successfully to reduce the fat content in sausages (Ho and others 1997) although they should be added to frankfurters at $<3.0\%$ in order to avoid an increased hardness and off-flavor and decreased juiciness, saltiness, and flavor intensity (Matulis and others 1995a). Taking into account that the reduction of fat in a meat emulsion product is generally accompanied by an increase in added water, this procedure will only be effective if this water is retained after thermal processing, cooling, and packaging. Therefore, starches and gums are being used as fat substitutes because they can maintain the functional properties of the product while imparting fat-like properties. Carragenan and oat fibre can improved the juiciness, cohesiveness, and lumpiness of low-fat sausages but none of them produce the same sensory attributes as the full-fat sausages (Cofrades and others 2000). Blends composed of carrageenan in combination with tapioca starch improve the final texture of low-fat sausages (Lyons and others 1999).

On the other hand, the manufacture of sausages with a reduced amount of salt is more difficult than expected and may cause sensory changes. So, the reduction in salt content decreases protein extraction and water binding in addition to altering palatability attributes. The lower ionic strength produces increased release of fat and gel liquid although it will depend on the degree of salt reduction (Matulis and others 1995b). Finally, processing conditions may affect sensory properties of frankfurters. The chopping time and final batter temperature of the comminuted product have a significant effect on the stability of meat batter. The mixing develops a uniform distribution of fat and lean particles but the changes in particle size affects sensory and physical characteristics more than changes in mixing time. In the case of additional mixing, a decrease in the particle size and increase of springiness and chewiness has been reported in cooked frankfurters (Small and others 1995).

On the other hand, flavor sensory attributes typically described in frankfurters are flavor intensity, frankfurter flavor, off-flavor, and spice flavor. However, their flavor attributes will depend on the additives added to the meat emulsion like spices and liquid smoke. Many compounds that contribute to the overall odor of frankfurters have been identified, being the smokiness and spiciness of frankfurters caused by phenols, terpenes, and other compounds such as aldehydes, ketones, furanthiols, and alicyclic sulfur compounds, derived from the meat fraction (Chevance and Farmer 1999). Saltiness is the most important taste attribute (Matullis and others 1995b; Ellekjaer and others 1996; Runsumen and

others 2003). Finally, other descriptors are color, appearance, and overall acceptability. In recent years, quality evaluations of commercial frankfurters have been done in order to evaluate consumer preferences (González-Viñas and others 2004) and to correlate physicochemical parameters with deterioration indexes (Sabbag and others 2005).

62.3.4 Cooked Ham

The main purpose in the manufacture of cooked ham is to develop the characteristic flavor and color, as well as an appropriate texture that allows the product to be sliced. Therefore, during processing the pork legs are cleaned from skin, bones, connective and adipose tissues, and also zones that can be nonattractive to consumers. Then, the hams are injected with a brine containing salt, sugar, nitrate or nitrite, ascorbate or erythorbate, aromas, and in some cases, polyphosphates and other authorized additives. Once injected, hams are vacuum-tumbled to allow the brine to penetrate the full piece. The typical nitrosmyoglobin cured color is developed and stabilized by cooking. The salt and phosphates contribute to the solubilization of proteins and the cohesion of the product which is favored under vacuum, especially with further cooking. After tumbling, the meat is vacuum-packaged in heat shrinkable cooking bags or canned, to be cooked at a final core temperature of around 67–71°C or higher, depending on the composition. This process stabilizes the product, from the microbial point of view, and its color, produces the characteristic texture of the ham by protein coagulation and finally, develops the characteristic flavor. This cooking process allows the ham to be sliced while keeping its structure.

There are many varieties of ham products made from pork leg or shoulder including traditional, modern tumbled, and canned. However, its sensory properties in relation to acceptability are not well defined (Delahunty and others 1997). In cooked hams, the sensory attributes related to appearance, texture, and flavor should be considered as can be observed in Table 62.4 where a high number of attributes are shown. Several studies have been done to compare traditional hams with those produced through modern technology. The evaluation of a large variety of hams (traditional, modern tumbled, and canned) by descriptive methods indicated that the better textured hams were not plastic, were flaky and fibrous with a stronger ham flavor, and without bitterness (Nute and others 1987). The hams with poorer appearance, texture, and flavor were those juicier and with a wetter appearance. In summary, the hams that were meaty, nongelatinous and lean were scored for a better appearance. The quality of the hams is influenced by the choice of meat cut, composition, and quantity of the brine injected, rate and extent of tumbling or massaging, and the cooking time and temperature. The effect of additives like sodium chloride or sodium nitrite on the sensory attributes of ham have been studied. Sodium chloride was related to saltiness and nitrite was positively related with the intensities of the appropriate sweet taste and aftertaste and negatively related to the inappropriate sour taste (Jeremiah and others 1996). Another study focused on the effect of intramuscular fat content on the sensory quality of cooked ham because it is generally accepted that intramuscular fat content has a positive influence on the sensory quality of pig meat. The intramuscular fat content did not significantly affect the sensory attributes of cooked hams except the perception of marbling (Fernandez and others 2000). Due to the effects that meat quality and processing conditions produce on sensory quality of cooked ham, many works have been done to study the effect of preslaughter treatment (Fernandez and others 2002), different cooking and cooling methods (Desmond and others 2000, 2002; Cheng and others 2005), and injection levels (Desmond and others 2002). different cooling methods applied during the processing of cooked ham affect the tenderness, juiciness, overall texture and acceptability, and the cured color (Desmond and others 2000). The halothane genotype of pigs can also affect the sensory quality of cooked ham affecting mainly the textural properties. So, cooked hams produced from nn pigs were drier, tougher, stringier, and less smooth than those produced from NN and Nn pigs (Fernandez and others 2002).

On the other hand, the effect of male sex hormone (androstenone) present in the muscle of noncastrated pigs and skatole on the sensory characteristics of cooked ham have also been studied obtaining that these compounds affect negatively the sensory attributes of odor and overall opinion. Attributes such as urine-like off-odor, flavor, off-flavor, urine-like off-flavor, and acid-like off-flavor have been described (Bonneau and others 1992).

The development of the characteristic cooked ham flavor depends on the cooking process through thermal reactions as already explained for bacon as well as any aromas added in the brine. However, no compound has been clearly identified yet for cured aroma in cooked ham (Guillard and others 1997).

62.3.5 Dry-Fermented Sausage

There is a wide variety of fermented sausages depending on the raw materials and processing conditions. Briefly, minced meat and additives are mixed and stuffed into casings. Then, sausages are placed in curing chambers for microbial growth during fermentation that usually takes 1–2 days and afterwards to ripening/drying that ranges between 7–90 days. The length of the process depends on many factors although the most important are the type of product, its diameter, drying conditions and desired flavor development. In general, sausages tend to be more humid and less flavored when they are short ripened.

In the case of texture, tenderness/hardness and juiciness are the most common evaluated descriptors (Berry and others 1979; Roncalés and others 1991; Hoz and others 2004; Moretti and others 2004; Pérez-Cacho and others 2005). The texture of sausages is initially affected by the acidification during the fermentation stage and afterwards by dehydration during drying/ripening. As a result of lactic acid accumulation, pH approaches the isoelectric point of proteins. Once pH is reached, proteins coagulate and reduce the water retention capacity that contributes to firmness (Talon and others 2002). Textural characteristics of the sausage like firmness, hardness, and cohesiveness of meat particles change during drying and are usually correlated to time, moisture content, sausage diameter, and the initial grinding size (Acton 1977). Dry-fermented sausages are usually sliced for consumption and this means they need a good consistency and as homogeneous as possible. Sometimes, drying is excessive and sausages tend to be softer in the center and harder in the rind (Toldrá 2002).

Color is mainly due to the reaction of nitrite with myoglobin producing the red color (Pegg and Shahidi 2000). Essentially, the nitrite initially added to the sausage is reduced to nitric oxide either enzymatically or chemically (favored by ascorbic/erythorbic acid). Then, myoglobin and nitric oxide interact forming red-colored nitric oxide myoglobin (Demeyer and Toldrá 2004). Sometimes, the color is not homogeneous through the entire slice due to moisture gradient into the sausage as a result of a noncorrect drying process (Pérez-Alvarez and others 1999). In addition to the color intensity, other descriptors are related to the appearance like particle size and fat content (Beilken and others 1990), visual cut appearance, total fat and external mould cover (Roncalés and others 1991).

The pH drop during carbohydrate fermentation is essential for the sensory characteristics of the sausages, especially taste. So, those sausages rapidly processed with an intense lactic acid generation and a deep pH drop below 4.8, exhibit a predominant sour taste and a poor aroma. Italian Milano salami is prefered when it is medium aged, having high pH values and low amount of lactic acid although the preference is reduced when product is excessively ripened and with a high salt/moisture ratio (Casiraghi and others 1996). In addition to sourness, saltiness is also oftenly evaluated because fermented sausages may contain between 2–3% of salt (Benito and others 2004; Moretti and others 2004).

Aroma descriptors are quite varied, as reflected in Table 62.5, and usually include terms like hot spice, smoke, rancid, butter, and fat. The aroma of the sausage depends on the generation of volatile compounds but this profile changes according to the specific starter culture used for fermentation, typically *Staphylococcus* and/or *Micrococcus*. These starters contribute to lipolysis and the metabolism of the released fatty acids as well as nitrate reduction to nitrite (Montel and others 1993; Toldrá and others 2001; Stahnke 2002). In this way, different aroma compounds may be found. For instance, the addition of *S. saprophyticus* and *S. warneri* contributes to the odor of butter which is correlated with acetoin, diacetyl, 1,3-butanediol, and 2,3-butanediol (Berdagué and others 1993a). 2-Pentanone, 2-hexanone, and 2-heptanone, correlated with curing odor, are obtained with the addition of *S. carnosus* + *P. acidilactici*, *S. carnosus* + *L. sakei*, *S. carnosus* + *P. pentosaceus*, and the addition of *S. saprophyticus* is related with lower rancidity.

The spices and condiments are typically added to dry and semi-dry-fermented sausages and have a strong contribution to the aroma profile of the product. So, it is relatively usual to find either pepper, paprika, mustard, oregano, rosemary, garlic, or onion (Ordoñez and others 1999). Depending on the added spice, different volatile compounds can be found. So, some terpenes like α-pinene, β-pinene, β-mircene, e-carene, and limonene are usually present in sausages produced with pepper while several sulfur compounds may appear when garlic was added (García-Regueiro and others 1998).

The improvement of the sensory properties of dry-fermented sausages has been recently studied by the addition of free amino acids (Herranz and others 2005) or through the addition of bacterial extracts that enhance the amino acid breakdown (Herranz and others 2006).

62.3.6 Dry-Cured Ham

Dry-cured ham is a typical product produced in certain areas of Europe, China, and United States. The process is generally very long, between 3 to 24 months, and depends on the type of product and desired quality. Main stages consists in salting, where the salt (salt with nitrate and nitrite) is rubbed onto the surface of the hams and maintained at refrigeration temperatures during several days for salt penetration, postsalting, where the hams are cleaned and left at refrigeration temperatures for salt diffusion, and finally, the ripening/drying stage where different temperatures and relative humidity are applied for drying and enzymatic development of flavor.

The development of the sensory characteristics of dry-cured hams is due to the action of the curing agents (salt, nitrite, or nitrate) and processing conditions. In this case, the stabilization of the ham is due to the dehydration of the product. The development of the characteristic color is due to the interaction of nitric oxide with myoglobin as explained before. In this type of product, cured flavor is developed through a complex mechanism that

generates flavor precursors through proteolysis and lipolysis (Toldrá and Flores 1998). In the last years, there are many studies of dry-cured ham aroma where 100 of volatile compounds were isolated and identified including their contribution to specific aromas (Flores and others 1998).

The sensory quality of dry-cured hams is highly affected by premortem factors (genetics, animal species, sex, etc.) meat quality, curing salt composition, and rate and extent of the drying process. Many different sensory attributes have been described in dry-cured ham and are summarized in Table 62.6. The feeding system of pigs can affect the sensory quality because when pigs are raised in a free-range system, give processed hams with better scores in oiliness, brightness of the lean, marbling, aroma, and flavor traits (Cava and others 2000). The effect of feed is quite pronounced and mainly affects the lipid content and fatty acids composition. In general, hams from females and Duroc-sired pigs give a better overall quality than those hams from Belgian Landrace-sired pigs characterized by a poor quality and rancid aromas (Armero and others 1999). Also, Duroc sire lines are more related to higher intramuscular and subcutaneous fat sensory perception, as well as lower sensory adhesiveness (Cilla and others 2006). The influence of meat quality on sensory attributes has been demonstrated by the effect of meat pH on sensory textural attributes, as it is the case of DFD hams (high pH meat) that give softer, pastier, more crumbly and adhesive dry cured hams than normal pH meat (Guerrero and others 1999).

The effect of salt content and processing conditions has been studied in Iberian dry-cured ham where the addition of lower salt content produced dry-cured hams less salty but with softer textures which could affect the overall quality of the hams (Andres and others 2004). These authors also studied the effect of modified processing conditions for dry-cured Iberian hams using lower temperatures during the drying stage but they lead to more rancid aromas. The length of the process constitutes another important factor of variation in quality attributes, especially in the aroma and taste traits of ham. The reason is that proteolysis and lipolysis are highly affect by the conditions of ripening/drying. Therefore, the generation of free amino acids is somehow correlated with the length of the process. This is the case found for glutamic acid, aspartic acid, methionine, isoleucine, leucine, and lysine (Flores and others 1997a; Toldrá and others 2000). Some of the generated free amino acids are also related to flavor. This is the case of lysine and tyrosine that are related with a better quality of aged taste of hams while asparragine is related to worse quality. Glutamic acid contributes to salty taste and phenylalanine and isoleucine to sour taste (Careri and others 1993). However, the sensory characteristics are highly affected by the origin of the product. For instance, little effect has been found of amino acids on the development of the aroma of cured meat in French-type ham (Buscailhon and others 1994). The effect of the length of the process is also important in the development of the cured aroma like in the case of Parma hams ripened for 12 months where an increase of several compounds was detected (3-methyl butanal, ethyl esters, and alcohols like propanol, 1-butoxy-2-propanol, and 2-butanol) (Bolzoni and others 1996). These hams contain a higher proportion of esters because nitrate is not added with the curing salt. Other compounds like 2-pentanone, 1-pentanol, ethanol, ethyl acetate, 1-penten-3-ol, and pentanal have been found to increase in French hams (Buscailhon and others 1993). The length of the process affects primary Iberian ham flavor while texture and appearance is not affected when comparing short and long processing times (Ruiz and others 1998) at the same time, slice location affects the texture attributes but it produces few differences in aroma and flavor attributes.

Iberian and Corsican hams are characterized by very long processing times, usually 24 or even more months, and exhibit a high intramuscular fat content due to genetics. Therefore, attributes such as yellowness of fat, pinkness and oiliness of fat are important to the sensory quality. These hams contain a higher amount of methyl ketones, aldehydes, branched aldehydes, and alcohols which are positively correlated with odor and flavor traits like flavor strength, cured flavor, and after taste (Ruiz and others 1998) and negatively for rancidity (Ruiz and others 1999). Other long processed hams, like Serrano hams, give scores with higher barnyard, sour and salty taste (Flores and others 1998b). Country-style hams and other short processed hams are characterized by a lower content in volatile compounds and a characteristic fresh-cured pork flavor. Regarding texture, the external muscle *Semimembranosus* tends to be harder and dryer than the internal *Biceps femoris* that tends to be softer and more humid (Cava and others 2000). Typical descriptors are hardness, dryness, fibrousness, and juiciness (Buscailhon and others 1994; Ruiz and others 1998, 2002; Guerrero and others 1999). The acceptability of Iberian dry-cured ham is highly dependent on juiciness and flavor intensity; therefore, the raw material and processing conditions are the main factors that influence acceptability, since juiciness is mainly based on intramuscular fat content which depends on raw material composition, and flavor is developed during processing (Ruiz and others 2002).

63.1 INTRODUCTION

"Fresh" is a frequent term used to describe food "quality." And "fresh" and safe milk products delivered to the customer becomes the goals of all dairy processors. It is to this end that the U.S. dairy industry has fine-tuned its milk collection, storage, and handling practices through a cooperative effort between the dairy cooperatives, milk processors, the State health agencies, and academia. Results of those efforts culminate in a published "model" guideline referred to as the "Grade A Pasteurized Milk Ordinance (PMO)" published by the U.S. Department of Health and Human Services Public Health Services, Food and Drug Administration, 5100 Paint Branch Parkway, College Park, MD. Much of what is discussed in this chapter is supported by that publication.

63.2 QUALITY BEGINS AT THE MILK SOURCE: THE DAIRY COW (Chambers 2002)

Paramount to producing quality, safe milk is the health state of the individual dairy cow. With today's trend toward larger dairy herds (cow numbers exceeding 1000), biosecurity of the dairy herd becomes important. Therefore, as new cows are imported into the milking units, they are placed in quarantine for a period of time to assess the health state of the dairy animal and milk production. Once the cow passes its quarantine, it is then introduced into the main milking herd.

Milking units are individual farm complexes where the dairy cows are housed and fed, breed, have calves, and are milked. These facilities provide a clean, efficient production environment for the production of large quantities of quality milk ready for delivery to a milk processing plant.

63.2.1 Defining Raw Milk Quality

Defined measurements of raw milk quality are the following Grade A Standards (USHHS) (Table 63.1). For details of the methodology for the above analyses, the reader is referred to the *Standard Methods for the Examination of Dairy Products* published by the American Public Health Association, Washington, DC.

TABLE 63.1 Grade A Standard Raw Milk.

Temperature	7°C (45°F)
Bacterial limits	100,000/mL
Antibiotics	No positive results
Somatic cell count, per mL	750,000 cows 1,000,000 goats
Sediment	Grade 2
Added water	Freeze point −0.525°C

The temperature standard refers to that temperature of the raw milk as stored in the farm bulk tank. The PMO requires that freshly collected milk must be brought to 7°C (45°F) (Table 63.1) within 2 h after collection and maintained at that temperature or below prior to pick-up. Higher temperatures could result in bacterial growth and biochemical activity with off odors and flavors developing. Milk safety issues might also develop such as the growth of *Staphylococcus aureus* and the production of an enterotoxin. This toxin is quite heat stable and could remain active after a pasteurization treatment.

The 100,000/mL bacterial limit reflects the cows' udder health, milk handling environment, and the cleanliness of the milking equipment. Usually, when high bacterial numbers are encountered, the milk contact surface areas of the milk-handling equipment become prime suspect for not being properly cleaned and sanitized. For example, if the caustic-chlorine cleaner is at an inadequate concentration or the cleaning solution temperature is lower than prescribed, its cleaning power becomes substantially weaker and milk soil may not be sufficiently removed. When this soil is contaminated with untreated well water, one has a condition to promote bacterial growth and high numbers of bacteria. When freshly collected raw milk passes over these bacteria-contaminated surfaces, the bacterial numbers go up in the milk prior to entering the farm bulk storage tank.

No antibiotic residues are permitted in Grade A raw milk. The presence of antibiotics in milk should be prevented with sound animal handling practices. That is, antibiotic treated cows should be **boldly** marked so that these cows can be milked separately and the milk collected does not enter commercial channels. It is a serious quality offense that is addressed by the regulatory agencies when antibiotic contaminated milk is detected in these channels. A dairy producer can receive severe financial penalties as well as lose their Grade A permit should he/she violate the antibiotic residue prohibition regulation three times within a 12-month calendar year. The underlying principles behind this prohibition are that low antibiotic residues promote consumer allergic reactions and resistance for disease producing bacteria.

As previously stated, sound cow health is essential to a quality milk source. While there are several health conditions that can develop in a dairy cow, the most common one is mastitis. Mastitis is caused by a multiple of infectious agents that can damage the milk producing cells in the udder thus, lowering the cow's milk synthesizing capacity. During the microbial infection process, the cow's defense system is stimulated and one response is the production of somatic cells (many are white blood cells) to isolate and fight off the infecting agent. So the Somatic Cell Count is used to assess the health condition of the cow's udder. Counts above 750,000 for cows usually can be correlated with the presence of udder infections within the milking herd. When the farm bulk tank milk samples demonstrate Somatic Cell Counts above this number, it becomes prudent to screen the cows of that milking unit for mastitis infections.

The Sediment Grade Standards, developed by the U.S. Department of Agriculture, evaluate the level of physical cleanliness of the raw milk at the farm level. This Standard is incorporated into the State health agency's farm inspection protocol, as well as, the milk producer's dairy cooperative's oversight. During the farm inspection process, samples are routinely taken from the bottom of the farm bulk tank and passed through a standardized filter pad. The test pad is compared to sediment pad standards to determine its assigned grade. Grade assignments above 2 indicate that poor cleaning of the cows' teats and udder are occurring. A higher sediment grade above 2 reflects that excessive soil and manure have entered the milk during the collection procedure.

Added water is an economic issue between the buyer (the dairy processor) and the seller (the milk producer). Two major factors enter into the enforcement of the added water standard. The first is the recognition that some incidental water will enter the milk during rinsing operations. General agreement of enforcement allows no more than 2% added water with a freezing point of -0.525°C. Higher freezing point values translate into an "added water" violation. The second factor is that raw milk is paid for based on its weight. Thus, by adding water to the bulk tank and blending it in with the milk increases the volume translation into weight that skews the economics in favor of the milk producer. Added water dilutes the milk solids and thereby reduces the dairy products, such as Cottage cheese, derived from that milk source.

63.2.2 Farm Bulk Tank Operation (Gösta 2000; Chambers 2002)

The farm bulk tank has two principle roles to play. The first is to collect and store the daily milk harvested. The second is to cool the raw milk from 35°C (95°F) down to 7°C (45°F) within 2 h after the milk enters the bulk tank. The bulk tank's cooling medium may be either a direct-expansion or ice bank system. The direct-expansion is a more efficient heat transfer system than the ice bank. The dairy farms operating under the Grade A PMO must deliver their raw milk to the dairy processing plant within 48 h after its collection. With the larger dairy cow milking units, sufficient quantities of milk are produced within 24 h that the milk, in specific cases, could fill an over-the-road tanker, on average, every 4 h and be shipped to commercial channels.

It should be noted that the farm bulk tank could be a source for milk quality problems. One problem lies within the failure of the dairy producer to turn on the refrigeration unit when newly collected milk enters the tank. The heat from the incoming milk either is not removed, thus maintaining ideal bacterial growth conditions and initiates lipase activity, or elevates the temperature of the previously cooled milk to activate microbial and enzymatic activity. Whether microbial or enzymatic activity does occur, in either case, flavor change can take place to the point that the raw milk could be unsaleable. Excessive agitation can result in a "churning" effect indicated by chunks of cream floating in the milk. A third common problem comes from a too efficient cooling of the milk resulting in the masking of potential sanitary problems with the tank itself. This latter problem is addressed by use of the Preliminary Incubation Count procedure when assessing the sanitary conditions of the farm bulk tank.

63.3 ENTERING THE PROCESSING ENVIRONMENT: THE DAIRY PLANT (Gösta 2000; Boor and Murphy 2002; Chambers 2002)

63.3.1 Receiving the Raw Milk at the Dairy Processing Plant

Depending on the distance of the raw milk source, time in transit may range from one hour up to as much as 72 h. Since the milk remains in the raw state, maintaining a temperature at 7°C (45°F) or below is critical to minimizing biological and chemical change.

At the dairy plant, the milk is checked for temperature, acidity, antibiotics, and added water. Failure to meet the previously defined Standards could result in rejection of that milk load. When this load is found acceptable, it is downloaded and passed through a plate cooler to reduce the temperature to 4°C (40°F) on its way to the silo storage tanks.

63.3.2 The Processing Environment

As raw milk is processed into a variety of fluid milk products, four overriding factors dictate the management of the processing environment. These are: the pasteurization process; standardizing the milk fat content; minimizing post-pasteurization contamination; and, maintaining the temperature of the finished product below 4°C (40°F).

63.3.2.1 The Pasteurization Process System (USHHS 1999 Revision; Gösta 2000). The pasteurization process system is well defined in the PMO. Because the PMO is given statutory law status in the United States by its adoption by the individual State legislatures, strict adherence to the PMO requirements must be followed. Item 16p of the PMO specifically states "Pasteurization shall be performed as defined in Section I, Definition V of this (PMO) *Ordinance.* Aseptic processing shall be performed in accordance with 21 *Code of Federal Regulations* Parts 113 [and] 108, and the Administrative Procedures of Item 16p, C, D, and E of this section."

The focus of the PMO requirements is to document critical control points relevant to time–temperature control in the pasteurization process. In addition, by system design, a means of diverting the under-pasteurized milk process stream back to a balance tank and incorporating a higher-pressure gradient on the heat exchanger plates are required. The latter is to prevent unpasteurized milk from short circuiting to the pasteurized side of the heat exchanger plates should "pin-holes" develop in the plate.

The *system components* of the commonly used high-temperature-short-time continuous-flow pasteurizer are the three heat exchangers, the timing pump, and the holding tube.

The *pasteurizer's heat transfer components* consist of three sections: heater, regeneration or water removal, and cooling. There are two basic methods of transferring heat into milk. The most common method is by indirect heat transfer through a physical barrier. The second method is by direct transfer of heat via steam infusion/injection.

Of the indirect methods used, the plate heat exchanger is most commonly used by the dairy industry. Depending on the targeted temperature range one is operating, hot water is the common medium used for putting heat into the milk (heater section) and, the incoming cold, raw milk (regeneration section) and chilled water (cooling section) are used to remove heat from the milk.

With respect to the use of the direct heating of milk, one must be sure to use only culinary steam for this purpose. Two approaches are used by the dairy industry, one is steam injection and the other is steam infusion (falling film). In both applications, water must be removed from the milk by evaporation, thus requiring an additional processing step and equipment. The more common applications for direct heating are in the heating of cultured cheese whey (steam injection is used) and pasteurizing ice cream and soft serve mixes (falling film is used).

The *timing pump* may either be a variable controlled positive displacement pump or a homogenizer. In either case, the appropriate flow rate is established and pressure is applied to the pasteurizer system. Whether a positive displacement pump or homogenizer is used, in either case, the pumping rate must be documented and the pump speed "sealed" by the State health agency for the established flow rate. The location in the system is after the regeneration section of the plate heat exchanger. A booster pump is used in front of the timing pump to maintain a milk flow in the pipeline and the raw side of the regeneration section. This pump is of centrifugal design and does not influence the milk flow

characteristics after the timing pump. Thus, the necessary 6.9 kPa (1 psi) pressure differential is established between the pasteurized milk and the raw milk across the regeneration heat exchanger plates by this arrangement.

The *holding tube* is incorporated into the pasteurizer system to establish the time in this process. The holding tube provides a defined volume in which the continuously flowing milk passes through. When combined with the flow rate of the timing pump, one has a specifically defined, controlled residence time that is part of the pasteurization process. Coupled with the temperature established by the pasteurizer heater section, the time–temperature parameters defined in the pasteurization process are established. To assure this critical control point is met, an indicator thermometer-recorder is located at the outlet of the holding tube along with a flow divert valve. Should the temperature drop below the critical set limit, the flow divert valve will be activated to the "flow diversion" mode and direct the "sub-legal" milk flow back to the balance tank located on the raw side of the system. The commonly used heat treatments and their respective time–temperature parameters for fluid milk will be discussed later in this chapter.

Features of a holding tube will: (1) have a slope up with at least a $\frac{1}{4}$-inch rise per 1 foot of tube length; (2) be free of air drafts; (3) not have attached heat boosters; (4) be under pressure to prevent heat "flashing"; and (5) be assembled in the identical manner prior to its disassembly.

63.4 THE PASTEURIZATION PROCESS (USHHS 1999 Revision; Gösta 2000; Boor and Murphy 2002)

The pasteurization process is simply the heat treatment of raw milk to a specific temperature and held at that temperature for a defined minimal amount of time. The premise for pasteurizing milk is to destroy most disease-producing, nonspore forming bacteria. The targeted microorganism for the process is *Coxiella burnetti*, a pathogen associated with Q-fever. The process is based on a linear, semilogarithmic relationship of temperature to time and its respective lethality on potential disease producing microorganisms.

63.4.1 The Process Parameters

Table 63.2 prescribes the minimal temperature–time relationships as defined by the PMO:

Important to note: The above temperature–time specifications are for milk-based products with a milk fat content of less than 10%. If the milk fat is 10% or more, or if contains added sweeteners, the specific temperature shall be increased by 3°C (5°F).

TABLE 63.2 Temperature–Time Relationships for Milk-Based Products (Min. Fat 10%).

Temperature	Time
Batch/vat 63°C (145°F)	30 min
High temp-short time 72°C (161°F)	15 s
High-temperature 89°C (191°F)	1.0 s
High-temperature 90°C (194°F)	0.5 s
High-temperature 94°C (201°F)	0.1 s
High-temperature 96°C (204°F)	0.05 s
High-temperature 100°C (212°F)	0.01 s

TABLE 63.3 Temperature–Time Relationships for Eggnog.

Temperature	Time
Vat/batch 69°C (155°F)	30 min
80°C (175°F)	25 s
83°C (180°F)	15 s

Provided, that eggnog shall be heated to at least the temperature and time specifications shown in Table 63.3.

Also, *provided further*, that nothing shall be construed as barring any other pasteurization process that has been recognized by the U.S. Food and Drug Administration to be equally efficient and which is approved by the regulatory agency.

63.4.2 Standardizing the Milk Fat Content (Gösta 2000)

As with any business, the market place dictates the types and quantity of the products to be produced. With respect to the fluid milk market place, the highest demand is for skim and low fat milk products. These products have a milk fat content ranging from 0.9% to 2%, respectively. Whole milk is defined having a milk fat level of 3.25%. Thus, when raw milk is received at a milk fat content of between 3.5% and 3.8%, a fat separation process must be employed to remove the fat. Higher milk fat content is usually observed in milk-based frozen-dessert mixes, half and half, and whipping cream.

Standardizing the milk fat content may occur in one of two methods. In multiproduct processing plants where other uses for the milk fat (as cream) are required, the raw milk may be separated at the time of receipt. The skim milk fraction going to a separate storage tank and the cream fraction stored in another. In this case, the cream is blended with the skim milk and homogenized at the standardized fat level for the milk product being processed. In-line sensors are used to monitor the fat content and adjust the blend rate of the cream with the skim milk.

In smaller or narrow focused dairy product manufacturing operations, the stored raw milk passes through a separator after being initially heated to about 60°C (140°F) in the pasteurizer's regeneration section. The separator is adjusted to remove only enough of the cream fraction to meet the fluid milk's product identity. That is, if the raw milk contains 3.6% milk fat and a 2% milk is being processed, the separator is adjusted to remove 1.6% milk fat from that milk stream. The excess milk fat, as thermalized cream, is commonly sold to a butter manufacturing plant.

63.4.3 Minimizing Postpasteurization Contamination

Postpasteurization contamination is a constant challenge to the processing of fluid milk. The most common reason for this contamination problem is a failure in the performance of the prescribed sanitary procedures specifically for pipelines, manually fitted connecting joints, and disassembled parts associated with filling machines. For pipelines, pitting of the metal surface can develop into habitats for biofilm formation. This becomes a growth environment for unwanted bacteria to grow. Manual fitting of connecting joints require gaskets to form a good seal for that connection. Cut gaskets or improper placement of gaskets can lead to a cleaning problem. And with some filling machines requiring disassembly to be cleaned, some machine parts may not receive an adequate

cleaning treatment. As previously discussed with the bacterial problems associated with farm milking equipment, one encounters a similar contamination problem with pasteurized milk. Most often, postpasteurization contamination can be correlated with inadequately cleaned and sanitized equipment and leads to short keeping quality of fluid milk products.

63.4.4 Filling Operations and the Market Milks Produced

Initially, pasteurized fluid milk was placed in returnable glass bottles that required washing at the dairy plant. In the mid-1950s, paper cartons were introduced, followed in the mid-1960s, with the introduction of plastic containers. Today, plastic packaging dominates the filling operations and the paper-board container is the secondary packaging operation. These packaging and filling operations fulfill most of the fluid milk demands that enter commercial channels. However, in the late 1980s, aseptically processed and packaged fluid milk products entered the marketplace with the approval from the USFDA for using hydrogen peroxide as a sterilizing agent for a multilaminated packaging and filling system. In Europe and Asia, aseptic processing and packaging of milk and milk-like products have gained wide acceptance.

63.4.5 High-Temperature-Short-Time (HTST) Pasteurized Fluid Milk Products

Most of the fluid milk products entering major U.S. supermarket chains are HTST processed. Compared to the higher temperature pasteurized milk, the retail shelf-life of HTST processed milk has a shorter keeping quality time and will remain acceptable to the consumer with a possible keeping quality attribute ranging from 5 to 10 days after purchase.

The HTST pasteurization process may affect the shelf-life through its degree of effectiveness in reducing the number of bacteria present in the raw milk's initial microflora. That is, bacteria with thermoduric (heat resistant) properties and spore producing bacteria could survive this pasteurization process. Combine the surviving microflora with a possible post-pasteurization contamination problem and permitting the finished fluid milk's temperature to rise above 4°C (45°F), could lead to a diminished shelf-life product.

63.4.6 Maintaining the Temperature of the Finished Product Below 4°C (40°F)

For all fluid milk products pasteurized under the above stated specifications, maintaining a cold storage condition under 4°C (40°F) prior to and between product use is very important to maintaining its quality attribute. The critical step in the pasteurization process is to bring the finished product temperature to between 2°C (36°F)–3°C (38°F) at the cooling phase of the process. Some product temperature rise can be expected at the filling operation and refrigeration conditions in the dairy plant cooler, during transportation and at the retail store can only maintain the temperature of the product after the process.

63.4.7 In-Container Sterilization

There are countries where cans and glass bottles are prefilled and then retorted to produce a shelf-stable milk. The heat treatments include temperatures from 105°C to 120°C for

20–40 min. Critical to this means of commercially sterilizing milk is the integrity of the container's seal, providing an airtight barrier and controlling the heat process. Predictable heat distribution characteristics of the retort and heat penetration into the product must be known when using this method for sterilizing fluid milk.

63.5 ASEPTIC PROCESSING AND PACKAGING OF FLUID MILK (EXTENDED SHELF-LIFE MILK) (Chambers and Nelson 1993; Gavin and Weddig 1995; Boor and Murphy 2002)

63.5.1 The Concept

The initial concept for aseptic processing has been credited to C. Olin Ball, a pioneer in developing the thermal processing concepts used worldwide today. Ball referred to the aseptic process as the heat-cool-fill (HCF) process. The first commercial HFC process used was in California where metal containers were filled with a cream product, then sterilized in a retort followed by a seaming operation where a steam sterilized metal lid was applied. This process was known as the Avoset process. The Dole aseptic process followed the Avoset system and provided the prototype, continuous process scheme now used by the food industry. Until FDA's approval of hydrogen peroxide as a chemical sterilant for packaging material, steam was the primary method used for sterilizing the food package, a metal container. This sterilized container was brought into a sterile filling environment, filled with the sterile product and then sealed with a steam sterilized lid.

63.5.2 Aseptic Processing and Packaging: The System

The concept for aseptic processing and packaging is simple. Sterilize the milk/food product and package separately, then place the milk/food material into the package under aseptic conditions and seal the package. Bridging the gap between concept and practice is the challenge. From the time the raw food materials are received, have passed through the process equipment and are placed into the package and sealed, many critical performance factors must be under control within the processing environment. At each phase of milk handling, processing and packaging, all aspects of the Good Manufacturing Practices and Hazardous Analysis Critical Control Points plan should be fully implemented to assure the safety and quality of the fluid milk products processed. Implementation should emphasize four essential sectors of the processing environment. These sectors are: (1) equipment design and operation; (2) written operating procedures which include good manufacturing practices, material handling protocols, instructions for the proper operation of handling and processing equipment, product formulations, and quality assurance critical control points; (3) proper training of operations personnel; and (4) regulatory compliance.

63.5.3 Equipment Design and Operation

Critical to the aseptic system's equipment design is its ability to hold a positive pressure from the positive displacement pump at the beginning of the system through to the back pressure valve just prior to the product surge tank. After the back pressure valve or pump, a slight pressure (usually 1–3 psig) is maintained on the product surge tank and pipeline to assure unsterile air can not be drawn into the sterile product as it proceeds on to the filling operation. Figure 63.1 presents a typical aseptic processing scheme. This scheme identifies

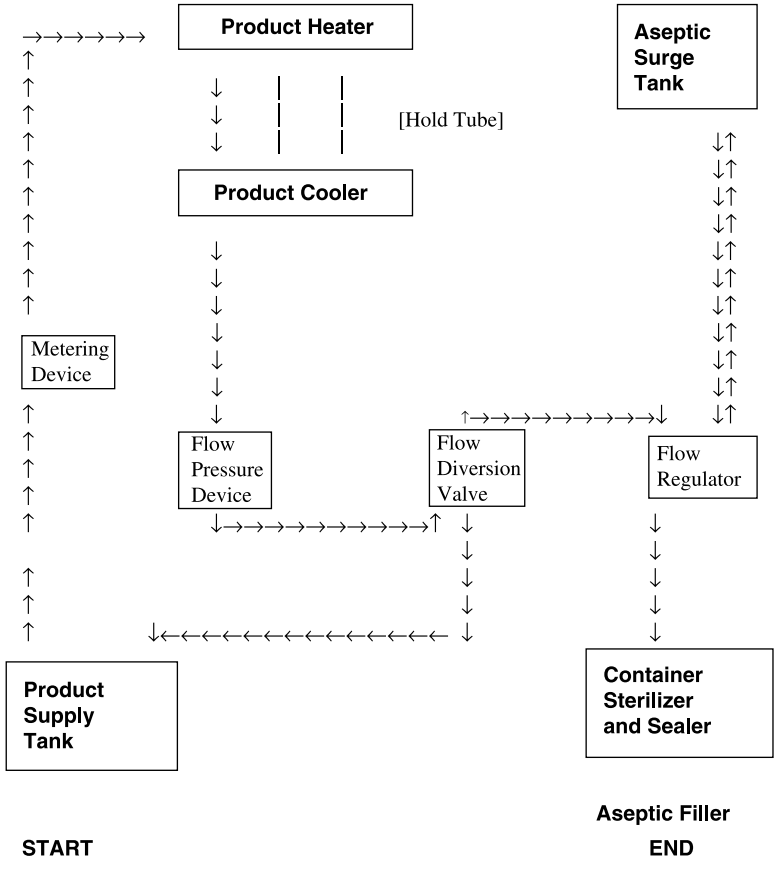

Figure 63.1 *Aseptic processing: a simplified scheme; ©2006, Science Technology System, West Sacramento, CA. Used with permission.*

several important unit operations that must function properly to process a safe and commercially sterile food product. As this aseptic system is assembled, three important design features must be incorporated into the construction of the system. The first design feature is to provide protective barriers between the internal, sterile sections of the equipment and the operating environment. Two critical unit operations where this feature is applied are the positive displacement pumps using steam tracers and a condensate bleeder and the valve assemblies where valve stems reciprocate into the sterile environment and may use sterile condensate, sterile air, or iodine or chlorine as the protective barrier. The second design feature that must be engineered into the aseptic operation is a gas/air filter system or a hyperfilter. Filter systems are placed down stream from the back-pressure valve and at the surge tank or bulk storage tank, depending on the application. Filter systems should require at least two filtering units placed in series at the gas/air inlet of the application site. The third design feature must assure the sealing integrity of connecting or joint applications. Two considerations must be given to assuring this sealing integrity. These are selection of the proper gasketing material as determined by the specific application and the method of connecting unit operations and pipelines (e.g., welding,

clamp joints). Dairy-style threaded joints are not recommended for use in aseptic processing applications.

The next important consideration for the aseptic operation is the thermal process. This operation is a critical control point in the system and must be designed carefully. There are two basic means for transferring heat into a milk-based product, namely, direct and indirect. If a direct heating method is used where steam is injected into the milk then either the dairy product formulation must compensate for the added water or a dewatering/flash unit operation must be used. For indirect heating, it is recommended that the milk undergo a deaeration step prior to entering the heat exchanger to remove undesireable air. The heat exchanger selection is determined by the viscosity characteristics of dairy product heated. For example, liquids that have Newtonian flow characteristics can be heated effectively through plate and tubular type heat exchangers. In contrast, higher viscous, homogenous materials such as ice cream and soft-serve mixes might require a scrape surface heat exchanger design for heating purposes.

Ultra-high-temperature (UHT) processing is commonly associated with aseptic processing. This is because the temperature range (130–150°C) utilized targets its lethality to both non-spore forming and spore forming bacteria that leads to a commercial sterilization of the dairy product. Holding times inversely decrease (vary from 8 s to 2 s) as the temperature increases to assure a nine-log reduction of thermophilic endospores and to ensure a 12-log reduction for *Clostridium botulinum*. UHT pasteurized/sterilized dairy products are aseptically packaged and then held under refrigeration during distribution into commercial retail channels. Usually, a 10-week shelf-life can be expected for UHT pasteurized milk often referred to as "extended-shelf-life milk."

In contrast, UHT sterilized milk will use temperature treatments above 135°C with a hold period of at least 2 s to assure adequate lethality. The sterilized milk is aseptically packaged but is distributed and sold under nonrefrigerated conditions.

Complimenting the heating method selected are four components required to monitor the thermal process. These components are: (1) the heat monitoring and controlling devices; (2) the heated milk's retention method; (3) a means to divert thermally underprocessed product back to the front of the process system (required for dairy products); and, (4) monitoring the pressure differential across the regeneration section of the heat exchanger. Since all thermal processes involve a temperature and time relationship, these operating parameters must be verified and constantly monitored to assure the established process has been achieved. In addition, most public health agencies that enforce regulations governing the thermal processing of low acid and acidified foods require records be kept and maintained on this critical control point. Typically, four components are engineered into the thermal process to assist in monitoring and documenting the temperature and time parameters. Essential to the process is the placement of the indicating temperature measuring device which must be referenced to the official temperature measure instrument, the mercury-in-glass thermometer. This temperature-indicating device must be placed at the end of the holding tube or bottom of the flow equalization/holding tank where the minimum hold time is determined. A thermometer or temperature indicating device is also required at the inlet of the detention unit to monitor temperature fluctuation of the heat exchanger. Included in the regulations is that a temperature recording and controlling device be installed to monitor and record the time–temperature parameters, and to initiate control of the heating medium if the temperature approaches a low or high critical limit. This same controlling device also activates the flow diversion valve at the end of the time detention unit if the temperature decreases below a predetermined low critical value. The

recording chart paper must be appropriate for the recording device used and standardized against the reference temperature-measuring instrument (the indicating thermometer) and an accurate timing device (analog clock with a sweep second hand). Positive displacement pumps are always used as the timing pump for aseptic processing. If this pump is a variable speed pump, the speed control of the pump, once set at a critical pumping rate, must be sealed against unauthorized adjustments to higher speeds. The fourth component of the thermal process is to provide a positive pressure (at least 1 psig) differential on the sterile product side of a plate where the heat exchanger utilizes a heat regeneration section.

63.5.4 Packaging Platforms

With approval of hydrogen peroxide as a packaging sterilant and its use in combination with heat or ultraviolet light to produce a reliable method for sterilizing packaging materials, several packaging systems have been introduced commercially to the dairy and food processing industry.

1. Thermoform-fill and seal
2. Form-fill plastic pouches
3. Web-fed paperboard laminates and plastic containers
4. Preformed bags
5. Blow-molded containers
6. Partially formed laminated paper containers
7. Preformed rigid and semirigid containers such as:
   a. Glass
   b. Metal
   c. Drums
   d. Composite
   e. Plastic cups and bottles

Advantages gained through the use of aseptic processing and packaging are that the milk, beverages, and food products processed, using this technology, deliver improved flavor, taste, or eating quality when compared to conventional thermally processed foods. The reason for this improved quality is the rapid movement of heat into and out of the product during the thermal process which results in a minimum chemical change to the food materials. Aseptic packaging add some additional benefits such as: is a less expensive packaging form; light weight materials can be used; is environmentally sound; and, can be easily transported and handled with a reduction in package damage.

63.5.5 Milk System Stability Considerations and Product Shelf Life (Richardson 1983; Kohlman and others 1988; Gösta 2000)

There are shelf life quality attributes and milk system stability considerations associated with aseptically processed milk. The major consideration is the “gelation phenomenon” experienced with aseptically processed milk. Research by Richardson (1983) and Kohlman and others (1988) have defined the probable milk system and mechanism involved with this phenomenon. It appears that the milk’s plasmin system consisting of native proteases and associated activators and inhibitors are responsible. The

denaturation of the plasminogen activators and the plasmin inhibitor by the heat process allows the milk plasminogen to convert to plasmin, thus, permiting the native, active proteases to breakdown the milk's casein. The result, a product shelf-life of 6–9 months due to gelation of the milk in the package. Other milk quality attributes affected are cream-lining, increased viscosity, sediment, Maillard reactions related to browning, and flavor changes.

63.6 WRITTEN STANDARD OPERATING PROCEDURES

Written standard operating procedures must include good manufacturing practices, material handling protocols, product formulations, instructions for the proper operation of handling and processing equipment, and enforcement of the hazardous critical control points as well as product quality control functions.

Special good manufacturing practice considerations for aseptic processing and packaging operations should include: a commitment to a "clean room" processing environment; close inspection of the food contact surface areas for cleanliness; and an effective sanitation program which includes steam sterilizing the aseptic processing lines and equipment. An effective GMP program contributes to the protection against and prevention from environmental contaminants gaining entry into the food materials. Considerable effort goes into establishing a sterile environment within the equipment, pipelines, and packaging operations that is further validated by bacterial spore challenge tests. Where food soil is permitted to build up on the heat transfer surface areas, fouling will develop that reduces the overall heat transfer efficiencies of the heat exchanger. Other problems attributed to fouling are flavor changes, system pressure build-up and loss of energy transfer.

How raw milk, its ingredients, labels, packaging materials, and other support materials are received, examined, accepted, and stored for use in the processing environment can have a very significant influence on the performance of the processing line and the final product quality. Materials that do not meet established performance specifications and slip through the critical receiving step or are improperly handled and stored can lead subsequential production problems. For example: storage conditions that subject food materials to excessive heat and moisture can accelerate deterioration of the food quality through oxidative and enzymatic mediated chemical changes and microbial growth; not meeting critical microbial specifications can result in high heat resistant spore populations being present in ingredients such as starches and sugars which can introduce spoilage organisms into the food product which survive the thermal process; and, careless labeling of opened ingredient bags can lead to possible cross mixing with other chemicals used for nonfood applications that could result in individuals being injured.

63.6.1 Employee Training

The productivity and efficiencies of any production system greatly depend on the people who operate the production lines, formulate and blend the ingredients of the finished product, operate the processing equipment, fill the food package, and provide the clean and sterile equipment. When everyone does their job correctly, the end result is a safe, high quality food product. However, everyone must know what is expected of them and they need to be properly trained in the execution of their assigned tasks. The main

point of reference for these tasks should be written procedures that clearly explain the purposes of each task and operation and who is responsible for each of those functions. As GMPs and Hazardous Analysis Critical Control Points are incorporated into those written procedures, the following criteria should be defined: (1) the hazard at issue should be identified (i.e., biological, chemical, or physical); (2) critical control points (CCP) must be identified and the controlling mechanism, process or agent (i.e., ultraviolet light) specified; (3) state what parameter(s) is/are to be monitored and recorded with critical value limits established so that proper interventions can be initiated; and, (4) identify who is/are responsible for correcting the out-of-control CCP and the follow up required to be sure the CCP is under control.

In the aseptic processing and packaging of food materials, the obvious hazard that the majority of the CCPs are targeted to is the biological/microbial hazard. Thus, on the thermal processing side of the operation, the production personnel would monitor for: (1) the temperature of the heated product at selected sites (as previously discussed); (2) a constant pressure level from the heat exchanger to the back pressure valve and the positive pressure between that valve and the filling unit, including the surge tank; (3) the timing pump speed; (4) the time–temperature profile as indicated on the chart recording; (5) air filter flow rates and pressures for the surge tank; and, (6) equipment malfunctions. Another important function of the thermal process equipment operator is to standardize the temperature of the recording device and to check the performance of the flow diversion valve at the critical low temperature limit.

For the packaging side of the aseptic system, the line production personnel would monitor: (1) the aseptic zone, established between the heating section of the heat source and the package sealing environment, for violation of that zone through operator error, malfunctioning process equipment, or filler/package failure; and (2) the package sterilization process which includes heat, hydrogen peroxide and irradiation as sterilant agents. During the package sterilizing step, it would be important to monitor the consumption rate of the hydrogen peroxide, its concentration, package contact time, and temperature. Package sealing integrity testing and measuring for hydrogen peroxide residuals are CCPs for aseptic packaging since these monitor for a biological and chemical hazard, respectively.

63.6.2 Compliance with Public Health Regulations (USHHS 1999 Revision)

The implementation of GMPs and HACCP in the dairy processing environment improves the reliability of that environment to manufacture a safe, wholesome commercial food product. These sanitary practices, monitoring and controlling activities help to protect and prevent accidental contamination or underprocessing of food products that otherwise might reach commercial channels. Thus, the well being of the consumer is protected from eating unsafe food products as the requirements of these principles are put into practice. Because of the public health implications of this important benefit, these principles and practices have been and are being incorporated into many of the food manufacturing regulations by most of the industrialized nations around the world. U.S. regulations governing the use of the aseptic processing and packaging technologies can be found in the Code of Federal Regulations under Title 9 and 21. These Title numbers are assigned to all regulations enforced by the U.S. Department of Agriculture (USDA) and the Food and Drug Administration (FDA), respectively. The USDA regulations covering aseptic

processing and packaging can be found under 9 CFR 318.3 and 9 CFR 381.3. USDA must approve the use of aseptic related equipment and procedures used in meat and poultry processing operations. In contrast, FDA only accepts or rejects process filling forms but does not approve the equipment used in aseptic processing and packaging operations. The FDA regulations for the thermal processing of low acid foods (21 CFR 113) and acidified foods (21 CFR 114) and the GMPs requirements (21 CFR 110) are also applicable to the aseptic processing and packaging technologies used in food processing applications.

63.7 A FINAL COMMENT

The information provided in this chapter discusses the minimal operating standards for a fluid milk collection, handling, and processing environment. Local handling and storage conditions may require additional strategies to protect the product quality and safety. That is the responsibility of the dairy company producing the products. It is imperative that production, operational, and management personnel adhere to the principles conveyed in the references provided below and compliance with the U.S. Code of Federal Regulations and the respective State's milk ordinances and regulations to assure a safe milk-based product.

64.1 INTRODUCTION

From physiological standpoint, milk is a unique biological secretion of the mammary gland endowed by nature to fulfill the entire nutritional needs of the neonate. Following parturition, milk is the secretion of normally functioning mammary gland of the females of all mammals. The yield and composition of milk varies among various species to entirely meet postnatal growth requirements of the offspring. Milk, therefore, contains all the chemicals in the form of six major nutrients, namely, water, fat, proteins, carbohydrates, minerals, and vitamins that are ideal for nourishment. Milk and milk products are used as components of many food products around the world.

Milk is an integral part of fermented milks including yogurt and considered by many as an ideal vehicle to deliver beneficial cultures as well as probiotics and ingredients known to stimulate activity of these organisms and the microflora of human gastrointestinal tract. The conversion of milk into fermented milks augments the nutritional value of inherent milk constituents. Additionally, fermentation process generates metabolic and cellular compounds which have positive physiological benefits for the consumer.

This chapter provides basic information relative to milk composition that is relevant to the processing of milk and dairy products. For detailed discussion, the reader is referred to Wong and others (1988); Jensen (1995); Swaisgood (1996); Fox and Sweeney (1998); and Walstra and others (1999).

64.2 DEFINITION OF MILK

Chemically speaking, milk is a complex fluid in which more than 100,000 separate molecules and chemical entities have been found, the levels of which vary with the species. In terms of physical chemistry, milk is an opaque, white heterogeneous fluid in which various constituents are held in multidispersed phases of emulsion, colloidal suspension, or solution.

Worldwide, milk from cows, water buffaloes, goats, sheep, camels, mares, and other mammals is used for human consumption. However, cows' milk entails by far the most important commercial significance.

According to the Food and Drug Administration of the United States, milk refers to cows' milk. Milk from other species must be labeled to indicate the species. For instance, milk from goats must be called goats' milk.

Milk is the whole, clean lacteal secretion of one or more healthy cows properly fed and kept, excluding that obtained within 15 days before calving and 3–5 days after. This would exclude colostrum, the milk secreted immediately after giving birth. The definition of Grade A milk as per FDA standards of identity is "the lacteal secretion practically free of colostrum, obtained by complete milking of one or more healthy cows, which contains not less than 8.25% milk solids – not fat to solids-not-fat less than 3.25% milk fat."

64.3 MILK COMPOSITION

Chemical make up of milk and its physicochemical behavior provide scientific basis for basic processing of milk and manufacture of products. The composition of milk is generally described in terms of its commercially important constituents, milk fat, and nonfat solids (NFS) or milk solids-not-fat (MSNF). The MSNF consists of protein, lactose and minerals. These solids are also referred to as "serum solids." The term "total solids" refers to the serum solids plus the milk fat. The major constituents of milk are given in Table 64.1.

The ash content is not quite equivalent to salt level in milk. In the determination of mineral content, some salts like chlorides and organic salts are volatilized or destroyed as a result of high-temperature exposure during routine mineral analysis by the ash method. The data given in Table 64.1 refers to all major breeds of cows in North America. Milk from Jersey and Guernsey breeds would be closer to higher fat and protein range.

64.3.1 Factors Affecting Composition of Milk

Apart from the differences due to the breed, certain additional factors also influence the gross composition of milk: (1) individuality of animal; (2) stages of milking; (3) intervals of milking; (4) completeness of milking; (5) frequency of milking; (6) irregularity of

TABLE 64.1 Composition of Bovine Milk.

milking; (7) portion of milking; (8) different quarters of udder; (9) lactation period; (10) yield of milk; (11) season; (12) feed; (13) nutritional level; (14) environmental temperature; (15) health status; (16) age; (17) weather; (18) oestrum or heat; (19) gestation period; (20) exercise; (21) excitement; and (22) administration of drugs and hormones. In general, these variables tend to average out in commercial pooled milk used by dairy processors, but it does display an interesting seasonal pattern. The seasonal variations in protein and mineral content have an important impact on viscosity and gel structure of yogurt and fermented products. During late spring and early summer months, milk in some areas of the United States registers low protein and calcium content resulting in poor viscosity in finished yogurt. During these months of low protein milk, it is necessary to compensate by raising the solids-not-fat content of yogurt mix by 0.25–0.50%.

64.4 PHYSICAL STRUCTURE

Various interactive forces between the chemical constituents of milk determine the technological behavior of milk. Milk has well-defined physical equilibrium between various constituents that exist mainly in three forms, namely, emulsion, and colloidal and true solution. Milk lipids are present as an "oil-in-water type," of emulsion in the form of microscopic globules varying from 0.1 to 22 μm in diameter. The colloidal phase contains casein micelles, calcium phosphates, and globular proteins. Whey proteins are in colloidal solution and the casein is in colloidal suspension. Lactose, vitamins, acids, enzymes, and some inorganic salts are present as true solutions. Table 64.2 gives the relative sizes of these particles in milk.

Certain factors tend to influence the physical equilibrium of milk that exists between colloidal dispersion and salts. These factors are: (1) addition of polyvalent ionizable salts; (2) concentration of serum solids; (3) changes in pH; (4) heat treatment (which may alter the surface charges or unfold proteins); (5) addition of alcohols (which reduces bound water associated with the colloidal constituents). All these factors tend to destabilize colloidal systems and thus influence the technological behavior of milk during product manufacture. In the production of cultured milks, as the fermentation proceeds, the colloidal calcium phosphate gets progressively converted to ionic form as the pH drops from 6.6 in milk to less than 4.6 in yogurt and fermented milks. Casein and the interacted whey proteins coagulate at the isoelectric point at pH 4.6, forming gelled structure.

Certain terms related to milk structure need clear understanding. Milk plasma is the fluid portion of milk minus fat globules being almost similar to skim milk. Milk serum is milk plasma minus milk fat and casein micelles. Removal of casein micelles

TABLE 64.2 Physical State and Particle Size Distribution in Milk.

Compartment	Size, Diameter (nm)	Type of Particles
Emulsion	2000–6000	Fat globules
Colloidal	50–300	Casein-calcium phosphate
Dispersion	4–6	Whey proteins
True solution	0.5	Lactose, salts, and other substances

from skim milk by clotting with rennet yields the liquid called whey. It is different from milk serum because it contains some polypeptides cleaved from casein by rennet.

64.5 CONSTITUENTS OF MILK

64.5.1 Major Constituents

64.5.1.1 Water. Water is the medium in which all the other components of milk (total solids) are dissolved or suspended. Water content varies from 85.4% to 87.7% in different species of cows (Table 64.1). A small percentage of the water in milk is hydrated to the lactose and salts and some is bound with the proteins.

64.5.1.2 Fat. Milk fat though, quite bland in taste, imparts richness/smoothness to fat containing dairy products. Milk fat in freshly secreted milk occurs as microscopic globular emulsion of liquid fat in aqueous phase of milk plasma. Fat content of milk varies from 3.4% to 5.1%, depending on the breed of the cow. Most of the raw milk used for dairy processing typically contains an average of 3.5–3.6% fat. Variability of milk fat also depends upon the individuality of animal, stage of lactation, feed, environmental factors, and stage of milking. The composition of milk fat is given in Table 64.3.

The milk fat of cows consists chiefly of triglycerides of fatty acids, which make up 95–96% of milk fat. The remaining milk fat is composed of percent diglycerides, monoglycerides, free fatty acids, phospholipids, and cholesterol as shown in Table 64.3.

The functional properties of milk fat are attributed to its fatty acid make up. More than 400 distinct fatty acids have been detected in milk. Typical milk fat consists of 62% saturated, 29% monounsaturated and 4% polyunsaturated fatty acids. It contains 7–8% short chain fatty acids (C_4–C_8), which is a unique characteristic of milk fat. The major fatty acids of milk fat are given in Table 64.4.

Milk fat functions as a concentrated source of energy as well as a source of fat-soluble vitamins A, D, E, and K and essential fatty acids, linoleic, and arachidonic acids. The essential fatty acids are not synthesized by human body. They must be supplied by the diet. Arachidonic acid with four double bonds is present in traces. Its precursor is linoleic acid. Omega-3-linoleic acid and its products EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid) are also present in trace but significant amounts. The positional location of individual fatty acids in the triglycerides is not random. In fact, the *syn*-1 and *syn*-2 positions on the glycerol molecule are mainly occupied by myristic ($C_{14:0}$),

$C_{17:0}$	–	0.34
$C_{18:0\ (branched)}$	–	0.35
$C_{18:0}$	Stearic	11.3
$C_{18:1}$	Oleic	27.42
$C_{18:2}$	Linoleic	1.5
$C_{18:3}$	Linolenic	0.59

palmitic ($C_{16:0}$), stearic ($C_{18:0}$), or oleic acids ($C_{18:1}$). The *syn*-3 positions contain butanoic ($C_{4:0}$), hexanoic ($C_{6:0}$) or oleic ($C_{18:1}$) acids.

Saturated fatty acids are solid at ambient temperature, while unsaturated fatty acids are liquid. Their ratio in milk fat has a profound effect on the hardness and spreadability of butter at low temperatures. The balance between C_4 and C_{18} fatty acids keeps milk fat liquid at body temperature (Otter 2003). The origin of fatty acids is either blood plasma lipids or they are synthesized in the mammary gland. There is a correlation between the fatty acid composition of feed lipids and butter hardness. A seasonal effect is seen as well. A softer butter is observed when the cow is on summer pasture or when the ration includes oils liquid at ambient temperature.

Cholesterol. The cholesterol content of milk is significantly affected by the species, breed, and feed, stage of lactation, and season of the year. Cholesterol content is generally lowest in the beginning of lactation period and progressively rises throughout the lactation period being highest towards the end of the lactation. The cholesterol content of colostrum is relatively high (570–1950 mg per 100 g fat) for the first milking after parturition and progressively declines to normal levels during subsequent milking.

In general, typical cholesterol content of whole milk (3.25% fat) is 10.4 mg/100 mL or 24.4 mg per serving of 8 fl. oz. It corresponds to 3–4 mg/g fat. Fat reduction in dairy products is accompanied by cholesterol reduction. By separating fat from milk, an 80% reduction in cholesterol content can be achieved in skim milk. Thus, nonfat milk/skim milk shows residual cholesterol level of 4.9 mg/8 oz serving. Dairy products, therefore, contain cholesterol content depending on the milk fat and nonfat solids content of the product.

Phospholipids. A number of factors influence the unique phospholipid content of milk. The total phospholipid content of cow's milk is approximately 36 mg/100 mL.

Milk Fat Globule. Milk fat occurs in milk as an emulsion of fat particles suspended in aqueous phase. The spherical particles are called fat globules (Fig. 64.1).

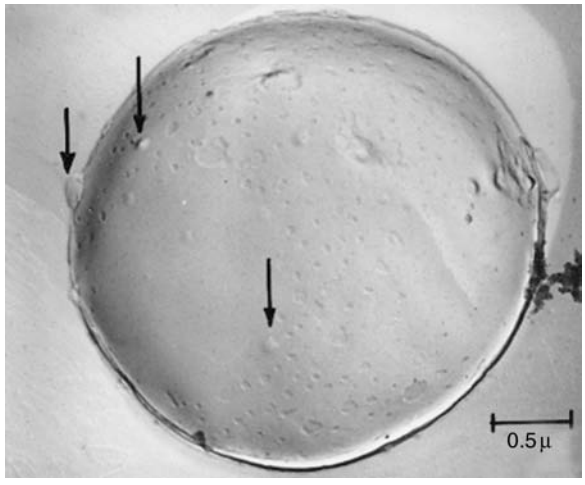

Figure 64.1 *Electron micrograph of freeze-etched fat globule of Jersey cow milk. Note the surface is smooth as well uneven, and some particle-like material protrudes out on the surface as depicted by arrows.*

The average size of fat globules in raw cow milk varies from 3.4 to 4.5 μm, depending on the breed of the cow. Jersey milk tends to have larger diameter than Holstein milk. Milk lipid globules fall into three overlapping size distributions (Table 64.5).

The use of a separator in dairy plants permits fractionation of whole milk into skim/low fat milk and cream. Fat globules are lighter (less dense) than the surrounding water phase and rise to the surface when milk is left undisturbed as per Stoke's law.

$$V = \frac{2r^2(\text{density of serum} - \text{density of fat}) \times g}{\text{Viscosity of milk} \times 9}$$

where, V is velocity of rise of fat globules, g is the gravitational force and r is the diameter of the fat globule. From the equation, it follows that V is directly proportional to g. If g is increased by centrifugal force, fat globules can be separated in a relatively short time. Also, g is inversely proportional to the viscosity of milk which decreases as the temperature goes up converting the fat into liquid state. Accordingly, V is increased. Thus, separation is more efficient at warmer temperatures. Skim milk should contain 0.05% fat or less, if the separator is functioning properly.

Processed milk products, namely homogenized milk, UHT milk, ice cream, yogurt, light cream, half and half, evaporated milk, and condensed milk, which have undergone homogenization have diameter of their globules of the order of 0.3–0.7 μm. In the

TABLE 64.5 Size Distribution of Milk Lipid Globules.

Class	Diameter (μm)	Proportion of the Total Globule Population (%)	Fraction of Total Milk Lipid (%)
Small	Below 2	70–90	<5
Intermediate	3–5	10–30	90
Large	8–10	0.01	1–4

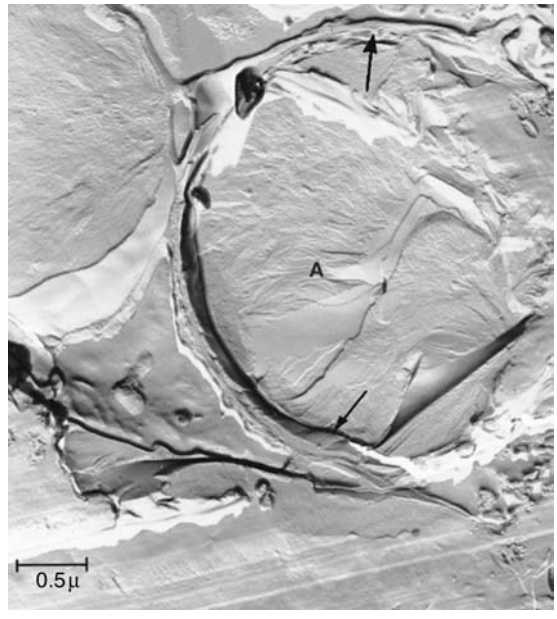

Figure 64.2 *Electron micrograph of freeze-etched fat globule membrane isolated from the globules of Jersey cow milk. Note the membrane as depicted by arrows.*

unhomogenized products like whipping cream fat globules show a diameter of 4.0 μm. Skim milk has smaller fat globules left over as a result of separator action and their diameter is around 1.3 μm. Cream layer is observed in products with relatively large fat globules, while the homogenized dairy products show virtually no cream layer during the shelf life of such products.

The fat globules are stabilized by a very thin membrane, closely resembling plasma membrane, only 5–10 nm thick (Fig. 64.2).

The fat globule membrane consists of proteins, lipids, lipoproteins, phospholipids, cerebrosides, nucleic acids, enzymes, trace elements, and bound water, details of which are given in Table 64.6.

The membrane is important in keeping the fat from separating as free oil when it is subjected to physical abrasion during handling/processing of milk. It also protects milk lipids against the action of enzymes, notably lipase, in development of rancidity. Certain

enzymes, such as the alkaline phosphatase and xanthine oxidase as well as certain important minerals as iron and copper are preferentially attached to the fat globule membrane. The membrane contains 5–25% of the total copper and 30–60% of total iron content of milk. Other elements associated with membrane are cobalt, calcium, sodium, potassium, magnesium, manganese, molybdenum, and zinc. Molybdenum is associated with the enzyme xanthine oxidase. Activity of nearly all the enzymes of milk has been detected in the membrane.

The proteins of membrane are unique and are not found in skim milk phase. Due to damage of the globule or as a result of homogenization, the membrane proteins contain skim milk proteins (casein and whey proteins). A hydrophobic protein, butyrophilin, has been isolated from the membrane, which shows extraordinary affinity for association with lipids.

The lipid fraction of the membrane constitutes about 1% of the total milk lipids. It contains phospholipids and neutral lipids in the ratio of 2 : 1. The phospholipids are phosphatidylcholine, phosphatidylethanolamine, and sphingomyelin in the ratio of 2 : 2 : 1 (Fox and McSweeney 1998). The major fatty acid content of phospholipids is 5% $C_{14:0}$, 25% $C_{16:0}$, 14% $C_{18:0}$, 25% $C_{18:1}$, 9% $C_{18:2}$, 3% $C_{22:0}$, and 3% $C_{24:0}$. Accordingly, unsaturated content of the membrane lipids is different from rest of milk lipids in terms of their high unsaturated fatty acid level. Thus, they are more susceptible to oxidative deterioration.

The neutral lipids of the membrane consist of approximately 83–88% triglycerides, 5–14% diglycerides, and 1–5% free fatty acids. The fatty acids contained therein are largely long chain. In order of their preponderence, they are palmitic, stearic, myristic, oleic, and lauric acids.

The sterols, vitamin A, carotenoids, and squalene are largely located in the fat core of the globule.

64.5.1.3 Proteins. Milk contains hundreds of proteins and most of them occur in trace amounts. The major proteins of milk are broadly classified as caseins and whey proteins. Caseins are defined as the proteins which are insolubilized and precipitate when the pH of milk is lowered to 4.6. The soluble fraction at pH 4.6 is termed as whey proteins. In addition, milk contains degradation products by plasmin, an inherent proteolytic enzyme. Thus, γ-casein and proteose peptones owe their origin to proteolysis of β-casein. Also, proteins derived of milk fat globule membrane are present. The membrane proteins are spilled into milk system following mechanical disruption of the fat globule, such as churning and homogenization processing. Milk also contains numerous enzymes, and biologically active proteins. Nonprotein nitrogen compounds like urea, uric acid, creatine, creatinine, orotic acid, and hippuric acid are also found.

Casein, the principal milk protein, makes up 80% of the total while whey proteins make up the remaining 20%. These fractions have been shown to be heterogeneous consisting of several proteins (Table 64.7).

Caseins. Typical of milk proteins, caseins display distinctive structure, charge, physical, and biological properties as well as nutritional role. The interaction of various caseins and calcium phosphate contributes to the formation of large colloidal complex particles called casein micelles. The whitish color of milk is ascribed to light scattering effect of colloidal micelles. The micelles are rough surfaced spherical particles varying in size from 50 to 500 nm. Electron picture analysis has shown that the micelles are composed of smaller particle or submicelles of 20 nm diameter or less. Hydrophobic interactions with

TABLE 64.7 Concentration of Various Proteins and Polypeptides in Milk.

Enzymes	–

calcium phosphate and submicelles seem to be involved in the formation of micelles. Micelle composition consists of 63% moisture and the dry matter consists of 92–94% protein and 6–8% colloidal calcium phosphate. Other associated salts are magnesium and citrate. Micelles have a porous structure with large voluminosity (approximately 4 mL/g of casein. They are considerably hydrated, showing 3.7 g water/g casein.

Caseins are further divided into α_{s1}-, α_{s2},-, β-, and κ-fractions (Table 64.7), which along with whey proteins, β-lactglobulin and α-lactalbumin, are gene derived proteins synthesized in the mammary gland. All these proteins are heterogeneous and exhibit genetic polymorphs. There are two to eight genetic variants differing from each other in one to 14 amino acids. The variants may have impact on the protein concentration and processing properties of milk. The γ-fraction is derived from the break down of β-casein by the native proteolytic enzymes of milk.

The caseins are phosphorylated proteins, containg one to 13 phosphoserine residues. κ-Casein exists in as many as nine glycosylated forms. It contains two cysteine molecules per molecule. As a result of disulfide bond formation, it can exist as polymers of two to eight units. Similarly, α_{S-2}-casein also contains two cysteines and exists in a dimeric form. The composition and size of various caseins are shown in Table 64.8.

Casein micelles contain α_{s1}-, α_{S2}-, β-, and κ-casein in the ratio of 3 : 1 : 3 : 1. Most of the fractions α_{s1}-, α_{S2}-, and β-casein are located in the interior of micelles with κ-casein predominantly wrapped around the surface of the micelle. Casein fractions in the interior

of micelle are sensitive to calcium and become insoluble in the presence of calcium. However, κ-casein is not sensitive to calcium and thereby keeps the micelles containing calcium-sensitive caseins intact and suspended in aqueous phase.

κ-Casein is a protein with hydrophilic carbohydrate moiety (sialic acid) that extends into aqueous phase. This arrangement further lends stability to the micelle. Casein micelles are stable at under most heating, homogenization, and other dairy processing conditions.

Caseins possess certain distinctive amino acid makeup which impacts their processing and functional properties. They are rich in apolar and hydrophobic amino acids, namely valine, leucine, isoleucine, phenylalanine, tyrosine, and proline. The apolar amino acids normally are insoluble in water, but their nature is balanced by phosphate groups so that caseins exhibit some solubility. Methionine and cysteine, the sulfur-containing amino acids are relatively low in caseins. This fact impacts their nutritional deficiency. On the other hand, the essential amino acid lysine content is high. In human diet, the high lysine content is helpful in complementing and balancing the low-lysine plant proteins. The ε-amino group of lysine present in caseins interacts with the aldehyde group of lactose at elevated temperature, leading to the formation of brown pigments (Maillard reaction). This also explains browning of heat-sterilized milk and nonfat dry milk during extended storage.

The high prolene content results in low α-helix and β-sheet in their secondary structure, giving them ability for more proteolytic degradation and enhanced digestion (Otter 2003).

Caseins possess limited secondary and tertiary structure. Accordingly, their molecular conformation is fairly flexible, and open. The polar and apolar amino acids in the primary structure of caseins contribute to hydrophilic and hydrophobic regions. This confers surface activity and contributes to emulsifying and foam-forming characteristics of caseins.

Caseins are very heat-stable under normal protein levels, environmental pH, and ionic concentrations. Moderate heat has little or no effect on casein molecules since they exist naturally in an open and extended state. However, heating of milk at elevated temperature for an appreciable length of time could result in hydrolytic cleavage of peptide and phosphate bond, which affects the stability of the complex, contributing to coagulation of milk.

Coagulation of milk is primarily a manifestation of micellar casein precipitation. This temperature-dependent phenomenon is critical in the manufacture of yogurt and fermented milks as well as in cheese making. The precipitation/coagulation mechanism consists of the following types:

ISOELECTRIC PRECIPITATION. Factors such as the pH strongly influence the electrostatic interactions in casein. Casein becomes insoluble and precipitates out when the milk is acidified and the pH is reduced to 4.6 at or above 20°C. At low temperature (4°C), no visible precipitation is observed. As the temperature is raised, coagulation is observed at or above 20°C. The proteins remaining in solution are whey proteins. The destabilization of micellar casein by added acid or by lactic acid produced during fermentation by lactic acid bacteria starts at pH 4.9 when colloidal calcium phosphate becomes soluble and changes to ionic form. As the pH reaches 4.6, calcium phosphate is cleaved in entirety from the micelle. At the same time, the isoelectric point of casein is reached and the micelle has no longer any charge to keep it suspended by repelling forces. The result is aggregation of casein micelles leading to dense coagulum. This type of coagulation is relevant in all fermented dairy products including cottage cheese and cream cheese. Many

textural attributes are controlled by the temperature, quiescent conditions, pH, and rate of acidification of milk.

RENNET COAGULATION. In cheese making, the mechanism of coagulation is not acid-based but is caused by enzymatic attack by acid proteinase, chymosin contained in rennet. This coagulation occurs at normal pH of milk. The specific cleavage of κ-casein molecule occurs at amino acid 105 (phenyl alanine) and 106 (methionine) to form para κ-casein and a macropeptide called glycomacropeptide (GMP). The GMP contains carbohydrate residues. Being hydrophilic, it is soluble and ends up in the whey fraction. Since micelle is stabilized by calcium-insensitive κ-casein, its hydrolysis by chymosin results in the exposure of calcium-sensitive α_s-caseins and β-casein to serum calcium, the overall effect is coagulum formation by aggregation of the micelles. Further hydrophobic interactions result in the expulsion of moisture from the coagulated micelles, causing syneresis and curd shrinkage. This coagulum is the basis of cheese curd formation. Para κ-casein is further degraded during cheese ripening to produce numerous flavor compounds and textural components.

POLYVALENT ION PRECIPITATION. Due to its disordered molecular structure, casein fractions also precipitate out in the presence of di- and polyvalent ions of various salts.

ALCOHOL PRECIPITATION. Casein micelles become unstable at 40% alcohol concentration at normal milk pH. At lower pH, the stability becomes even less and lower alcohol levels can precipitate milk. Dehydration of casein micelles appears to be major cause of this type of precipitation.

HEAT COAGULATION. Severe and extensive heating of milk can cleave the calcium phosphate complexes with casein micelle, resulting in destabilization, aggregation, and precipitation. Casein can withstand normal heating processes in dairy plants, interactions do occur with the whey proteins.

Among the minor caseins of milk, γ-casein is the C-terminal fragment of β-casein, a product of attack by natural proteolytic enzyme plasmin. The N-terminal residue is the proteose–peptone fraction. These hydrolysis products of β-casein occur at a range of 3–10% of the total casein content of milk. The stage of lactation and health status of the cow affect their concentration.

Peptides derived from caseins are biologically active and display significant extra nutritional attributes for maintaining normalcy of physiological functions in human subjects.

Whey/Serum Proteins. Whey proteins consist of β-lactoglobulin and α-lactalbumin, bovine serum albumin, immunoglobulins (mainly IgG1, IgG2, and IgM), lactoferrin, proteose-peptone, and a number of diverse enzymes. Table 64.9 shows some characteristics of whey proteins.

Compared to caseins, whey proteins have a relatively more ordered globular structure, which contains disulfide linkages. Accordingly, unlike caseins, they are soluble and not vulnerable to precipitation under acidic conditions or by polyvalent ions. Like other globular proteins, they are very heat labile and can be denatured at 90°C, resulting in gel formation. β-Lactoglobulin complexes with κ-casein in milk when subjected to rigorous heat treatment. All the whey proteins are superior in biological value as compared to caseins

TABLE 64.9 Composition and some Characteristics of Whey Proteins.

Whey Protein	Approx. % of Total Whey Protein	No. of Amino Acid Residues	Approx. Mol. Wt.-Dalton	Isoelectric pH
β-Lactoglobulin	7–12	162	18,277	5.2
α-Lactalbumin	2–5	123	14,175	5.1
Bovine serum albumin	0.7–1.3	582	69,000	4.8
Immunoglobulins	1.9–3.3	–	150,000–1,000,000	4.6–6.0
Proteose peptone	2–6	–	4,000–40,000	3.7

Source: Fox (2003); Otter (2003).

and compare with the quality of egg albumins. Major differences in the behavior of caseis and whey proteins are summarized in Table 64.10.

β-LACTOGLOBULIN. This major whey protein of milk displays the presence of four genetic variants. Besides the two genetic variants, namely A and B, variants, C and D have also been reported. β-Lactoglobulin is rich in sulfur amino acids, containing five cysteine residues. It exists as a dimmer linked by one to three disulfide bonds. It is a fairly heat labile protein. Heat treatment of 60°C results in partial denaturation. Differential scanning calorimetry results show peak maximum of denaturation at 80°C and formation of reactive sulfhydryl groups which can interact with κ-casein and/or α-lactalbumin by disulfide linkages. Further heating liberates hydrogen sulfide which is associated with "cooked" favor. β-Lactoglobulin stimulates lipolysis and generation of rancidity. It also acts as a carrier of vitamin A. The large numbers of lysine residues can result in lactosylation and accompanying changes in physical properties of the protein.

α-LACTALBUMIN. α-Lactalbumin is the major protein of human milk, but in cow milk it is second in preponderence to β-lactoglobulin. Three genetic variants are reported, but western cows contain variant B only. This protein is rich in tryptophan and sulfur amino acids cysteine and methionine. There are four disulfides in the molecule and it exists as a monomer. α-Lactalbumin has 54 amino acid linkages identical with the enzyme lysozyme. It is a glycoprotein as well as a metalloprotein. One mole of calcium is bound to each protein molecule, which confers heat stability on α-lactalbumin. This protein has been shown to possess a physiological role in the synthesis of lactose in the mammary gland. It is a component of lactose synthetase along with uridine diphosphate–galactosyl transferase, catalyzing the transfer of galactose to glucose to form lactose.

TABLE 64.10 Major Differences in Physical and Chemical Properties of Casein and Whey Protein.

Casein	Whey Protein
Strong hydrophobic regions	Both hydrophobic and hydrophilic regions
Phosphate residues	No phosphate residues
Little cysteine content	Both cysteine and cystine content
Random coil structure	Globular structure and helical structure
Very heat stable	Heat denatured and precipitates
Precipitates at pH 4.6	Soluble at pH 4.6
Precipitates with di- and polyvalent ions.	Relatively resistant to the ions

Source: Chandan (1997).

IMMUNOGLOBULINS. There are five major classes of immunologlobulins, namely, IgA, IgD, IgE, IgG, and IgM. Their concentration is very high (100 g/L) in first two to three milkings after calf birth, but falls to 0.6–1 g/L soon after. Immunoglobulins are antibodies synthesized in response to stimulation by specific antigens. These offer nonspecific humoral response to Gram-negative enteric and aerobic bacteria. Accordingly, they provide passive immune protection to the newly born calf. The basic structure of all Igs is similar, which is composed of two identical light chains (23,000 Daltons) and two identical heavy chains (53,000 Daltons). The four chains are joined together by disulfide bonds. The complete molecule has a molecular weight of about 180,000 Daltons. The antigenic sites are located at the $-NH_2$ terminal of the respective chain. Of the five-immunoglobulin classes, IgG is the predominant fraction of milk, comprising of about 90% of the total colostral immunoglobulins. Relatively smaller concentrations of IgM and IgA are also present in progressively decreasing amounts.

BOVINE SERUM ALBUMIN. As the name indicates, this protein originated from blood and during synthesis in the udder spills into milk. It is a large molecule with binding ability for fatty acids and metals.

LACTOFERRIN/LACTOTRANSFERRIN. This is a glycoprotein, which displays strong tendency to bind ionic iron due to the presence of two metal binding sites. The average lactoferrin content of 0.32 mg/mL has been found for cow milk. The molecular weight of lactoferrin varies between 73,700 and 74,000 Daltons. Lactoferrin display very strong chelating tendency for ionic iron and forms a salmon red color pigment. Lactoferrin is a single peptide chain, with two lobes, each of which is capable of binding iron. Iron free form of lactoferrin is known as apolactotransferrin, which is colorless in appearance. Lactoferrin displays strong inhibitory effect towards Gram-negative enteropathogenic bacteria by virtue of its ability to bind free ionic iron, which is essentially required for the growth of enteropathogenic microorganisms. Apart from the antibacterial effect in the gut of a calf, a nutritional role in iron metabolism has also been ascribed to lactoferrin.

Biologically Active Proteins and Peptides. A number of proteins and peptides derived from milk proteins have physiological activity. They are: (1) immunoglobulins, lactoperoxidase, lactoferrin, and folate-binding protein; (2) insulin-like growth factors (IGF-1 and IGF-2), mammary derived growth factors MDGF-I and MDGF-II), transforming growth factors ($TGF_{\alpha 1}$, $TGF_{\alpha 2}$, TGF_{β}), fibroblast growth factors, platelet-derived growth factors, bombesin, and bifidus factor; and (3) peptides derived from milk proteins, such as glycomacropeptides from κ-casein, phosphopeptides from caseins, caseinomorphins, immunomodulating peptides, platelet-modifying peptide, angiotensin-converting enzyme (ACE) inhibitor that lowers blood pressure, calmodulin-binding peptides, and bactericidal peptides from lactotransferrin (Otter 2003).

Milk Enzymes. Milk is a repository of a variety of enzymes. Over 60 indigenous enzymes have been reported in cows' milk. They are either associated with milk fat globule membrane (xanthine oxidase, sulfhydryl oxidase and γ-glutamyltransferase), with skim milk serum (catalase, superoxide dismutase), or with micelles of casein (plasmin and lipoprotein lipase). The partition and distribution of these enzymes is affected by processing and storage condition of milk. Other enzymes present are lactate dehydrogenase, malate dehydrogenase, lactoperoxodase, galactosyl transferase, alkaline phosphatase, phosphoprotein phosphatase, ribonuclease, lysozyme, fructose biphosphate

aldolase, and glucose phosphate isomerase. The enzymes in milk come either from the cow's udder (original enzymes) or from bacteria (bacterial enzymes). Several of the enzymes in milk are utilized for quality testing and control. Some of the enzymes, which are important from processing point of view, are described below:

ALKALINE PHOSPHATASE. This enzyme has assumed significance because of the association with the temperature at which it is inactivated and the temperature employed for pasteurization of milk. The basis of pasteurization is that the spore-forming pathogens, which may be present in milk, are completely destroyed by heat treatment designated in the pasteurization process. In turn, alkaline phosphatase activity is also destroyed by the pasteurization heat treatment. Thus, efficiently pasteurized milk should be safe from pathogens, and concomitantly, should not display any alkaline phosphatase activity. Contamination of pasteurized milk with raw milk can also be detected by positive phosphatase activity in milk. Alkaline phosphatase is distributed through milk. Its concentration is higher in the cream fraction. The optimum pH for the action on alkaline phosphatase on p-nitrophenylphosphate is 9.5. The K_m value for this substrate is 6.6×10^{-4} M for skim milk enzymes, whereas for the cream alkaline phosphatase the corresponding value is 3.6×10^{-4} M.

LIPOPROTEIN LIPASE. This enzyme brings about hydrolytic cleavage of glycerides, liberating free fatty acids and glycerol. The volatile short chain free fatty acids generate undesirable rancid flavor in milk. Thus, the activity of this enzyme can result in rancid flavor defects in dairy products. Lipase is activated by homogenization of fat globule membrane in raw milk. Similarly, lipase can degrade milk fat and develop off-flavor in short period of storage, if raw milk accidentally gets mixed with homogenized milk. The optimum pH for the enzymatic activity ranges from 8.4 to 9.0, while optimum temperature for enzymatic activity is 37°C. Sodium chloride and magnesium chloride have stimulatory effect on these enzymes whereas calcium chloride and manganese chloride have inhibitory effect. Residual activity of lipase remaining in processed milk or milk products tends to reduce their shelf life.

PROTEASE/PLASMIN. This enzyme is responsible for the hydrolytic degradation of proteins. The optimum activity is observed at a temperature of 37°C and a pH of 8.0. Nearly 82% of proteolytic activity is lost when milk is pasteurized. Native proteases of milk are more heat labile compared to the microbial proteases, which tend to survive even UHT processing treatment. Residual proteolytic activity in processed milk and milk products leads to decrease in shelf-life.

LACTOPEROXIDASE. This enzyme catalyzes oxidation of substrate in the presence of an oxygen donor such as hydrogen peroxide. It displays optimum activity at pH of 6.0 and is stable over a wide pH range of 5–10. This enzyme has gained significance in view of its supportive role for the preservation of raw milk employing LP-system under ambient conditions.

LYSOZYME. This is a relatively small, single peptide chain protein. The variant found in bovine milk has 129–130 amino acid residues, with molecular weight of 14,000. The lysozyme cleaves the glycosidic linkage between N-acetylmuramic acid and N-acetylglucosamine of bacterial cell wall. Gram-positive bacteria are generally more susceptible because they have a simpler cell wall providing greater accessibility of the

substrate compared to the Gram-negative bacteria. Cow milk contains about 13 μg/100 mL of lysozyme. More recently, emphasis has been focused on the antibacterial role of lysozyme as a natural defense in milk. During mastitis, lysozyme levels in milk tend to increase considerably, being in the range of 100–200 μg/100 mL. It has also been suggested that lysozyme may have an indirect effect on the defense systems as an immunomodulator through the stimulation of break-down products of the peptidoglucan on the immunosystem.

Functional Attributes of Major Milk Proteins. Milk proteins are used in various foods to impart desirable effects. Table 64.11 shows such characteristics of milk proteins which are helpful in their use as functional ingredients.

64.5.1.4 Lactose. The major carbohydrate of milk, lactose monohydrate, ranges from 4.8% to 5.2%. Lactose content of milk is relatively constant. In colostrum and mastitic milk, its concentration is significantly lower. It forms 52% of milk solids-not-fat and 34% whey protein concentrate, and 70% of whey solids. It a disaccharide of one residue each of D-glucose and D-galactose. Structurally, lactose is 4-O-β-D-galactpyranosyl-D-glucopyranose. Fresh milk contains small amounts of glucose (100 mg/100 mL), galactose (100 mg/100 mL) and oligisaccharides (10 mg/100 mL). It is a reducing sugar and extensive heating of milk results in Maillard reaction between lactose and proteins creating brown pigments and brownish color of milk.

In isolated form, lactose exists in either of the two crystalline forms, α-hydrate and anhydrous-β or as amorphous "glass" mixture of α- and β-lactose. In solution both the forms exist in equilibrium with a ratio of (α : β) 1.68 at 20°C. Lactose has an asymmetric carbon and therefore displays optical activity. Lactose anomers rotate plane polarized light and their concentration can be assayed by polarimetric measurements. The α-lactose anomer is more dextrorotatory than β-lactose. If lactose crystallizes from solution like milk or whey below 93.5°C, α-lactose is usually formed, while above 93.5°C, β-lactose

TABLE 64.11 Functional Properties of Milk Proteins.

Functionality	Casein or Caseinates	Whey Proteins
Water binding	Very high, minimum at pH 4.6	Water-binding capacity increases with denaturation of the protein
Solubility	Insoluble at pH 4.6	Soluble at all pH levels. If denatured, insoluble at pH 5
Viscosity	High at or above pH 4.6	Low for native protein. Higher, if denatured
Gelation	No thermal gelation except in the presence of Ca^{2+}. Micelles gel with rennin	Heat gelation at 70°C (158°F) or higher and influenced by pH and salts
Emulsification	Excellent at neutral and basic pH	Good except at pH 4–5, if heat denatured
Foaming	Good overrun. K-Casein best followed by β- and α_{s1}-caseins Poor foam stability	Good foam/overrun β-lactoglobulin better than α-lactalbumin
Flavor binding	Good	Retention varies with degree of denaturation

Source: Chandan (1997); Fox (2003).

usually crystallizes. During crystallization, the β-form mutarotates to α-lactose. Crystals of α-lactose monohydrate are shaped like tomahawk and other shapes arise as a result of co-crystallization on the face of lactose crystals. The rate of crystallization, size and shape of lactose crystals depend on the degree of super saturation of lactose solution and the inhibitor (β-form) level.

The α-form is less soluble (70 g/L at 15°C) than the β-form. Crystallization of lactose, when milk is concentrated is of importance in regard to the texture. An equilibrium mixture of α- and β-lactose, formed by mutarotation, exhibits a solubility of about 155 g/L at 10°C and 119 g/L of water at 0°C. The relatively poor solubility at low temperatures (4°C or below) contributes to sandy texture in high milk solids ice cream, processed cheese products and condensed milk products. As a general rule, a concentration of lactose exceeding 13 g/100 mL water in a dairy product tends to promote crystallization of α-lactose monohydrate and accompanying sandy texture defect. In the manufacture of non-hygroscopic dry milk and whey, lactose crystallization plays an important role. In rapid drying conditions, lactose glass (amorphous lactose) is formed. This form of lactose is very hygroscopic and causes caking in dried products containing moisture levels of 8% or more. Under such conditions, the conversion of lactose glass to α-lactose monohydrate crystals is responsible for binding powder particles together as a "cake."

In sweetening power, lactose is only 16–33% as sweet as sucrose. This makes lactose uniquely suitable for certain food applications. Toppings icing and various types of fillings are examples of use where its inclusion in the formulations can improve the quality. The pharmaceutical industry has used lactose for many years for tablet or pill formation. Being a reducing sugar, it reacts with proteins to form a highly flavored golden brown substance, commonly found on the crust of baked foods. Lactose contributes significantly to the flavor, texture, appearance, shelf-life, and toasting qualities of baked foods.

A compound formed from lactose in heated milk products is lactulose. It stimulates the growth of *Bifidobacterium bifidum* and is thus beneficial in establishing useful microflora in the gut.

The role of lactose in yogurt and fermented milks is extremely important because the culture nutritionally requires it as a substrate for growth. It is a source of carbon and after fermentation about 30% of the lactose content is converted to lactic acid. Lactose is easily hydrolyzed by β-D-galactosidase or lactase enzyme of the culture to glucose and galactose. Glucose is readily metabolized by the Embden-Meyerhof-Parnas pathway, while galactose tends to accumulate. One molecule of lactose gives one molecule of galactose and two molecules of lactic acid. Energy is generated in this reaction. The acid production lowers the pH enough so that the fermented food is safe from most pathogens. The shelf-life of fermented milks is significantly increased because many spoilage organisms cannot grow at their low pH.

Digestion of lactose presents a problem in some individuals. They lack the enzyme β-D-galactosidase in their gastrointestinal tract. Consequently, dietary lactose is not hydrolyzed and it reaches the colon intact where it is metabolized by colonic bacteria forming gases like methane and hydrogen. It leads to discomfort caused by bloating and diarrhea. This lactose malabsorption is alleviated by yogurt containing live cultures, because the culture furnishes the lactose hydrolyzing enzyme and normal digestion pattern is restored.

64.5.1.5 Minerals. Average normal milk is considered to contain 0.70% ash and this amount represents a salt content of about 0.90%. The percentage of salt and ash in milk

TABLE 64.12 Typical Mineral Content of Cows' Milk.

Major Mineral	Mean (mg/100 mL)	Range (mg/100 mL)
Calcium-total	121	114–130
Calcium-ionic	8	6–16
Citrate	181	171–198
Chloride	100	90–110
Magnesium	12	9–14
Phosphorus, inorganic	65	53–72
Potassium	144	116–176
Sodium	58	35–90
Trace Elements	**μg/100 g of Milk**	**μg/100 g of Milk**
Boron	27	–
Chromium	1	0.8–1.3
Cobalt	0.1	0.05–0.13
Copper	20	10–60
Fluoride	12	3–22
Iodine	26	–
Iron	45	30–60
Manganese	3	2–5
Molybdenum	7	2–12

Zinc	390	200–600

Source: Swaisgood (1996); Fox (2003).

varies with the breed, feed, season, and stage of lactation and disease. The white residue after incineration of a given weight of milk is used as a measure of the mineral content of milk. Ash content is not identical to milk mineral level because of decomposition and volatilization of certain minerals due to heat. The ash contains substances derived from both the organic and inorganic compounds in the milk. The CO_2 of the carbonates is formed mostly from the organic components; the SO_3 of the sulfates is considered to be a decomposition product of the proteins. Part of the P_2O_5 arises from the casein, since this protein contains phosphorous equivalent to about 1.62% P_2O_5. Citric acid is completely lost. Chloride is partly lost (45–50%) by the high temperature employed for ashing. This loss can be minimized by keeping the temperature below 600°C. The mineral content of milk is given in Table 64.12.

Mineral make-up of milk is crucial to the stability of the physico-chemical equilibrium in milk. The minerals of milk exist in colloidal and soluble form. Table 64.13 gives approximate phase composition of the minerals.

They are present in a complex equilibrium consisting of colloidal state and soluble state. The soluble state exists in both ionic and nonionic form, and their ratio is influenced by pH of milk. Their concentration is less than 1% in milk but the technological behavior of milk is impacted a great deal by them. For instance, the following characteristics are influenced:

1. Heat stability and alcohol coagulation of raw milk.
2. Preparation, quality and storage stability of products like concentrated/condensed, evaporated milk products.
3. Clumping of fat globules upon homogenization of cream.

TABLE 64.13 Partition of Major Minerals in Colloidal and Solution Phases.

	Percent of Total Mineral as	
Major Mineral	Colloidal	Dissolved
Calcium	67	33
Magnesium	36	64
Sodium	4	96
Potassium	6	94
Phosphate	55	45
Citrate	6	94
Chloride	0	100
Sulfate	0	100

4. The calcium content of milk influences the firmness of curd during cheese making and the viscosity of fermented milks. From nutritional standpoint, milk is an excellent source of calcium and phosphorus. Their ratio in milk is optimal for bone formation and bone health.

Sodium, potassium, and chloride are almost completely (95–96%) present in true solution and in ionic form and therefore diffuse freely across the membrane during ultrafiltration and electrodialysis of milk and whey. Calcium and magnesium, phosphate and citrate are partly in solution and partly in colloidal suspension, depending on the pH of milk. Approximately 20–30% of diffusible Ca and Mg exist as free ions and the remainder as salts of citrate and phosphate. As the pH of milk drops in the manufacture of yogurt and fermented milks, the colloidal form is converted progressively to the ionic form. At pH 4.4 most of the minerals are in ionic, soluble and diffusible form.

64.5.2 Vitamins and Some Other Minor Constituents

The concentration of fat soluble vitamins A, D, E, and K, and water soluble vitamins B and C, and minor constituents of milk are given in Table 64.14.

Milk contains both fat soluble (A, D, E, and K) and several water soluble vitamins. In the production of low fat and skim milk, the fat soluble vitamins get concentrated in the cream fraction. Whole milk is a good source of vitamin A but the separation process leads to low vitamin A content in low fat and skim milk. The FDA regulations require fortification of low fat and skim milk to restore and to make the vitamin A content of low fat and skim milk equivalent to that of whole milk. The regulations require 2000 IU of vitamin A per quart of milk. The objective is to insure essentially the same dietary vitamin A contribution of all fluid milk beverages. Natural vitamin A activity in milk is due to retinol and the pigment β-carotene. Their level as well as those of vitamin D and E varies in milk according to the season and feed profile. Vitamin D is important in bone health and vitamin E in an antioxidant. Vitamin K is present in milk but its dietary nutritional role is minor.

Milk is an important source of dietary B vitamins. They are stable to various heating and processing conditions milk is normally subjected to. Riboflavin is vulnerable to light (wavelength <610 nm), generating sunlight flavor defect in milk. Ascorbic acid

TABLE 64.14 Vitamins and some Minor Components of Milk.

Vitamins	Per 100 g of Milk
A	40 μg RE
D	4 IU
E	100 μg
K	5 μg
B_1	45 μg
B_2	175 μg
Niacin	90 μg
B_6	50 μg
Pantothenic acid	350 μg
Biotin	3.5 μg
Folic acid	5.5 μg
B_{12}	0.45 μg
C	2 mg
Nonprotein Nitrogen Compounds	
Total NPN	23–31 mg
Urea N	8–13 mg
Creatine N	0.6–2 mg
Uric acid N	0.5–0.8 mg
Orotic acid N	1.2 mg
Peptides N	3.2 mg
Ammonia N	4–5 mg
Choline	4–28 mg
Carnitine	1–1.7 mg
N-acetyl neuraminic acid	12–27 mg
Miscellaneous Compounds	
Nucleic acids and nucleotides	56 mg
Phosphoric esters	30 mg
Ethanol	0.3 mg
Lactic acid	3.5–10 mg
Citric acid	175 mg
Acetic acid	0.3–5 mg
Formic acid	1–8.5 mg

(vitamin C) content of milk is very low and not significant. Also, it is inactivated by heat processing.

As shown in Table 64.14, some nonprotein nitrogen compounds and several miscellaneous compounds are also detected in milk.

64.6 PHYSICAL CHARACTERISTICS OF MILK

64.6.1 Optical Properties

64.6.1.1 Color. The color and appearance of milk has significance because the consumers perceive it as parameter of quality. The opaque, white, or turbid color of milk is due to scattering of light by the dispersed phase of fat globules, casein micelles, and the colloidal calcium phosphate. The intensity of color is directly proportional to the size and number of these particles. The smaller particles scatter light of shorter wavelength. The creamy color of whole milk is due to its β-carotene content. Some breeds (e.g., Guernsey cows) have

more of this pigment and their color is yellowish/"golden." In cases of goat milk and water buffalo milk, the pigment content is very low. β-Carotene is a precursor of vitamin A and in milk of goats and water buffaloes, it is inherently converted to vitamin A. Accordingly, their milk has white color as opposed to creamy color of cows' milk.

Extended heating imparts a slightly brown color to milk as a result of Maillard's reaction between lactose and proteins.

Homogenization increases the number and total volume of fat globules. This results in whiter color of homogenized products than their unhomogenized counterparts. Lack of fat globules and water-soluble pigment riboflavin produces a bluish green tint in skim milk. In the absence of fat globules, light scattering is primarily by casein micelles which scatter more blue (short wave lengths of light) than the red. The color thus becomes distinctly green fluorescence in whey after removal of casein particles from skim milk. Yellow color of cow milk fat in butter and cream is due to the presence of fat-soluble pigments carotene and xanthophyll.

64.6.1.2 Refractivity. The refraction of light by a solution is a function of the molecular concentration of the solute in solution. Each solute maintains its own refractivity, and the refractive index of a mixture is that of the total of the refractive indices of the substances plus that of the solvent. The components of milk contributing to its refractive index in descending order of importance are water, proteins, lactose, and minor constituents. Specific refractive increments in water at wavelength 589.3 nm and 20°C, in mL/g, for casein complex, whey proteins, lactose, and other dissolved substances are 0.207, 0.187, 0.140, and 0.170, respectively. The fat globules do not contribute to refractive index of milk because refraction occurs at the interface of plasma and air.

Refractive index of a substance varies with the wavelength of the light and temperature of measurement. It is generally measured at 20°C with D line of sodium spectrum (wave length 589.3 nm) and represented as n_D^{20}. The value of n_D^{20} of cow milk generally falls in the range 1.3440–1.3485. Refractive index of human and goat milks have slightly higher value. The refractive index of milk fat ranges from 1.4537 to 1.4552 at 40°C and is used for verification of its authenticity.

64.6.2 Flavor

Taste and aroma are critical to the assessment of milk. Flavor constitutes a critical criterion of quality for the consumer. It is a sensory property in which odor and taste interact. The sweet taste of lactose is balanced against the salty taste of chloride, and both are somewhat moderated by proteins. This balance is maintained over a fairly wide range of milk composition even when the chloride ion level varies from 0.06% to 0.12%. Saltiness can be detected by sensory tests in samples containing 0.12% or more of chloride ions and becomes marked in samples containing 0.15%. Some workers attribute the characteristic rich flavor of dairy products to the lactones, methylketones, certain aldehydes, dimethyl sulfide, and certain short-chain fatty acids.

Although milk has a clean, pleasantly sweet flavor, it is quite bland, and therefore, any off-flavors are readily discernible. Off flavors result when the balance of flavor compounds is altered due to the microbiological activity or processing treatments, or chemical or biochemical reactions. The fat globules have a large surface area and tend to adsorb aromatic odors (for example, onion, and garlic) readily.

Some off flavors in milk are shown in Tables 64.15 to 64.18.

TABLE 64.15 Off-Flavors in Milk Caused by Absorption from the Feed and Environment.

Off-flavor	Description	Possible Cause
Feed	Aromatic, onion, garlic	Cows fed 0.5–3 h before milking
Cowy	Chemical after-taste, cow's breath odor	Cows with ketosis/acetonemia
Barny	Unclean, reminiscent of barn, silage	Poor ventilation, build up of aromatic silage/barn odors

TABLE 64.16 Milk Off-Flavors of Microbiological Origin.

Off-Flavor	Description	Possible Causes
Malty	Grape nut-like, caramelized, burnt	Unsanitary equipment, insufficient cooling and storage at $>10^{\circ}$C.
Bitter/unclean	Musty, spoiled, stale, dirty, bitter	Exposure to warm temperature, dirty utensils, weeds
Fruity/fermented	Odor resembling fruits like apple/pineapple	Old milk, too long storage of raw milk
Sour	Tingling acidic taste	Growth of lactic and other organisms

TABLE 64.17 Off-Flavors in Milk of Biochemical Origin.

Off-Flavor	Description	Possible Cause
Rancid	Bitter, soapy, foul odor, unclean	Homogenized raw milk stored too long, mixture of pasteurized and raw milk, raw milk agitated vigorously
Oxidized/light induced	Medicinal chemical taste, reminiscent of burnt feather or tallow	Milk in transparent plastic/glass bottles exposed to sunlight or UV light in refrigerated cases

64.6.3 Acidity and pH

Freshly drawn milk shows certain acidity as determined by titration with an alkali (sodium hydroxide) in the presence of an indicator phenolphthalein (equivalent to pH 8.3). This acidity, also called titratable acidity, as determined by titration, is known as "natural" or "apparent" acidity. It is caused by the presence of casein, acid-phosphates, citrates, and so on, in milk. The natural acidity of individual milk varies considerably depending on species, breed, individuality, stage of lactation, physiological condition of

TABLE 64.18 Off-Flavors Arising from Processing Conditions.

Off-Flavor	Description	Possible Cause
Cooked	Sulfur-like odor, caramelized, scorched	Too high pasteurization temperature and holding time too long, Excessive heat treatment
Foreign	Non-milk like odor/flavor	Contamination with sanitizers, cleaning compounds
Flat	Watery	Too low milk solids, watered milk

the udder, and so on, but the natural acidity of fresh, herd/pooled milk is much more uniform. The higher the solids-not-fat content in milk, the higher the natural acidity and vice versa. The tiratable acidity of individual cow milk varies from 0.12% to 0.18%, but in commercial pooled milk the range is only 0.14–0.16%. "Developed" or "real" acidity is due to lactic acid, formed as a result of bacterial action on lactose in the milk. Hence, the titratable acidity of stored milk is equal to the sum of natural acidity and developed acidity. The titratable acidity is usually expressed as a "percentage of lactic acid." The higher the serum solids, the higher are the titratable acidity, but pH remains relatively the same. The titratable acidity (or pH measurement) is a critical parameter in yogurt and fermented milk production. It determines the end point of fermentation process. Measuring pH is preferable because unlike titratable acidity, it does not vary with the total milk solids-not-fat in yogurt mix.

The pH of normal, fresh, sweet milk usually varies between 6.6 and 6.8. Higher pH values for fresh milk indicate udder infection (mastitis) and lower values, bacterial action. Skimming and dilution with water raise the pH of milk while sterilization usually lowers it.

64.6.4 Buffering Capacity

The pH is a measure of acidity or inverse of the logarithm of the hydrogen ion concentration in milk. The relationship of hydrogen ion concentration and pH is shown by the following equation. A weak acid (HA) dissociates as follows:

$$K_a = \frac{(H^+)(A^-)}{(HA)}$$

where, K_a is dissociation constant, (H^+) is hydrogen ion concentration, and (A^-) is the concentration of the anion and (HA) is the concentration of the acid HA.

$$pH = \log\frac{1}{(H^+)} = pK_a + \log\frac{(A^-)}{(HA)}$$

where pK_a equals to $-\log_{10} pK_a$. When pH equals pK_a, the weak acid is 50% dissociated and the buffering capacity is maximum. Proteins contain many basic and acid groups in their molecule. Generally, their maximum buffering capacity is at their isoelectric point.

Milk displays innate ability to resist the changes in the pH or buffering capacity (dB/dpH). This is mainly due to the presence of amino acid residues of caseins and whey proteins, and colloidal salts (calcium phosphate complex, citrates, etc.). Caseins display maximum buffering capacity at their isoelectric pH of 4.6 and phosphates around pH 7.0. Whey proteins show maximum buffering capacity at pH 4–5. The buffer index of milk is defined as the amount of acid or alkali (moles/L) required changing pH of one liter of milk by one unit.

Buffering capacity has some significance in the survival of live cultures in the stomach where high acid conditions are deleterious to the survival of yogurt cultures. Since yogurt pH is close to their isoelectric point, the milk proteins of yogurt exercise maximum buffering capacity. Accordingly, the impact of acidic conditions on the culture cells is somewhat moderated for better survival rates in the stomach.

64.6.5 Electricochemical Properties

64.6.5.1 Oxidation Reduction Potential. The oxidation-reduction (E_h) potential of milk is expressed in volts. It is measured relative to the potential of the standard hydrogen electrode which is assigned 0 volt at pH 0. It is due to the presence of several soluble constituents capable of yielding or accepting electrons. In milk E_h is controlled by the factors such as dissolved oxygen, ascorbic acid, riboflavin, cystine–cysteine transformation and pH value. Fresh cow milk displays values of +0.2 to +0.3 volt at 30°C. It is due largely to dissolved oxygen, ascorbic acid and riboflavin. Bacterial growth reduces the oxygen tension. Methylene blue reduction test, used for assessing the microbial quality of milk is based on this phenomenon. The ascorbic acid oxidation in stored milk leads to the formation of singlet oxygen, which in turn is involved in lipid oxidative deterioration. Riboflavin in milk exposed to light near 450 nm, assists in photooxidation of methionine residues of whey proteins to produce methional, the principal cause of "sunlight" flavor defect. Heating of milk increases the reducing capacity of milk and above 70°C also causes noticeable decrease in the Eh due to liberation of −SH groups from whey proteins. The increase in reducing capacity of yogurt mix after heat treatment is significant in promoting the growth of yogurt bacteria which are microaerophilic in nature.

64.6.5.2 Electrical Conductivity. Current passes through the milk by virtue of the activity of its ionic mineral constituents, of which chloride ions carry 60–68% of the current. There is, therefore, a close correlation between the electrical conductivity of milk and its chloride content. The specific electrical conductivity of milk at 25°C ranges between 0.004 ohm/cm and 0.0055 ohm/cm, corresponding to that of approximately 0.25% NaCl solution (w/w). Higher values usually represent mastitic infections. Sodium, potassium, and chloride ions are the major contributors to electrical conductance of milk. Whey and permeate from ultrafiltration have higher conductivity than skim milk. The presence of fat tends to decrease the specific conductance. Conductivity of milk may be used to detect added neutralizers.

The development of acidity by bacterial action during fermentation of milk increases its conductance because of conversion of calcium and magnesium to ionic forms. Thus measuring their electrical conductance can follow the progress of fermentation during manufacture of yogurt and other fermented dairy products. Electrical conductance can also be used to follow demineralization of whey leading to loss of ionic minerals, during manufacture of whey protein concentrates. Electrical conductance is directly proportional to temperature. Conductance of milk increases by about 0.0001 ohm/cm/C.

64.6.6 Thermal Properties

64.6.6.1 Thermal Expansion. When warmed the volume of milk increases which affects the design considerations for storage and flow rates through processing treatments. The coefficient of thermal expansion of fresh milk (4% fat, 8.95% SNF) is approximately 0.335 $cm^3/kg/C$ at temperature range of 5–40°C.

64.6.6.2 Heat Capacity. Heat capacity of milk and milk products, a function of total solids of the sample, decreases with their increasing contents. Heat capacity is expressed as (SI units). It equates to 1/4186 cal/g/°C in cgs units. Heat capacity of whole milk, skim milk, whey, milk fat, 40% cream, and dried skim powder at 15–20°C is 0.93, 0.95, 0.97,

0.52, 0.68, 0.30 cal/g/°C, respectively. Heat capacity increases linearly with increase in temperature in skim milk from 3906 J/kg/K at 50°C to 4218 J/kg/K at 140°C, according to the following equation (Goff and Hill 1993):

$$\text{Heat capacity} = 2.814 \times \text{Temperature in } ^\circ\text{C} + 3824$$

The heat capacity of milk and cream depends strongly upon fat content. Milk fat has a heat capacity of 2177 J/kg/K. The heat of fusion is 8.37 J/g. The heat capacity of milk in the range of 50–140°C can be estimated according to the equation:

$$\text{Heat capacity of milk} = 2.976 \times \text{Temperature in } ^\circ\text{C} + 3692$$

64.6.6.3 Specific Heat. Specific heat is the ratio between the amount of heat necessary to raise a given weight of a substance to a specified temperature and the amount of heat necessary to raise an equal weight of water to the same temperature. It is nearly identical to heat capacity figure as the heat capacity of water (1 cal/g/°C or 4186 J/kg/K) is fairly constant over the range of 0–100°C. It is important in processing for determining the amount of heat or refrigeration necessary to change the temperature of milk.

64.6.6.4 Thermal Conductivity. Thermal conductivity determines how fast milk is cooled or heated. It is the rate of heat transfer by conduction in J/m/s/K. Thermal conductivity increases as temperature increases. It decreases as the concentration level increases and for a given temperature and concentration, the higher the fat content, the lower the thermal conductivity. Thermal conductivity of proteins, carbohydrates, fat, milk, solids, and water at 30°C is 0.20, 0.245, 0.18, 0.26, 0.573, kcal/m/h/C, respectively. The thermal conductivity for milk at 37°C is 193 J/m/s/K, and 223 J/m/s/K at 80°C. There is a marked decrease in the thermal conductivity with increase in either fat or total solids.

64.6.6.5 Effects of Heat. Dairy plants routinely use heat processes to make milk safe from pathogenic organisms and to extend the shelf-life of milk and milk products. The pasteurization and sterilization temperatures and holding times employed in such treatments have profound effects on milk proteins, enzymes, fat globule membrane, some vitamins, and physical state of minerals and other constituents. Caseins of milk are relatively stable to moderate heating regimes under conditions of normal pH and ionic balance. The serum proteins are globular proteins. They are more prone to denaturation to heat. At 60–65°C, β-lactoglobulin molecules begins to uncoil themselves and start interaction with κ-casein located in casein micelle forming disulfide linkages. The denaturation process is complete at 90–95°C when milk is held for 5 min. Under this heat treatment, α-lactalbumin is relatively less vulnerable to heat, undergoing reversible denaturation. However, the immnnoglobulins are fully denatured. In the manufacture of yogurt, this heating treatment is beneficial in increasing water-holding capacity and in reducing syneresis of the coagulum. Also, the resultant viscosity increase assists in optimizing the texture of yogurt. High heat treatment is deleterious to rennin curd formation, and should be avoided.

Normal pasteurization treatment causes “cream plug phenomenon” in which some fat globules break down to free fat that sticks to other fat globules giving rise to the plug. On homogenization, the plug is broken down. Exposure to higher temperatures (>135°C),

results in partial aggregation of proteins of milk fat globule membrane and a more dense membrane that is less permeable.

Severe heat treatment above 100°C gives rise to brown pigments (melanoidin polymers) in milk. The Maillard reaction between the ε-amino group of lysine residue of proteins and carbonyl group of lactose gives brown color to milk. Such heat treatment also results in nutritional compromise. Cooked flavor results from the production of sulfhydryl groups arising from the breakdown of disulfide linkages.

64.6.6.6 Heat Stability. In the manufacture of certain high heat treated/concentrated milk products, heat stability of milk plays a significant role. A number of factors interact in a complex manner, which ultimately determines the heat coagulation of milk. On the basis of significant findings the role of various interacting factors may be summarized as follows.

Protein Composition. Various genetic variants of the casein fractions display variable heat stability. The heat coagulation of milk is related to the ratio between κ-casein and β-lactoglobulin. Higher heat coagulation temperature is observed at higher levels of β-lactoglobulin.

Mineral Balance. The heat stability of milk is mainly determined by the make up of proteins as well as the relative concentration of various salts present in colloidal and ionic states. The molar ratios between various cations and anions (both monovalent/polyvalent) strongly impact the physical equilibria of milk and the heat stability. Heat stability is maximum at the optimum salt equilibria defined by the relative concentration of Ca^{2+}, Mg^{2+}, $citrate^{3-}$, and $phosphates^{3-}$.

The molar ratio between cations and anions mainly determines whether milk will be stable at certain temperature and pH employed for processing. When milk is heated, salts of calcium and magnesium display an inverse solubility curve manifested by progressive transition of calcium and manganese from colloidal state to the ionic state. However, the solubility of the salts of sodium and potassium increases with the rise in processing temperature.

pH. The pH plays a critical role in determining the heat stability of milk. The pH effects both the molecular disassociation of casein components and formation of aggregated protein complexes through protein–protein interactions. Further, pH strongly affects the salt equilibrium between the colloidal and ionic states of the minerals of milk. Maximum heat stability is observed between pH 6.6–6.8.

Concentration of Milk Solids. In general, the heat stability of milk decreases progressively as milk is concentrated to higher levels of total solids. This is accompanied by concomitant shift of salt from ionic state to the colloidal state as well as drop in the pH values.

Homogenization. Although fat itself does not affect heat stability of milk, homogenization of milk brings about certain significant changes in the physical equilibria of milk. During homogenization of milk, the original fat globule is disrupted and surface area increases by many folds. Resurfacing of the newly formed fat globules take place instantly, predominantly by the adsorption of micellar casein. A shift in the colloidal

state due to the adsorption of caseins affects the equilibria between the colloidal and ionic states, which ultimately reduces the heat stability, although only marginally.

64.6.7 Density and Specific Gravity

64.6.7.1 The Density. The density of milk (mass/volume) is the sum total of the densities of its constituents, their concentration, and state at a particular temperature. The density of milk is a useful parameter to convert volumetric measurements to gravimetric and vice versa. Milk is purchased on weight basis and is sold in volumetric packages. Yogurt is sold in avoirdupois/weight units, while fermented milks are packaged in volumetric unit. Most of the dairy plants process milk and other products in gallons, a volumetric measure. Density is also useful in estimating degree of concentration during condensed milk manufacture by a simple hydrometer reading.

Milk density at 20°C ranges from 1.027 to 1.033 with an average of 1.030 g/cm^{-3}. Accordingly, the weight of 1 L of milk would range from 1.027 kg to 1.033 kg. The density of milk at 20°C can be calculated according to the following formula.

$$d_{20^\circ C} = \frac{100}{F/0.93 + SNF/1.608 + Water\%} g/cm^{-3}$$

where, d represents density, F = %fat, SNF = %solids-not-fat, and Water% = 100-F-SNF.

The density of some fluid milk products is given in Table 64.19.

64.6.7.2 The Specific Gravity. The specific gravity of milk is the ratio of density of milk to that of water at a given temperature. Yogurt mix and other dairy mixes containing sugar and added milk solids exhibit higher density and specific gravity than milk. For instance, the specific gravity of ice cream mix is 1.0544–1.1232, while that of fresh whole milk lies in the range 1.030–1.035, with an average of 1.032. Milk fat, milk solids-not-fat, skim milk, and evaporated whole milk, at 15.5°C, have specific gravity of 0.93, 1.614, 1.036, and 1.066, respectively. The specific gravity of milk is influenced by the proportion of its constituents, each of which has a different specific gravity approximately, as follows: water, 1.000; fat, 0.930; protein, 1.346; lactose, 1.666; salts, 4.120; and solids-not-fat, 1.616. As the milk fat is the lightest constituent, the more there is of it, the lower the specific gravity will be and vice versa. Determination of density of milk is

TABLE 64.19 Density of Fluid Milk Products at Various Temperatures.

	Density (kg cm^{-3}) at Various Temperatures			
Product	4.4°C	10°C	20°C	38.9°C
Raw milk, 4% fat	1.035	1.033	1.030	1.023
Homogenized milk, 3.6% fat	1.033	1.032	1.029	1.022
Skim milk, 8.9% SNF	1.036	1.035	1.033	1.0026
Half and half, 12.25% fat	1.027	1.025	1.020	1.010
Light cream, 20% fat	1.021	1.018	1.012	1.000
Whipping cream, 36.6% fat	1.008	1.005	0.994	0.978

Source: Goff and Hill (1993).

carried out by first warming the milk to 40°C to allow melting of fat and then adjusting the temperature down to desired working temperature.

The percentage of total solids or SNF in milk can be estimated by the following formula:

$$\%\text{TS} = 0.25\text{D} + 1.22\text{F} + 0.72$$
$$\%\text{SNF} = 0.25\text{D} + 0.22\text{F} + 0.72$$

where, D = 1000 (d − 1), d = density of sample of milk at 20°C, F = fat percentage of sample.

64.6.8 Viscosity

The viscosity of milk and cream creates the impression of "richness" to the consumer. From an organoleptic standpoint, viscosity contributes to mouth feel and flavor release. Fluidity is the inverse of viscosity. It has a bearing on fat separation/creaming, rate of heat transfer and flow conditions during processing of milk. Assuming laminar flow with parallel stream lines, viscosity may be defined as the ratio of shearing stress (force per unit area) to shear rate (velocity difference divided by distance, in reciprocal seconds). In dairy industry, the common units are centipoise (cp) or (poise $\times 10^{-2}$).

Viscosity of milk and dairy products depends on the temperature and on concentration and state of casein micelles and fat globules. Representative values at 20°C are whole milk: 1.9 cp, skim milk 1.5 cp and whey 1.2 cp. Viscosity of milk and cream increases with homogenization and the increase is proportional to the homogenization pressure. Increase in viscosity can be attributed to the fine state of fat globules and formation of a coat of plasma proteins on them.

The casein micelles of milk contribute more to the viscosity of milk than any other constituent. Viscosity varies not only with changes in physical nature of fat but also with the hydration of proteins. Alterations in the size of any dispersed constituents result in viscosity changes. The fat contributes less than caseins but more than whey proteins. When fat globules are greatly subdivided by homogenization, an increase in viscosity is observed. The viscosity of skim milk decreases on heating to 62°C after which it increases apparently due to changes in protein hydration. An increase in temperature causes a marked reduction in viscosity. For example at 20°C, milk is about half as viscous as at 0°C, and at 40°C, is approximately one-third of the value at 0°C.

Viscosity is critical in the texture development of yogurt and cultured milks. It is a crucial attribute in defining mouthfeel, flavor release, and refreshing quality of the product. It forms an important parameter in quality control programs of culture dairy plants. In yogurt, the viscosity is of the order of 15,000 to 25,000 centipoises.

64.6.9 Surface Activity

It is involved in adsorption phenomena and the formation and stability of emulsions. It is relevant to creaming, fat globule membrane function, foaming, and emulsifier use in dairy products. Normal cow milk has an inherent surface activity. Its surface

tension approximates 70% of that of water (72 dynes/cm). The surface tension of cow whole milk ranges from 50 to 52 dynes/cm, and for skim milk, 55–60 dynes/cm at 20°C. For cream it is approximately 46–47 dynes/cm. Casein, along with the proteolysis products protease-peptones is largely responsible for the surface activity. Whey proteins make little contribution. Fat reduces surface tension by a physical effect. Lactose and most of the salts tend to raise it when they are present in true solution.

Surface tension decreases as milk temperature rises. Processing treatments such as heating, sterilization, homogenization, and shear tend to increase surface tension. However, homogenization of imperfectly pasteurized milk or contamination of homogenized pasteurized milk with raw milk causes partial hydrolysis of milk fat resulting in low surface tension, bitter flavor, and rancidity of milk.

64.6.9.1 Foaming. Milk and milk products high in milk fat and/or milk proteins interact frequently with air and form foams. Sometimes the process is desirable as in whipping of cream and sometimes it has a nuisance value as in handling of skim milk. Fat globules and free fat make foam less stable. Heating of milk to such an extent that whey proteins are denatured yields more voluminous and more stable foam on heating. However, sterilization diminishes its foaming capacity. A concentrate of 30% dry matter that has been vigorously homogenized forms very stable foam.

Foaming of milk is minimum at 30–35°C. At 60°C, the foam volume is independent of the fat content. Below 20°C and above 30°C, the foaming tendency appears to increase. Fat tends to stabilize the foam formed below 20°C, for instance, during churning for butter production. Skim milk produces slightly more stable foam above 30°C than whole milk or light cream.

The formation of stable foam depends upon two main factors. First, the lowering of the surface tension allows the gathering and spreading of the surface-active components into thin films. Second, the films must be sufficiently elastic and stable to prevent the coalescence of the gas cells. Stable foam is thus formed when the surface tension of the liquid is not great enough to withdraw the film from between the gas cells and when the stabilizing agent has great internal viscosity.

Foaming properties affect handling of milk products and how dairy-based ingredients are incorporated into other products. Foam formation and its stability constitute important factors in getting the necessary overrun and texture in ice cream and frozen dairy desserts including frozen yogurt and whipped yogurt. Many yogurt plants use antifoaming agents as processing aid to control foam formation during the preparation of yogurt mix. Foam control is also necessary from proper pasteurization standpoint because organisms suspended in foam are resistant to common heat pasteurization time–temperature regime.

64.6.10 Curd Tension

This property is considered important in relation to the cheese making characteristics as well as digestibility of milk. The curd tension of milk is 28–54 g. Heat treatment of milk causes a reduction of curd tension, as does homogenization treatment. Addition of some of the salts such as the sodium citrate and sodium hexametaphosphate tend to reduce the curd tension of milk.

64.6.11 Colligative Properties

64.6.11.1 Osmotic Pressure. The number of molecules or particles, not the weight of solute, control osmotic pressure; thus 100 molecules of size 10 will have 10 times the osmotic pressure of 10 molecules of size 100. It follows that for a given weight, the smaller the molecules the higher the osmotic pressure.

Milk is formed from blood, the two being separated by a permeable membrane; hence they have the same osmotic pressure. In other words, milk is isotonic with blood. The osmotic pressure of blood is remarkably constant although the composition, as far as pigment, protein and so on, are concerned, may vary. The osmotic pressure is basically a function of salt balance and lactose content of milk.

64.6.11.2 Freezing Point. Pure water freezes at 0°C. Milk freezes at a temperature slightly lower than water due to the presence of soluble constituents such as lactose and soluble salts. Freezing point of milk depends on molar concentration of its soluble, low molecular weight compounds. Lactose, potassium, sodium, and chloride are the principal milk constituents responsible for 75–80% of the entire freezing point depression. Since it is a fairly constant property of milk, it is routinely used for detecting adulteration of incoming milk with water, using a cryoscope. Adulteration of milk with water lowers the molal concentration of lactose and salts, and thus increases the freezing point. Earlier work was done with Hortvet Cryoscope using mercury-in-glass thermometer and results on freezing point were based on Hortvet scale. More recent work with thermistor measuring devices has shown that Celsius and Hortvet scales are not identical. The following relationship has been reported (Harding 1995).

$$^{\circ}\mathrm{C} = 0.96418^{\circ}\mathrm{H} + 0.00085$$
$$^{\circ}\mathrm{H} = 1.03711^{\circ}\mathrm{C} - 0.00085$$

Accordingly, −0.540°H is actually −0.521°C. Most of the industry data is reported in °H. Freezing point depression is positive version of freezing point. Accordingly, freezing point depression of 0.540°H is equivalent to freezing point of −0.540°H. On adulteration with water, zero degree being the reference point, freezing point depression (FPD) decreases, while freezing point registers an increase. Milk from individual cows shows a narrow range in their FPD (0.530–0.525), but pooled milk has average of 0.543°H. It is generally agreed that milk of FPD higher than 0.535°H may be presumed to be water free. But readings between 0.530°H and 0.534°H warrant a letter to the supplier for a check on their plant operation. When FPD readings are between 0.525°H and 0.529°H, there is a strong suspicion of added water to the milk. Any time, the reading is 0.525°H or less, assumption of extraneous water in milk is justified.

We will now illustrate how freezing point method detects adulteration of milk with extraneous water. Milk with no added water should freeze at −0.540°C. When 10% water is added, its freezing point should be −0.486°C. As little as 3% water added to milk can be detected by this method. In general, percentage added water is calculated as follows:

$$\%\ \text{added water} = \frac{0.540 - \text{FPD}}{0.540} \times (\text{100-total milk solids})$$

Fermented milks show significant lowering in FPD because of conversion of lactose to lactic acid and transformation of minerals to ionic form. The freezing point of cream, skim milk, and whey are identical with that of the milk from which they are prepared. Therefore, the freezing point test does not detect the addition of skim milk or removal of fat from milk samples. Moreover, watered milk, which has soured, may pass the test because souring results in an increase of the FPD due to an increase in the amount of soluble molecules. Hence, the freezing point should be determined in fresh samples (having no developed acidity) for greatest accuracy.

64.6.11.3 Boiling Point. A solution boils at a higher temperature than does the pure solvent, according to the concentration of the dissolved substance. The milk constituents in true solution are mainly responsible for the elevation of the boiling point above 100°C. Elevation of the boiling point is based on the same principles as depression of freezing point. However, for detecting added water, the freezing point method is far superior on the grounds of accuracy and convenience. The boiling point of milk is 100.17°C.

65.1 INTRODUCTION

Throughout the world, large domestic livestock such as cows, goats, sheep, water buffalo, and to lesser degree, other mammals including horses (Malacarne and others 2002), camels (Al-Awadi and Srikumar 2001), and even reindeer and African eland are utilized for their milk. Equally reputable sources report different concentrations of components for individual milk components and production capacities of various mammals. Variability in reported values is not surprising, considering that milk yield, somatic cell count and milk components are all influenced by breed, parity, type of birth, nutrition, environmental conditions, stage of lactation, and genetic variability across and within species (Gonzalo and others 1994; Goonewardene and others 1999). Interspecies variability likely results from physiological metabolic process differences in the species as well as varying needs of the respective young (Jenness 1988).

Intraspecies variability in milk production and individual milk components results from genetic mutations, parity, multiple births, season, stage of lactation, and so on. For instance, milk production is stimulated by long-day photoperiod (Dahl and others 2000). Milk production, and subsequent lactation casein yield, typically increases as parity increases (Hayes and others 1984). Similarly, milk yield increases with number of offspring in a single birth (Goonewardene and others 1999). Within a single lactation, milk production reaches a peak after about 4 weeks, remains relatively high up to 5 or 6 months, after which production decreases rapidly (Bertilsson and others 1997). However, fat and protein production are inversely related to milk production. With advancing age of cows, whey protein concentration increases, while β-casein concentration declines (Ng-Kwai-Hang and others 1987). Finally, milk production tends to decrease in times of external stress such as weather extremes or injury, and serum protein is more subject to environmental influences than casein (Hayes and others 1984). In summary, lactation is influenced both by genetic and environmental factors (Togashi and Lin 2004). This chapter will focus on several genetic factors that influence variability in milk composition within and across ruminant species, and the implications of compositional differences on dairy products.

65.2 INTERSPECIES AND INTRASPECIES GENETIC VARIATION

65.2.1 Production

In the United States, cows are the species of choice for milk volume production. The commercial significance of cow milk ensures that it is the most exhaustively studied of all milks. As of December 31 2005, 8.2 million milk cows were reported to be in the 23 largest milk-producing states. This number is up 82,000 cows from the previous year. For the year 2005, milk production in those top 23 states totaled 73.1 billion kg (National Agricultural Statistical Service 2006).

Although cows predominate in the relatively pampered conditions that define western dairy farms, elsewhere in the world, goats, sheep, and water buffalo are commonly utilized for their durability in extreme conditions. Goats are utilized in areas where grass and other feeds are sparse. The goat typically covers 10 km per day foraging and makes use of browse (Haenlein 2001), yielding an advantage in climates that experience seasonal droughts and subsequent exhaustion of grass resources. The goat also has a high digestive rate, permitting a more rapid passage of poor quality feeds (Haenlein 2001).

TABLE 65.1 Production and Composition of Cow, Goat, and Sheep Milk Compared.

	Cow	Goat	Sheep
Component (%)	Mean	Mean	Mean
Water	87.1	87	83.2
Protein	3.4	3.6	5.9
Casein	2.7	2.9	4.7
Whey	0.7	0.8	0.9

Source: Adrizzo 1992; Haenlein and Ace 1984; Holsinger 1982; Jenness 1980; Loewenstein and others 1980; Morand-Fehr 1982; Ramos and Juarez 1986.

At the end of 2002, there were 1.3 million goats in the United States, and worldwide, more people consume the milk of goats than of any other species (Haenlein 2001; Anonymous 2002). In 1988, the total worldwide milk production was 524 million tons. Of that total, goats and sheep accounted for about 8.2 tons (7420 kg) and 9.0 tons (8145 kg), respectively (Anonymous 2002). In addition to goats being used as an alternative to cows for milk production, water buffalo have also been used, as they prosper in the tropical environments in which they evolved. They are especially efficient as a dual use animal in less developed Asian countries where they are also used for draft (Thu 1997), and can outperform cows (Thu 2003) when fed regional crop residues, such as rice straw (Thu 1997).

While cows produce the greatest quantity of milk per animal, cow milk typically contains more water than other species with lower production capacities (Table 65.1). Sheep milk has significantly more total solids than cow or goat milk, and is a rich source of fat and protein, particularly casein. As approximately 90% of the fat and 90% of the protein from milk are retained in cheese, it is logical that sheep milk has a higher cheese yield compared to the cheese yield of cow milk. The reason why cheese yield from goat milk is not higher than cow milk, though it would be expected to be higher than reported, will be explained later in this chapter. Mammals producing milk with even higher nutrient density than the reported species include rabbit, reindeer and whale, with differences attributed to the specialized nutrient needs of their young.

A great deal of genetic variation in milk production and milk composition can be observed for the common U.S. cow and goat breeds (Tables 65.2 and 65.3, respectively). The Holstein cow breed stands out as the milk volume producer, while Jerseys stand out as

TABLE 65.2 Influence of Breed on Gross Composition of Cow Milk.

Breed	Water (%)	Fat (%)	Protein (%)	Lactose (%)	Ash (%)	Weight† (kg)
Jersey	85.6	5.1	4.0	4.8	0.8	5060
Guernsey	86.0	4.7	3.8	4.7	0.8	5270

highest milk component producers. For goats, Nubians produce milk with the richest composition, while Saanens lead in milk volume production. Although the implications of differences in production capacity are obvious and translate to differences in overall volumes of milk, the implications of component differences are worthy of greater elaboration and will be discussed individually.

65.2.2 Composition

65.2.2.1 Milk Fat. For all species, fat is the most variable component in milk. The contributions that fat makes to the flavor of dairy products has driven research into that component. In humans and cows, fat composes roughly 4% of the milk, but the proportion can rise to as high as 50% among marine mammals (Oftedal and Iverson 1995). Fat possesses a high caloric density, while exerting little osmotic pressure, and permits delivery of large quantities of energy to the suckling neonate.

What stands out most when comparing the fatty acid (FA) composition of human and ruminant milk is the predominance of short and medium chain length FAs in ruminant milk. For the food scientist, these short and medium chain FAs are particularly important as flavor elements. The presence of short and medium chain FAs is likely dictated by the requirement that the milk fat of each species possess a melting point near the body temperature of the animal. Short and medium chain FAs in ruminants substitute for the unsaturated FAs in nonruminants in depressing milk fat melting points.

Milk fat, composed primarily (97%) of triacylglycerides, is synthesized in the mammary gland, either *de novo* (new) or from blood precursors. Short chain FA (C : 4 to C : 14) components of milk fat are synthesized *de novo*, almost exclusively, in the cytoplasm of mammary gland epithelial cells (Table 65.4). In all species, *de novo* synthesis requires

TABLE 65.4 Proportional Contribution of Sources of Fatty Acids (FA) in Cow Milk.

Fatty Acid	% of FA from De Novo Synthesis	% of FA from VLDL Fatty Acid
C4–C10	100	0
C12	80–90	10–20
C14	30–40	60–70
C16	20–30	70–80
C18	0	100

Source: Iverson and Oftedal 1995.

short carbon chains (acetyl-CoA), and reducing equivalents (nicotinamide adenine dinucleotide phosphate, reduced form). In the ruminant, the carbon sources used for FA synthesis are acetate and β-hydroxybutyrate (Grummer 1991) while in nonruminants, glucose is used for a carbon source in FA synthesis (Dils 1983). Similarly, about half of the palmitic acid (C : 16) found in milk is synthesized in mammary tissue (Mansbridge and Blake 1997). This *de novo* fat synthesis in the mammary gland accounts for approximately half of the total milk fat, depending upon the species. The remaining fat is derived from the blood. Early in lactation, these fats are mobilized from endogenous stores, but as the lactation progresses, the diet becomes the largest contributor (Grummer 1991).

In nonruminants, since the FA composition of the diet can directly affect the FA composition of the milk, feeding supplemental dietary fat can increase milk fat yield and FA composition of the milk fat (Iverson and Oftedal 1995). Ruminant milk fat composition is not greatly influenced by diet, as diets are typically low in lipids and dietary lipid is metabolized by rumen microflora (Grummer 1991). One notable exception is the antitumorigenic conjugated linoleic acid (CLA), which can be increased in milk by feeding the ruminant a diet high in linoleic acid (Kelly and others 1998) CLA results from the incomplete reduction of linoleic acid by rumen microflora. FA profiles can be manipulated to a degree with bypass fats, which allow the lipids to pass directly to the intestine and become part of the FA profile of the VLDL and chlyomicrons (Jensen 2002; Perfield and others 2002; Sanz and others 2004). Bypass fats are encapsulated or otherwise protected from the rumen environment.

In addition to containing higher percentages of fat (Table 65.1), goat and sheep milks naturally contain a higher proportion of short-chain volatile FAs than cow milk (Haenlein 2001). The volatile FAs, including butyric acid (C : 4), caproic acid (C : 6), caprylic acid (C : 8) and capric acid (C : 10), have characteristic aromas and flavors, commonly referred to as "goaty." These short chain FAs could not contribute to the evolution of "goaty" flavors in milk were it not for lipolysis. Short chain FAs are preferentially esterified in the labile *sn*-3 position of the triacylglyceride, though the preference diminishes as the chain lengthens. Similarly, lipase preferentially de-esterifies the *sn*-3 position four-to-one over the *sn*-1 position (Jensen and Newberg 1995). As such, the incidence of shorter chain FAs in the *sn*-1 position contributes disproportionately to flavor development. Even refrigerated milk can undergo lipolysis due to the action of lipoprotein lipase (LPL). Although cow milk contains high levels of endogenous LPL, the rate of "spontaneous lipolysis" in cow milk is less than in goat milk, possibly due to the differing compartmentalization of LPL. In goat milk (and human milk), LPL is bound to the milk fat globule membrane. However, in cow milk, LPL is bound to the casein micelle (Chilliard and others 2003). This compartmentalization can be disrupted by handling. Both rapid cooling and rough mechanical treatment of raw milk can dislodge LPL from the casein micelle, permitting it to reattach itself to the milk fat globule, facilitating spontaneous lipolysis (Swaisgood 1995).

It is notable that goat milk contains a small amount of 4-ethyldecanoic acid, noted for imparting a distinctly "goaty" flavor or smell. This FA has the lowest flavor threshold level yet determined and may serve the goat as a pheromone (Brennand and others 1989). Additionally, individual caprine breeds exhibit a wide variability in LPL activity and its attendant rate of spontaneous lipolysis. The LPL activity measured in Norwegian goat milk is 70 μm FA lipolyzed/h/mL, which correlates to a spontaneous lipolysis rate of 4.6 mmol of FFA/day/L. In Alpine goat milk, these activities are 35 μm FA lipolyzed/h/mL, with a spontaneous lipolysis rate of 0.5 mmol of FFA/day/L. In Saanen milk,

the activities are 21 μm FA lipolyzed/h/mL and the spontaneous rate is 1.1 mmol of FFA/day/L (Chilliard and others 2003). Thus, one would expect the Norwegian goat to exhibit the most rapid spontaneous development of goaty flavors. It is important to note that the rate of spontaneous lipolysis is not directly proportional to total LPL activity.

Among commercially milked species, all exhibit a high degree of saturation (Table 65.5). Saturated FAs compose 70%, 69%, 68%, and 66% of total fat in buffalo, sheep, goats, and cows, respectively. Polyunsaturated FAs are limited in these species, with sheep milk possessing the highest degree of polyunsaturation and buffalo milk the lowest (Table 65.5). All of the unsaturated FAs have long chain lengths. Monounsaturated FAs range from 26% to 30% in all species presented.

Goat milk may be described as "naturally homogenized" because little or no surface cream layer forms during storage. This is the result of two qualities of goat milk. First, goat milk lacks agglutinins (Jenness 1980; Attaie and Richter 2000; Haenlein 2001). Agglutinins, including immunoglobulin M, are "sticky" proteins that aid in the agglomeration or clumping of fat globules in cow milk (Huppertz and others 2003). Second, goat milk contains a higher proportion of small fat globules than cow milk (Attaie and Richter 2000; Haenlein 2001). Individual goat milk fat globules range from approximately 0.7 to 8.6 μm in diameter, while cow milk fat globules range from approximately 0.9 to 15.8 μm in diameter (Attaie and Richter 2000). Although higher in fat content, ewe milk also creams slowly both at room and refrigerator temperatures (Fahmi and others 1956a). The range and size distribution of ewe milk fat globules closely resembles those of goat milk (Fahmi and others 1956b). In a comparative study, Attaie and Richter (2000) found that 90% of the fat globules in goat milk were less than 5.1 μm in diameter,

while 90% of the fat globules in bovine milk were less than 6.4 μm. Camel (*Camelus dromedarius*) milk also exhibits a very slow creaming rate for both raw and heated milk at refrigerator and room temperatures, even though fat globule size distribution is similar to cow milk (Farah and Ruegg 1991). It was concluded that insufficient quantity of agglutinin in camel milk was mainly responsible for the slow rate of creaming (Farah and Ruegg 1991). Supporting data can be found comparing creaming rates of cow and buffalo milks. Although the volume of the milk fat globule of the water buffalo is double that of the cow, its creaming rate resides between milks of goats and sheep and cows (Fahmi and others 1956a). Were globule size the sole contributing factor, buffalo milk would cream faster than cow milk.

65.2.2.2 Milk Sugar. In contrast to fat, lactose is not highly variable within commercially utilized species or individual animals. This lack of variability is dictated by the physiological requirement that milk and blood possess the same osmolarity. The health of the lactating animal requires that milk and blood must be in osmotic balance, though not necessarily in equilibrium. While proteins and minerals contribute to the osmolarity of milk, the primary osmole is milk sugar. In animals of commercial importance, this sugar is lactose. As the primary milk osmole, milk production (in terms of volume) is largely dictated by lactose synthesis (Kuhn 1983). Although milk production is highly correlated with glucose uptake by the mammary gland, blood glucose availability is not generally a limiting factor in cows (Miller and others 1991). This is critical, as essentially all glucose available to a ruminant is derived from gluconeogenesis since little glucose survives the rumen for absorption in the small intestine.

Lactose is synthesized in the Golgi lumina. The Golgi membrane is impermeable to lactose, so water must be drawn into the lumen to restore osmotic balance. This results in an observable swelling of the Golgi preceding its exocytotic attachment to the apical membrane. There may be more water absorption across the apical membrane, but ultimately the milk will achieve an osmotic pressure of 6.6 atmospheres, the same as blood (Mepham 1987).

Lactose, a disaccharide composed of glucose and galactose, is only found naturally in milk serum and it is structurally identical across all species. As such, goat milk must not be used as a substitute for cow milk for lactose intolerant patients. Among species, lactose ranges from absent (marsupials and polar bears), to as high as 5.6% in human milk (Mepham 1987). In humans, the osmotic consequence of this high lactose content is offset by exceptionally low protein, especially casein, and a low mineral content (Davies and others 1983).

In marsupials, lactose is replaced by the trisaccharide *O*-β-D-galactopyranosyl-(1 → 3)-*O*-β-D-*galactopyranosyl-(1 → 4)*-D-glucose (3′-galactosyl-glucose) (Messer and others 1980). In polar bears, an entire spectrum of polysaccharides fulfill the role of lactose (Urashima and others 2000). Oligosaccharides also make a considerable contribution to the carbohydrate content of human milk. These oligosaccharides compose up to 1.4% of the content of human milk (Coppa and others 1999), exceeding protein as the third greatest component of milk. Some of these oligosaccharides are also found in ruminant milk, although at a much lower concentration (Martin and Addeo 1996). While lactose is critically important in fermented dairy products and must be managed in frozen dairy products, the significance of these oligosaccharides to dairy product manufacture is even less well understood than its role in neonatal nutrition. The evolutionary purpose of these oligosaccharides has not been clearly elucidated, although some

oligosaccharides seem to possess antibacterial and antiviral activities (Kawakami 1979; Dai and others 2000) in the human intestine and may defend against gastrointestinal infections by favoring bifidobacterial colonization of the infant intestine (Rueda and others 1998; Newburg 2000). As such, it seems conceivable that these oligosaccharides might also influence microbial growth in dairy products.

65.2.2.3 Milk Protein. The milk of cows, goats, and sheep all contain the major caseins, alpha$_{s1}$-(α_{s1}-CN), alpha$_{s2}$-(α_{s2}-CN), beta-(β–CN), and kappa-(κ–CN) and whey proteins, beta-lactoglobulin (β–LG) and alpha-lactalbumin (α–LA) (Bouniol and others 1989; Brignon and others 1990; Bouniol and others 1993). However, the quantities and amino acid structure of each protein vary among and within species (Ono and Creamer 1986). The structure of cow and goat milk casein micelles, as well as the four proteins that make up the micelles, are remarkably similar (Brignon and others 1990), however the proportion of the casein and the size of the micelles differ. Average micelle diameter is 175, 255, and 202 nm in the milk of cows, goats, and sheep, respectively (Brulé and others 2000). Casein composition in caprine and bovine milks is summarized in Table 65.6. While the predominant casein in cow milk is α_{s1}-CN, β-CN predominates in goat milk. This has implications for cheesemaking, which will be discussed in more detail later in this chapter.

In cow milk, submicellar aggregates are primarily assembled from α_{s1}-CN : κ-CN and α_{s1}-CN : β-CN, which are held together with hydrophobic bonds and salt bridges (Ono and Creamer 1986; Walstra 1990). However, in goat milk, β-CN self-association complexes and κ-CN : α_{s2}-CN complexes prevail because α_{s1}-CN is limited (Brulé and others 2000; Ono and Creamer 1986). κ-CN appears to have a similar size-determining role and surface function in both species' micelles (Ono and Creamer 1986; Walstra 1990; Tziboula and Horne 1996).

Goat milk micelles have greater mineralization, calcium, and phosphate, and lower hydration than cow milk micelles, possibly accounting for the lower heat stability and more ready sedimentation and coagulation of goat micelles even at cool temperatures (Jenness 1973; Ono and Creamer 1986; Brulé and others 2000). At low temperatures, β-CN dissociates from the micelle as seen in cow milk, but more freely (Ono and Creamer 1986).

Genetic variants in the amino acid sequence of cow milk proteins have been well documented (Eigel and others 1984; Gonyon and others 1987; Huang and others 1994). Gonyon and colleagues (Gonyon and others 1987) suggested that genetic differences account for approximately 25% of the variation in milk yield and as much as 50% of the variation for fat, protein and solids-non-fat in milk. Genetic variants not only influence milk composition, but also gelation properties and cheese-producing ability (Aleandri and others 1990; Huang and others 1994). For instance, Aleandri and others (1990) showed

TABLE 65.6 Average Casein Composition of Caprine and Bovine Milks.

Casein	Percentage in Caprine	Percentage in Bovine
α_{s1}-CN	4–26	36–40
α_{s2}-CN	5–19	9–11
β-CN	42–64	34–41
κ-CN	10–24	10–13

Source: Walstra and Jenness 1984.

that α_{s1}-casein genotypes significantly influenced milk yield, fat yield, and protein yield. Bovenhuis and others (1992) reported that the β-LG gene or a very closely linked gene affects fat percentage, while κ-CN or a very closely linked gene affects protein percentage in milk. They reported that effects of β-CN genotypes on milk production, fat percentage, and protein yield were significant. The β-LG genotypes also had important consequences on milk production and protein yield, but the authors could not conclude whether those outcomes were due to effects of milk protein genes themselves or to effects of linked genes (Bovenhuis and others 1992).

Although percent protein in cow milk is positively influenced by α_{s1}-CN and κ-CN genotypes, an increase in percent protein does not necessarily increase lactation protein yield because total milk yields may actually be lower (Aleandri and others 1990). A balance must be achieved between milk yield and the ability of the milk to be made into cheese, if cheese is the goal. Aleandri and others (1990) looked at associations between casein and whey protein genotypes in cow milk and found that some protein combinations result in better cheesemaking ability than others. It was concluded that selection can and should be based on genetic combinations that will lead to optimal cheese production, rather than on the basis of protein or fat content of the milk (Aleandri and others 1990).

The primary structures of the four caseins have been reported for goat milk (Richardson and Creamer 1973; Boulanger and others 1984; Bouniol and others 1989; Brignon and others 1990). Caprine α_{s1}-CN has 88% and 97% sequence homology with its bovine and ovine counterparts, respectively (Brignon and others 1989). α_{s1}-CN is particularly interesting because it influences milk, fat and protein yields and rennet coagulation properties of cow and goat milk (Ambrosoli and others 1988; Mariani and others 1988; Aleandri and others 1990). Goat milks with high α_{s1}-CN tend to have a greater content of total solids (including fat, protein, casein, and phosphorus), lower pH, and higher curd firmness and cheese yield than milks with low α_{s1}-CN (Ambrosoli and others 1988; Martin and Addeo 1996). Goat milks with low levels of α_{s1}-CN tend to exhibit shorter coagulation time and weaker resistance to heat treatments than milks with high levels of α_{s1}-CN (Ambrosoli and others 1988; Mora-Gutierrez and others 1993).

Genetic variation has been reported for goat α_{s1}-CN, α_{s2}-CN, β-CN, and κ-CN (Richardson and Creamer 1974; Brignon and others 1990; Martin and Addeo 1996). Genetic variation of goat α_{s1}-CN alone is under the control of approximately 10 alleles, which differ by substitutions or deletions of amino acids in the genetic backbone of each protein (Grosclaude and others 1987; Mahe and Grosclaude 1989; Brignon and others 1990; Martin and Addeo 1996). Grosclaude and colleagues (Grosclaude and others 1987) observed a positive correlation between polymorphisms of α_{s1}-CN and the total casein content in milk and suggested that each genetic variant plays a role in dictating α_{s1}-CN synthesis. Casein content was found to be higher in milks containing the "high type" alleles (α_{s1}-CNA, B, and C), and lower in milks containing "low type" alleles (α_{s1}-CND, F, and G) (Grosclaude and others 1987; Brignon and others 1990; Martin and Addeo 1996). The relative amounts of α_{s2}-CN, β-CN, and κ-CN increase as the relative amount of α_{s1}-CN decreases (Grosclaude and others 1987; Law and Tziboula 1992).

Research on protein polymorphism in sheep milk is limited. Apparently α_{s1}-CN and β-LG are polymorphic, but not in every breed (Brulé and others 2000). More research should be conducted in this area to confirm genetic variability and wider implications.

65.2.2.4 Milk Enzymes. Raw milk naturally contains low levels of endogenous enzymes, including alkaline phosphatase, plasmin, and lipase (Whitney 1988). The

absence of alkaline phosphatase after pasteurization indicates effective pasteurization was accomplished. Plasmin, which is stable at pasteurization temperature, hydrolyzes both β- and α_{s1}-CN in milk and in cheese during maturation (Banks and Williams 2004). Goat milk reportedly contains less alkaline phosphatase, lipase and xanthine oxidase than cow milk (Haenlein 2001).

Of particular interest in the category of naturally-occurring milk enzymes are lipases. It is reported that milk contains a major lipase with pH optimum 8.5–9.0, and two other lipases with pH optimum at 6.5–7.0, and at 7.9 (Jandal 1995). Lipases are associated with fat metabolism and with quality deterioration in dairy products (Jandal 1995). The lipoprotein lipase (LPL) found in milk is identical to the LPL in blood and represents a spillover from the mammary tissues (Weihrauch 1988).

Other enzymes of processing significance include lysozyme and lactoperoxidase. Lysozyme attacks the glycosidic bonds found in Gram-positive bacterial cell walls. The enzyme lactoperoxidase is employed in developing countries to preserve raw milk in the absence of refrigeration. When supplied with hydrogen peroxide and thiocyanate, lactoperoxidase will catalyze the formation of anti-Gram-positive bacteriocides (Jensen 1995a).

65.2.2.5 Milk Vitamins and Minerals. Since the purpose of milk is to serve the nutritional needs of the suckling neonate, it is expected that milk should supply micronutrient needs as well as requirements for protein and energy. As such, milk is well supplied with an appropriate balance of vitamins (Jensen 1995b) and minerals. Some of these nutrients are of importance in dairy processing, such as calcium and phosphorous, while others are primarily of nutritional interest.

As with lactose, low molecular weight water-soluble components such as minerals contribute to the osmotic balance between blood and milk. And, as noted above in the discussion of milk lactose, their total contribution to the osmotic pressure of milk must equal 6.6 atm. But milk is far richer in soluble carbohydrates, calcium, phosphorous, and potassium than blood, as these are compartmentalized in concentrations that far exceed that found in extracellular fluids. Milk contains 1/7 as much Na, five times as much K, 13 times as much Ca, and 10 times as much P as blood plasma (Peaker 1978). The chlorides and lactose in milk account for about 75% of milk's osmotic pressure.

Calcium and casein concentrations correlate closely with each other, as calcium and phosphate, and citrate, are all integral to the formation of the casein micelle in the Golgi apparatus (Neville and others 1983). Calcium is actively transported into the Golgi while phosphate appears in the Golgi as a consequence of lactose synthesis (Atkinson and others 1995). By assembling the casein complex from these building blocks, calcium and phosphorous are balanced with protein in concentrations adequate to support the rapid growth of the neonate. The cosecretion of calcium, phosphate, and casein ensures that this balance is maintained and explains why human milk is simultaneously low in calcium, protein, and phosphorous, relative to cows, goats, and sheep, and why sheep milk is highest among this group for these components.

Once again, vitamins appear in milk for use by the suckling neonate. As Darwinian fitness is determined by how successfully an individual produces viable offspring, the milk is well supplied with vitamins. That water-soluble vitamins appear in milk as a result of active transport is evidenced by the fact that vitamin levels are maintained in the milk even during episodes of maternal depletion (Picciano 1995).

65.2.2.6 Milk Somatic Cell Content. Somatic cells, including lymphocytes, neutrophils, and epithelial cells, are naturally higher in goat and sheep milks than in cow milk (Leitner and others 2004). While high somatic cell counts (SCC) are associated with mastitis in cow (Politis and Ng-Kwai-Hang 1988) and sheep milk (Gonzalo and others 2002), goats may have high SCC, even in the absence of mammary infection (Droke and others 1993; Haenlein 2002). Nonleucocytic cell-like particles are normally observed in goat milk as a result of the apocrine secretion process of the goat mammary gland (Oliszewski and others 2002). The cytoplasm of the milk-making cell (alveolus) breaks off when goat milk is produced in the udder (apocrine process), while little cell destruction occurs during production of cow and sheep milk (merocrine process). Because most somatic cell enumeration techniques do not distinguish between different cells, testing equipment and procedures are of limited reliability and applicability to goat milk, unless appropriate correction factors and calibration with goat milk are used. The only reliable method for arbitration seems to be the pyronin Y-methyl green stain (Haenlein 2002). The pyronin Y-methyl green stain test confirmed that bulk tank milk from commercial dairy goat herds in California, Arkansas, Michigan, and Wisconsin contained 9.9% macrophages, 2.8% lymphocytes, and 87% neutrophils (Droke and others 1993). SCCs tended to be high (greater than 1,000,000 cells/mL) and increased neutrophils contributed to high SCC in the bulk tank goat milk (Droke and others 1993). These species differences are reflected in the disparate standards for SCCs in cow and goat milk. Grade A goat milk is allowed a higher legal limit of somatic cells (1,000,000 cells/mL) than cow milk (750,000 cells/mL) (U.S. Department of Health and Human Services 1999).

65.2.3 Implications

65.2.3.1 Milk Fat. Since casein and fat are the principal components of cheese, milk fat content will obviously have implications upon cheese yield. In fact, the ratio of casein to fat is often standardized in cheesemaking, in order to ensure consistency and optimize yield. Failure to standardize can result in reductions in yield efficiency, lack of moisture control during manufacture, and production of substandard cheese that does not meet specifications for fat in dry matter (Banks and Williams 2004). From a nutritional standpoint, the amount of fat in a given cheese varies more in response to cheese making practices and moisture content than by genetic and species differences.

Due to the vulnerable nature of milk fat globule membranes, the presence of LPL, and the presence of unsaturated fats, milk fat of all species is vulnerable to a number of quality defects. Raw milk must be handled especially carefully, as LPL is active until pasteurization. Raw milk must not be excessively agitated or allowed to foam because milk fat globule membranes can be disrupted, enabling LPL attack on triacylglycerols. Raw milk must never be mixed with pasteurized milk, as the active LPL can enter the sensitized milk fat globules damaged by, and reformed after homogenization, causing lipolysis. Goat and sheep milk, with their greater structural exposure to LPL and higher concentration of short chain FAs in the *sn*-3 position, appear to be especially prone to rancid off-flavors.

It should be noted, however, that rancid flavors are often appreciated in cheeses, particularly feta, Romano, Roquefort, and blue. Goat milk cheeses naturally have piquant, pepper-sharp flavors, while sheep milk cheeses are smooth, mellow, and highly aromatic (Kosikowski and Mistry 1997). The high fat content of sheep milk does not necessarily translate to high fat content in cheeses (Table 65.7).

TABLE 65.7 Typical Compositions of Sheep, Cow, and Goat Hard Cheeses.

	Sheep Cheese Varieties			Cow Cheese Varieties			Goat Cheese Varieties	
Component	Feta	Manchego	Roquefort	Cheddar	Gouda	Blue	Metsovone	Corfu
Water (%)	47	43	39	38	43	42	42	36
Fat (%)	25	27	32	32	30	30	26	27
Protein (%)	19	25	21	25	25	20	27	30

Although pasteurization inactivates LPL, unsaturated FAs remain susceptible to the attack of light, metals, and free radicals (auto-oxidation). To minimize the potential for development of metallic off-flavors, milk should not contact copper or iron pipes or fittings (Bodyfelt and others 1988). Light-induced oxidation always occurs in glass and plastic consumer packages not shielded with UV-barriers. The extent of auto-oxidation is time dependent. Minor differences in levels of oxidation can be noted only by individuals trained in the art of detection, so minor differences in level of unsaturation in FAs among species, breeds, or animals are not of practical significance with respect to oxidation.

Goat enthusiasts frequently tout the digestibility of goat milk compared to cow milk, so a report on supportive research is appropriate for this chapter. Several investigators have studied the digestibility of goat milk compared to cow milk (Alfreez and others 2001; Barrionuevo 2002). The digestive utilization of fat was greater in rats receiving a diet of goat milk (rich in medium-chain triglycerides) than those given a cow-milk-based diet, and more closely approached the digestibility values obtained for olive oil. The consumption of goat milk reduced levels of cholesterol in the rats while levels of triacylglycerides and high-density lipoprotein remained within the normal ranges for the rats (Alfreez and others 2001). In a similar study, the apparent digestibility coefficient for iron in rats was highest with the goat milk diet, followed by the standard diet and lowest with the cow milk diet (Barrionuevo and others 2002). The apparent digestibility coefficient of copper was higher in the animals fed the goat milk diet than that in the two groups of animals fed the other diets. The studies suggest a beneficial effect of goat milk, with respect to cow milk, on the metabolism of fat, iron, and copper in control rats, especially those with malabsorption syndrome (Alfreez and others 2001; Barrionuevo and others 2002).

65.2.3.2 Milk Sugar. The presence of lactose, rather than glucose or maltose, as the primary carbohydrate in milk is of considerable consequence in the dairy industry. The capacity to hydrolyze galactose $\beta(1-4)$ glucose is rare among microorganisms (Newburg and Neubauer 1995) and facilitates our manufacture of fermented milk products. If more bacteria were able to rapidly use lactose, our manufacture of fermented milk products would be greatly complicated. Milk from our economically important species contains a surplus of lactose for lactic acid bacteria to utilize as their primary energy source in the conversion to lactic acid in fermented dairy products. Since lactose is not limiting to microorganisms, differences in lactose content in milk of species commonly used for fermented dairy products has little practical significance.

Lactose in milk is nearly unique in nature and its nutritional consequences are not well elaborated. But one clear advantage to lactose, compared to glucose, is that in secreting a dissacharide instead of a monosaccharide, the mammary gland can deliver twice the carbohydrate to the neonate without doubling the volume of milk, as osmotic considerations would otherwise demand. Also, as mentioned above, the galactose β(1−4) bond is rare in nature and few microorganisms can metabolize it. Finally, the galactose moiety may support galactolipid synthesis and consequently, neonatal brain growth (Newburg and Neubauer 1995).

Because the chemical structure of lactose is identical among species, individuals with lactose intolerance or who are lactose maldigesters will suffer similar consequences after drinking either cow or goat milk. Lactose maldigesters either lack or have reduced production of the enzyme β-galactosidase (lactase), required for the hydrolysis of lactose into its glucose and galactose subunits for subsequent absorption. Lactose maldigesters' intestinal discomfort arises from hindgut fermentation of the lactose by intestinal microflora. Lactose maldigesters need not and should not eliminate dairy products from their diet (Miller and others 2000). A patient's tolerance to dairy foods may be influenced by the amount of lactose, type of dairy food, whether the food has been fermented or hydrolyzed with an enzyme preparation, whether the lactose-containing food is eaten with a meal, and colonic adaptation (Miller and others 2000). A concentrated form of lactase may be consumed by patients, in the form of a tablet prior to ingestion of milk or ice cream, to ease potential symptoms. Lactase is also utilized by manufacturers to make a variety of commercial products for lactose maldigesters (Lactaid® milk and ice cream). Because lactose is reduced nearly to zero in most hard cheeses, lactose maldigesters need not avoid those foods. Additionally, buttermilk, yogurt and acidophilus milk are commonly comfortably consumed by lactose maldigesters because the microbial β-galactosidase aids in digestion of lactose (Miller and others 2000).

65.2.3.3 Milk Protein. From a technological standpoint, genetic variation in proteins can have profound effects on manufacturing properties of milk, including gelation properties, cheese curd formation, and cheese yield (Marziali and others 1986c; Ng-Kwai-Hang and others 1987). Huang and others (1994) demonstrated that subtle changes, involving as few as two amino acid residues in the primary structure of β-LG, resulted in significant changes in gelation temperature and rheological properties of the gel formed. Aleandri and others (1990) reported that α_{s1}-CN genotype significantly influenced milk yield, fat yield, protein yield, and lactation cheese yield, with the highest yields obtained for genotype BB. They also concluded that cheese yield was related to β-LG genotype, with highest estimates for the BB genotype (Aleandri and others 1990). κ-CN genotype BB was associated with the highest percentage of protein in the milk (Aleandri and others 1990). Marziali and Ng-Kwai-Hang (Marziali and Ng-Kwai-Hang 1986a,c) went as far as to report that milk containing β-CN A1A1, κ-CN BB and β-LG BB would maximize the solids entering the cheese mass, thus maximizing yield. Ojala and colleagues (1997) used a more conservative, multitrait animal model to estimate effects of κ-CN, β-CN, and α_{s1}-CN on fat percentage and milk and protein production in Holsteins. A joint effect of alleles had a positive relationship with production data. The authors cautioned that before their reported composite κ-β-α_{s1}-CN genotypes or the corresponding haplotypes be used for selection to improve milk production traits, the results be confirmed using sufficiently large data for more than on breed and/or within large herds (Ojala and others 1997).

It was stated earlier that goat milk contains significantly less α_{s1}-CN than cow milk. The consequences of this feature are two-fold, since α_{s1}-CN is a structural component of the casein micelle and plays a functional role in cheese curd formation (Walstra and Jenness 1984). Low levels of α_{s1}-CN result in soft curds and soft curds are associated with low cheese yields, even when total casein levels are similar (Marziali and others 1986c; Remeuf and Lenoir 1986; Ambrosoli and others 1988; Clark and Sherbon 2000a). Clark and Sherbon (2000a,b) reported that goat milk that lacked α_{s1}-CN had lower percentages of milk components and poorer coagulation properties than milk that contained α_{s1}-CN, suggesting that the presence of α_{s1}-CN in milk should improve coagulation properties. Since percent total solids, SNF and protein were more highly correlated with coagulation properties than α_{s1}-CN itself, quantification of the former was recommended to be more practical in predicting cheese-making potential than measuring α_{s1}-CN, which is more tedious and costly. Othmane and others (2002), who studied dairy sheep, also discouraged casein content as a selection criterion in dairy sheep. However, since heritabilities for protein and casein contents were very similar in sheep, the authors concluded that protein content is an adequate, more economical measure for selection.

One consequence of genetic polymorphism in proteins is the differing amino acid composition in individual caseins and whey proteins (Ng-Kwai-Hang and others 1987), but this difference is of minor nutritional significance. A quick comparison of the nutrient profiles of the most commonly milked species with human milk (Table 65.8) reveals a considerable disparity. Most notable are the much lower protein and mineral contents of human milk. The protein difference would appear to be even more considerable when one considers that, unlike ruminant milk, serum proteins predominate in human milk, with a consequently lower casein content (Jenness and Sloan 1970).

On the other hand, the amino acid profiles of the most commonly milked species do not depart radically from the profile of human milk (Fig. 65.1), especially among the essential amino acids, making the difference one of quantity rather than quality. Even so, infant formula manufacturers supplement their products made from cow milk to more closely resemble human milk.

One consequence of consuming nonhuman milk is the increased likelihood of adverse reactions to milk components. Infants, in particular, occasionally experience either cow milk protein allergy (CMPA) or cow milk protein intolerance, depending upon whether the reaction is immunological in origin (Host 1994). The incidence of adverse reaction

TABLE 65.8 Proximate Analysis of Milk from Different Species.

Proximate Analysis	Cow milk	Goat Milk	Sheep Milk (Amount/100 g)	Buffalo Milk	Human Milk

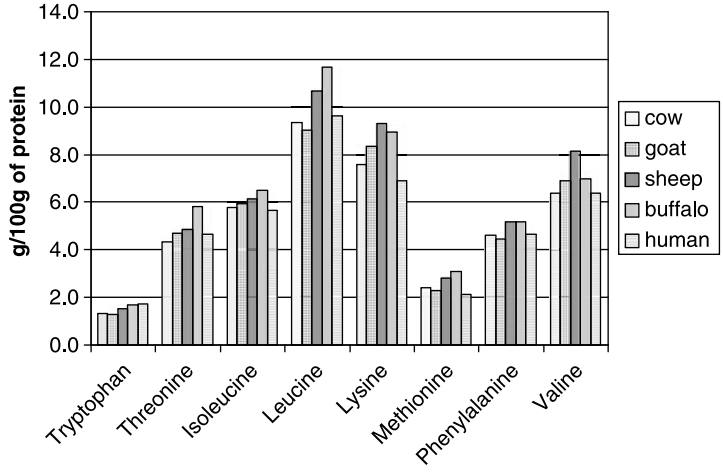

Figure 65.1 *Essential amino acid profiles of milk from various species (USDA 2004).*

to cow milk may be as high as 2% or 3%, with allergic reactions accounting for about 1.4%. Allergies may develop to any of the proteins in milk, including caseins, β-LG and α-LA (Bouniol and others 1993).

Contradictory results have been reported on the use of goat milk as an alternative to in cow milk in cases of allergy. Because of goat and cow milk composition similarities, immunologic cross-reactivity exists between many goat and cow milk proteins (Darnton-Hill and others 1987). Should a child exhibit allergic symptoms to cow milk, goat milk is unlikely to serve as a safe substitute, as there is a high rate of cross-allergenicity with cow milk (Dean and others 1993). However, due to genetic polymorphisms, cross-reactivity with goat milk proteins may not be experienced. A study was designed, using a guinea pig model of cow milk allergy, to test if discrepancies in allergic responses could be due to the high genetic polymorphism of goat milk proteins (Bevilacqua and others 2001). Fourty guinea pigs were fed over a 20-day period with pelleted diets containing either soybean proteins (group S), cow milk proteins (group CM), goat milk proteins with high (group GM1) or low (group GM2) α_{s1}-casein content. Parenteral sensitization to GM1 and GM2 proteins was measured (ADGA 2003) by systemic IgG1 antibodies directed against bovine or caprine β-LG, α-LA, and whole caseins, and (Al-Awadi and Srikumar 2001) by intestinal anaphylaxis. Guinea pigs fed on CM and GM1 developed high titers of anti-β-LG IgG1, with an important cross reactivity between goat and cow β-LG. However, in guinea pigs fed on GM2, anti-goat β-LG IgG1 antibodies were significantly decreased compared with GM1 guinea pigs, and the intestinal anaphylaxis was significantly decreased compared with that observed in GM1 guinea pigs. Animals receiving GM1 or GM2 proteins via the parenteral route developed a marked sensitization. These results suggest that discrepancies observed in the use of goat milk in cow milk allergy could be due, at least in part, to the high genetic polymorphism of goat milk proteins (Bevilacqua and others 2001).

Soy milk is a proposed alternative to cow milk formulas, but soy milk is not without its perils. In a study that switched young children with CMPA to soy milk, it was found that 14% developed allergic symptoms to the soy (Zeiger and others 1999). In addition to

allergic reactions, soy injects the added complications of feminizing phytohormones. Soy is rich in isoflavones and recent research into the effect of these compounds on humans, especially males, has given alarm (Setchell and others 1997). Infants receiving soy-based infant formulas are exposed to between six and 11 times the isoflavone dosage demonstrated to exert hormonal effects upon adults (Setchell and others 1997). Others have insisted that evidence yet revealed does not justify those concerns (Merritt and Hanks 2004).

65.2.3.4 Milk Enzymes. Raw milk is somewhat resistant to LPL because of the protective nature of the milk fat globule membrane (Weihrauch 1988). However, during milk processing (cooling, agitation, homogenization, and heat treatments), the milk fat globule membrane is altered, making it more susceptible to the action of LPL (Gervilla and others 2001). If activated by severe agitation, temperature fluctuations, or other means, LPL hydrolyzes FAs from triacylglycerides, leading to rancid off-flavors in milk and subsequent cheese. While rancid flavors may be expected and even desired in some cheeses (blue, Romano, feta), rancid milk is always offensive. Rancidity in milk may be detectable at acid degree values exceeding 1.2 meq/L (Bodyfelt and others 1988; Weihrauch 1988). Jandal (1995) demonstrated that LPL activity in both goat and cow milk increased with agitation and alkaline pH, and was reduced by pasteurization, cooling, sodium chloride addition, and acidic pH. As described previously, goat milk's reputation for being more susceptible to off flavors than cow milk is more likely due to vulnerable structure of the milk fat globule membranes (Chilliard and others 2003) than total LPL activity. Heating of milk to 80°C for 20 s. destroys all lipases in all milk (Weihrauch 1988). Regardless of species, to prevent enzymatic degradation, it is of critical importance to avoid agitation and foaming of dairy products, particularly raw milk. Pasteurization of milk soon after collection is a safeguard against rancid off-flavors in milk and subsequent manufactured dairy products.

65.2.3.5 Milk Vitamins and Minerals. As calcium and phosphorous are structural components of the casein micelles, content of these minerals in the milk will influence the end products of milk processing. Indeed, calcium is occasionally added to milk to increase curd firmness during Cheddar cheese manufacture (Lenoir and others 2000b). Calcium content is also known to influence the rheological properties of soft cheeses as well (Solorza and Bell 1998). Higher calcium content enhances rennet activity and protein–protein interactions by masking negative charges (Green and Marshall 1977).

One might then predict that the higher calcium content of sheep milk would yield a firmer cheese than cow milk. But as mentioned previously, the protein quantity and quality varies dramatically among species, making it impracticable to tease out the effects of endogenous minerals on product characteristics.

Residual calcium in the final cheese has been implicated as a contributing factor in calcium lactate crystal formation in Cheddar cheese (Dybing and others 1988).

Water soluble vitamins are satisfactorily heat stable, survive pasteurization, and find their way into most final products (Jensen 1995b). The exception is cheese, where most of the water soluble vitamins are lost in the whey because of their dissolution from the casein micelle at low pH (USDA 2004).

65.2.3.6 Milk Somatic Cell Counts. In cows, high SCCs are associated with mammary infection. SCCs of cow milk are also associated with milk coagulating

properties, including increased rennet clotting time and decreased curd firmness (Politis and Ng-Kwai-Hang 1988). Since firm curds improve efficiency of cheesemaking and reduce losses of milk components in the whey, reduced curd firmness translates to losses in cheese yield (Politis and Ng-Kwai-Hang 1988).

Regardless of SCC, mammary infections change milk composition, increase casein degradation, depress milk yield and cheese yield, and increase milk-clotting time (Leitner and others 2004). In sheep, analysis of 4352 monthly test-day records for milk yield, SCC, and bacteriology showed that uninfected ewes or ewes infected by minor pathogens had the lowest SCC and the highest milk yields, whereas those infected by major pathogens had high SCC and milk yield losses between 8.8 and 10.1% (Gonzalo and others 2002). Othmane and colleagues (Othmane 2002) demonstrated that a high SCC was accompanied by an in crease in serum protein content and involved a loss in milk yield in dairy sheep. Leitner and colleagues (Leitner and others 2004) reported a 30% reduction in milk yield in infected glands of goats, compared to the 53% reduction in milk yield of infected glands of sheep reported by Gonzalo and others (1994), suggesting greater vulnerability of sheep to subclinical mammary infections than goats. Because of the negative correlation between milk yield and SCC, El-Saied and others (1998) concluded that selection for increased milk yield alone should result in a decrease in SCC in dairy sheep.

65.3 SUMMARY/CONCLUSION

Considering that milk evolved from neonate nutrition, and was not originally intended to serve as a raw material for the food processor to make cheese, ice cream or yogurt from, nor for adolescents or adults to use as beverage, it is remarkable that milk has fulfilled these roles. The consistency, yet great variability of milks provided by different species or breeds within a species has provided us with a bountiful assortment of dairy products from which to choose. Cheeses made from sheep or goat milk possess flavors and textures not conveniently, or faithfully reproducible from cow milk. Additionally, the components of milk lend themselves to convenient modification for our palates. Understanding and appreciation of the commonalities and differences among the milks of domesticated animals, combined with technological advances in food science enables food scientists to explore and create beyond what was ever imagined when these treasured animals were first domesticated.
