Handbook of Food Products Manufacturing

The Wiley Bicentennial–Knowledge for Generations

Each generation has its unique needs and aspirations. When Charles Wiley first opened his small printing shop in lower Manhattan in 1807, it was a generation of boundless potential searching for an identity. And we were there, helping to define a new American literary tradition. Over half a century later, in the midst of the Second Industrial Revolution, it was a generation focused on building the future. Once again, we were there, supplying the critical scientific, technical, and engineering knowledge that helped frame the world. Throughout the 20th Century, and into the new millennium, nations began to reach out beyond their own borders and a new international community was born. Wiley was there, expanding its operations around the world to enable a global exchange of ideas, opinions, and know-how.

For 200 years, Wiley has been an integral part of each generation's journey, enabling the flow of information and understanding necessary to meet their needs and fulfill their aspirations. Today, bold new technologies are changing the way we live and learn. Wiley will be there, providing you the must-have knowledge you need to imagine new worlds, new possibilities, and new opportunities.

Generations come and go, but you can always count on Wiley to provide you the knowledge you need, when and where you need it!

Preface

It is obvious that professionals from the government, industry, and academia need reference books on the manufacturing of food products. Publishers serve this market by publishing three categories of books:

1. Books on the principles of food processing with or without a discussion of manufacturing selected food commodities. The discussion of the manufacturing of specific food products, if included, is usually limited to a representative few.
2. Books on the processing of one category of food products, for example, bakery, seafood, poultry. There are hundreds of such books in the market.
3. Multivolume reference books such as handbooks and encyclopedia covering all areas of food science, technology, and engineering, including the manufacturing of selected food products. Obviously, the number of food products included is also limited.

The cost and the relative need of multivolume reference books in food science, technology, and engineering make the purchase of books under the third group unrealistic and prohibitive for many libraries and personal bookshelves. The *Handbook of Food Products Manufacturing* is designed to fill the gap in the above book categories in terms of relative cost and coverage. It is presented in two volumes and has the following profiles:

- Covers the manufacturing of selected food products and the process of development of selected food products from specific food ingredients.
- Supplements many food processing texts already in the market.
- Serves as a general reference treatise of a reasonable size and cost that will provide information on manufacturing of some food products and topics of related interest.

One can appreciate the difficulty of this task from the simple observation that books with the same coverage are not common. The editors of this proposal, with the help of professionals from academia, government, and industry, hope to achieve these objectives. However, it is important to emphasize the following premises:

1. The coverage is not entirely comprehensive if one considers the wide spectrum of food products in the market. Additionally, scientific and technological advancement in food processing will always outpace publishing.
2. Several factors determine the selection of topics coverage:
   i. Some products are popular for many consumers.
   ii. Some products are seldom covered in other books on similar topics.
   iii. Expertise of members of the editorial team.
   iv. Availability of chapter contributors in terms of time, background, expertise, etc.
3. Since this is a general reference text, the depth of coverage is limited to competencies associated with general users rather than specialists.

Based on the above premises, these two volume texts cover the following chapters:

- Fifty-four chapters on the direct manufacturing of specific food products. These chapters cover: bakery, beverages, cheese, confectionery, fats and oils, fruits, meats, milk and dairy products, poultry, seafood, and vegetables.
- Thirty-two chapters on the use of specific food ingredients to develop food products new or otherwise. These chapters cover products development from many known food ingredients. The products to be developed cover traditional foods (food flavors, bakery, fruit juices, milk and dairy products, and poultry products) and new foods (fresh-cut fruits, functional foods for consumers, and medical foods for treating and preventing diseases).
- Five chapters on the recent development of food flavors in view of the role of food flavors in all aspects of food manufacturing. These chapters cover extraction, distillation, biotechnology, and other topics.
- Five chapters on legal requirements in the United States for food classification and manufacturing of food products such as good manufacturing practice (GMP), hazard analysis and critical control points (HACCP), and establishment inspection.

Although this book is relevant to many professions, it will probably be most useful to:

1. Undergraduate and graduate students for research for classroom assignments or preliminary research investigation for potential topics.
2. Professionals from industry, government, and academia interested in topics peripheral to their specialties.
3. Small start-up food manufacturing companies looking for potential products for development.

From the above list of potential users it is obvious that this book is uniquely designed for private or public libraries, small or large. This work is the result of the combined efforts of nearly 200 professionals from industry, government, and academia worldwide. They represent more than 35 countries with diverse expertise and background in the science and

technology of food manufacturing and food products development. An international editorial team of 13 members from five countries led these experts. Each contributor or editor was responsible for researching and reviewing subjects of immense depth, breadth and complexity. Care and attention were paramount to ensure technical accuracy for each topic. In sum, this volume is unique. It is our sincere hope and expectation that it will serve as an essential reference on the manufacturing of food products, for professionals in government, industry, and academia.

The editorial team wishes to thank all the contributors for sharing their expertise throughout our journey. We also thank the reviewers for giving their valuable comments on how to improve the contents of each chapter. All these professionals made this book possible. We trust that you will benefit from the fruits of their labor.

We know firsthand the challenges in developing a book of this scope. What follows are the difficulties in producing the book. We thank the editorial and production teams at John Wiley, Inc. and Techset Composition Ltd., Salisbury, UK, for their time, effort, advice, and expertise. You are the best judge of the quality of this work.

1.1 INTRODUCTION AND GOALS

This chapter provides an overview of the basic principles of food manufacturing (processing). The goals of modern food manufacturing can be summarized as follows:

- *Formulation*. A logical basic sequence of steps to produce an acceptable and quality food product from raw materials.
- *Easy Manufacturing Procedures*. Development of methods that can facilitate the various steps of production.
- *Time Economy*. A cohesive plan that combines the science of production and manual labor to reduce the time needed to produce the product.

- *Consistency*. Application of modern science and technology to ensure the consistency of each batch of products.
- *Product and Worker Safety*. Close working relationship between government and manufacturers (processors), ensuring wholesome products for public consumption and a safe working environment for workers.
- *Buyer Friendly*. Assuming the buyer likes the product, the manufacturer must do everything humanly possible to ensure that the product is user friendly (size, cooking instruction, keeping quality, convenience, etc.).

Obviously, to achieve all the above goals is not a simple matter. This chapter is concerned mainly with the scientific principles of manufacturing safe food products. With this as a premise, the first question we can ask ourselves is the following: Why do we want to manufacture (process) food? At present, there are many *modern* reasons why foods are manufactured, for example, adding value to a food, improving the visual appeal, convenience. However, traditionally, the single most important reason that we wish to manufacture (process) food is to make it last longer without spoiling. Probably the oldest methods of achieving this goal are drying of cereals, fruits, and vegetables, salting of meat and fish, fermenting of milk, and pickling of vegetables. The next section discusses food spoilage and foodborne diseases.

1.2 FOOD SPOILAGE AND FOODBORNE DISEASES

1.2.1 Food Spoilage

Foods are made from natural materials, and, like any living matter, will deteriorate in time. The deterioration of food, or food spoilage, is the natural way of recycling, restoring carbon, phosphorus, and nitrogenous matters to the good Earth. However, spoilage (deterioration, putrefaction) will usually modify the quality of foods from good to bad, in the form of poor appearance (discoloration), offensive smell, and inferior taste. Food spoilage could be caused by a number of factors, chiefly biological, but also by chemical and physical factors. Consumption of spoiled foods can cause sickness, and even death. Thus, food safety is the major concern in spoiled foods.

1.2.1.1 Food Spoilage and Biological Factors. Manufactured (processed) and natural foods are composed mainly of carbohydrates, proteins, and lipids (fats and oils). The major constituents in vegetables and fruits are carbohydrates, including sugars (sucrose, glucose, and so on), polymers of sugars (starch), and other complex carbohydrates such as fibers. Lipids are the major components of oilseeds, milk and most cheeses, and proteins are the chief constituents of muscle foods. Under natural storage conditions, foods start to deteriorate once the living cells in the foods (of plant and animal origins) are dead or damaged. Secretion of internal proteases such as chymotrypsin and trypsin breaks up proteins at specific amino-acid positions, lipases and lyases from lyzosomes disintegrate the cells, de-esterificate fats (triglycerides) into fatty acids and glycerol, hydrolases hydrolyze proteins into amino acids, and starch into simpler sugars. The exposure of foods and damaged cells to the environment would attract microorganisms (e.g., bacteria, molds, and viruses), and insects, which in turn would further accelerate the decomposition of the food. Foods with contaminated microorganisms lead to foodborne illnesses, which, as reported by the Center for Disease Control and

TABLE 1.1 Most Common Bacteria Genera Found in Certain Food Types.

Microorganisms	Foods
Corynebacterium, Leuconostoc	Dairy products
Achromobacter	Meat, poultry, seafoods
Bacteriodes, Proteus	Eggs and meats
Pseudomonas	Meats, poultry, eggs

Prevention (CDC), causes approximately 76 million illnesses and 5000 deaths in the United States yearly (http//www.cdc.gov/foodsafety/). For most food poisoning, the spoilage has not reached the stage where the sensory attributes (appearance, smell, taste, texture, and so on.) of the food are abnormal.

Illness from food can be mainly classified as:

- Foodborne infection caused by pathogenic bacteria (disease-causing microorganisms, such as *Salmonella* bacteria, multiplying in a victim's digestive tract, causing diarrhea, vomiting, and fever, and so on), and
- Foodborne intoxication (food poisoning resulting from a toxin produced by pathogenic microorganisms, for example, *Clostridium botulinum* and *Staphylococcus aureus*, in the food itself).

Foodborne illness also has a major economic impact on society, costing billions of dollars each year in the form of medical bills, lost work time, and reduced productivity (McSwane and others 2003). Some genera of bacteria found in certain food types are listed in Table 1.1, and some common types of microorganisms found in foods are listed in Table 1.2. Some major bacterial and viral diseases transmitted to humans through foods are listed in Table 1.3. The interactive behavior of microorganisms may contribute to their growth and/or spoilage activity (Gram and others 2002).

1.2.1.2 Food Spoilage and Chemical (Including Biochemical) Factors. In many cases, when foods are oxidized, they become less desirable or are even rejected. The odor, taste, and color may change and some nutrients may be destroyed. Examples

TABLE 1.2 Most Common Pathogenic Bacteria and Viruses Found in Foods.

Bacteria	
Clostridium botulinum	*Listeria monocytogenes*
Salmonella spp.	*Staphylococcus aureus*
Clostridium perfringens	*Escherichia coli*
Botulinum spp.	*Campylobacter jejuni*
Streptococci spp.	*Bacillus cereus*
Lactobacillus spp.	*Proteus* spp.
Shigellas spp.	*Pseudomonas* spp.
Salmonella spp.	*Vibrio* spp.
Virus	
Hepatitis A virus	Echovirus
Rotavirus	Calcivirus

TABLE 1.3 Some Major Bacterial and Viral Diseases Transmitted to Humans Through Food.

Bacteria	Diseases
Campylobacter jejuni	Campylobacteriosis
Enterobacteriaceae	Enteric disease
Listeria monocytogenes	Listeriosis
Salmonella spp.	Salmonellosis
Salmonella typhi	Typhoid fever
Shigella dysenteriae	Dysentery
Vibrio cholerae	Cholera
Yersinia enterocolitica	Diarrheal disease
Virus	**Diseases**
ECHO virus	Gastroenteritis
HAV virus	Hepatitis type A
Norwalk agent	Viral diarrhea
Rotavirus	Infant diarrhea

are the darkening of the cut surface of a potato and the browning of tea color with time. Oxidative rancidity results from the liberation of odorous products during breakdown of unsaturated fatty acids. These products include aldehydes, ketones, and shorter-chain fatty acids.

Browning reactions in foods include three nonenzymatic reactions (Maillard, caramelization, and ascorbic acid oxidation), and one enzymatic reaction (phenolase browning) (Fennema 1985). Heating conditions in the surface layers of food cause the Maillard browning reaction between sugars and amino acids, for example, in the browning of baked bread and cakes. The high temperatures and low moisture content in the surface layers also cause caramelization of sugars, and oxidation of fatty acids to other chemicals such as aldehydes, lactones, ketones, alcohols, and esters (Fellows 1992). Moisture and heat can also produce hydrolytic rancidity in fats, in this case fats are split into free fatty acids, which may cause off-odors and rancid flavors in fats and oils (Potter and Hotchkiss 1995). Thermal decomposition of ascorbic acid under both aerobic and anaerobic conditions, by oxidative or nonoxidative mechanisms, in either the absence or presence of amino compounds, can also cause browning (Wedzicha and McWeeny 1974). The formation of ripening fruit flavor often results from Strecker degradation (the transamination and decarboxylation) of amino acids, such as the production of 3-methylbutyrate (apple-like flavor) from leucine (Drawert 1975). Further heating of the foods can break down some of the volatiles generated by the Maillard reaction and Strecker degradation to produce burnt or smoky aromas associated with browning. Enzymatic browning occurs on cut surfaces of light-colored fruits (apples, bananas) and vegetables (potatoes), due to the enzymatic oxidation of phenols to orthoquinones, which in turn rapidly polymerize to form brown pigments known as melanins.

1.2.1.3 Food Spoilage and Physical Factors. Food spoilage can also be caused by physical factors, such as temperature, moisture, and pressure acting upon the foods. Moisture and heat can also produce hydrolytic rancidity in fats (mentioned earlier), with production of off-odors and rancid flavors in fats and oils as mentioned earlier (Potter and Hotchkiss 1995). Excessive heat denatures proteins, breaks emulsions, removes moisture from food, and destroys nutrients such as vitamins. However, excessive coldness, such as freezing, changes their texture and/or cracks their outer coatings to permit contamination by microorganisms. Foods under pressure will be squeezed and transform

into unnatural conformation. The compression will likely break up the surface structure (cracking of eggs), release degradative enzymes (bruising of fruits such as apples and pears), and expose the damaged food to exterior microbial contamination.

Of course, many health officials consider physical factors to include such things as sand, glass, wood chip, rat hair, animal urine, bird droppings, insect parts, and so on. They may not spoil the food, but they can present health hazards. Some of these foreign substances do lead to spoilage. Insects and rodents can consume and damage stored foods, and insects can lay eggs and leave larvae in the foods, causing further damage later. Such foods are no longer reliable because they contain hidden contaminants. The attack of foods by insects and rodents can also contaminate foods further with microbial infections.

1.2.1.4 Prevention and Retardation of Food Spoilage. Food spoilage can be prevented by proper sanitary practices in food handling and processing, appropriate preservation techniques, and standardized storing conditions.

Food Handling and Processing. The entire process, from raw ingredients to a finished product for storage, must comply with a standard sanitation program. In the United States, the practice of HACCP (hazard analysis critical control points), mandatory at present for several industries, may eventually become so for all food industries. At present, the application of HACCP is voluntary for most food processors. Similar sanitary programs apply to workers. It is important to realize that a food processing plant must have a basic sanitation system program before it can implement a HACCP program.

Food Preservation. There are many techniques used to preserve food, such as legal food additives, varying levels of food ingredients or components, traditional and new technologies. Legal food additives, among other functions, can prevent oxidation and inhibit or destroy harmful microorganisms (molds and bacteria). Vitamin E or vitamin C can serve as antioxidants in many food products and benzoate in beverages can act as an antimicrobial agent. We can preserve food by manipulating the levels of food ingredients or components to inhibit the growth of microorganisms or destroy them, for example, by keeping the food low in moisture content (low water activity), high in sugar or salt content, or at a low pH (less than pH 5). Other traditional technologies such as canning (thermal processing), fermentation, refrigeration, and freezing are well-established preservation methods. Recently, new or alternative technologies have become available to preserve food. Because they are new, their applications are carefully monitored. Nothing in the last two decades seems to have generated more publicity than the use of X-rays in food processing. Although food irradiation has been permitted in the processing of several categories of food, its general application is still carefully regulated in the United States.

Food Packaging and Storage. Raw and processed foods should be packaged to prevent oxidation and microbial contamination, insect infestation, and loss of moisture and integrity. Storage of foods (when not contaminated) below $-20^{\circ}C$ can allow food to be kept for several months or a year. Foods stored at $4^{\circ}C$ can have their shelf-life extended to several days or a week (note that some bacteria such as *Listeria monocytogenes* can still grow and multiply even in foods at refrigerated temperatures).

Newly developed techniques to preserve foods include the incorporation of bacteriocin in plastic to retain activity and to inhibit surface growth of bacteria on meat (Siragusa and others 1999), and the application of an intelligent Shelf Life Decision System for quality optimization of the food chill chain (Giannakourou and others 2001).

1.2.1.5 Sources of Information. At present, all major Western government authorities have established Web sites to educate consumers and scientists on the safe processing of food products. Internationally, two major organizations have always been authoritative sources of information: World Health Organization (WHO) and Food and Agriculture Organization (FAO). They also have comprehensive Web sites.

In the United States, major federal authorities on food safety include, but are not limited to the following:

- Department of Agriculture (USDA),
- Food and Drug Administration (FDA),
- Centers for Disease Control (CDC),
- Environmental Protection Agency (EPA),
- National Institutes of Health (NIH).

Many trade associations in Western countries have Web sites that are devoted entirely to food safety. Some examples in the United States include

- American Society of Microbiologists,
- Institute of Food Technologists,
- International Association of Food Protection,
- National Food Processors Association,
- Food Products Association,
- National Restaurants Association.

All government or trade association Web sites are easily accessible by entering the agency name into search engines.

1.3 PRODUCT FORMULATIONS AND FLOW CHARTS

As mentioned earlier, for many food products, processing is an important way to preserve the product. However, for some food products, many self-preserving factors play a role, such as ingredients and their natural properties. Three good examples are pickles, barbecue sauces, and hard candies. Preserving pickles is not difficult if the end product is very sour (acidic) or salty. Traditionally, barbecue sauces have a long shelf-life because of the high content of sugar and acids. Most unwrapped hard candies keep a long time, assuming the environment is at room temperature and not very humid. Most wrapped hard candies last even longer if the integrity of the wrappers is maintained. For baked products (cookies, bread), measures against spoilage take second place to consumer acceptance of freshness. So, the objectives of processing of foods vary with the product. However, one aspect is essential to all manufacturers, as discussed below.

To manufacture a food product, it is assumed that the manufacturer (processor) has a formula for the product. In countries all over the world, small family-owned food businesses usually start with home recipes for popular products instead of a scientific formula. Most of us are aware of such humble beginnings of major corporations manufacturing cola (carbonated), soft drinks, cheeses, breakfast cereals, and many others. When these family businesses were started, there was not much science and technology involved.

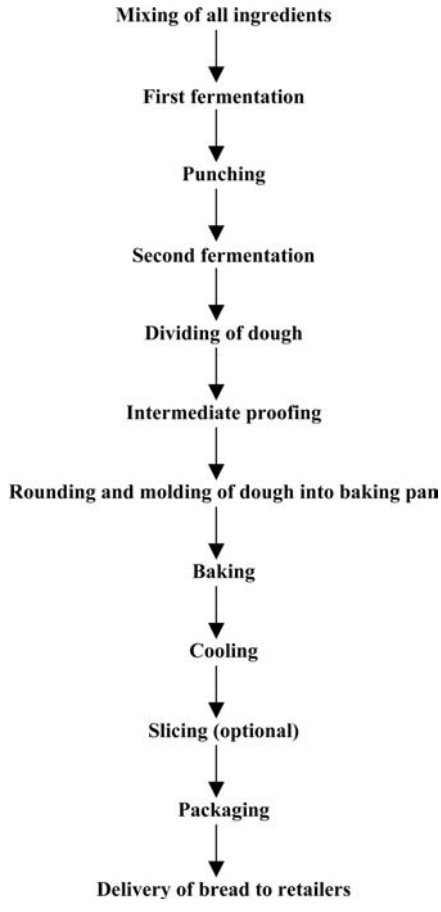

Figure 1.1 *A general flow chart for the manufacture bread.*

As the companies grew and had many employees, they started to hire food scientists, food technologists, and food engineers to study the "recipe(s)" and refine every aspect of the product until the entire manufacturing process was based on sound scientific, technical, and engineering principles. After that, all efforts were directed towards production and marketing. Even now, somewhere a person will start making "barbecue sauce" in his garage and selling it to his neighbors. Although very few of these starters will succeed, this trend will continue to be the case in view of the free enterprise spirit of the West.

Although any person can start manufacturing food using a home recipe, the federal government in the United States has partial or total control over certain aspects of the manufacturing processes for food and beverage products. This control will automatically affect the recipes, formulas, or specifications of the products. Although the word "control" here refers mainly to safety, it is understood that it will affect the formulations to some extent, especially critical factors such as temperature, pH, water activity, and so on.

Flow charts differ from formula in that they provide an overview of the manufacturing process. For illustration, Figures 1.1 to 1.8 provide examples of flow charts for the manufacture of bakery (bread), dairy (yogurt), grain (flour), fruits (raisins), vegetables (pickles), meat (frankfurters, frozen chicken parts), and seafood (canned tuna).

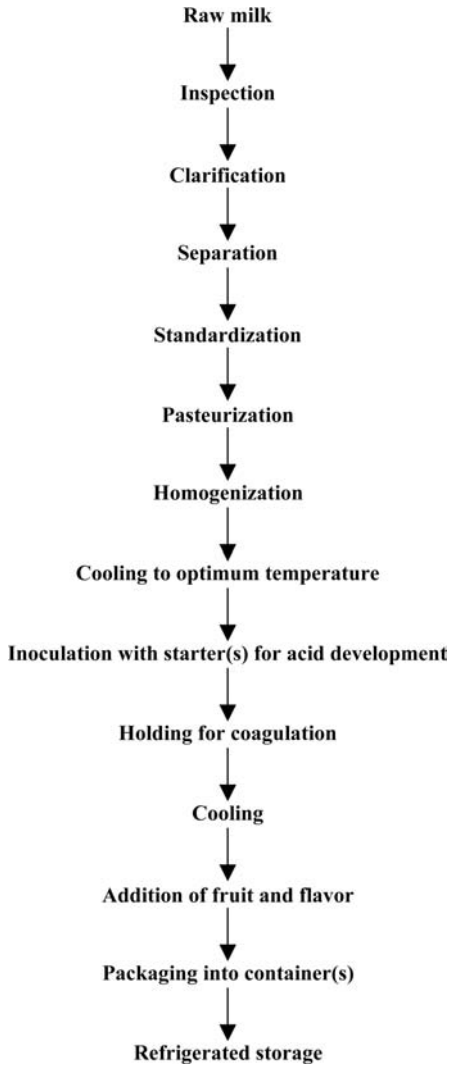

Figure 1.2 *A general flow chart for the manufacture of Yogurt.*

1.4 UNITS OF OPERATIONS

The manufacturing (processing) of most food products involves many of the following unit operations:

- Raw materials,
- Cleaning,
- Separating,
- Disintegrating,
- Forming, raw,
- Pumping,

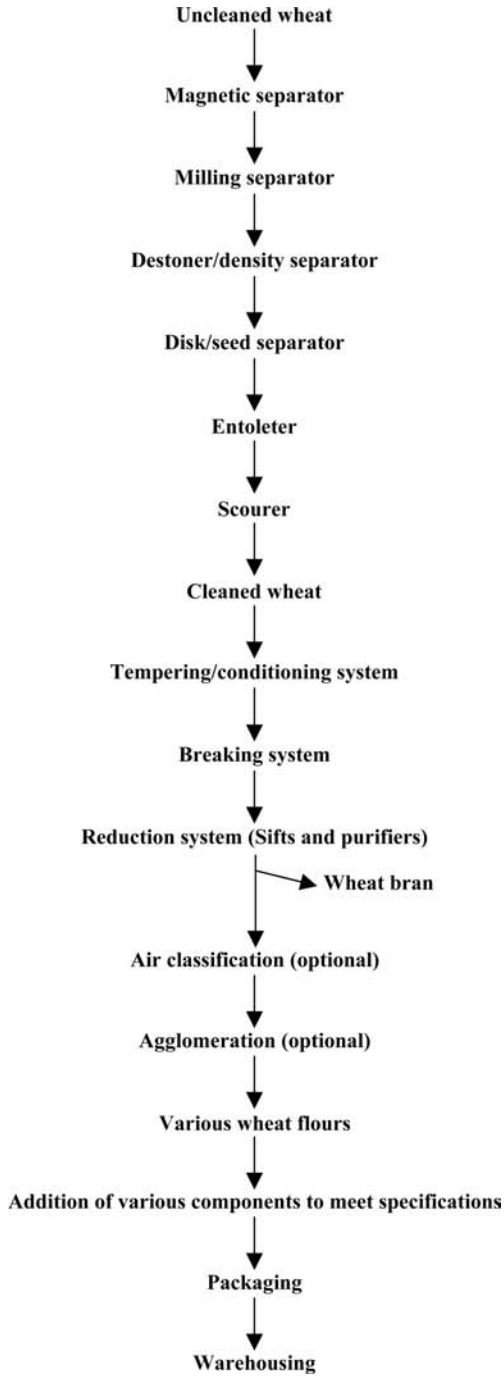

Figure 1.3 *A general flow chart for the production of flour from wheat.*

Figure 1.4 *A general flow chart for the production of raisins.*

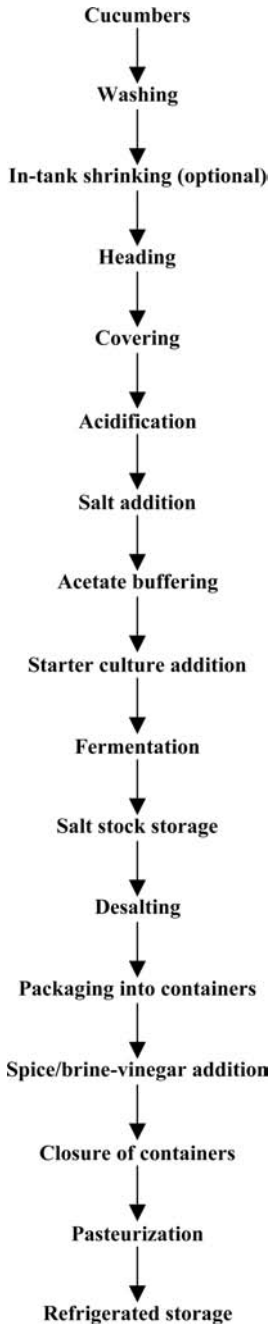

Figure 1.5 *A general flow chart for the production of pickles.*

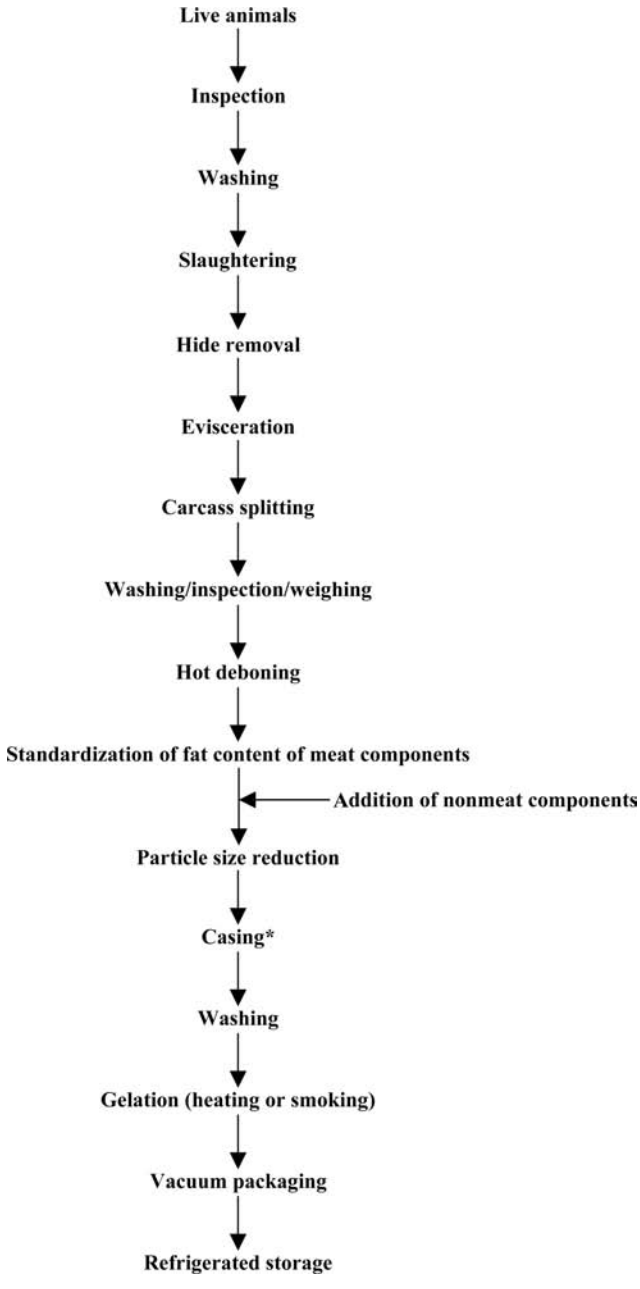

Figure 1.6 *A general flow chart for the production of Frankfurters.*

- Mixing,
- Application methods (formulations, additives, heat, cold, evaporation, drying, fermenting, and so on),
- Combined operations,
- Forming, finished product.

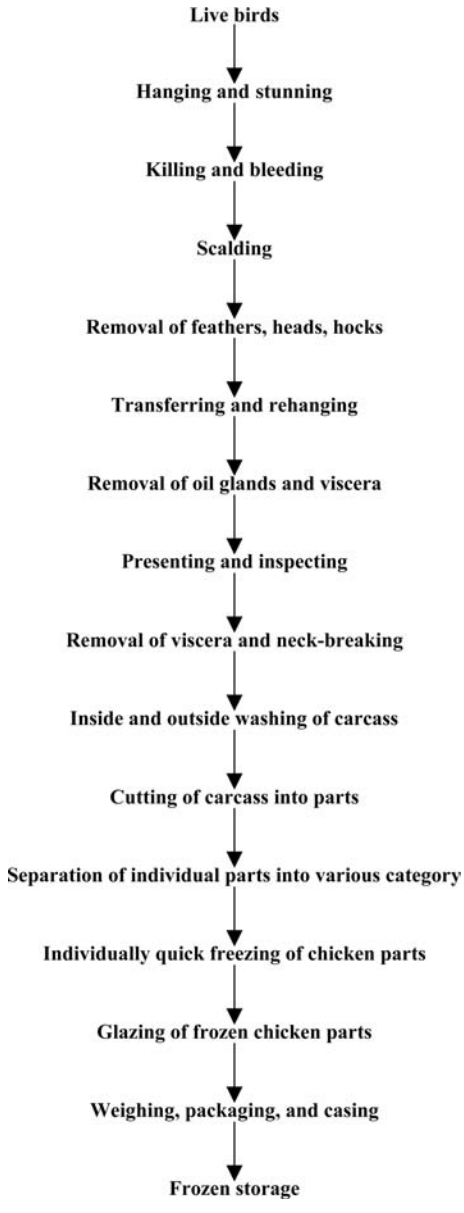

Figure 1.7 *A general flow chart for the production of frozen chicken parts.*

Instead of classifying the following as units of operations, we will discuss them and similar procedure as separate topics:

- Heating,
- Cooling,
- Sanitation,
- Quality control,
- Packaging.

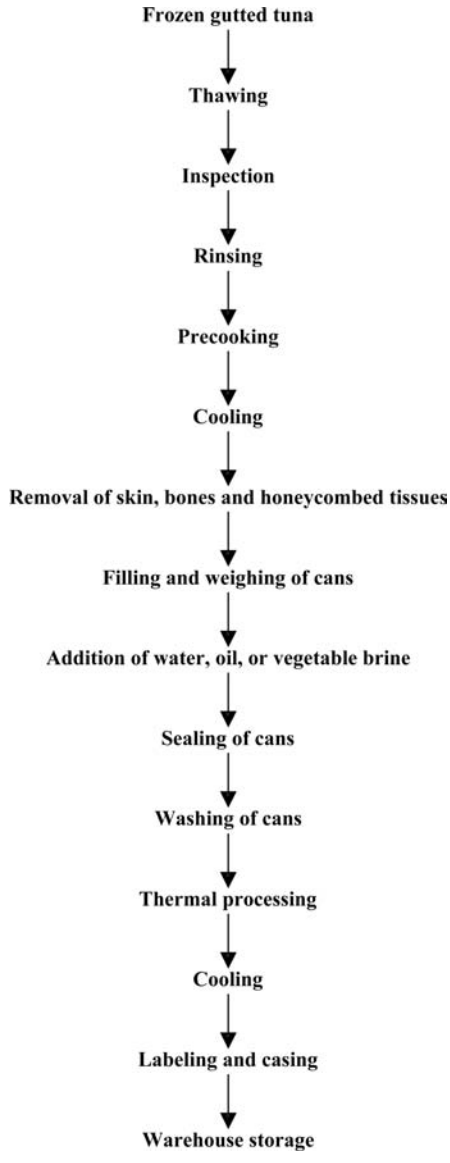

Figure 1.8 *A general flow chart for the production of canned tuna.*

According to the United States Department of Labor, there are hundreds of different categories of food products being manufactured. Correspondingly, there are hundreds of companies manufacturing each category of food product. In sum, there are literally thousands of food manufacturers. Two major reasons for this explosion of new companies are the constant introduction of new products and improvement in manufacturing methods and equipment.

To facilitate the technological processing of food at educational and commercial levels, food manufacturing (processing) professionals have developed unified principles and a systematic approach to the study of these operations. The involved processes of the food industry can be divided into a number of common operations, termed unit operations. Depending on the manufacturer (processor), such unit operations vary in name and

number. For ease of discussion, we use the following unit operations (in alphabetical order) for the most common ones:

- Cleaning,
- Coating,
- Controlling,
- Decorating,
- Disintegrating,
- Drying,
- Evaporating,
- Forming,
- Heating,
- Mixing,
- Packaging,
- Pumping,
- Raw materials handling,
- Separating.

During food processing, the manufacturer selects and combines unit operations into unit processes, which are then combined to produce more complex and comprehensive processes. Although emerging technology plays an important role in food processing as time progresses, these units, in the order they appear in a food processing plant, still apply.

1.4.1 Raw Materials Handling

Raw materials are handled in various ways, including:

- Hand and mechanical harvesting on the farm;
- Trucking (with or without refrigeration) of fruits and vegetables;
- Moving live cattle by rail; and
- Conveying flour from transporting vehicle or boats to storage bins.

Some good examples are as follows.

- Oranges are picked on the farm by hand or mechanical devices, moved by truck trailers, usually refrigerated, to juice processing plants, where they are processed. Of course, the transport must take into account the size of the trucks, length of time during transport, and temperature control. The major objective is to avoid spoilage. In recent years, the use of modified atmosphere packaging/storage has increased the odds in favor of the farmers and producers.
- Handling sugar and flour poses great challenges. When dry sugar reaches the processing plants, via truck trailers or rail, it is transported to storage bins via a pneumatic lift system. The sugar will cake if the storage time, temperature, and humidity are not appropriate. Improper transfer of sugar may result in dusting and buildup of static electricity, which can cause an explosion, because sugar particles are highly combustible. The same applies to finely divided flour.

In handling raw materials, one wishes to achieve the following major objectives:

- Proper sanitation;
- Minimal loss of product;
- Acceptable product quality;
- Minimal bacterial growth,
- Minimal holding time.

1.4.2 Cleaning

We all know what cleaning a raw product means. Before we eat a peach, we rinse it under the faucet or with potable water. Before we make a salad, we wash/rinse the vegetables with potable water. Before we eat crabs, we clean them. Of course, the difference in cleaning between home kitchens and a food processing plant is the volume. We clean one peach; they clean a thousand peaches.

Depending upon the product and the nature of the dirt, cleaning can be accomplished with the following methods or devices, individually or in combination:

- Air (high-velocity),
- Brushes,
- Magnets,
- Steam,
- Ultraviolet light,
- Ultraviolet sound,
- Vacuum,
- Water.

There are other new technologies that will not be discussed here.

Water is probably the most common cleaning agent and its applications vary. Examples include the following:

- Clams, oysters, crabs, and other shellfish are commonly hosed to remove mud, soil, and other foreign debris. If they are contaminated, they may have to be purged by incubating them in running clean seawater.
- City water will not be acceptable for manufacturing beverages. It will have to be further treated with chemical flocculation, sand filtration, carbon purification, microfiltration, deaeration, and so on. This is not considered a simple cleaning. Rather it is a process in cleaning.
- Eviscerating poultry can be considered a cleaning operation if we make use of water. However, the actual process of removing the entrails may involve vacuuming in addition to water.
- With a product like pineapple, the irregular surface is usually cleaned by the scrubbing action of high-pressure water jets.

Just as in a home kitchen where pots and pans require frequent cleaning, state and federal regulations require that the equipment used in a food processing plant be

cleaned and sanitized after each use. After dirt and mud are removed, some raw products also require special sanitizing procedures. The use of sanitizers can be a complicated matter involving different types of sanitizers, federal regulations, expertise, and so on.

1.4.3 Separating

In food processing, the step of separating may involve separating

- A solid from a solid, as in peeling of potatoes;
- A solid from a liquid, as in filtration;
- A liquid from a solid, as in pressing juice from a fruit;
- A liquid from a liquid, as in centrifuging oil from water;
- A gas from a solid or a liquid, as in vacuum canning.

One of the time-honored techniques in the separating operation is the hand sorting and grading of individual units, such as mushrooms, tomatoes, oranges. Many mechanical and electronic sorting devices have now replaced human hands in handling various types of raw food products. An electronic eye can identify differences in color as the products are going along the conveyor belt. Built-in mechanisms can sort the products by color, into "good" versus "bad" color. The current invention of the electronic nose also shows promises, and automatic separation according to size is easily accomplished by passing fruits or vegetables over differently sized screens, holes, or slits.

1.4.4 Disintegrating

Disintegrating means subdividing large masses of foods into smaller units or particles. This may include

- Cutting;
- Grinding;
- Pulping, homogenizing; or
- Other methods.

Examples include

- Automatic dicing of vegetables;
- Mechanical deboning of meat;
- Manual and automatic cutting of meat into wholesale and retail sizes;
- Cutting of bakery products with electric knives and other products with water jets (high-velocity and high-pressure);
- Disintegrating various categories of food products with high-energy beams and laser beams;

- Homogenization using commercial blenders, high-pressure traveling through a valve with very small openings, ultrasonic energy, and so on. Homogenization is probably one of the most important stages (if not the most important) in dairy manufacturing. Homogenization produces disintegration of fat globules in milk or cream from large globules and clusters into minute globules. This is done by forcing the milk or cream under high pressure through a valve with very small openings.

1.4.5 Forming

Forming is an important operation in manufacturing many foods:

- Meat and poultry patties;
- Confections such as candies, jelly beans, fruit juice tablets;
- Breakfast cereals;
- Pasta;
- Kinds such as some cheese cubes, processed cheese slices, potato chips, and others.

1.4.5.1 Meat and Poultry Patties. Patty-making machines are responsible for making ground meat and poultry patties by gently compacting the product into a disk shape. Uniform pressure is applied to produce patties with minimal variation in weight. Excessive pressure may result in tough cooked patties.

1.4.5.2 Pasta. Pasta products are formed by forcing dough through extrusion dies of various forms and shapes before drying in an oven.

1.4.5.3 Confectionery. The shapes and forms in the confectionery industry, such as candies and jellies, are made in several ways. Two of the most popular methods are the use of molds and cutting:

- *Molds*. The traditional use of molds is applied in making confectionery such as fondants, chocolate, and jellies. The product is deposited into molds to cool and harden.
- *Cutting*. Hard candies and toffee are cut into pieces after kneading or pulling.

1.4.6 Pumping

In food processing, pumping moves food (liquid, semi-solid, paste, or solid) from one step to the next or from one location to another. There are many types of pumps available, some with general, others specialized, applicability. The type of pump used depends on the food (texture, size, etc.). For example, broth, tomato pastes, ground meat, corn kernels, grapes, and other categories of food all require a “different” pump to do the job. Two of the most important properties of pumps are the ability to break up foods, and ease of cleaning.

1.4.7 Mixing

The operation of mixing, for example, includes

- Kneading,
- Agitating,
- Blending,
- Emulsifying,
- Homogenizing,
- Diffusing,
- Dispersing,
- Stirring,
- Beating,
- Whipping, and
- Movements by hands and machines.

Examples of mixing include

- Homogenization to prevent fat separation in milk;
- Mixing and developing bread dough, which requires stretching and folding, referred to as kneading;
- Beating in air, as in making an egg-white foam;
- Blending dry ingredients, as in preparing a ton of dry cake mix;
- Emulsifying, as in the case of mayonnaise.

Commercial mixers for food processing come in many shapes and forms because many types of mixtures or mixings are possible. Two examples are provided as illustration:

1. *Mixing solids with solids*, for example, a dry cake mix. The mixer must cut the shortening into the flour, sugar, and other dry ingredients in order to produce a fluffy homogeneous dry mix. A ribbon blender is used.
2. *Beating air into a product while mixing*, for example, using a mixer-beater in an ice-cream freezer. The mixer turns in the bowl in which the ice-cream mix is being frozen. This particular operation permits the mixer to achieve several tasks or objectives: it beats air into the ice-cream to give the desired volume and overrun, and it keeps the freezing mass moving to produce uniformity and facilitate freezing.

1.5 PROCESSING AND PRESERVATION TECHNIQUES

1.5.1 Heat Application

Heat exchanging, or heating, is one of the most common procedures used in the manufacture of processed foods. Examples include pasteurizing of milk, manufacturing of bakery products, roasting peanuts, and canning. Foods may be heated or cooked using

- Direct injection of steam,
- Direct contact with flame,

- Toasters,
- Electronic energy as in microwave cookers, and
- Many new forms of technology.

Whatever the method, precise control of temperature is essential. Heating is used in

- Baking,
- Frying,
- Food concentration,
- Food dehydration, and
- Package closure.

1.5.1.1 Why are Foods Heated? All of us know why we cook food at home: to improve texture, to develop flavors, to facilitate mixing of water, oil, and starch, to permit caramelization, and so on. Commercially, the basic reasons for heating are simple and may include the following:

1. Destruction of microorganisms and preservation of food (food canning and milk pasteurization are common examples);
2. Removal of moisture and development of flavors (ready-to-eat breakfast cereals and coffee roasting are common examples);
3. Inactivation of natural toxicants (processing soy-bean meal is a good example);
4. Improvement of the sensory attributes of the food such as color, texture, and mouth-feel;
5. Combination of ingredients to develop unique food attributes and to attract consumer preferences.

Traditional thermal processing of foods uses the principles of transferring heat energy by conduction, convection, radiation, or a combination of these. Foods are heated in a variety of traditional equipment by applying basic food engineering principles using heat exchangers, tanks or kettles, retorts, and toasters. Other methods may include direct injection of steam, and direct contact with flame. Heating food with electronic energy (microwave) is a relatively new technique. Later in this chapter, other new technologies for heating foods will be discussed.

1.5.1.2 Heat Exchangers for Liquid Foods. As foods are sensitive to heat, special consideration is needed. Dark color, burnt flavors, and loss of nutrients can result from heating, especially prolonged heating. Heat exchangers have special advantages. They permit

1. Liquid food to have a maximal contact with the heat source and
2. Rapid heating and cooling.

For example, a plate-type heat exchanger is used to pasteurize milk. The equipment is composed of many thin plates. When milk flows through one side of the plates, it is heated by hot water on the other side. This provides maximal contact between the heat source and milk, resulting in rapid heating in a short time. The cooling is the reverse process after the milk has been heated. Instead of hot water, cooling water or brine is used.

1.5.1.3 Tanks or Kettles for Liquid Foods. During heating, hot water or pressurized steam circulating in the jackets of the tanks or kettles heats the food, and the reverse for cooling. This technique works for full liquid foods or partially liquid foods such as soups.

1.5.1.4 Pressure Cookers or Retorts for Packaged Foods. The most common method of sterilizing canned foods uses pressure cookers or retorts. Beginning in the early 1970s, the risk of botulism in canned food with low acidity prompted the U.S. FDA to implement stringent regulations governing this group of foods. Although the name of Hazards Analysis Critical Control Points (HACCP) did not have wide usage at the time, the regulations governing the production of low-acid canned foods can be considered the earliest form of HACCP program. Large pressure cookers or retorts are used to ensure that the canned goods are heated above the boiling point of water. The high temperature is generated by steam under pressure in a large retort designed to withstand such pressure and temperature. In this case, convection and conduction of heat energy are achieved. Steam hits the outside of the cans and energy is conducted into the can. Some form of moving or agitating device permits improved convection to occur inside the cans. Although there are other modern techniques of heating canned food products, many smaller companies still depend heavily on these traditional methods.

1.5.1.5 Roasters or Heated Vessels in Constant Rotation. Instead of one or two pieces of equipment, this system contains several units: loading containers, conveyor belts, hoppers, vats or vessels. The vessels are usually cylindrical in shape with built-in heating devices. Heat is generated via one of the following methods:

1. Circulation of heated air, which heats the food products inside the vessels;
2. Application of direct heat to the outside of the vessel by means of steam, flame (gas), and air (hot), for example, whereby heat is radiated from the inside walls of the vessels to the food.

The above unit system is best for roasting coffee beans or nuts.

1.5.1.6 Tunnel Ovens. This can be used for a variety of food products. The product is placed on a conveyor belt, which moves under a heat source. Sometimes, the product is vibrated so that heat distribution is even. Temperature control is essential, enabling products such as coffee beans or nuts to be roasted using this method.

1.5.2 Heat Removal or Cold Preservation

Cold preservation is a preservation method achieved by the removal of heat. It is among the oldest methods of preservation. Since 1875, with the development of mechanical ammonia refrigeration systems, commercial refrigeration and freezing processes have been available. A reduction in the temperature of a food reduces the rate of quality changes during storage caused by a number of factors. At low temperatures, microbial growth is retarded and its reproduction prevented. The rate of chemical reactions (e.g., oxidation, Maillard browning, formation of off-flavor), biochemical reactions (e.g., glycolysis, proteolysis, enzymatic browning, and lipolysis), and physical changes between

food components and the environment (e.g., moisture loss in drying out of vegetables) can also be reduced.

Most food spoilage organisms grow rapidly at temperatures above 10°C, although some grow at temperatures below 0°C, as long as there is unfrozen water available. Most pathogens do not grow well at refrigeration temperatures, except some psychrophilic bacteria such as *Listeria monocytogenes*, which commonly grows in dairy products. Below −9.5°C, there is no significant growth of spoilage or pathogenic microorganisms.

In general, the longer the storage period, the lower the temperature required. Pretreatment with intensive heat is not used in this process operation and, together with adequate control over enzymatic and microbiological changes, the food maintains its nutritional and sensory characteristics close to fresh status and results in a high-quality product. In comparing chilled and frozen foods, chilled food has a higher quality but a shorter shelf-life, and frozen food has a much longer shelf-life, but the presence of ice in the frozen product may contribute some undesirable changes in food quality.

1.5.2.1 Chilling and Refrigeration Process. The chilling process is the gentlest method of preservation, generating the least significant changes in taste, texture, nutritive value, and other attributes of foods. Generally it refers to a storage temperature above freezing, between about 16°C and −2°C. Most foods do not freeze until −2°C or slightly lower because of the presence of solutes such as sugars and salts. Commercial and household refrigerators usually operate at between 4.5°C and 7°C.

In low-acid chilled foods, strict hygienic processing and packaging areas required to ensure food safety. The chilling process is usually used in combination with other preservation methods such as fermentation, irradiation, pasteurization, mild heat treatment, chemicals (acids or antioxidants), and controlled atmosphere. The combination of these methods avoids the extreme conditions that must otherwise be used to limit microbial growth, thus providing a high-quality product (e.g., marinated mussels and yogurt).

Not all foods can be stored under chilled conditions. Tropical and subtropical fruits suffer chilling injury when stored below 13°C, resulting in abnormal physiological changes: skin blemishes (e.g., banana), browning in the flesh (e.g., mango), or failure to ripen (e.g., tomato). Some other foods should not be refrigerated; for example, breads stale faster at refrigeration temperature than at room temperature. Starch in puddings also tends to retrograde and result in syneresis.

There are several important considerations in producing and maintaining high-quality chilled foods.

1. *Quick Removal of Heat at the Chilling Stage*. Ideally, refrigeration of perishable foods starts at the time of harvest, slaughter, or at the finishing production line. Cooling can be accelerated by the following techniques.
   a. *Evaporative cooling*: Spray water and then subject food to vacuum (e.g., leafy vegetables).
   b. *Cryogenic cooling*: Nitrogen gas from evaporating liquid nitrogen, dry ice, and liquid carbon dioxide are used to remove heat for different products.
   c. *Heat exchangers*:
      i. Thin plates where warm bulk liquid foods pass chilled or "super-chilled" cooling fluid, separated by a thin stainless steel plate.
      ii. Cooling coils for liquid food.

2. *Maintaining Low Temperature During the Chill Storage*. This can be affected by the following factors:
   a. *Refrigeration design* (i.e., cooling capacity and insulation): This must be taken into account because temperature can be affected by heat generated by lights and electric motors, people working in the area, the number of doors and how they are opened, and the kinds and amounts of food products stored.
   b. *Refrigeration load*: Quantity of heat that must be removed from the product and the storage area in order to decrease from an initial temperature to the selected final temperature and then to maintain this temperature for a specific time.
   c. *Types of food*:
      i. *Specific heat of food*: Quantity of heat that must be removed from a food to lower it from one temperature to another. The rate of heat removal is largely dependent on water content.
      ii. *Respiration rate of food*: Some foods (fruits and vegetables) respire and produce their own heat at varying rates. Products with relatively high respiration rates (snap beans, sweet corn, green peas, spinach, and strawberries) are particularly difficult to store.
3. *Maintaining Appropriate Air Circulation and Humidity*. Proper air circulation helps to move heat away from the food surface toward refrigerator cooling coils and plates. Air velocity is important, especially in commercial coolers or freezers, in maintaining the appropriate relative humidity (RH), because if the RH is too high, condensation of moisture on the surface of cold food may occur, thus causing spoilage through microbial growth or clumping of the product. However, if RH is too low, dehydration of food may occur instead. Therefore, it is important to control the RH of the cooler and have proper packaging of food.
4. *Modification of Gas Atmosphere*. Chilled storage of fresh commodities is more effective if it is combined with control of the composition of the storage atmosphere. A reduction in oxygen concentration and/or increase in carbon dioxide concentration of the storage atmosphere reduces the rate of respiration (and thus maturation) of fresh fruits and vegetables, and also inhibits rates of oxidation, microbial, and insect growth. The atmospheric composition can be changed using three methods:
   a. *Controlled Atmosphere Storage* (*CAS*), where the concentration of oxygen, carbon dioxide, and ethylene are monitored and regulated throughout the storage. It is used to inhibit overripening of apples and other fruits in cold storage. Stored fruit and vegetables consume O_2 and give off CO_2 during respiration.
   b. *Modified Atmosphere Storage* (*MAS*), where the initially modified gas composition in a sealed storage is allowed to change by normal respiration of the food, but little control is exercised. The O_2 is reduced but not eliminated, and CO_2 is increased (the optimum levels differ for different fruits).
   c. *Modified Atmosphere Packaging* (*MAP*), where the fruit and vegetables are sealed in a package under flushed gas (N_2 or CO_2), and the air in the package is modified over time by the respiring product. Fresh meat (especially red meats) is packaged similarly.
5. *Efficient Distribution Systems*. To supply high-quality chilled foods to consumers, a reliable and efficient distribution system is also required. This involves chilled stores, refrigerated transportation, and chilled retail display cabinets. It requires careful control of the storage conditions, as above.

1.5.2.2 Freezing and Frozen Storage. Freezing is a unit operation in which the temperature of a food is reduced below the freezing point and a proportion of the water undergoes a phase change to form ice. Proper freezing preserves foods without causing major changes in their shape, texture, color, and flavor. Good frozen storage requires temperatures of $-18^{\circ}C$ or below; however, it is cost prohibitive to store lower than $-30^{\circ}C$. Frozen foods have increased in their share of sales since freezers and microwaves have become more available.

The major commodities commonly frozen are

- Fruits (berries, citrus, and tropical fruit), either whole, pureed, or as juice concentrate;
- Vegetables (peas, green beans, sweet corn, spinach, broccoli, Brussels sprouts, and potatoes such as French fries and hash browns);
- Fish fillets and seafoods, including fish fingers, fish cakes, shellfish, and prepared dishes with sauces;
- Meats (beef, lamb, and poultry) as carcasses, boxed joints, or cubes, and meat products (sausages and beef burgers);
- Baked goods (bread, cakes, pastry dough, and pies);
- Prepared foods (pizzas, desserts, ice cream, and dinner meals).

Principles of Freezing. The freezing process implies two linked processes: lowering of temperature by the removal of heat and a change of phase from liquid to solid. The change of water into ice results in an increase in concentration of the unfrozen matrix and therefore leads to dehydration and lowering of water activity. Both the lowering of temperature and water activity contribute to freezing as an important preservation method.

In order for a product to freeze, the product must be cooled below its freezing point. The freezing point of a food depends on its water content and the type of solutes present. The water component of a food freezes first and leaves the dissolved solids in a more concentrated solution, which requires a lower temperature to freeze. As a result, the freezing point decreases during freezing as the concentration increases. Different solutes depress the freezing point to a different degree.

Rate of Freezing. Faster freezing produces small crystals, necessary for high-quality products such as ice-cream. There are two main opposing forces affecting the freezing rate. The driving force includes the difference in temperatures between the freezing medium and the product; the bigger the difference, the faster the product will cool down. High thermal conductivity of the freezing medium (the efficiency with which the refrigerating agent extracts heat) and direct surface contact between medium and product also help to freeze the product quickly. On the other hand, the resistance force to quick freezing includes the product being packed in big sizes, irregular product geometry affecting direct contact with the freezing agent, and the product composition having a high heat capacity. Thermal conductivity of food packages such as cardboard and plastics will act to insulate heat transfer and thus slow down the freezing rate.

1.5.2.3 Quality Changes in Food as a Consequence of Freezing and Frozen Storage. As a consequence of the formation of ice, some negative changes in the quality of food result. The two major causes are freeze concentration effect and ice recrystallization.

Effect of Concentration of Solutes on Food Quality. The quality of products will change if solutes in the frozen product precipitate out of solution, for example, leading to a loss of consistency in reconstituted frozen orange juice because of aggregated pectic substances, and syneresis of starch pudding because of starch aggregation. The increase in ionic strength can lead to "salting out" of proteins, causing protein denaturation (a reason for the toughening of frozen fish). An increase in solute concentration may lead to the precipitation of some salts, and the anion/cation ratio of colloidal suspensions would then be disturbed and causes changes in pH. Such changes would also cause precipitation of proteins and changes in color of anthocyanin in berries. The concentration of solutes in the extracellular fluid will cause dehydration of adjacent tissues in fruit and vegetables, which would not be able to rehydrate after thawing. Lastly, the concentration of reactive compounds would accelerate reactions such as lipid oxidation.

Large Ice Crystal and Recrystallization Damage. If the food is not stored under sufficiently cold and steady temperatures, ice crystals will grow, or recrystallize to large ice crystals, which may cause damage to the food texture. Damage such as the physical rupture of cell walls and membranes and separation of plant and animal cells cause limp celery or green beans, and drips in thawed berries and meat. Enlarged ice crystals also disrupt emulsions (butter and milk), frozen foams (ice-cream), and gels (frozen pudding and pie fillings), thus making these frozen products less homogenous, creamy, and smooth.

Freezer Burn. Another quality damage relating to ice recrystallization is the freezer-burn problem. Freezer-burn occurs when there is a headspace in the packaged food and the food is subjected to fluctuating storage temperature. When the temperature increases, ice at the warmer surface will sublime into the headspace. As the temperature of the freezer or surroundings cools down, the water vapor will recrystallize on the inner surface of the package instead of going back into the product. This leads to dehydration of the surface of the product. If the frozen product is not packaged, the freezer-burn problem is more common and more severe.

1.5.2.4 Types of Common Freezers with Different Cooling Media

1. *Cold air Freezers.*
   a. *Blast/belt freezers* are large insulated tunnels in which air as cold as $-40^{\circ}C$ is circulated to remove heat. The process is cheap, simple, and geared toward high-volume production. Rotating spiral tiers and multilayered belts are incorporated to move product through quickly and avoid "hot spots".
   b. *Fluidized bed freezers* are modified blast freezers in which cold air is passed at a high velocity through a bed of food, contained on a perforated conveyor belt. This produces a high freezing rate, but is restricted to particulate foods (peas, shrimp, and strawberries).
2. *Cold Surface Freezers.*
   a. *Plate freezers* work by increasing the amount of surface area that comes into direct contact with the product to be frozen. Typically, refrigerant runs in the coils that run through plates or drums on which products are laid out. Double-plated systems further increase the rate of heat transfer to obtain higher

quality. This system is suitable for flat and uniform products such as fish fillets, beef burgers, and dinner meals.

b. *Scraped-surface freezers* work by having a liquid or semisolid food (ice-cream) frozen onto the surface of the freezer vessel, and a rotor scrapes the frozen portion from the wall. Typically, ice-cream is only partially frozen in a scraped-surface freezer to about $-6^{\circ}C$, and the final freezing is completed in a hardening room ($-30^{\circ}C$).

3. *Cold Liquid Freezers.* Brine freezers using supersaturated solutions for maximum surface contact immerse the product in a liquid freezing agent, in particular for irregularly shaped product, such as crabs. Their main disadvantage is that products are subject to absorption of salt as well as bacteria if not properly packed.
4. *Cryogenic Freezer.* Liquid nitrogen or liquid carbon dioxide (which vaporize at $-178^{\circ}C$ and $-80^{\circ}C$, respectively), freeze product extremely quickly. This is only suitable for freezing premium products such as shrimp and crab legs because of the high cost of the nonrecoverable gas.

Tips for obtaining top-quality frozen product include the following:

- Start with high-quality product – freezing can maintain quality but not enhance it.
- Get the heat out quickly, by removing any nonedible parts from the food.
- Maintain the integrity of the frozen product – proper cutting and packaging avoids drips.
- Store the product at the coldest temperature economically possible, in a well-designed and maintained facility. Use proper inventory techniques to avoid deterioration.
- Avoid temperature fluctuation during storage and shipping.

1.5.3 Evaporation and Drying

During food processing, evaporation is used to achieve the following goals:

- Concentrate food by partial removal of water;
- Remove undesirable food volatiles;
- Recover desirable food volatiles.

Traditionally, evaporation is achieved via the following methods:

- Using solar energy to evaporate water from seawater to recover the salts left behind;
- Using a heated kettle or similar equipment to boil water from liquid or semisolid foods, for example, sugar syrup;
- Using the improved method of evaporating under a vacuum, where the term vacuum evaporator refers to a closed heated kettle or similar equipment connected to a vacuum pump. One principle to remember is that a major objective of vacuum evaporators is to remove water at temperatures low enough to avoid heat damage to the food.

There are, at present, many specialized pieces of equipment used for evaporating food products. However, overall, the above three methods are most common.

Drying differs from evaporating in that the former takes the food to nearly total dryness or the equivalence of 97% or 98% solids. The oldest method of drying food is to put the food under the hot sun. This practice probably started thousands of years ago. Although sun drying is still practiced, especially in many Third World countries, modern food drying has been modified to a nearly exact science. Drying has multiple objectives:

- To preserve the food from spoilage;
- To reduce the weight and bulk of the food;
- To make the food enjoy an availability and consumption pleasure similar to canned goods;
- To develop "new" or "novelty" items such as snacks.

Some well-known products prepared from drying include

- Dried milk powder,
- Instant coffee,
- Fish and shellfish,
- Jerky,
- Dried fruits, and
- Dried potato flakes.

The central equipment in drying food is the dryer. There are many types of dryer: spray dryers: drum dryers, roller dryers, and others, each of which can be used to meet specific needs.

1.5.4 Food Additives

One popular method of food preservation is the addition of chemicals, legally known as food additives in the United States. In January of 1992, the U.S. FDA and the International Food Information Council released a brochure presenting an overview of food additives. The information in this section has been derived from this document, with an update.

Perhaps the main functional objectives of the use of food additives are the following:

- What keeps bread mold-free and salad dressings from separating?
- What helps cake batters rise reliably during baking and keeps cured meats safe to eat?
- What improves the nutritional value of biscuits and pasta, and gives gingerbread its distinctive flavor?
- What gives margarine its pleasing yellow color and prevents salt from becoming lumpy in its shaker?
- What allows many foods to be available year-round, in great quantity, and with the best quality?

Food additives play a vital role in today's bountiful and nutritious food supply. They allow our growing urban population to enjoy a variety of safe, wholesome, and tasty foods, year-round. Also, they make possible an array of convenience foods without the inconvenience of daily shopping.

Although salt, baking soda, vanilla, and yeast are commonly used in foods today, many people tend to think of any additive added to foods as being a complex and sometimes

harmful chemical compound. All food additives are carefully regulated by federal authorities and various international organizations to ensure that foods are safe to eat and are accurately labeled. The purpose of the brochure from which this information is taken is to provide helpful background information about food additives, why they are used in foods, and how regulations govern their safe use in the food supply.

1.5.4.1 Why are Additives Used in Foods? Additives perform a variety of useful functions in foods that are often taken for granted. As most people no longer live on farms, additives help keep food wholesome and appealing while en route to markets sometimes thousands of miles away from where it is grown or manufactured. Additives also improve the nutritional value of certain foods and can make them more appealing by improving their taste, texture, consistency, or color.

Some additives could be eliminated if we were willing to grow our own food, harvest and grind it, spend many hours on cooking, or accept increased risks of food spoilage. However, most people today have come to rely on the many technological, aesthetic, and convenience benefits that additives provide in food.

Additives are used in foods for five main reasons.

- *To Maintain Product Consistency*. Emulsifiers give products a consistent texture and prevent them from separating. Stabilizers and thickeners give smooth uniform texture. Anticaking agents help substances such as salt to flow freely.
- *To Improve or Maintain Nutritional Value*. Vitamins and minerals are added to many common foods such as milk, flour, cereal, and margarine to make up for those likely to be lacking in a person's diet or lost in manufacturing. Such fortification and enrichment have helped reduce malnutrition in the U.S. population. All products containing added nutrients must be appropriately labeled.
- *To Maintain Palatability and Wholesomeness*. Preservatives retard product spoilage caused by mold, bacteria, fungi, yeast, or air. Bacterial contamination can cause foodborne illness, including the life-threatening botulism. Antioxidants are preservatives that prevent fats and oils in baked goods and other foods from becoming rancid or developing an off-flavor. They also prevent cut fresh fruits such as apples from turning brown when exposed to air.
- *To Provide Leavening or Control Acidity/Alkalinity*. Leavening agents, which release acids when heated, can react with baking soda to help cakes, biscuits, and other baked goods to rise during baking. Other additives help modify the acidity and alkalinity of foods for proper flavor, taste, and color.
- *To Enhance Flavor or Impart Desired Color*. Many spices and natural and synthetic flavors enhance the taste of foods. Colors, likewise, enhance the appearance of certain foods to meet consumer expectations. Examples of substances that perform each of these functions are provided in Table 1.4.

Many substances added to food may seem foreign when listed on the ingredient label, but are actually quite familiar. For example, ascorbic acid is another name for Vitamin C; alpha-tocopherol is another name for Vitamin E; and beta-carotene is a source of Vitamin A. Although there are no easy synonyms for all additives, it is helpful to remember that all food is made up of chemicals. Carbon, hydrogen, and other chemical elements provide the basic building blocks for everything in life.

TABLE 1.4 Common Uses of Food Additives in Food Categories.

Common Uses of Additives and Examples*	Foods Where Likely Used
Impart/Maintain Desired Consistency	
Alginates, lecithin, mono- and diglycerides, methyl-cellulose, carrageenan, glyceride, pectin, guar gum, sodium aluminosilicate	Baked goods, cake mixes, salad dressings, ice-cream, process cheese, coconut, table salt
Improve/Maintain Nutritive Value	
Vitamins A and D, thiamine, niacin, riboflavin, pyridoxine, folic acid, ascorbic acid, calcium carbonate, zinc oxide, iron	Flour, bread, biscuits, breakfast cereals, pasta, margarine, milk, iodized salt, gelatin desserts
Maintain Palatability and Wholesomeness	
Propionic acid and its salts, ascorbic acid, butylated hydroxy anisole (BHA), butylated hydroxytoluene (BHT), benzoates, sodium nitrite, citric acid	Bread, cheese, crackers, frozen and dried fruit, margarine, lard, potato chips, cake mixes, meat
Produce Light Texture; Control Acidity/Alkalinity	
Yeast, sodium bicarbonate, citric acid, fumaric acid, phosphoric acid, lactic acid, tartrates	Cakes, cookies, quick breads, crackers, butter, chocolates, soft drinks
Enhance Flavor or Impart Desired Color	
Cloves, ginger, fructose, aspartame, saccharin, FD&C Red No.40, monosodium glutamate, caramel, annatto, limonene, turmeric	Spice cake, gingerbread, soft drinks, yogurt, soup, confections, baked goods, cheeses, jams, gum

*Includes generally recognized as safe (GRAS) and prior-sanctioned substances as well as food additives.

1.5.4.2 What is a Food Additive? In its broadest sense, a food additive is any substance added to food. Legally, the term refers to "any substance the intended use which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristics of any food." This definition includes any substance used in the production, processing, treatment, packaging, transportation, or storage of food.

Direct Additive. If a substance is added to a food for a specific purpose in that food, it is referred to as a direct additive. For example, the low-calorie sweetener aspartame, which is used in beverages, puddings, yogurt, chewing gum, and other foods, is considered a direct additive. Many direct additives are identified on the ingredient label of foods.

Indirect Food Additives. Indirect food additives are those that become part of the food in trace amounts due to its packaging, storage, or other handling. For instance, minute amounts of packaging substances may find their way into foods during storage. Food packaging manufacturers must prove to the FDA that all materials coming in contact with food are safe, before they are permitted for use in such a manner.

1.5.4.3 What is a Color Additive? A color additive is any dye, pigment, or substance that can impart color when added or applied to a food, drug, or cosmetic, or to the human body. Color additives may be used in foods, drugs, cosmetics, and certain medical devices such as contact lenses. Color additives are used in foods for many reasons, including to offset color loss due to storage or processing of foods and to correct natural variations in food color.

Colors permitted for use in foods are classified as certified or exempt from certification. Certified colors are man-made, with each batch being tested by the manufacturer and FDA to ensure that they meet strict specifications for purity. There are nine certified colors approved for use in the United States. One example is FD&C Yellow No.6, which is used in cereals, bakery goods, snack foods, and other foods.

Color additives that are exempt from certification include pigments derived from natural sources such as vegetables, minerals, or animals. For example, caramel color is produced commercially by heating sugar and other carbohydrates under strictly controlled conditions for use in sauces, gravies, soft drinks, baked goods, and other foods. Most colors exempt from certification must also meet certain legal criteria for specifications and purity.

1.5.4.4 How are Additives Regulated? Additives are not always byproducts of twentieth-century technology or modern know-how. Our ancestors used salt to preserve meats and fish, added herbs and spices to improve the flavor of foods, preserved fruit with sugar, and pickled cucumbers in a vinegar solution. Over the years, however, improvements have been made in increasing the efficiency and ensuring the safety of all additives. Today, food and color additives are more strictly regulated than at any other time in history. The basis of modern food law in the United States is the Federal Food, Drug, and Cosmetic (FD&C) Act of 1938, which gives the FDA authority over food and food ingredients and defines requirements for truthful labeling of ingredients.

The Food Additives Amendment to the FD&C Act, passed in 1958, requires FDA approval for the use of an additive prior to its inclusion in food. It also requires the manufacturer to prove an additive's safety for the ways it will be used. The Food Additives Amendment exempted two groups of substances from the food additive regulation process. All substances that the FDA or the USDA had determined were safe for use in specific food prior to the 1958 amendment were designated as *prior-sanctioned* substances. Examples of prior-sanctioned substances are sodium nitrite and potassium nitrite, used to preserve cured meats. However, at present, nitrites are called color-fixing agents for cured meats, and not preservatives, according to the FDA. The second category of substances excluded from the food additive regulation process are *generally recognized as safe* or GRAS substances. These substances are those whose use is generally recognized by experts as safe, based on their extensive history of use in food before 1958 or based on published scientific evidence. Salt, sugar, spices, vitamins, and monosodium glutamate are classified as GRAS substances, along with several hundred other substances. Manufacturers may also request FDA to review the use of a substance to determine if it is GRAS.

Since 1958, FDA and USDA have continued to monitor all prior-sanctioned and GRAS substances in light of new scientific information. If new evidence suggests that a GRAS or prior-sanctioned substance may be unsafe, federal authorities can prohibit its use or require further studies to determine its safety.

In 1960, Congress passed similar legislation governing color additives. The Color Additives Amendments to the FD&C Act require dyes used in foods, drugs, cosmetics, and certain medical devices to be approved by FDA prior to their marketing. In contrast

to food additives, colors in use before the legislation were allowed continued use only if they underwent further testing to confirm their safety. Of the original 200 provisionally listed color additives, 90 have been listed as safe and the remainder have either been removed from use by FDA or withdrawn by industry.

Both the Food Additives and Color Additives Amendments include a provision that prohibits the approval of an additive if it is found to cause cancer in humans or animals. This clause is often referred to as the Delaney Clause, named for its Congressional sponsor, Rep. James Delaney (D-N.Y.).

Regulations known as Good Manufacturing Practices (GMP) limit the amount of food and color additives used in foods. Manufacturers use only the amount of an additive necessary to achieve the desired effect.

1.5.4.5 How are Additives Approved for Use in Foods? To market a new food or color additive, a manufacturer must first petition to FDA for its approval. Approximately 100 new food and color additives petitions are submitted to FDA annually. Most of these petitions are for indirect additives such as packaging materials.

A food or color additive petition must provide convincing evidence that the proposed additive performs as it is intended. Animal studies using large doses of the additive for long periods are often necessary to show that the substance would not cause harmful effects at expected levels of human consumption. Studies of the additive in humans also may be submitted to FDA.

In deciding whether an additive should be approved, the agency considers the composition and properties of the substance, the amount likely to be consumed, its probable long-term effects, and various safety factors. Absolute safety of any substance can never be proven. Therefore, FDA must determine if the additive is safe under the proposed conditions of use, based on the best scientific knowledge available.

If an additive is approved, FDA issues regulations that may include the types of foods in which it can be used, the maximum amounts to be used, and how it should be identified on food labels. Additives proposed for use in meat and poultry products also must receive specific authorization by USDA. Federal officials then carefully monitor the extent of Americans' consumption of the new additive and results of any new research on its safety to assure its use continues to be within safe limits.

In addition, FDA operates an Adverse Reaction Monitoring System (ARMS) to help serve as an ongoing safety check of all additives. The system monitors and investigates all complaints by individuals or their physicians that are believed to be related to specific foods, food and color additives, or vitamin and mineral supplements. The ARMS computerized database helps officials decide whether reported adverse reactions represent a real public health hazard associated with food, so that appropriate action can be taken.

In summary, additives have been used for many years to preserve, flavor, blend, thicken, and color foods, and have played an important role in reducing serious nutritional deficiencies among Americans. Additives help assure the availability of wholesome, appetizing, and affordable foods that meet consumer demands from season to season. Today, food and color additives are more strictly regulated than at any time in history. Federal regulations require evidence that each substance is safe at its intended levels of use before it may be added to foods. All additives are subject to an ongoing safety review as scientific understanding and methods of testing continue to improve.

1.5.4.6 Additional Information About Additives. Table 1.5 provides additional information about food additives.

TABLE 1.5 Answers to Some of the Most Popular Questions About Food Additives.

Q	*What is the difference between "natural" and "artificial" additives?*
A	Some additives are manufactured from natural sources such as soybeans and corn, which provide lecithin to maintain product consistency, or beets, which provide beet powder used as food coloring. Other useful additives are not found in nature and must be man-made. Artificial additives can be produced more economically, with greater purity and more consistent quality than some of their natural counterparts. Whether an additive is natural or artificial has no bearing on its safety.
Q	*Is a natural additive safer because it is chemical-free?*
A	No. All foods, whether picked from your garden or your supermarket shelf, are made up of chemicals. For example, the vitamin C or ascorbic acid found in an orange is identical to that produced in a laboratory. Indeed, all things in the world consist of the chemical building blocks of carbon, hydrogen, nitrogen, oxygen, and other elements. These elements are combined in various ways to produce the starches, proteins, fats, water, and vitamins found in foods.
Q	*Are sulfites safe?*
A	Sulfites added to baked goods, condiments, snack foods, and other products are safe for most people. A small segment of the population, however, has been found to develop hives, nausea, diarrhea, shortness of breath, or even fatal shock after consuming sulfites. For that reason, in 1986 FDA banned the use of sulfites on fresh fruits and vegetables intended to be sold or served raw to consumers. Sulfites added as a preservative in all other packaged and processed foods must be listed on the product label.
Q	*Does FD&C Yellow No. 5 cause allergic reactions?*
A	FD&C Yellow No. 5, or tartrazine, is used to color beverages, dessert powders, candy ice-cream, custards, and other foods. The color additive may cause hives in fewer than one out of 10,000 people. By law, whenever the color is added to foods or taken internally, it must be listed on the label. This allows the small portion of people who may be sensitive to FD&C Yellow No. 5 to avoid it. Actually, any certified color added to food is required to be listed on the label.
Q	*Does the low-calorie sweetener aspartame carry adverse reactions?*
A	There is no scientific evidence that aspartame causes adverse reactions in people. All consumer complaints related to the sweetener aspartame have been investigated as thoroughly as possible by federal authorities for more than five years, in part under FDA's Adverse Reaction Monitoring System. In addition, scientific studies conducted during aspartame's preapproval phase failed to show that it causes any adverse reactions in adults or children. Individuals who have concerns about possible adverse reactions to aspartame or other substances should contact their physicians.
Q	*Do additives cause childhood hyperactivity?*
A	No. Although this theory was popularized in the 1970s, well-controlled studies conducted since that time have produced no evidence that food additives cause hyperactivity or learning disabilities in children. A Consensus Development Panel of the National Institutes of Health concluded in 1982 that there was no scientific evidence to support the claim that additives or colorings cause hyperactivity.
Q	*Why are decisions sometimes changed about the safety of food ingredients?*
A	As absolute safety of any substance can never be proven, decisions about the safety of food ingredients are made on the best scientific evidence available. Scientific knowledge is constantly evolving. Therefore, federal officials often review earlier decisions to ensure that the safety assessment of a food substance remains up to date. Any change made in previous clearances should be recognized as an assurance that the latest and best scientific knowledge is being applied to enhance the safety of the food supply.

(*Continued*)

TABLE 1.5 ***Continued.***

Q	*What are some other food additives that may be used in the future?*
A	Among other petitions, FDA is carefully evaluating requests to use ingredients that would replace either sugar or fat in food. In 1990, FDA confirmed the GRAS status of Simplesse (registered trademark), a fat replacement made from milk or egg-white protein, for use in frozen desserts. The agency has also confirmed the use of the food additive Olestra, which will partially replace the fat in oils and shortenings.
Q	*What is the role of modern technology in producing food additives?*
A	Many new techniques are being researched that will allow the production of additives in ways not previously possible. One approach, known as biotechnology, uses simple organisms to produce additives that are the same food components found in nature. In 1990, FDA approved the first bioengineered enzyme, rennin, which traditionally has been extracted from calves' stomachs, for use in making cheese.

1.5.5 Fermentation

The availability of fermented foods has a long history among different cultures. Acceptability of fermented foods also differs among cultural habits. A product highly acceptable in one culture may not be so acceptable by consumers in another culture. The number of fermented food products is countless. Manufacturing processes of fermented products vary considerably due to variables such as food groups, form, and characteristics of final products, kinds of ingredients used, and cultural diversity. Fermented foods can be prepared from various products derived from dairies, grains, legumes, fruits, vegetables, muscle foods, and so on.

1.5.6 New Technologies

At present, some alternative or new technologies in food processing are available. On June 2, 2000, the U.S. FDA released a report titled "Kinetics of Microbial Inactivation for Alternative Food Processing Technologies." This report evaluates the scientific information available on a variety of alternative food-processing technologies. The purpose of the report is to help FDA evaluate each technology's effectiveness in reducing and inactivating pathogens of public health concern.

The information in this section has been completely derived from this report. For ease of reading, all references have been removed. Consult the original documents for unabridged data. The citation data for this document are: A report of the Institute of Food Technologists for the Food and Drug Administration of the U.S. Department of Health and Human Services, submitted March 29, 2000, revised June 2, 2000, IFT/FDA Contract No. 223-98-2333, Task Order 1, How to Quantify the Destruction Kinetics of Alternative Processing Technologies, http://www.cfsan.fda.gov/~comm/ift-pref.html.

This section will discuss briefly the following new technologies:

- Microwave and radio frequency processing,
- Ohmic and inductive heating,
- High-pressure processing,
- Pulse electric fields,
- High-voltage arc discharge,

- Pulse light technology,
- Oscillating magnetic fields,
- Ultraviolet light,
- Ultrasound, and
- Pulse X-rays.

1.5.6.1 Microwave and Radio Frequency Processing. Microwave and radio frequency heating refers to the use of electromagnetic waves of certain frequencies to generate heat in a material through two mechanisms, dielectric and ionic. Microwave and radio frequency heating for pasteurization and sterilization are preferred to conventional heating because they require less time to come up to the desired process temperature, particularly for solid and semisolid foods. Industrial microwave pasteurization and sterilization systems have been reported on and off for over 30 years, but commercial radio frequency heating systems for the purpose of food pasteurization or sterilization are not known to be in use.

For a microwave sterilization process, unlike conventional heating, the design of the equipment can dramatically influence the critical process parameters – the location and temperature of the coldest point. This uncertainty makes it more difficult to make general conclusions about processes, process deviations, and how to handle deviations. Many techniques have been tried to improve the uniformity of heating. The critical process factor when combining conventional heating and microwave or any other novel processes would most likely remain the temperature of the food at the cold point, primarily due to the complexity of the energy absorption and heat transfer processes. As the thermal effect is presumably the sole lethal mechanism, time–temperature history at the coldest location will determine the safety of the process and is a function of the composition, shape, and size of the food, the microwave frequency, and the applicator (oven) design. Time is also a factor in the sense that, as the food heats up, its microwave absorption properties can change significantly and the location of cold points can shift.

1.5.6.2 Ohmic and Inductive Heating. Ohmic heating (sometimes also referred to as Joule heating, electrical resistance heating, direct electrical resistance heating, electroheating, and electroconductive heating) is defined as the process of passing electric currents through foods or other materials to heat them. Ohmic heating is distinguished from other electrical heating methods either by the presence of electrodes contacting the food, frequency, or waveform.

Inductive heating is a process in which electric currents are induced within the food due to oscillating electromagnetic fields generated by electric coils. No data about microbial death kinetics under inductive heating have been published.

A large number of potential future applications exist for ohmic heating, including its use in blanching, evaporation, dehydration, fermentation, and extraction. The principal advantage claimed for ohmic heating is its ability to heat materials rapidly and uniformly, including products containing particulates. The principal mechanisms of microbial inactivation in ohmic heating are thermal. Although some evidence exists for nonthermal effects of ohmic heating, for most ohmic processes, which rely on heat, it may be unnecessary for processors to claim this effect in their process filings.

1.5.6.3 High-Pressure Processing (HPP). High-pressure processing (HPP), also described as high-hydrostatic-pressure (HHP) or ultra-high-pressure (UHP) processing, subjects liquid and solid foods, with or without packaging, to pressures between 100 and 800 MPa. Process temperature during pressure treatment can be specified from below 0°C to above 100°C. Commercial exposure times can range from a millisecond pulse to over 20 min. Chemical changes in the food generally will be a function of the process temperature and treatment time.

The HPP process acts instantaneously and uniformly throughout a mass of food independent of size, shape, and food composition. Compression will uniformly increase the temperature of foods approximately 3°C per 100 MPa. The temperature of a homogeneous food will increase uniformly due to compression. Compression of foods may shift the pH of the food as a function of imposed pressure and must be determined for each food treatment process. Water activity and pH are critical process factors in the inactivation of microbes by HPP. An increase in food temperature above room temperature and to a lesser extent a decrease below room temperature increases the inactivation rate of microorganisms during HPP treatment. Temperatures in the range of 45 to 50°C appear to increase the rate of inactivation of food pathogens and spoilage microbes. Temperatures ranging from 90 to 110°C in conjunction with pressures of 500–700 MPa have been used to inactivate spore-forming bacteria such as *Clostridium botulinum*. Current pressure processes include batch and semicontinuous systems, but no commercial continuous HPP systems are operating.

The critical process factors in HPP include pressure, time at pressure, time to achieve treatment pressure, decompression time, treatment temperature (including adiabatic heating), product initial temperature, vessel temperature distribution at pressure, product pH, product composition, product water activity, packaging material integrity, and concurrent processing aids. Other processing factors present in the process line before or after the pressure treatment are not included.

Because some types of spores of *C. botulinum* are capable of surviving even the most extreme pressures and temperatures of HPP, there is no absolute microbial indicator for sterility by HPP. For vegetative bacteria, nonpathogenic *L. innocua* is a useful surrogate for the foodborne pathogen *L. monocytogenes*. A nonpathogenic strain of *Bacillus* may be useful as a surrogate for HPP-resistant *E. coli* O157:H7 isolates.

1.5.6.4 Pulsed Electric Fields (PEF). High-intensity pulsed electric field (PEF) processing involves the application of pulses of high voltage (typically 20–80 kV/cm) to foods placed between two electrodes. The process may be applied in the form of exponentially decaying, square wave, bipolar, or oscillatory pulses and at ambient, subambient, or slightly above ambient temperatures for less than 1 s. Energy loss due to heating of foods is minimized, reducing detrimental changes in the sensory and physical properties of foods.

Some important aspects in PEF technology are the generation of high electric field intensities, the design of chambers that impart uniform treatment to foods with minimum increase in temperature, and the design of electrodes that minimize the effect of electrolysis. Although different laboratory- and pilot-scale treatment chambers have been designed and used for PEF treatment of foods, only two industrial-scale PEF systems are available. The systems (including treatment chambers and power supply equipment) need to be scaled up to commercial systems.

To date, PEF has been applied mainly to improve the quality of foods. Application of PEF is restricted to food products that can withstand high electric fields, have low electrical conductivity, and do not contain or form bubbles. The particle size of the liquid food in both static and flow treatment modes is a limitation.

Several theories have been proposed to explain microbial inactivation by PEF. The most studied are electrical breakdown and electroporation. Factors that affect microbial inactivation with PEF are process factors (electric field intensity, pulse width, treatment time and temperature, and pulse wave shapes), microbial entity factors (type, concentration, and growth stage of the microorganism), and media factors (pH, antimicrobials, and ionic compounds, conductivity, and medium ionic strength).

Although PEF has potential as a technology for food preservation, existing PEF systems and experimental conditions are diverse, and conclusions about the effects of critical process factors on pathogens of concern and kinetics of inactivation need to be further studied.

1.5.6.5 High-Voltage Arc Discharge. Arc discharge was an early application of electricity for pasteurization of fluids by applying rapid discharge voltages through an electrode gap below the surface of an aqueous suspension of microorganisms. A multitude of physical effects (intense wave) and chemical compounds (electrolysis) are generated, inactivating the microorganisms. The use of arc discharge for liquid foods may be unsuitable, largely because electrolysis and the formation of highly reactive chemicals occur during the discharge. More recent designs may show some promise for use in food preservation, although the reported results should be confirmed by independent researchers.

1.5.6.6 Pulsed Light Technology. Pulsed light is a method of food preservation that involves the use of intense and short-duration pulses of broad spectrum "white light" (ultraviolet to the near infrared region). For most applications, a few flashes applied in a fraction of a second provide a high level of microbial inactivation. This technology is applicable mainly in sterilizing or reducing the microbial population on packaging or food surfaces. Extensive independent research on the inactivation kinetics under a full spectrum of representative variables of food systems and surfaces is needed.

1.5.6.7 Oscillating Magnetic Fields. Static (SMF) and oscillating (OMF) magnetic fields have been explored for their potential to inactivate microorganisms. For SMFs, the magnetic field intensity is constant with time, but an OMF is applied in the form of constant amplitude or decaying amplitude sinusoidal waves. An OMF applied in the form of pulses reverses the charge for each pulse. The intensity of each pulse decreases with time to about 10% of the initial intensity. Preservation of foods with OMF involves sealing food in a plastic bag and subjecting it to 1 to 100 pulses in an OMF with a frequency between 5 and 500 kHz at temperatures of 0 to 50°C for a total exposure time ranging from 25 ms to 100 ms.

The effects of magnetic fields on microbial populations have produced controversial results. Consistent results concerning the efficacy of this method are needed before considering this technology for food preservation purposes.

1.5.6.8 Ultraviolet Light. There is a particular interest in using ultraviolet (UV) light to treat fruit juices, in particular apple juice and cider. Other applications include disinfection of water supplies and food contact surfaces. Ultraviolet processing involves the use of radiation from the UV region of the electromagnetic spectrum. The germicidal properties

of UV irradiation (UVC 200–280 nm) are due to DNA mutations induced by DNA absorption of the UV light. This mechanism of inactivation results in a sigmoidal curve of microbial population reduction.

To achieve microbial inactivation, the UV radiant exposure must be at least 400 J/m^2 in all parts of the product. Critical factors include the transmissivity of the product, the geometric configuration of the reactor, the power, wavelength, and physical arrangement of the UV source(s), the product flow profile and the radiation path length. Ultraviolet light may be used in combination with other alternative process technologies, including various powerful oxidizing agents such as ozone and hydrogen peroxide, among others.

1.5.6.9 Ultrasound. Ultrasound is energy generated by sound waves of 20,000 or more vibrations per second. Although ultrasound technology has a wide range of current and future applications in the food industry, including inactivation of microorganisms and enzymes, most current developments for food applications are nonmicrobial.

Data on inactivation of food microorganisms by ultrasound in the food industry are scarce, and most applications use it in combination with other preservation methods. The bactericidal effect of ultrasound is attributed to intracellular cavitations, that is, micromechanical shocks that disrupt cellular structural and functional components up to the point of cell lysis. The heterogeneous and protective nature of food with the inclusion of particulates and other interfering substances severely curtails the singular use of ultrasound as a preservation method. Although these limitations make the current probability of commercial development low, combination of ultrasound with other preservation processes (e.g., heat and mild pressure) appears to have the greatest potential for industrial application.

Critical processing factors are assumed to be the amplitude of the ultrasonic waves, the exposure/contact time with the microorganisms, the type of microorganism, the volume of food to be processed, the composition of the food, and the temperature of treatment.

1.5.6.10 Pulsed X-Rays. It is important to realize that pulsed X-ray is one form of irradiation that has been applied to the preservation of several categories of food in the United States. Electrons have a limited penetration depth of about 5 cm in food, but X-rays have significantly higher penetration depths (60–400 cm), depending upon the energy used.

Pulsed X-ray is a new alternative technology that utilizes a solid state-opening switch to generate electron beam X-ray pulses of high intensity (opening times from 30 ns down to a few nanoseconds; repetition rates up to 1000 pulses/s in burst mode operation). The specific effect of pulses in contrast to nonpulsed X-rays has yet to be investigated.

The practical application of food irradiation by X-rays in conjunction with existing food processing equipment is further facilitated by (1) the possibility of controlling the direction of the electrically produced radiation; (2) the possibility of shaping the geometry of the radiation field to accommodate different package sizes; and (3) its high reproducibility and versatility.

Potentially, the negative effects of irradiation on food quality can be reduced.

1.6 PACKAGING

The obvious reason for packaging a food product is to protect the food so its elements will not be exposed until it is ready to be prepared and consumed. In the world of food

manufacturing, this is not a small matter, because the FDA has rigid control over the materials used in food packaging. As far as the FDA is concerned, any packaging material is considered a food additive. All packaging materials used to contain food must comply with rigid regulations for the use of a food additive. The term "food additive" means any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristics of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; if such substance is not generally recognized as safe). Recently, the FDA has established the Food Contact Notification Program. It issues administrative guidance and regulations for the use of packaging materials, among others. FDA's website (www.FDA.gov) provides details for this program.

Different materials are used as packaging containers, including, but not limited to

- Glass,
- Plastic,
- Laminates (paper-based), and
- Metal can.

Most chapters in this book contain a section on food packaging.

2.1 INTRODUCTION

The availability of fermented foods has a long history in many different cultures. The acceptability of fermented foods also differs because of cultural habits. A product highly acceptable in one culture may not be so acceptable to consumers in another culture. There are countless fermented food products. The manufacturing processes for these fermented products vary considerably owing to variables such as food groups, form and characteristics of the final products, kind of ingredients used, and cultural diversity. It is beyond the scope of this chapter to address all the manufacturing processes used to produce fermented foods. Instead, this chapter is organized based on food groups such as dairy, meat, cereal, soy, and vegetables. Within each food group, manufacturing processes of typical products are examined. This chapter is only an introduction to manufacturing processes for selected fermented food products. Readers should consult the references at the end of the chapter, and other available literature, for detailed information.

2.2 FERMENTED DAIRY PRODUCTS

2.2.1 Ingredients and Kinds of Products

Fermented dairy products are commonly made in milk-producing countries and by nomadic people. These products are highly acceptable in these cultures. They have been gradually accepted by other cultures as a result of cultural exchange. It is generally accepted that

most fermented dairy products were first discovered and developed by nomadic people. The production of a fermented dairy product nowadays can be a highly sophisticated process. However, it can still be conducted in a fairly primitive manner in another location. The quality of a fermented dairy product varies due to the milk, microorganisms, and other ingredients used in the manufacturing process. Many factors affect the gross composition of milk (Jenness 1988; Kosikowski and Mistry 1997; Early 1998; Spreer, 1998; Walstra and others 1999). The factors most significant to the processing of milk products are breed, feed, season, region, and herd health. Reviews of animals' milk are available in the literature. Table 2.1 lists the approximate composition of cow's milk (Robinson 1986; Jenness 1988; Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Walstra and others 1999). In industrial countries, milk composition is standardized to meet a country's requirements. However, it is understood that the requirements in one country may not be the same as those in another; thus, the composition may vary for the same product. International agreements to standardize some products are now available. However, products made in different locations can still vary because of microorganisms and culturing practices used in their production.

Fermented dairy products can be grossly divided into three main categories: cheeses, yogurts, and fermented liquid milks. Within each of these categories, there are subcategories. Table 2.2 presents examples for each of these categories (Robinson 1986; Jenness 1988; Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Walstra and others 1999).

In the manufacturing of fermented dairy products, various ingredients, such as the milk itself, microorganism(s), coagulants, salt, sugar, vitamins, buffering salts, bleaching (decolorizing) agents, dyes (coloring agents), flavoring compounds, stabilizers and emulsifiers, may be used. The uses of these ingredients in fermented liquid milks, yogurts, and natural and processed cheeses are summarized in Table 2.3 (Robinson 1986; Jenness 1988; Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Walstra and others 1999).

Various microorganisms, such as lactic acid bacteria, yeasts, and molds, are used in the manufacturing of fermented dairy products to give the various characteristics of these products. Table 2.4 lists some of the more common dairy microorganisms and their uses in fermented liquid dairy products, yogurts, and cheeses (Davies and Law 1984; Robinson 1990; Jay 1996). Cultures of the different microorganisms are available in various forms, such as liquid, frozen, or freeze-dried. Examples of their usage in the manufacturing of fermented dairy products are listed in Table 2.5 (Robinson 1986; Jenness 1988;

TABLE 2.1 Approximate Composition of Cow's Milk.

Components	Average Content in Milk (% w/w)	Range (% w/w)	Average Content in Dry Matter (% w/w)

TABLE 2.2 Types of Fermented Dairy Products with Examples.

Kinds	Examples
Fermented Liquid Milks	
Lactic fermentation	Buttermilk, Acidophilus,
With alcohol and lactic acid	Kefir, Koumiss
With mold and lactic acid	Villi
Concentrated	Ymer, Skyr, Chakka
Yogurts	
Viscous/liquid	Yogurt
Semi-solid	Strained yogurt
Solid	Soft/hard frozen yogurt
Powder	Dried yogurt
Cheeses	
Extra hard	Parmesan, Romano, Sbrinz
Hard with eyes	Emmental, Gruyere, Swiss
Hard without eyes	Cheddar, Chester, Provolone
Semi-hard	Gouda, Edam, Caerphilly
Semi-hard, internally mold ripened	Roquefort, Blue, Gorgonzola
Semi-soft, surface-ripened with bacteria	Limburger, Brick, Munster
Soft, surface mold ripened	Brie, Camembert, Neufchatel
Soft, unripened	Cream, Mozzaella, U.S. cottage

Source: Robinson (1986), Jenness (1988), Kosikowski and Mistry (1997), Early (1998), Spreer (1998), Walstra and others (1999).

Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Walstra and others 1999). Because the starter cultures are available in different forms, the preparation steps for these cultures before inoculation are different. Table 2.6 lists some of the preparation procedures used in the industry for different forms of starter cultures (Robinson 1986; Jenness 1988; Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Walstra and others 1999). Different microorganisms have different temperature requirements for their optimum growth and functioning. Some fermented dairy products, such as mold-ripened cheeses, may require more than one microorganism to complete the manufacturing process. These molds function best during the long ripening period and therefore have standard incubation temperatures in the refrigerated range. This is also true for some cheeses that require long ripening periods. Microorganisms requiring higher incubation temperatures are used in the production of fermented liquid milks that require only a short incubation time. Table 2.7 lists some of the dairy microorganisms used and their incubation temperatures (Davies and Law 1984; Robinson 1990; Nath 1993; Jay 1996; Law 1997; Specialist Cheese Association 1997; Scott and others 1998; Emmons 2000).

2.2.2 Cheeses

Cheeses can be classified into different categories based on their moisture, the way the milk is processed, and the types of microorganisms used for the ripening process (Table 2.8) (Robinson 1986; Jenness 1988; Early 1998). In the processing of cheese, the amount of curd used for each block of cheese differs considerably, and thus produces different block weights (Table 2.9) (Robinson 1986; Jenness 1988; Nath 1993;

Kosikowski and Mistry 1997; Law 1997; Specialist Cheesemakers Association 1997; Early 1998; Scott and others 1998). Harder cheeses are produced in much larger blocks than the soft cheeses. This may be due to their ease of handling after ripening.

Cheeses are packaged in different forms to satisfy consumer consumption patterns and to some extent to be compatible with the way the cheese is ripened and for marketing purposes. The various packaging materials are selected to protect the cheeses in a sanitary condition, extend shelf-life and delay the deterioration of the final product. Table 2.10 lists some of the requirements of cheese packaging materials (Robinson 1986; Kosikowski and Mistry 1997; Nath 1993; Specialist Cheesemakers Association 1997; Early 1998; Spreer 1998; Scott and others 1998; Walstra and others 1999; Emmons 2000).

All cheeses produced must be coagulated from acceptable milk to form the curd, followed by removal of the whey. Most cheeses are made from standardized and pasteurized milk. Nonpasteurized milk is also used in some exceptional cases, provided that it does not carry pathogens. The majority of cheeses are made from cow's milk. Milks from other animals are also used for specialty products. The coagulation process is conducted through the addition of a coagulant (rennin or chymosin) and incubation of appropriate lactic acid bacteria in milk to produce enough acid and appropriate pH for curdling of the milk. After the casein is recovered, it is salted and subjected to fermentation, with or without inoculation with other microorganisms, to produce the desirable characteristics of the various cheeses. Variations in the different manufacturing steps thus produce a wide variety of cheeses with different characteristics. Table 2.11 summarizes the basic steps in the cheese manufacturing process (Davies and Law 1984; Jenness 1988; Robinson 1986; Robinson 1990; Nath 1993; Jay 1996; Kosikowski and Mistry 1997; Specialist Cheesemakers Association 1997; Early 1998; Scott and others 1998; Spreer 1998;

TABLE 2.5 Dairy Starter Cultures.

Physical Form	Usage
Liquid cultures in skim milk or whole milk (antibiotic free)	For inoculation of intermediate cultures
Liquid culture – frozen	For inoculation of intermediate cultures For inoculation into bulk cultures

Mistry 1997; Specialist Cheesemakers Association, 1997; Early 1998; Spreer 1998; Scott and others 1998; Watsra and others 1999).

2.2.2.1 Cottage Cheese Manufacturing. Cottage cheese is a product that has had very mild fermentation treatment. It is produced by incubating (fermenting) the standardized and pasteurized skim milk with the starter lactic acid bacteria to produce enough acid and appropriate pH for the curdling of milk. The curd is then recovered and washed, followed by optional salting and creaming. The product is then packed and ready for marketing. No further ripening is required for this product. This is different from most fermented cheeses, which require a ripening process. Table 2.13 lists the various steps involved in the production of cottage cheese (Robinson 1986; Nath 1993; Kosikowski and Mistry 1997; Early 1998; Scott and others 1998; Spreer 1998; Walstra and others 1999).

2.2.2.2 Cheddar Cheese Manufacturing. Cheddar cheese is a common hard cheese without eyes that is used in the fast-food industry and in the household. Its production process is characterized by a requirement for milling and cheddaring of the curd. This cheese can be ripened with a wax rind or can be rindless (sealed under vacuum in plastic bags.) It is also

TABLE 2.12 Cheese Ripening Conditions.

Types of Cheese	Storage Period (days)	Temperature (°C)	Relative Humidity (%)
Soft	12–30	10–14	90–95
Mold-ripened	15–60	4–12	85–95
Cooked (e.g., Emmental)			
Cold room	7–25	10–15	80–85
Warm room	25–60	18–25	80–85
Hard (e.g., Cheddar)	45–360	5–12	87–95

Source: Davies and Law (1984), Robinson (1986, 1990), Jenness (1988), Robinson and Tamime (1991), Nath (1993), Jay (1996), Kosikowski and Mistry (1997), Specialist Cheesemakers Association (1997), Early (1998), Scott and others (1998), Spreer (1998), Walstra and others (1999).

TABLE 2.13 Basic Steps in Making Cottage Cheese.

Standardize the skim milk
Pasteurize the milk with standard procedure and cool to 32°C
Inoculate active lactic starter, add rennet, and set the curd
Rennet addition: at 2 ml single strength (prediluted, 1 : 40) per 1000 kg milk within 30 min of starter addition

Type of activity	Short set	Medium set	Long set
Starter concentration	5%	3%	0.5%
Temperature of milk set	32°C	27°C	22°C
Setting to cutting	5 h	8 h	14–16 h

Final pH and whey titratable acidity are 4.6 and 0.52%, respectively

Cut the curd with 1.3; 1.6; or 1.9-cm wire cheese knife
Cook the curd:
Let curd cubes stand for 15–30 min and cook to 51–54°C with 1.7°C per 10 min
Roll the curds gently every 10 min after initial 15–30 min wait
Test curd firmness and hold 10–30 min longer to obtain proper firmness
Wash the curd
First wash with 29°C water temperature
Second wash with 16°C water temperature
Third wash with 4°C water temperature
Gravitationally drain the washed curd for about 2.5 hr
Salt and cream at 152 kg creaming mixture per 454 kg with final 0.5–0.75% salt content and 4% fat content (varies with products and optional)
Package in containers
Store at refrigerated temperature

Source: Robinson (1986), Kosikowski and Mistry (1997), Early (1998), Scott and others (1998), Speer (1998), Walstra and others (1999).

categorized into regular, mild, or sharp based on the aging period (45–360 days). The longer the aging period, the sharper is the flavor, and it is sometimes more costly. It is packaged as a large block or in slices. Table 2.14 lists the basic steps in the manufacture of cheddar cheese (Robinson 1986; Nath 1993; Kosikowski and Mistry 1997; Early 1998; Scott and others 1998; Spreer 1998; Walstra and others 1999).

2.2.2.3 Swiss Cheese Manufacturing. Swiss cheese is also a common cheese used in the fast-food industry and in the household. It is characterized by having irregular eyes inside the cheese. These eyes are produced by *Propionicbacterium freudenreichii* subsp. shermanii, which generates gases that are trapped inside the block of cheese during fermentation and ripening. A cheese with eyes like Swiss cheese has become an icon for cheese in graphics. Swiss cheese is also characterized by its propionic acid odor. The salting process for Swiss cheese utilizes both the dry- and brine-salting processes. Like cheddar cheese, it can be categorized into regular, mild, and sharp depending on the length of the curing process. Table 2.15 lists the basic steps in the manufacture of Swiss cheese (Robinson 1986; Nath 1993; Kosikowski and Mistry 1997; Early 1998; Scott and others 1998; Spreer 1998; Walstra and others 1999).

2.2.2.4 Blue Cheese. Blue cheese is characterized by its strong flavor and by blue mold filaments generated by *Penicillium roqueforti* inside the cheese. It is commonly

TABLE 2.14 Basic Steps in the Making of Cheddar Cheese.

Standardize the cheese milk
Homogenize the milk
Pasteurize and additionally heat the milk
Cool the milk to 31°C
Inoculate the milk with lactic starter (0.5–2% active mesophilic lactic starter)
Add rennet or other protease(s): 198 ml single strength (1 : 15,000) rennet per 1000 kg milk. Dilute the measured rennet 1 : 40 before use. Agitate at medium speed.
Set the milk to the proper acidity, 25 min
Cut the curd using 0.64-cm or wider wire knife. Stir for 5 min at slow speed
Cook the curd at 38°C for 30 min with 1°C every 5 min increment. Maintain temperature for another 4–5 min and agitate periodically at medium speed.
Drain the curd at 38°C
Cheddar the curd at pH 5.2–5.3
Mill the curd slabs
Salt the curd at 2.3–3.5 kg salt per 100 kg curd in 3 portions in 30 min
Waxed cheddar cheese
Hoop and press at 172 kPa for 30–60 s then 172–344 kPa overnight
Dry the cheese at 13°C at 70% relative humidity for 2–3 days
Paraffin whole cheese at 118°C for 6 sec
Rindless cheddar cheese
Press at 276 kPa for 6–18 h
Pre-press for 1 min followed by 45 min under 686 mm vacuum
Remove and press at 345 kPa for 60 min
Remove and vacuum seal in bags with hot water shrinkage at 93°C for 2 s
Ripen at 85% relative humidity at 4°C for 60 days or longer, up to 9–12 months, or at 3°C for 2 months then 10°C for 4–7 months, up to 6–9 months

Source: Robinson (1986), Nath (1993), Kosikowski and Mistry (1997), Early (1998), Scott and others (1998), Spreer (1998), Walstra and others (1999).

consumed as cheese or made into a salad dressing. In the manufacturing of blue cheese, as in that of Swiss cheese, salting is accomplished by the application of dry-salting and brining processes. It is characterized by a cream-bleaching step to show off the blue mold filament against a lighter background and by needling of the block of curd so that the mold can spread the blue mold filaments inside the block. It also has a soft and crumbly texture due to the needling process and the gravity draining procedure to drain the curd. The curing period of two to four months is shorter than that for hard cheeses. Its shelf-life of two months is also shorter than that of its harder counterparts. Table 2.16 lists the basic steps in the manufacture of blue cheese (Robinson 1986; Nath 1993; Kosikowski and Mistry 1997; Early 1998; Scott and others 1998; Spreer 1998; Walstra and others 1999).

2.2.2.5 American-Style Camembert Cheese. American-style Camembert cheese is categorized as a soft cheese. It is characterized by having a shell of mold filament on the surface produced by *Penicillium camemberti*. Brie cheese is a similar product. Addition of annatto color is optional. Like blue cheese, it is gravity drained, and it therefore has a soft, smooth texture. This cheese is surface salted and has a total curing period of 3 weeks before distribution. It is usually cut into wedges and wrapped individually for direct consumption. Table 2.17 lists the basic steps in the manufacture of American-style Camembert cheese (Robinson 1986; Nath 1993; Kosikowski and Mistry 1997; Early 1998; Scott and others 1998; Spreer 1998; Walstra and others 1999).

TABLE 2.15 Basic Steps in of Making Swiss Cheese.

Standardize cheese milk to 3% milk fat; treat with H_2O_2-catalase (optional)
Pasteuriz the milk
Inoculate with starters:
Streptococcus thermophilus, 330 ml per 1000 kg milk
Lactobacillus delbrueckkii subsp. bulgaricus, 330 ml per 1000 kg milk
Propionibacterium freudenreichii subsp. shermanii, 55 ml per 1000 kg milk
Add rennet, 10–20 min after inoculation:
154 ml single strength (1 : 15,000) rennet extract per 1000 kg milk, pre-diluted 1 : 40 with tap water before addition
Stir for 3 min
Set (coagulation) of milk in 25–30 min
Cut the curd with 0.61-cm wire knife and let curd stand undisturbed for 5 min and stir at medium speed for 40 min
Cook the curd slowly to 50–53°C for about 30 min and stir at medium speed; then turn off steam and continue stirring for 30–60 min with pH reaching 6.3–6.4
Drip the curd for 30 min
Press the curd with preliminary pressing, then at 69 kPa overnight
First salting: in 23% salt brine for 2–3 days at 10°C
Second salting: at 10–16°C, 90% relative humidity for 10–14 days by wiping the cheese surface from brine soaking followed by sprinkling of salt over cheese surface daily
Third salting: at 20–24°C, 80–85% relative humidity. Wash cheese surface with salt water and sprinkle with dry salt 2–3 times weekly for 2–3 weeks
Rinded block Swiss cheese:
Cure at 7°C or lower (United States) or 10–25°C (Europe) for 4–12 months
Package in container and store at cool temperature
Rindless block Swiss cheese:
Wrap the block or vacuum pack the blocks
Cure the stacked cheese at 3–4°C for 3–6 weeks
Store at cool temperature

Source: Robinson (1986), Nath (1993), Kosikowski and Mistry (1997), Early (1998), Scott and others (1998), Spreer (1998), Walstra and others (1999).

2.2.2.6 Feta Cheese Manufacturing. Feta cheese is a common cheese in Mediterranean countries. It is a soft cheese and is characterized by its brine curing (maturation) process, which is not common in cheese making. Instead, its manufacture is similar to that of sufu (Chinese fermented tofu, see later in this chapter). Like the other soft cheese, the curing period is only 2 to 3 months. Table 2.18 lists the basic steps in the manufacture of feta cheese (Robinson and Tamime 1991).

2.2.3 Yogurt

Yogurt can be considered as a curdled milk product. Plain yogurt is yogurt without added flavor, stabilizer, or coagulant. Its acceptance is limited to those who really enjoy eating it. With the development of technology, other forms of yogurt, such as flavored and sweetened yogurt, stirred yogurt, yogurt drinks, and frozen yogurt, are now available. Its popularity varies from location to location. It is considered a health food when active or live cultures are added to the final product. Table 2.19 lists the basic steps involved in the manufacture of yogurt. Table 2.3 should also be consulted for reference to other ingredients (Chandan and Shahani 1993; Tamime and Robinson 1999).

Most commercially produced yogurt and its products contain sweeteners, stabilizers, or gums (Table 2.20), fruit pieces, natural and synthetic flavors (Table 2.21), and coloring

TABLE 2.16 Basic Steps in Making Blue Cheese.

Milk preparation
  Separate cream and skim milk
  Pasteurize skim milk by high temperature short time (HTST), cool to 30°C.
  Bleach cream with benzoyl peroxide (optional) and heat to 63°C for 30 s
  Homogenize hot cream at 6–9 mPa and then 3.5 mPa, cool and mix with pasteurized skim milk
Inoculate milk with 0.5% active lactic starter at 30°C. Let stand for 1 h
Add rennet: 158 ml single strength (prediluted 1 : 40) per 1000 kg milk and mix well
Coagulate or set in 30 min
Cut curd with 1.6-cm standard wire knife
Cook curd at 30°C followed by 5 min standing and then agitate every 5 min for 1 h. Whey should have 0.11–0.14 titratable acidity.
Draining of whey by gravity for 15 min
Inoculation with *Penicillium roqueforti* spores: 2 kg coarse salt and 28 g *P. roqueforti* spore powder per 100 kg curd followed by thorough mixing. Addition of food-grade lipase optional.
First salting: dip the curd in 23% brine for 15 min followed by pressing or molding at 22°C with turning every 15 min for 2 h and every 90 min for rest of the day
Second salting: on cheese surface every day for 5 days at 16°C, 85% relative humidity
Final dry salting or brine salting in 23% brine for 24–48 h. Final salt concentration about 4%.
Incubate for 6 days at 16°C, 95% relative humidity
Wax and needle air holes or vacuum pack and needle air holes
Mold filament development in air holes at 16°C for 6–8 days
Curing at 11°C, 95% relative humidity, for 60–120 days
Clean and store:
  Strip off the wax or vacuum packaging bag
  Clean cheese, dry, and re-pack in aluminum foil or vacuum packaging bags
  Store at 2°C.
Product shelf-life, 2 months

Source: Robinson (1986), Nath (1993), Kosikowski and Mistry (1997), Early (1998), Scott and others (1998), Spreer (1998), Walstra and others (1999).

TABLE 2.17 Basic Steps in Making American-Style Camembert Cheese.

Standard the milk
Homogenize the milk
Pasteurize the milk at 72°C for 6 s
Cool milk to 32°C
Inoculate with 2% active lactic starter followed by 15–30 min acid ripening to 0.22% titratable acidity
Add annatto color at 15.4 ml per 1000 kg milk (optional)
Add rennet: 220 ml single strength (prediluted 1 : 40) per 1000 ml followed by mixing for 3 min and standing for 45 min
Cut curd with 1.6-cm standard wire knife
Cook curd at 32°C for 15 min with medium-speed stirring
Drain curd at 22°C for 6 h with occasional turning
Inoculate with *Penicillium camemberti* spores using spray gun on both sides of the cheese once
Pressing and mold curd by pressing for 5–6 h at 22°C without any weight on surface
Surface salt the cheese and let stand for about 9 h
Cure at 10°C, 95% relative humidity for 5 days undisturbed, then turn once and continue curing for 14 days
Package, store, and distribute:
  Wrap cheese and store at 10°C, 95–98% relative humidity for another 7 days
  Move to cold room at 4°C and cut into wedges, if required, and re-wrap
  Distribute immediately

Source: Early (1998), Kosikowski and Mistry (1997), Nath (1993), Robinson (1986), Scott and others (1998), Spreer (1998), Walstra and others (1999).

TABLE 2.18 Basic Steps in of Making Feta Cheese.

Standardize milk with 5% fat, enzyme treat and decolorize
Homogenize the milk
Pasteurize by standard procedure and cool to 32°C
Inoculate with 2% active lactic starter as cheddar cheese followed by 1 h ripening
Add rennet at 198 ml single strength (prediluted, 1 : 40) per 1000 kg milk followed by 30–40 min setting
Cut the curd with 1.6-cm standard wire knife followed by 15–20 standing
Drip the curd for 18–20 h at 12–18 kg on 2000 sq. cm with pH and titratable acidity developed to 4.6 and 0.55%, respectively
Prepare cheese blocks of 13 × 13 × 10 cm each
Salt in 23% salt brine for 1 day at 10°C
Can and box the cheese blocks in 14% salt brine (sealed container)
Cure for 2–3 months at 10°C
Soak cured cheese in skim milk for 1–2 days before consumption to reduce salt
Yield: 15 kg/100 kg of 5% fat milk

Source: Robinson and Tamime (1991).

compounds (Table 2.22) (Chandan and Shahani 1993; Tamime and Robinson 1999). Different countries also have different standards on the percentage of fat and solids-not-fat (SNF) in their yogurt products (Table 2.23) (Chandan and Shahani 1993; Tamime and Robinson 1999).

The different variables described above make the situation complicated. The term "yogurt" in one country may not have the same meaning in another country. This also creates difficulties for international trade. Consensus or agreement among countries, and proper labeling, are needed to identify the products properly.

2.2.4 Fermented Liquid Milks

In milk-producing countries, it is common to have fermented milk products. These products were first discovered or developed by accident. Later, the process was modified for commercial production. Fermented liquid milks are similar to plain yogurt drinks, basically milk that has gone through an acid and/or alcoholic fermentation. The final product is maintained in liquid form rather than in the usual soft-gel form of yogurt. There are different fermented liquid milks available, but only sour milk, kefir, and acidophilus milk are discussed below. Readers should refer to the references and other available literature on related products.

TABLE 2.19 Basic Steps in the Production of Yogurt.

Standardize the liquid milk
Homogenize the liquid milk
Heat treat or pasteurize the liquid milk at 90°C for 5 min or equivalent
Cool the pasteurized milk to 1–2°C above inoculation temperature
Add starter (inoculation), 1–3% operational culture
Add flavor, sweetener, gums, and/or color (optional)
Incubate at 40–45°C for 2.5–3.0 h for standard cultures
Break curd (optional)
Cool to 15–20°C in 1–1.5 h
Add live culture (optional)
Package
Store at $\leq$10°C

Source: Chandan and Shahani (1993), Tamime and Robinson (1999).

TABLE 2.20 Some Common Gums that Could be Used in Yogurt Manufacturing.

Kind	Name of Gum
Natural	Agar
	Alginates
	Carageenan
	Carob gum
	Corn starch
	Casein
	Furcelleran
	Gelatin
	Gum arabic
	Guar gum
	Karaya gum

2.2.4.1 Sour Milk Manufacturing. Table 2.24 presents the basic steps in the manufacture of the most basic fermented liquid milk, sour milk. The milk is standardized, pasteurized, inoculated, incubated, homogenized, and packaged. It is a very straightforward procedure compared to those for the other two products, kefir and acidophilus milk (Davies and Law 1984; Jenness 1988; Robinson 1990; Jay 1996; Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Walstra and others 1999).

TABLE 2.24 Basic Steps in Sour Milk Processing.

Standardize the milk
Heat the milk to 85–95°C followed by homogenization
Cool the milk to 19–25°C and transfer the milk to the fermentation tank
Add 1–2% start culture (inoculation)
Shock-free fermentation to pH 4.65–4.55
Homogenize the gel
Cool to 4–6°C
Filter into bottles, jars, or one-way packs or wholesale packs

Source: Davies and Law (1984), Jenness (1988), Robinson (1990), Jay (1996), Kosikowski and Mistry (1997), Early (1998), Spreer (1998), Walstra and others (1999).

TABLE 2.25 Basic Steps in Kefir Processing.

Preparation of Mother Kefir
Standardize the milk for preparation of mother "Kefir"
Pasteurize milk at 90–95°C for 15 min and cool to 18–22°C
Spread kefir grains at the bottom of a container (5–10 cm thick) and add pasteurized milk (20–30 times the volume of kefir grains)
Ferment for 18–24 h, mixing 2–3 times. Kefir grains float to the surface
Filter out the kefir grains with a fine sieve; wash the grains with water and save for the next fermentation
Save the fermented milk for the next-step inoculation
Preparation of Drinkable Kefir
Blend fermented milk from above with 8–10 times the volume of fresh, pasteurized, and untreated milk.
Filter into bottles, close and ferment for 1–3 days at 18–22°C.
(Another option is to mix the fermented milk with fresh milk at 1–5%; ferment at 20–25°C for 12–15 h until reaching pH 4.4–4.5, followed by ripening in storage tanks for 1–3 days at 10°C. Product is not as traditional but acceptable.)
Cool to refrigerated temperature
Store and distribute

Source: Davies and Law (1984), Jenness (1988), Robinson (1990), Jay (1996), Kosikowski and Mistry (1997), Early (1998), Spreer (1998), Walstra and others (1999).

2.2.4.2 Kefir Manufacturing. Kefir is a fermented liquid milk product characterized by the small amount of alcohol it contains, and its inoculant, the kefir grains. It is a common product in Eastern European countries, and is considered to have health benefits. Among all the fermented dairy products, only this and similar products contain a small amount of alcohol. Also, among all other fermented dairy products, pure cultures of

TABLE 2.26 Basic Steps for Processing Sweet Acidophilus Milk.

Procedure #1
Standardize milk
Heat milk to 95°C for 60 min, cool to 37°C and hold for 3–4 h, re-heat to 95°C for 10–15 min, cool to 37°C
Inoculate with 2–5% bulk starter
Incubate for up to 24 h or to 1% lactic acid
Cool to 5°C
Pack and distribute
Procedure #2
Standardize milk
Homogenize milk at 14.5 MPa
Heat to 95°C for 60 min
Cool to 37°C
Inoculate with direct vat inoculation (DVI) starter
Incubate for 12–16 h or to about 0.65% lactic acid
Ready ultra high temperature (UHT) of 140–145°C for 2–3 s to eliminate undesirable contaminants
Cool to 10°C or lower
Package and distribute

Source: Davies and Law (1984), Jenness (1988), Robinson (1990), Jay (1996), Kosikowski and Mistry (1997), Early (1998), Spreer (1998), Walstra and others (1999).

bacteria, yeasts, and/or mold are used, but in kefir, the kefir grains are used and recycled. Kefir grains are masses of bacteria, yeasts, polysaccharides, and other products of bacterial metabolism, together with curds of milk protein. Production of kefir is a two-step process: (1) first the production of mother kefir, and (2) production of the kefir drink. Table 2.25 lists the basic steps in kefir manufacture (Davies and Law 1984; Robinson 1986, 1990; Jenness 1988; Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Farnworth 1999; Jay 1996; Walstra and others 1999).

2.2.4.3 Acidophilus Milk. Acidophilus milk is considered to have probiotic benefits. Like yogurt, it is advertised as having live cultures of *Lactobacillus acidophilus* and *Bifidobacterium bifidum* (optional). These live cultures are claimed to provide benefit by maintaining a healthy intestinal microflora. Traditional acidophilus milk contains a considerable amount of lactic acid and is considered to be too sour for regular consumers in some locations. Therefore, a small amount of sugar is added to the final product to make it more palatable. This product is called sweet acidophilus milk. Table 2.26 lists the basic steps in the manufacture of acidophilus milk (Davies and Law 1984; Robinson 1986, 1990; Jenness 1988; Jay 1996; Kosikowski and Mistry 1997; Early 1998; Spreer 1998; Walstra and others 1999).

2.3 MEAT PRODUCTS

2.3.1 Ingredients and Types

Fermented meat products such as ham and sausages have been available to various cultures for centuries. It is interesting to learn that the ways these products are produced are essentially very similar in these different cultures. Besides the meat, nitrite and salt, and sugar (optional), pure cultures are sometimes used, especially in fermented sausages. Microorganisms do not merely provide the characteristic flavor of the products; the lactic acid bacteria also produce lactic and other acids that can lower the pH of the products. Pure cultures are sometimes used in hams to lower the pH and thus inhibit the growth of *Clostridium botulinum*. The raw meat for ham manufacturing is just a large chunk of meat, and it is difficult for microorganisms to penetrate into the center, unless they are injected into the interior. Microbial growth is mainly on the surface and the microbial enzymes are gradually diffused into the center. By contrast, in sausages, the cultures, if used, are mixed with the ingredients (ground or chopped meats) at the beginning and the fermentation is carried out without difficulty. Besides, sausages are much smaller than hams. Table 2.27 lists some of the ingredients used in the manufacture of hams and sausages (Townsend and Olsen 1987; Cassens 1990; Hammes and others 1990; Roca and Incze 1990; Incze 1998; Skrokki 1998; Xiong and others 1999; Huang and Nip 2001; Toldra and others 2001).

2.3.2 Hams

Hams, as indicated earlier, are made from large chunks of meat. In Western cultures, ham is manufactured using either a dry cure and/or a brine cure process, sometimes followed by a smoking process. Tables 2.28 and 2.29 list the basic steps involved with the dry cure and brine cure of hams, respectively. These two processes are similar except for the salting step (Townsend and Olsen 1987; Cassens 1990).

TABLE 2.27 Raw Ingredients for Fermented Meat Products.

Ingredient	Ham	Sausage
Meat		
Pork	Yes	Yes
Beef	No	Optional
Casing	No	Yes
Salt	Yes	Yes
Sugar	Optional	Optional
Starter microorganisms	Optional	Optional
Lactobacillus sakei, L. curvatus, L. plantarum, L. pentosus, L. pentoaceus		
Pediococcus pentosaceus, P. acidilactic		
Staplyococcus xylosus, S. carnosus		
Kocuria varians		
Debaryomyces hansenit		
Candida famata		
Penicillium nagiovense, P. chrysogenum		
Spices	Optional	Optional
Other flavoring compounds	Optional	Optional
Moisture retention salts	Optional	Optional
Preservatives	No	No

Source: Townsend and Olsen (1987), Cassens (1990), Hammes and others (1990), Roca and Incze (1990), Incze (1998), Skrokki (1998), Xiong and others (1999), Huang and Nip (2001), Toldra and others (2001).

Chinese hams are manufactured using a dry curing process. Procedures differ slightly depending on the regions where the hams are made. The most famous Chinese ham is the Jinghua ham made in Central China. Yunan ham from Southern China also has a good reputation. In the old days (without refrigeration facilities during processing, transportation and storage), it is believed that the ham completed its aging process during the transportation and storage stages. Today, with controlled temperature and relative humidity rooms, the hams are produced under controlled conditions. Table 2.30 lists the current process used in China for Jinghua ham (Xiong and others 1999; Huang and Nip 2001).

TABLE 2.28 Basic Steps in Dry Cured Ham Processing.

Prepare pork for dry curing
Mix the proper ratio of ingredients (salt, sugar, nitrite and inocula (optional))
Rub the curing mixture into the meat
Stack the green ham for initial dry curing at 36–40°C
Re-rub the green ham and stack for additional curing at 36–40°C (The ham should be left in the cure for the equivalent of 3 days per pound of meat)
Soak the cured ham for 2–3 h, followed by thorough scrubbing
Place green ham in tight-fitting stocknette and hang in smokehouse to dry overnight
Smoke at about 60 or 80°C with 60% relative humidity for 12–36 h
Cool
Vacuum pack and cool store

Source: Townsend and Olsen (1987), Cassens (1990).

TABLE 2.29 Basic Steps in Brine Cured Ham Processing.

Prepare pork for brine curing
Mix the proper ratio of ingredients (salt, sugar, and nitrite with inocula optional; five gallons of brine for 100 lb meat)
Soak the meat in the prepared brine, or stitch pump the brine into the meat (10% of the original weight of the meat), followed by soaking in the brine for 3–7 days vacuum tumbling or massaging (optional)
Remove the meat from the cover brine and wash
Place green ham in tight-fitting stocknette and hang in smokehouse to dry overnight
Smoke at about 60 or 80°C with 60% relative humidity for 12–36 h
Cool
Vacuum pack and cool store

Source: Towsend and Olsen (1987), Cassens (1990).

TABLE 2.30 Basic Steps in Chinese Jinghua Ham Processing.

Select pork hind leg, 5–7.5 kg
Trim
Salt, 7–8 kg salt per 10 kg ham
Stack and overhaul at 0–10°C for 33–40 days
Wash with cold water and brush
Dry in the sun for 5–6 days
Ferment (cure) for 2–3 months at 0–10°C with harmless green mold developing on surface
Brush off the mold and trim
Age for 3–4 months, maximum 9 months; alternate aging process in temperature-programmable room with 60% relative humidity for 1–2 months
Grade
(Yield: about 55–60%)
Pack and distribute

Source: Xiong and others (1999), Huang and Nip (2001).

2.3.3 Sausages

Many European-type sausages are manufactured using a fermentation process. These sausages have their own characteristic flavors due to the formulations and curing processes used. It is not the intent of this chapter to list the various formulations. Readers should consult the references in this chapter and other references available elsewhere. Commercial inocula are available. Bacteria and some yeasts grow inside the sausage during the ripening period, producing a characteristic flavor. Molds can grow on the surface during storage if the sausages are not properly packaged and stored in the refrigerator. Because these sausages are not sterilized, fermentation is an ongoing process and aged sausages carry a stronger flavor. Table 2.31 lists the basic steps in the manufacture of dry-fermented sausages (Hammes and others 1990; Roca and Incze 1990; Incze 1998; Toldra and others 2001).

TABLE 2.31 Basic Steps in Dry (Fermented) Sausage Processing.

Select meat for processing
Chop and mix chopped meat with spices, seasonings, and inocula at a temperature of about 10°C
Stuff the mixture in suitable casings
Link
Cure or dry for 1–3 months in rooms with temperature, relative humidity, and air circulation regulated according to the type of sausages being produced
Pack and cool store

Source: Hammes and others (1990), Roca and Incze (1990), Incze (1998), Toldra and others (2001).

2.4 FERMENTED CEREAL PRODUCTS (BREADS AND RELATED PRODUCTS)

2.4.1 Types of Products and Ingredients

In wheat-producing countries or areas, baked yeast bread is a major staple in people's diet. This is common in the major developed countries. In other countries, other forms of bread may be the major staple. Baked bread may come in different forms such as regular yeast breads, flat breads, and specialty breads. Today, even retarded (chilled or frozen) doughs are available to meet consumers' preferences for a semblance of home-cooked food. For countries or areas with less available energy, other forms of bread such as steamed bread and boiled breads are available. Fried breads are consumed mainly as breakfast or snack items. Table 2.32 lists some examples of different types of breads (Pyler 1988; Groff and Steinbaecher 1995; Quarooni 1996; Cauvain and Young 1998; Quail 1998; Huang 1999).

Today, as a result of centuries of selection, there are different types of wheat available to suit production environments in various regions with diverse climatic conditions. Wheat used for making bread is hard wheat, soft wheat, or a combination of both, to meet product specifications. Wheat kernels are milled with removal of the bran and germ and further processed into wheat flour. Traditionally, this flour is the major ingredient for baking bread. For some health-conscious consumers, whole-wheat flour is now the flour of choice for making bread. Wheat bran is also added to increase the fiber content of the product. Table 2.33 lists the approximate composition of wheat and some of the common wheat products (Pyler 1988; Groff and Steinbaecher 1995; Cauvain and Young 1998).

In the manufacture of various wheat-based breads and related products, the major ingredients are wheat flour, yeast, sourdough bacteria (optional), salt, and water. Other ingredients vary considerably with type of product. These may be classified grossly as optional ingredients, additives, or processing aids. Each country has its own regulations and requirements. Table 2.34 lists basic ingredients, optional ingredients, additives, and processing aids used in the manufacturing of bread and related products (Pyler 1988; Groff and Steinbaecher 1995; Cauvain and Young 1998).

2.4.2 Regular Bread

Table 2.35 lists the basic steps in bread manufacturing (Pyler 1988; Groff and Steinbaecher 1995; Cauvain and Young 1998). There are three basic processes in

TABLE 2.32 Types of Bread and Related Products.

Type	Examples
Baked breads	
Regular yeast breads	Bread (white, whole wheat or multigrain)
Flat (layered) breads	Pocket bread, croissants
Specialty breads	Sourdough bread, rye bread, hamburger bun, part-baked bread, Danish pastry, stuffed bun
Chilled or frozen doughs	Ready-to-be-baked doughs, retarded pizza doughs, frozen proved dough
Steamed breads	Chinese steam bread (mantou), steamed stuffed bun
Fried breads	Doughnuts
Boiled breads	Pretzels

Source: Pyler (1988), Groff and Steinbaecher (1995), Qarooni (1996), Cauvain and Young (1998), Quail (1998), Huang (1999).

TABLE 2.33 Composition of Wheat, Flour, and Germ.

Material	Moisture (%)	Protein (%)	Fat (%)	Total CHO (%)	Fiber (%)	Ash (%)
Wheat						
Hard red spring	13	14	2.2	69.1	2.3	1.7
Hard red winter	12.5	12.3	1.8	71.7	2.3	1.7
Soft red winter	14	10.2	2	72.1	2.3	1.7
White	11.5	9.4	2	75.4	1.9	1.7
Durum	13	12.7	2.5	70.1	1.8	1.7
Flour, straight

commercial bread making: the straight dough process, the sponge-and-dough process, and the continuous-baking process. The process used is determined by the manufacturer and the equipment available in the baking plant. Table 2.36 lists the basic steps in the different processes. The major difference is in the way the dough is prepared and handled (Pyler 1988; Groff and Steinbaecher 1995; Cauvain and Young 1998). Because the dough may be prepared in various ways, the amounts of ingredients used differ accordingly. Table 2.37 lists two formulations, comparing the differences in ingredients that arise

TABLE 2.34 Breadmaking Functional Ingredients.

Kind	Examples
Basic ingredient	
Wheat flour	Bread flour, whole wheat flour
Yeast	Compressed yeast, granular yeast, cream yeast, dried yeast, instant yeast, encapsulated yeast, frozen yeast, pizza yeast, deactivated yeast *Saccharomyces cervisiae*, *S. carlsburgenis*, *S. exisguus*
Salt	
Water	
Optional ingredients	Whole wheat flour, gluten, soya flour, wheat bran, other cereals or seeds, milk powder, fat, malt flour, egg, dried fruit, vitamins Sourdough bacteria: *Lactobacillus plantarum*, *L. brevis*, *L. fermentum*, *L. sanfrancisco* Other yeasts
Additives	
Emulsifier	Diacetylated tartaric acid esters of mono- and di-glycerides of fatty acids (DATA esters), sodium stearyl-2-lactylate (SSL), distilled monoglyceride, lecithin
Flour treatment agents	Ascorbic acid, L-cysteine, potassium bromate, potassium iodate, azodicarbonamide
Preservatives	Acetic acid, potassium acetate, sodium diacetate, sorbic acid, potassium sorbate, calcium sorbate, propionic acid, sodium propionate, calcium propionate, potassium propionate
Processing aids	Alpha-amylase, hemicellulose, proteinase, novel enzyme systems (lipases, oxidases, peroxidases)

TABLE 2.36 Various Breadmaking Processes.

Straight Dough Baking Process
Weigh out all ingredients
Add all ingredients to mixing bowl
Mix to optimum development
First fermentation, 100 min, room temperature, or at 27°C for 1.5 h
Punch
Second fermentation, 55 min, room temperature, or at 27°C for 1.5 h
Divide
Intermediate proofing, 25 min, 30–35°C, 85% relative humidity
Mold and pan
Final proofing, 55 min at 30–35°C, 85% relative humidity
Bake at 191–232°C for 18–35 min to 100°C internal temperature
Sponge-and-Dough Baking Process
Weigh out all ingredients
Mix part of flour, part of water, yeast and yeast food to a loose dough (not developed)
Ferment 3–5 h at room temperature, or at 21°C for 12–16 h
Add other ingredients and mix to optimum development
Fermentation (floor time), 40 min
Divide
Intermediate proofing, 20 min, 30–35°C, 85% relative humidity, or 27°C for 30 min
Mold and pan
Final proofing, 55 min, 30–35°C, 85% relative humidity
Baking at 191–232°C for 18–35 min to 100°C internal temperature
Continuous-Baking Process
Weigh out all ingredients
Mix yeast, water, and maybe part of flour to form liquid sponge
Add remaining flour and other dry ingredients
Mix in dough incorporator
Fermentation, 2–4 h, 27°C
Pump dough to development chamber
Dough development under pressure of 80 psi
Extrusion within 1 min at 14.5°C and pan
Proof for 90 min
Bake at 191–232°C for 18–35 min to ∼100°C internal temperature

Source: Pyler (1988), Groff and Steinbaecher (1995), Cauvain and Young (1998).

TABLE 2.37 Sample Bread Recipes.

White Pan Bread (*Bulk Fermentation or Straight Dough Process*)

Ingredients	Percent (on flour weight)
Flour	100.0
Yeast	1.0
Salt	2.0
Water	57.0
Optional dough improving ingredients	
Fat	0.7
Soya flour	0.7
Malt flour	0.2

White Pan Bread (*sponge and Dough Process*)

Sponge ingredients	Percent (of total flour)
Flour	25.0
Yeast	0.7
Salt	0.5
Water	14.0
Dough ingredients	**Percent (of total flour)**
Flour	75.0
Yeast	2.0
Salt	1.5
Water	44.0
Optional improving ingredients	
Fat	0.7
Soya flour	0.7
Malt flour	0.2

from differences in the dough preparation processes (Pyler 1988; Groff and Steinbaecher 1995; Cauvain and Young 1998).

2.4.3 Retarded Dough

As indicated earlier, retarded dough is also available to some consumers. This type of dough is more accessible in developed countries as refrigerators and freezers are more common. Dough is prepared so that the fermentation is carefully controlled and the dough is packed inside a container. Storage of this package is also carefully controlled. When the package is opened, consumers can just follow the instructions on the package to bake their own bread. The technology is proprietary to the manufacturers, but there are some guidelines available (Table 2.38) (Pyler 1988; Groff and Steinbaecher 1995; Cauvain and Young 1998).

2.4.4 Flat (Layered) Bread

Flat bread is a general term for bread products that do not rise to the same extent as regular bread. Flat breads are common commodities in Middle Eastern countries and in countries or areas with less accessible energy. In developed countries, flat breads are considered specialty breads. The making of the dough is similar to that for regular bread. However, the dough is

TABLE 2.38 General Guidelines for Retarded Dough Production.

Reduce yeast levels as storage times increase
Keep yeast levels constant when using separate retarders and provers
Reduce yeast levels as the dough radius increases
Reduce yeast levels with higher storage temperatures
The lower the yeast level used, the longer the proof time will be to a given dough piece volume
Yeast levels should not be normally be less than 50% of the level used in scratch production
For doughs stored below $-5^{\circ}C$, the yeast level may need to be increased
Reduce the storage temperature to reduce expansion and weight loss from all dough pieces
Lower the yeast levels to reduce expansion and weight losses at all storage temperatures
Dough pieces of large radius are more susceptible to the effects of storage temperatures
The lower freezing rate achieved in most retarder–provers combined with the poor thermal conductivity of dough can cause quality losses
Prove dough pieces of large radius at a lower temperature than those of small radius
Lower the yeast level in the dough to lengthen the final proof time and to help minimize temperature differentials
Maintain a high relative humidity in proof to prevent skinning

Source: Pyler (1988), Groff and Steinbaecher (1995), Cauvain and Young (1998).

flattened and sometimes layered before it is baked directly inside the hearth or in an oven. Table 2.39 lists the general production scheme for flat breads (Qarooni 1996; Quail 1998).

2.4.5 Croissants and Danish Pastries

Croissants and Danish pastries can be considered products that result from modification of the basic bread-making process. The dough preparation steps are similar, but their ingredients are different. Table 2.40 compares the ingredients used in making croissants and Danish pastries. From this table, it is clear that even within each group, the ingredient formulation can vary considerably, producing a wide variety of available products (Pyler 1988; Groff and Steinbaecher 1995; Cauvain and Young 1998).

2.4.6 Steamed Bread (Mantou)

Steamed bread is common in the Chinese community. Plain steamed bread is consumed as the major staple in the northern provinces of China. However, stuffed steamed breads are

TABLE 2.39 General Production Scheme for Flat Bread.

Ingredient preparation
Mixing of ingredients (dough formation)
Fermentation
Dough cutting and rounding
Extrusion and sheeting (optional)
First proofing
Flattening and layering
Second proofing
Second pressing (optional)
Baking or steaming
Cooling
Packaging and distribution

TABLE 2.41 Basic Steps in Steamed Bread Processing.

Selection of flour and ingredients such as milk powder and sugar (optional)
Mixing of dough
Fermentation:
Full fermentation – 1–3 h
Partial fermentation – 0.5–1.5 h
No-time fermentation – 0 h
Remixed fermentation dough – remixing of fully fermented dough with up to 40% of flour by weight
Neutralization with 40% sodium bicarbonate and remixing
Molding
Proofing at 40°C for 30–40 min (no-time dough)
Steaming for about 20 min
Steamed bread is maintained at least warm to preserve quality

Source: Huang (1999).

consumed as specialty items in various parts of China. Manufacture of steamed bread differs from that of regular bread mainly in the dough solidification process. Regular bread uses a baking process, whereas in steamed bread, steaming is used. Consequently, in steamed bread, there is no brown crust on the bread surface because the temperature used is not high enough to cause the browning reaction. Steamed bread is always consumed hot or held in a steamer, because the bread is soft at this temperature. Sometime steamed bread is deep-fried before consumption. Steamed bread hardens when it cools, making it less palatable. Various procedures are available for production of steamed bread. Table 2.41 lists the basic steps in steamed bread processing in China (Huang 1999).

2.5 FERMENTED SOY PRODUCTS

2.5.1 Types of Products and Ingredients

Soybeans have been available to the Chinese people for centuries, and various fermented soy products have been developed and spread to neighboring countries. These countries further developed their own fermented soy products. Soy sauce originating in China is probably the most famous and widely accepted fermented soy product. The credit for this wide acceptance also goes to the Kikkoman Company from Japan, which has

helped promote the availability of soy sauce worldwide through their marketing strategy. Fermented whole soybeans such as ordinary natto, salted soybeans (e.g., Japanese Hama-natto and Chinese Dou-chi), and tempe (Indonesia); fermented soy pastes (e.g., Japanese miso, and Chinese Dou-pan-chiang); and fermented tofus (e.g., sufu and stinky tofu or chao-tofu of Chinese origin) are more acceptable to ethnic groups. Consumers worldwide are gradually accepting these products through cultural exchange activities. The manufacture of these products varies widely. Table 2.42 summarizes the ingredients needed for the manufacture of common fermented soy products (Ebine 1986; Liu 1986, 1997, 1999; Sugiyama 1986; Winarno 1986; Steinkraus 1996; Yoneya 2003; Teng and others 2004).

2.5.2 Soy Sauce

There are many types of soy sauce, which differ in the ratio of ingredients (wheat and soybeans), the fermentation and extraction procedures, and the flavoring ingredients (caramel and others) used. However, the procedures for manufacturing are similar. Soy sauce is made by fermenting cooked soybeans in salt or brine under controlled conditions to hydrolyze the soy proteins and starches into smaller flavoring components. The soy sauce is then extracted from the fermented soybeans for standardization and packaging. Table 2.43 Lists a generalized scheme for the manufacture of soy sauce. More detailed information is presented in the references listed in this chapter and in the available literature elsewhere (Elbine 1986; Liu 1986, 1997, 1999; Sugiyama 1986; Yoneya 2003).

2.5.3 Fermented Whole Soybeans

2.5.3.1 Ordinary (Itohiki) Natto. Ordinary natto is a typical Japanese fermented whole soybean product. The sticky mucilageous substance on the surface of soybeans is its major characteristic and is now considered to have health benefits. It is produced by a brief fermentation of cooked soybeans with *Bacillus natto*, and it has a short shelf-life. Table 2.44 lists the basic steps in the manufacture of ordinary natto. For detailed information on ordinary natto, please refer to the references in this chapter (Liu 1997, 1999; Yoneya 2003).

2.5.3.2 Hama-natto and Douchi. Hama-natto is fermented whole soybeans produced in the Hama-matsu area of Japan. Similar products are produced in Japan prefixed with different names taken from the production location. A very similar product in the Chinese culture is "tou-chi", or "dou-chi". It is produced by fermenting the cooked soybeans in salt, brine, or soy sauce, and then drying them as individual beans. Hama-natto includes ginger in the flavoring, whereas the inclusion of ginger flavoring is optional in Dou-chi. Table 2.45 lists the basic steps in the production of Hama-natto and Douchi.

TABLE 2.43 Production Scheme for Soy Sauce.

Selection and soaking of beans
Cooking of clean or defatted soybean, pressurized steam cooking at 1.8 kg/cm^2 for 5 min
Cooling of cooked bean to 40°C
Roasting and crushing of wheat
Mixing of prepared soybeans and wheat
Inoculation with *Aspergillus oryzae* or *sojae*
Incubation of mixture to make starter koji at 28–40°C
Addition of brine (23% salt water) to make moromi (mash)
Inoculation with halophilic yeasts and lactic acid bacteria (optional)
Brine fermentation at 15–28°C
Addition of saccharified rice koji (optional)
Aging of moromi (optional)
Separation of raw soy sauce by pressing or natural gravity
Refining
Addition of preservative and caramel (option)
Packaging and storage

Source: Elbine (1986), Liu (1986, 1997, 1999), Sugiyama (1986), Yoneya (2003).

TABLE 2.44 Production Scheme for Itohiki (Ordinary) Natto.

Cleaning of whole soybean
Washing and soaking at 21–25°C for 10–30 h
Pressurized steam cooking of soybean at 1–1.5 kg/cm^2 for 20–30 min
Draining and cooling of soybean at 80°C
Inoculation with *Bacillus natto*
Mixing and packaging in small packages
Incubation:
40–43°C for 12–20 h, or
38°C for 20 h plus 5°C for 24 h
Final product
Refrigeration to prolong shelf-life

Source: Liu (1997, 1999), Yoneya (2003).

For further information, readers should refer to the references in this chapter and other available literature (Liu 1986, 1997, 1999; Yoneya 2003).

2.5.4 Fermented Soy Pastes

Fermented soy pastes are available in both the Chinese and Japanese cultures and they are made in a similar manner. However, the usage of these two products is quite different.

TABLE 2.45 Production Scheme for Soy Nuggets (Hamanatto and Douchi).

Cleaning of whole soybean
Washing and soaking for 3–4 h at 20°C
Steam cooking of soybean at ambient pressure for 5–6 h, or at 0.8 to 1.0 kg/cm^2 for 30–40 min
Draining and cooling of soybean to 40°C
Addition of alum (optional for douchi)
Mixing with wheat flour (optional for Hamanatto)
Inoculation with *Aspergillus oryzae*
Procedure #1 (*Hamanatto*)
Incubation for 50 h at 30–33°C
Soaking of inoculated soybean in flavoring solution for 8 months
Incubation under slight pressure in closed containers
Procedure #2 (*Douchi*)
Incubation at 35–40°C for 5 days
Washing
Incubation for 5–6 days at 35°C
Removal of beans from liquid for drying
Mixing with ginger soaked in soy sauce (Hamanatto only)
Final product (soy nuggets)
Packaging
Refrigeration to prolong shelf-life (optional)

Source: Liu (1986, 1997, 1999), Yoneya (2003).

TABLE 2.46 Production Scheme for Fermented Soybean Pastes (Miso).

Cleaning of whole soybean
Washing and soaking at 15°C for 8 h
Cooking at 121°C for 45–50 min or equivalent
Cooling and mashing the soybeans
Preparation of soaked, cooked, and cooled rice (optional)
Preparation of parched barley (optional)
Inoculation of rice or barley with *Aspergillus oryzae* (tane-koji, optional)
Mixing of koji and rice or barley mixture
Addition and mixing of salt to koji and rice or barley mixture
Inoculation of halophilic yeasts and lactic acid bacteria (optional)
Packing of mixture (mashed soybean and koji) into fermenting vat with 20–21% salt brine
Fermentation at 25–30°C for 50–70 days
Blending and crashing of ripened miso
Addition of preservative and colorant (optional)
Pasteurization (optional)
Packaging and storage

Source: Ebine (1986), Liu (1986, 1997, 1999), Sugiyama (1986), Steinkraus (1996), Yoneya (2003).

The Japanese use their fermented soy paste, miso, in making miso soup, and to a lesser extent, for example, in marinating/flavoring of fish. Miso soup is common in traditional Japanese meals. The Chinese use their fermented soy paste, dou-pan-chiang, mainly as a condiment in food preparation. Dou-pan-chiang can also be made from wing beans, but this is beyond the scope of this chapter. Table 2.46 lists the basic steps in the manufacture of miso. For detail information on miso and dou-pan-chiang, readers should consult the references for this chapter and other literature available elsewhere (Ebine 1986; Liu 1986, 1997, 1999; Sugiyama 1986; Steinkraus 1996; Yoneya 2003).

2.5.5 Fermented Tofu

2.5.5.1 Sufu or Fermented Soy Cheese. Sufu, or fermented soy cheese, is made by fermenting tofu, which is made by coagulating the soy protein in soymilk with calcium and/or magnesium sulfate. It is similar to feta cheese in its fermentation process. Both products are matured in brine in sealed containers. Some packed sufu contains flavoring ingredients. Table 2.47 lists the basic steps in the manufacture of sufu. For detailed information, readers should refer to the list of reference in this chapter and the other available literature (Liu, 1986, 1997, 1999; Teng and others 2004).

2.5.5.2 Stinky Tofu. Stinky tofu is a traditional Chinese food made by fermenting tofu briefly in "stinky brine" produced by fermenting vegetables under special conditions. The tofu is hydrolyzed slightly during this brief fermentation and develops its characteristic flavoring compounds. When this raw stinky tofu is deep-fried, these compounds volatilize and produce the characteristic stinky odor, thus the name "stinky tofu". It is usually consumed with chilli and soy sauces. Stinky tofu is also steamed with condiments for consumption. Table 2.48 lists the basic steps in the manufacture of stinky tofu. Readers should consult the references in this chapter for further reading (Liu 1986, 1997, 1999; Teng and others 2004).

TABLE 2.47 Production Scheme for Sufu (Chinese Soy Cheese).

Cleaning of whole soybean
Soaking
Grinding with water
Straining through cheesecloth to recover soymilk
Heating to boiling and then cooling
Coagulation of soymilk with calcium and/or magnesium sulfate
Cooled to 50°C
Pressing to remove water (formation of tofu)
Sterilization at 100°C for 10 min in a hot-air oven
Inoculation with *mucor*, *actinomucor*, and/or *rhizopus* sp.
Procedure #1
Incubation in dry form for 2–7 days depending on inocula
Incubation (fermentation in 25–30% salt brine) for 1 month or longer
Brining and aging in small containers with or without addition of alcohol or other flavoring ingredients
Procedure #2
Incubation at 35°C for 7 days until covered with yellow mold
Packing in closed container with 8% brine and 3% alcohol
Fermentation at room temperature for 6–12 months
Final product (sufu or Chinese soy cheese)

Source: Liu (1986, 1997, 1999), Teng and others (2004).

TABLE 2.48 Production Scheme for Stinky Tofu.

Cleaning of whole soybean
Soaking
Grinding with water
Straining through cheesecloth to recover soymilk
Heating to boiling and then cooling
Coagulation of soymilk with calcium and/or magnesium sulfate
Cooling to 50°C
Pressing to remove water (formation of tofu)
Pressing to remove additional water
Soaking in fermentation liquid for 4–20 h at 5–30°C
Fresh stinky tofu ready for frying or steaming
Refrigeration to prolong shelf-life

Source: Liu (1986, 1997, 1999), Teng and others (2004).

2.5.6 Tempe (Tempeh)

Tempe is a traditional, commonly consumed Indonesian food. It is made by fermenting cooked soybeans wrapped in wilted banana leaves or plastic wraps. The mold *Rhizopus oligosporus* produces its mycelia and these mycelia penetrate into the block of soybeans. The mold mycelia also surround the block. This fermentation is similar to molded cheese fermentation. Tempe is gradually being accepted by vegetarians in the West as a nutritious and healthy food. It is generally consumed as a deep-fried product. Table 2.49 lists the basic steps in the production of tempe (Winarno 1986; Liu 1997, 1999; Yoneya 2003).

TABLE 2.49 Production Scheme for Tempe.

Cleaning of whole soybeans
Re-hydration in hot water at 93°C for 10 min
Dehulling
Soaking with or without lactic acid overnight
Boiling for 68 min
Draining and cooling to 38°C
Inoculation with *Rhizopus oligosporus* with or without *Klebsiella pneumonia*
Incubation on trays at 35–38°C, 75–78 % relative humidity for 18 h
Dehydration
Wrapping

2.6 FERMENTED VEGETABLES

2.6.1 Types of Products and Ingredients

Fermented vegetables were produced in different cultures, in past times, to preserve harvested vegetables for when they were not available or due to climatic limitations. Some of these products started as traditional cultural foods, but became widely accepted in other cultures. It is interesting that most of these processes are similar. Salt can be used in the production of the product or the salt stock. Natural lactic acid fermentation, to produce enough lactic acid to lower pH, is the major microbial activity in these processes. The added salt and produced lactic acid create an environment that can inhibit the growth of other spoilage microorganisms. Leafy vegetables, fruits (commonly used as vegetables), and roots are used as the raw materials. Starter cultures are occasionally used. Vinegar is used in some products. Chilli pepper and other spices are used in many products. Preservatives may also be used to extend shelf-life after the package is opened. Table 2.50 compares the ingredients used in different fermented vegetable

TABLE 2.50 Raw Ingredients for Fermented Vegetables.

Ingredient	Sauerkraut	Western Pickles	Jalenpo Pappers	Kimchi	Oriental Vegetables
Vegetables					
Head cabbage	Yes	No	No	Optional	Optional
Chinese cabbage	No	No	No	Major	Optional
Mustard green	No	No	No	Optional	Optional
Turnip	No	No	No	Optional	Optional
Jalenpo pepper	No	No	Yes	Optional	Optional
Chilli pepper	No	No	No	Yes	Optional
Pickle/cucumber	No	Yes	No	Optional	Optional
Salt	Yes	Yes	Yes	Yes	Yes
Starter culture (lactic acid bacteria)	Optional	Optional	Optional	No	No
Added vinegar	No	Yes	Yes	No	Optional
Added spices	No	Optional	Optional	Optional	Optional
Other added flavors	No	Yes	No	Optional	Optional
Preservative(s)	No	Optional	Optional	Optional	Optional

TABLE 2.51 Basic Steps in Sauerkraut Processing.

Selection and trimming of white head cabbage
Coring and shredding of head cabbage to 1/8 in. thick
Salting with 2.25–2.50% salt by weight with thorough mixing
Storage of salted cabbage in vats with plastic cover weighed with water to exclude air in the cabbage
Fermentation at 7–23°C for 2–3 months or longer to achieve an acidity of 2.0% (lactic)
Heating to 73.9°C before filling the cans or jars, followed by exhausting, sealing, and cooling
Storage and distribution

Source: Desroiser (1977), Fleming and others (1984), Brady (1994), Hang (2003).

products (Desroiser 1977; Fleming 1984; Duncan 1987; Anonymous 1991; Beck 1991; Brady 1994; Chiou 2003; Hang 2003; Lee 2003; Park and Cheigh 2003).

2.6.2 Sauerkraut

The term sauerkraut literally means sour (sauer) cabbage (kraut). It is a traditional German fermented vegetable product that has spread to other cultures, and it is used on its own or in food preparations. Its sequential growth of lactic acid bacteria has long been recognized. Each lactic acid bacterium dominates the fermentation until its end product becomes inhibitory for its own development, and creates another environment suitable for another lactic acid bacterium to take over. The fermentation continues until most of the available fermentable sugars are exhausted. The production of sauerkraut is not risk-free, and sanitary precautions must be taken to avoid spoilage. Table 2.51 presents the basic steps in sauerkraut processing (Desroiser 1977; Fleming and others 1984; Anonymous 1991; Hang 2003).

2.6.3 Pickles

Western-style pickles are produced by salting pickling cucumbers in vats in salt stocks for long-term storage, followed by desalting, and bottling in sugar and vinegar, with or without spices. The fermentation is still lactic acid fermentation. However, it is more susceptible to spoilage because air may be trapped inside the slightly wax-coated cucumbers. In the salt-curing of cucumbers, therefore, spoilage can occur, and precautions should be taken to avoid its occurrence. Because of their high acidity and low pH as well as the high salt content, the products are generally mildly heat-treated to sterilize or pasteurize them. Table 2.52 lists the basic steps in the production of Western-style

TABLE 2.52 Basic Steps in Fermented Pickles Processing.

Sizing and cleaning of cucumbers
Preparation of 5% (low salt) or 10% (salt stock) brine
Curing (fermenting) of cucumbers in brine for 1–6 weeks to 0.7–1.0% acidity (lactic) and pH 3.4–3.6 dependent on temperature, with salinity maintained at desirable level (15% for salt stock) (addition of sugar, starter culture and spices are optional)
Recovery of pickles from brine followed by rinsing or de-salting (salt stock)
Grading
Packing of pickles into jars and filling with vinegar, sugar, spices and alum depending on formulation
Pasteurization at 74°C for 15 min followed by refrigerated storage, or exhausting to 74°C at cold point followed by sealing and cooling, or vacuum packing followed by heating at 74°C (cold point) for 15 min and then cooling
Storage and distribution

pickles (Desroiser 1977; Fleming and others 1984; Duncan 1987; Anonymous 1991; Beck 1991; Brady 1994).

2.6.4 Kimchi

Kimchi is a traditional Korean fermented vegetable. Most kimchi is characterized by its hot taste because of the fairly high amount of chilli pepper used in the product and its visibility. However, some kimchi are made without chilli pepper, but with garlic and ginger as well as vegetables and ingredients. This kind of kimchi still has the hot taste, but does not have the red color. Vegetables used in making kimchi vary with its formulations – Chinese cabbage, cucumber, and large turnip are most common. Either chilli pepper or garlic and ginger can be used to provide a hot sensation. Other ingredients may also be added to provide a typical flavor. The fermentation is still lactic acid fermentation. Traditionally, kimchi was made in every household in rural areas of Korea to provide vegetables for the winter when other fresh vegetables were not readily available. Today, it is a big industry in Korea, and kimchi is available all year round. Small South-Korean-made kimchi refrigerators are now available to meet the demands of consumers living in cities in South Korea and other parts of the world. In other parts of the world where Koreans are residents, kimchi is available either as a household item or as a commercial product. Kimchi is usually not heat sterilized after packaging in jars. Pasteurization is optional. It is considered to be perishable and stored refrigerated. Kimchi is now gradually being accepted in other cultures and Koreans are attempting to set standards for handling kimchi. Today, China also exports a considerable amount of kimchi to South Korea. Table 2.53 lists the basic steps in the manufacture of kimchi (Lee 2003; Park and Cheigh 2003).

2.6.5 Chinese Pickled Vegetables

The Chinese people also manufacture a wide range of pickled vegetables. Various kinds of vegetables are used as the raw materials. The fermentation can be either a dry-salting or brining process, depending on the product to be manufactured. However, the fermentation is still lactic acid fermentation. The major difference between Chinese-style pickled vegetable products and the Western-style pickles is that desalting is usually not practiced in the manufacture of Chinese-style pickled vegetables. The desalting process is left to the consumers, if needed. Also, some Chinese-style vegetables are made into intermediate-moisture products, which are not available in the Western-style counterparts.

TABLE 2.53 Basic Steps in Kimchi Processing.

Selection of vegetables (Chinese cabbage, radish, cucumber, or others)
Washing of vegetables
Cutting of vegetables, if necessary
Preparation of 8–15% brine
Immersion of vegetables in brine for 2–7 h to achieve 2–4% salt in vegetable
Rinsing and draining briefly
Addition of seasoning
Fermentation at 0°C to room temperature for about 3 days
Package (can also be conducted before fermentation)
Storage at 3–4°C

Source: Lee (2003), Park and Cheigh (2003).

TABLE 2.54 Basic Steps in Fermented Chinese Vegetables.

Selection and cleaning of vegetables
Cutting of vegetables (optional)
Procedure #1
Wilting of vegetables for 1–2 days to remove moisture
Dry salting of vegetables in layers with weights on top (5–7.5% salt)
Fermentation for 3–10 days
Washing
Drying or pressing of fermented vegetables (optional)
Addition of spices and flavoring compounds
Packaging
Sterilization (optional)
Procedure #2
Wilting of cut vegetables
Hot water rinsing of fermentation container
Filling of the container with cut vegetables
Addition of 2–3% brine and other flavoring compounds (optional)
Ferment at 20–25°C for 2–3 days
Ready for direct consumption or packaging and cool storage

Source: Chiou (2003), Lee (2003).

Table 2.54 lists some of the basic steps in the manufacturing of selected Chinese pickled vegetables (Chiou 2003; Lee 2003).

2.7 APPLICATION OF BIOTECHNOLOGY IN THE MANUFACTURING OF FERMENTED FOODS

With advances in biotechnology, microorganisms with special characteristics for the manufacturing of fermented foods have become available. The most significant example is the approval by the FDA of Chy-Max (chymosin produced by genetic manipulation), used in the production of cheese. Its availability greatly reduces the reliance on chymosin from young calves and generates economic savings. Other products with similar or other properties are also available in the market. Genetically modified lactic acid bacteria and yeasts used in fermented food production are also now available to reduce production costs. Gradual acceptance by consumers is the key to the further development and success of biotechnology (Geisen and Holzapfel 1996; Jay 1996; Kosikowski and Mistry 1997; Scott and others 1998; Spreer 1998; Barrett and others 1999; Henriksen and others 1999; Early 1998; Walstra and others 1999). Readers should refer to the references in this chapter and other references available for further information.

2.8 PROCESS MECHANIZATION IN THE MANUFACTURE OF FERMENTED FOODS

Fermented foods produced by traditional methods are labor-intensive and rely a great deal on the experiences of the manufacturers. The main problem is product inconsistency. In most developed countries, products such as cheeses, yogurts, breads, sausages, and soy sauce are now made by highly mechanized processes in order to standardize the products

(Belderok 2000; Caudill 1993; Dairy and Food Industries Supply Association 1993; Gilmore and Shell 1993; Hamada and others 1991; Iwasaki and others 1992; Kamel and Stauffer 1993; Luh 1995; Muramatsu and others 1993; Prasad 1989). This not only provides product consistency, but also reduces production costs. Consumers benefit from these developments. However, some consumers, even in developed countries, still prefer the traditional products, even at an increased cost, because of their unique product characteristics. There are also fermented products that are still made by traditional or semi-mechanized processes because mechanization processes have not been developed for them.

3.7 Industry Group 206: Sugar and Confectionery Products 103
3.7.1 Cane Sugar, Except Refining (2061) 103
3.7.2 Cane Sugar Refining (2062) 104
3.7.3 Beet Sugar (2063) 104
3.7.4 Candy and Other Confectionery Products (2064) 104
3.7.5 Chocolate and Cocoa Products (2066) 105
3.7.6 Chewing Gum (2067) 106
3.7.7 Salted and Roasted Nuts and Seeds (2068) 106
3.8 Industry Group 207: Fats and Oils 106
3.8.1 Cottonseed Oil Mills (2074) 106
3.8.2 Soybean Oil Mills (2075) 106
3.8.3 Vegetable Oil Mills, Except Corn, Cottonseed, and Soybean (2076) 107
3.8.4 Animal and Marine Fats and Oils (2077) 107
3.8.5 Shortening, Table Oils, Margarine, and Other Edible Fats and Oils, Not Elsewhere Classified (2079) 108
3.9 Industry Group 208: Beverages 108
3.9.1 Malt Beverages (2082) 108
3.9.2 Malt (2083) 109
3.9.3 Wines, Brandy, and Brandy Spirits (2084) 109
3.9.4 Distilled and Blended Liquors (2085) 109
3.9.5 Bottled and Canned Soft Drinks and Carbonated Waters (2086) 110
3.9.6 Flavoring Extracts and Flavoring Syrups, Not Elsewhere Classified (2087) 110
3.10 Industry Group 209: Miscellaneous Food Preparations And Kindred 111
3.10.1 Canned and Cured Fish and Seafoods (2091) 111
3.10.2 Prepared Fresh or Frozen Fish and Seafoods (2092) 111
3.10.3 Roasted Coffee (2095) 112
3.10.4 Potato Chips, Corn Chips, and Similar Snacks (2096) 112
3.10.5 Manufactured Ice (2097) 113
3.10.6 Macaroni, Spaghetti, Vermicelli, and Noodles (2098) 113
3.10.7 Food Preparations, Not Elsewhere Classified (2099) 113

3.1 INTRODUCTION

In a modern society, trade and commercial transactions, when reduced to the simplest terms, are made by three parties, willingly or unwillingly: government, business or industry, and consumers. A business manufactures a quality product according to the needs and preferences of consumers. The government monitors the activities of the businesses or firms and incorporates such activities into a database. It uses the information for a variety of reasons, including taxation, safety of consumers and workers in the workplace, technology transfers, economic profiles of various industries, the country's growth in relation to any particular industry, and so on. This approach is practiced in most Western countries in the world. The foundation of this government activity or its database accordingly is to classify manufacturing businesses such as car manufacturers, chemical manufacturers, computer manufacturers, food manufacturers, and so on.

The Standard Industrial Classification (SIC) is an establishment–industry classification system that is prepared by the U.S. government for use by all federal agencies, especially those involved in statistics, labor, consumer safety, and so on. Food manufacturing is included in this classification. The SIC is used, among other functions, in the presentation of state and local area estimates of earnings and employment by industry, records of worker injuries, and so on. It is used by the federal government for estimating in the private sector only, although it is designed to cover both public and private economic activities. To understand food manufacturing in the United States, it is important to know the classification of various establishments engaged in food manufacturing in this industry. This is especially important to a food company, because state agencies also use the classification system to assist its state officials in monitoring the food manufactured by each company in terms of

- Compliance with state standards;
- Product safety for the consuming public; and
- Potential economic fraud involving the products.

In the SIC, establishments are classified by the primary activity in which they are engaged, and each establishment is assigned an industry code. The information is provided in the "SIC Manual", which is distributed by the Occupational Safety and Health Administration (OSHA) of the U.S. Department of Labor. The SIC is divided into divisions A to J, where Division D is "Manufacturing". Division D is further divided into major groups. Group 20 refers to "Food and Kindred Products". This major group includes establishments manufacturing or processing foods and beverages for human consumption, and certain related products such as manufactured ice, chewing gum, vegetable and animal fats and oils, and prepared feeds for animals and fowls. Products described as dietetic are classified in the same manner as nondietetic products (e.g., as candy, canned fruits, cookies). Many other establishments such as ingredient manufacturers (e.g., chemical sweeteners) are classified in other major groups under Division D. Table 3.1 describes the structure of Division D.

TABLE 3.1 SIC Major Industrial Group 20, "Foods and Kindred Products".

Industrial Group	Subgroups
201: Meat products	2011: Meat packing plants
	2013: Sausages and other prepared meat products
	2015: Poultry slaughtering and processing
202: Dairy products	2021: Creamery butter
	2022: Natural, processed, and imitation cheese
	2023: Dry, condensed, and evaporated dairy products
	2024: Ice-cream and frozen desserts
	2026: Fluid milk
203: Canned, frozen, and preserved fruits, vegetables	2032: Canned specialties
	2033: Canned fruits, vegetables, preserves, jams, and jellies
	2034: Dried and dehydrated fruits, vegetables, and soup mixes
	2035: Pickled fruits and vegetables, vegetable sauces and seasonings, and salad dressings
	2037: Frozen fruits, fruit juices, and vegetables
	2038: Frozen specialties, not elsewhere classified
204: Grain mill products	2041: Flour and other grain mill products
	2043: Cereal breakfast foods
	2044: Rice milling
	2045: Prepared flour mixes and doughs
	2046: Wet corn milling
	2047: Dog and cat food
	2048: Prepared feed and feed ingredients for animals and fowls, except dogs and cats
205: Bakery products	2051: Bread and other bakery products, except cookies and crackers
	2052: Cookies and crackers
	2053: Frozen bakery products, except bread
206: Sugar and confectionery products	2061: Cane sugar, except refining
	2062: Cane sugar refining
	2063: Beet sugar
	2064: Candy and other confectionery products
	2066: Chocolate and cocoa products
	2067: Chewing gum
	2068: Salted and roasted nuts and seeds
207: Fats and oils	2074: Cottonseed oil mills
	2075: Soybean oil mills
	2076: Vegetable oil mills, except corn, cottonseed, and soybean
	2077: Animal and marine fats and oils
	2079: Shortening, table oils, margarine, and other edible fats and oils, not elsewhere classified
208: Beverages	2082: Malt beverages
	2083: Malt
	2084: Wines, brandy, and brandy spirits
	2085: Distilled and blended liquors
	2086: Bottled and canned soft drinks and carbonated waters
	2087: Flavoring extracts and flavoring syrups, not elsewhere classified
209: Miscellaneous food preparations and kindred	2091: Canned and cured fish and seafoods
	2092: Prepared fresh or frozen fish and seafoods
	2095: Roasted coffee
	2096: Potato chips, corn chips, and similar snacks
	2097: Manufactured ice
	2098: Macaroni, spaghetti, vermicelli, and noodles
	2099: Food preparations, not elsewhere classified

3.2 INDUSTRY GROUP 201: MEAT PRODUCTS

3.2.1 Meat Packing Plants (2011)

This group covers establishments primarily engaged in the slaughtering, for their own account or on a contract basis for the trade, of cattle, hogs, sheep, lambs, and calves for meat to be sold or to be used on the same premises in canning, cooking, curing, and freezing, and in making sausage, lard, and other products. Also included in this industry are establishments primarily engaged in slaughtering horses for human consumption. Establishments primarily engaged in slaughtering, dressing, and packing poultry, rabbits, and other small game are classified in Industry 2015, and those primarily engaged in slaughtering and processing animals not for human consumption are classified in Industry 2048. Establishments primarily engaged in manufacturing sausages and meat specialties from purchased meats are classified in Industry 2013, and those primarily engaged in canning meat for baby food are classified in Industry 2032. In summary, this subgroup covers

- Bacon, slab and sliced;
- Beef;
- Blood meal;
- Boxed beef;
- Canned meats, except baby foods and animal feeds;
- Corned beef;
- Cured meats;
- Dried meats;
- Frankfurters, except poultry;
- Hams, except poultry;
- Hides and skins, cured or uncured;
- Horsemeat for human consumption;
- Lamb;
- Lard;
- Luncheon meat, except poultry;
- Meat extracts;
- Meat packing plants;
- Meat;
- Mutton;
- Pork;
- Sausages;
- Slaughtering plants; except animals not for human consumption;
- Variety meats, edible organs;
- Veal.

3.2.2 Sausages and Other Prepared Meat Products (2013)

This subgroup includes establishments primarily engaged in manufacturing sausages, cured meats, smoked meats, canned meats, frozen meats, and other prepared meats and

meat specialties, from purchased carcasses and other materials. Prepared meat plants operated by packing houses as separate establishments are also included in this industry. Establishments primarily engaged in canning or otherwise processing poultry, rabbits, and other small game are classified in Industry 2015. Establishments primarily engaged in canning meat for baby food are classified in Industry 2032. Establishments primarily engaged in the cutting up and resale of purchased fresh carcasses, for the trade, (including boxed beef) are classified in Wholesale Trade, Industry 5147. In summary, this subgroup includes

- Bacon, slab and sliced;
- Beef;
- Bologna;
- Calf's-foot jelly;
- Canned meats, except baby foods and animal feeds;
- Corned beef;
- Corned meats;
- Cured meats: brined, dried, and salted;
- Dried meats;
- Frankfurters, except poultry;
- Hams, except poultry;
- Headcheese;
- Lard;
- Luncheon meat, except poultry;
- Meat extracts;
- Meat products: cooked, cured, frozen, smoked, and spiced;
- Pastrami;
- Pigs' feet, cooked and pickled;
- Pork: pickled, cured, salted, or smoked;
- Potted meats;
- Puddings, meat;
- Sandwich spreads, meat;
- Sausage casings, collagen;
- Sausages;
- Scrapple;
- Smoked meats;
- Spreads, sandwich: meat;
- Stew, beef and lamb;
- Tripe;
- Vienna sausage.

3.2.3 Poultry Slaughtering and Processing (2015)

This subgroup includes establishments primarily engaged in slaughtering, dressing, packing, freezing, and canning poultry, rabbits, and other small game, or in manufacturing

products from such meats, for their own account or on a contract basis for the trade. This industry also includes the drying, freezing, and breaking of eggs. Establishments primarily engaged in cleaning, oil treating, packing, and grading of eggs are classified in Wholesale Trade, Industry 5144; and those engaged in the cutting up and resale of purchased fresh carcasses are classified in Wholesale and Retail Trade. In summary, this subgroup covers

- Chickens, processed: fresh, frozen, canned, or cooked;
- Chickens: slaughtering and dressing;
- Ducks, processed: fresh, frozen, canned, or cooked;
- Ducks: slaughtering and dressing;
- Egg albumen;
- Egg substitutes made from eggs;
- Eggs: canned, dehydrated, desiccated, frozen, and processed;
- Eggs: drying, freezing, and breaking;
- Frankfurters, poultry;
- Game, small: fresh, frozen, canned, or cooked;
- Game, small: slaughtering and dressing;
- Geese, processed: fresh, frozen, canned, or cooked;
- Geese: slaughtering and dressing;
- Ham, poultry;
- Luncheon meat, poultry;
- Poultry, processed: fresh, frozen, canned, or cooked;
- Poultry: slaughtering and dressing;
- Rabbits, processed: fresh, frozen, canned, or cooked;
- Rabbits, slaughtering and dressing;
- Turkeys, processed: fresh, frozen, canned, or cooked;
- Turkeys: slaughtering and dressing.

3.3 INDUSTRY GROUP 202: DAIRY PRODUCTS

3.3.1 Creamery Butter (2021)

This subgroup cover establishments primarily engaged in manufacturing creamery butter, and therefore incorporates

- Anhydrous butterfat;
- Butter oil;
- Butter powder;
- Butter, creamery and whey;
- Butterfat, anhydrous.

3.3.2 Natural, Processed, and Imitation Cheese (2022)

This subgroup relates to establishments primarily engaged in manufacturing natural cheese (except cottage cheese), processed cheese, cheese foods, cheese spreads, and cheese analogs (imitations and substitutes). These establishments also produce byproducts such as raw liquid whey. Establishments primarily engaged in manufacturing cottage cheese are classified in Industry 2026, and those manufacturing cheese-based salad dressings are classified in Industry 2035. In summary, subgroup 2022 covers

- Cheese analogs;
- Cheese products, imitation or substitutes;
- Cheese spreads, pastes, and cheese-like preparations;
- Cheese, except cottage cheese;
- Cheese, imitation or substitutes;
- Cheese, processed;
- Dips, cheese-based;
- Processed cheese;
- Sandwich spreads, cheese;
- Whey, raw: liquid.

3.3.3 Dry, Condensed, and Evaporated Dairy Products (2023)

In this subgroup are establishments primarily engaged in manufacturing dry, condensed, and evaporated dairy products. Included in this industry are establishments primarily engaged in manufacturing mixes for the preparation of frozen ice-cream and ice milk, and dairy and nondairy base cream substitutes and dietary supplements:

- Baby formula: fresh, processed, and bottled;
- Buttermilk: concentrated, condensed, dried, evaporated, and powdered;
- Casein, dry and wet;
- Cream substitutes;
- Cream: dried, powdered, and canned;
- Dietary supplements, dairy and nondairy base;
- Dry milk products: whole milk, nonfat milk, buttermilk, and whey;
- Eggnog, canned: nonalcoholic;
- Ice-cream mix, unfrozen: liquid or dry;
- Ice milk mix, unfrozen: liquid or dry;
- Lactose, edible;
- Malted milk;
- Milk, whole: canned;
- Milk: concentrated, condensed, dried, evaporated, and powdered;
- Milkshake mix;
- Skim milk: concentrated, dried, and powdered;
- Sugar of milk;
- Whey: concentrated, condensed, dried, evaporated, and powdered;

- Whipped topping, dry mix;
- Yogurt mix.

3.3.4 Ice-Cream and Frozen Desserts (2024)

This includes establishments primarily engaged in manufacturing ice-cream and other frozen desserts. Establishments primarily engaged in manufacturing frozen bakery products, such as cakes and pies, are classified in Industry 2053. In summary, this subgroup covers

- Custard, frozen;
- Desserts, frozen: except bakery;
- Fruit pops, frozen;
- Ice-cream: e.g., bulk, packaged, molded, on sticks;
- Ice milk: e.g., bulk, packaged, molded, on sticks;
- Ices and sherbets;
- Juice pops, frozen;
- Mellorine;
- Parfait;
- Pops, dessert: frozen flavored ice, fruit pudding and gelatin;
- Pudding pops, frozen;
- Sherbets and ices;
- Spumoni;
- Tofu frozen desserts;
- Yogurt, frozen.

3.3.5 Fluid Milk (2026)

This subgroup covers establishments primarily engaged in processing (e.g., pasteurizing, homogenizing, vitaminizing, bottling) fluid milk and cream, and related products, including cottage cheese, yogurt (except frozen), and other fermented milk. Establishments primarily engaged in manufacturing dry-mix whipped toppings are classified in Industry 2023; those producing frozen whipped toppings are classified in Industry 2038; and those producing frozen yogurt are classified in Industry 2024. This subgroup does include

- Buttermilk, cultured;
- Chocolate milk;
- Cottage cheese, including pot, bakers', and farmers' cheese;
- Cream, aerated;
- Cream, bottled;
- Cream, sour;
- Dips, sour cream based;
- Eggnog, fresh: nonalcoholic;
- Flavored milk drinks;
- Half and half;

- Milk processing (pasteurizing, homogenizing, vitaminizing, bottling);
- Milk production, except farm;
- Milk, acidophilus;
- Milk, bottled;
- Milk, flavored;
- Milk, reconstituted;
- Milk, ultra-high temperature;
- Sour cream;
- Whipped cream;
- Whipped topping, except frozen or dry mix;
- Yogurt, except frozen;

3.4 INDUSTRY GROUP 203: CANNED, FROZEN, AND PRESERVED FRUITS, VEGETABLES

3.4.1 Canned Specialties (2032)

This subgroup of Industry Group 203 includes establishments primarily engaged in canning specialty products, such as baby foods, nationality specialty foods, and soups, except seafood. Establishments primarily engaged in canning seafoods are classified in Industry 2091. So, in summary, subgroup 2032 covers

- Baby foods (including meats), canned;
- Bean sprouts, canned;
- Beans, baked: with or without meat, canned;
- Broth, except seafood: canned;
- Chicken broth and soup, canned;
- Chili con carne, canned;
- Chinese foods, canned;
- Chop suey, canned;
- Chow mein, canned;
- Enchiladas, canned;
- Food specialties, canned;
- Italian foods, canned;
- Macaroni, canned;
- Mexican foods, canned;
- Mincemeat, canned;
- Nationality specialty foods, canned;
- Native foods, canned;
- Pasta, canned;
- Puddings, except meat: canned;
- Ravioli, canned;
- Soups, except seafood: canned;

- Spaghetti, canned;
- Spanish foods, canned;
- Tamales, canned;
- Tortillas, canned.

3.4.2 Canned Fruits, Vegetables, Preserves, Jams, and Jellies (2033)

Establishments included in this subgroup are primarily engaged in canning fruits, vegetables, and fruit and vegetable juices; and in manufacturing catsup and similar tomato sauces, or natural and imitation preserves, jams, and jellies. Establishments primarily engaged in canning seafoods are classified in Industry 2091; those manufacturing canned specialties, such as baby foods and soups, except seafood, are classified in Industry 2032. In summary, this subgroup covers

- Artichokes in olive oil, canned;
- Barbecue sauce;
- Catsup;
- Cherries, maraschino;
- Chili sauce, tomato;
- Fruit butters;
- Fruit pie mixes;
- Fruits, canned;
- Hominy, canned;
- Jams, including imitation;
- Jellies, edible: including imitation;
- Juice, fruit: concentrated–hot pack;
- Juices, fresh: fruit or vegetable;
- Juices, fruit and vegetable: canned or fresh;
- Ketchup;
- Marmalade;
- Mushrooms, canned;
- Nectars, fruit;
- Olives, including stuffed: canned;
- Pastes, fruit and vegetable;
- Preserves, including imitation;
- Purees, fruit and vegetable;
- Sauces, tomato-based;
- Sauerkraut, canned;
- Seasonings (prepared sauces), tomato;
- Spaghetti sauce;
- Tomato juice and cocktails, canned;
- Tomato paste;
- Tomato sauce;

- Vegetable pie mixes;
- Vegetables, canned.

3.4.3 Dried and Dehydrated Fruits, Vegetables, and Soup Mixes (2034)

Establishments primarily engaged in sun-drying or artificially dehydrating fruits and vegetables, or in manufacturing packaged soup mixes from dehydrated ingredients are included in this subgroup. Establishments primarily engaged in the grading and marketing of farm dried fruits, such as prunes and raisins, are classified in Wholesale Trade, Industry 5149. So, this subgroup covers

- Dates, dried;
- Dehydrated fruits, vegetables, and soups;
- Fruit flour, meal, and powders;
- Fruits, sulfured;
- Olives, dried;
- Potato flakes, granules, and other dehydrated potato products;
- Prunes, dried;
- Raisins;
- Soup mixes;
- Soup powders;
- Vegetable flour, meal, and powders;
- Vegetables, sulfured.

3.4.4 Pickled Fruits and Vegetables, Vegetable Sauces and Seasonings, and Salad Dressings (2035)

Establishments primarily engaged in pickling and brining fruits and vegetables, and in manufacturing salad dressings, vegetable relishes, sauces, and seasonings are included here. Establishments primarily engaged in manufacturing catsup and similar tomato sauces are classified in Industry 2033, and those packing purchased pickles and olives are classified in Wholesale or Retail Trade. Establishments primarily engaged in manufacturing dry salad dressing and dry sauce mixes are classified in Industry 2099. In summary, subgroup 2035 relates to

- Blue cheese dressing;
- Brining of fruits and vegetables;
- Cherries, brined;
- French dressing;
- Fruits, pickled and brined;
- Horseradish, prepared;
- Mayonnaise;
- Mustard, prepared (wet);
- Olives, brined: bulk;
- Onions, pickled;

- Pickles and pickle salting;
- Relishes, fruit and vegetable;
- Russian dressing;
- Salad dressings, except dry mixes;
- Sandwich spreads, salad dressing base;
- Sauces, meat (seasoning): except tomato and dry;
- Sauces, seafood: except tomato and dry;
- Sauerkraut, bulk;
- Seasonings (prepared sauces), vegetable: except tomato and dry;
- Soy sauce;
- Thousand Island dressing;
- Vegetable sauces, except tomato;
- Vegetables, pickled and brined;
- Vinegar pickles and relishes;
- Worcestershire sauce.

3.4.5 Frozen Fruits, Fruit Juices, and Vegetables (2037)

Establishments included here are primarily engaged in freezing fruits, fruit juices, and vegetables. These establishments also produce important byproducts such as fresh or dried citrus pulp. In summary, this subgroup covers

- Concentrates, frozen fruit juice;
- Dried citrus pulp;
- Frozen fruits, fruit juices, and vegetables;
- Fruit juices, frozen;
- Fruits, quick frozen and coldpack (frozen);
- Vegetables, quick frozen and coldpack (frozen).

3.4.6 Frozen Specialties, Not Elsewhere Classified (2038)

This subgroup covers establishments primarily engaged in manufacturing frozen food specialties, not elsewhere classified, such as frozen dinners and frozen pizza. The manufacture of some important frozen foods and specialties is classified elsewhere. For example, establishments primarily engaged in manufacturing frozen dairy specialties are classified in Industry Group 202, those manufacturing frozen bakery products are classified in Industry Group 205, those manufacturing frozen fruits and vegetables are classified in Industry 2037, and those manufacturing frozen fish and seafood specialties are classified in Industry 2092. Categories included in this subgroup are

- Dinners, frozen: packaged;
- French toast, frozen;
- Frozen dinners, packaged;
- Meats, frozen;
- Native foods, frozen;

- Pizza, frozen;
- Soups, frozen: except seafood;
- Spaghetti and meatballs, frozen;
- Waffles, frozen;
- Whipped topping, frozen.

3.5 INDUSTRY GROUP 204: GRAIN MILL PRODUCTS

3.5.1 Flour and Other Grain Mill Products (2041)

Establishments primarily engaged in milling flour or meal from grain, except rice, are included here. The products of flour mills may be sold plain or in the form of prepared mixes or doughs for specific purposes. Establishments primarily engaged in manufacturing prepared flour mixes or doughs from purchased ingredients are classified in Industry 2045, and those milling rice are classified in Industry 2044. Those products that are in this subgroup 2041 include

- Bran and middlings, except rice;
- Bread and bread-type roll mixes;
- Buckwheat flour;
- Cake flour;
- Cereals, cracked grain;
- Corn grits and flakes for brewers' use;
- Dough, biscuit;
- Doughs, refrigerated or frozen;
- Durum flour;
- Farina, except breakfast food;
- Flour mills, cereals: except rice;
- Flour mixes;
- Flour: blended, prepared, or self-rising;
- Flour: buckwheat, corn, graham, rye, and wheat;
- Frozen doughs;
- Graham flour;
- Granular wheat flour;
- Grits and flakes, corn: for brewers' use;
- Hominy grits, except breakfast food;
- Meal, corn;
- Milling of grains, dry, except rice;
- Mixes, flour: e.g., pancake, cake, biscuit, doughnut;
- Pancake batter, refrigerated or frozen;
- Pizza mixes and prepared dough;
- Semolina (flour);
- Sorghum grain flour;

- Wheat germ;
- Wheat mill feed.

3.5.2 Cereal Breakfast Foods (2043)

Establishments primarily engaged in manufacturing cereal breakfast foods and related preparations, except breakfast bars, are included in this subgroup. Establishments primarily engaged in manufacturing granola bars and other types of breakfast bars are classified in Industry 2064. In summary, then, this subgroup covers

- Breakfast foods, cereal;
- Coffee substitutes made from grain;
- Corn flakes;
- Corn, hulled (cereal breakfast food);
- Farina, cereal breakfast food;
- Granola, except bars and clusters;
- Hominy grits prepared as cereal breakfast food;
- Infants' foods, cereal type;
- Oatmeal (cereal breakfast food);
- Oats, rolled (cereal breakfast food);
- Rice breakfast foods;
- Wheat flakes.

3.5.3 Rice Milling (2044)

Establishments primarily engaged in cleaning and polishing rice, and in manufacturing rice flour or meal are incorporated here. Other important products of this industry include brown rice, milled rice (including polished rice), rice polish, and rice bran. In summary, the following are included:

- Flour, rice;
- Milling of rice;
- Polishing of rice;
- Rice bran, flour, and meal;
- Rice cleaning and polishing;
- Rice polish;
- Rice, brewers';
- Rice, brown;
- Rice, vitamin and mineral enriched.

3.5.4 Prepared Flour Mixes and Doughs (2045)

This subgroup includes establishments primarily engaged in preparing flour mixes or doughs from purchased flour. Establishments primarily engaged in milling flour from grain and producing mixes or doughs are classified in Industry 2041. So, this subgroup covers

- Biscuit mixes and doughs;
- Bread and bread-type roll mixes;
- Cake flour;
- Cake mixes;
- Dough, biscuit;
- Doughnut mixes;
- Doughs, refrigerated or frozen;
- Flour: blended or self-rising;
- Frozen doughs;
- Gingerbread mixes;
- Mixes, flour: e.g., pancake, cake, biscuit, doughnut;
- Pancake batter, refrigerated or frozen;
- Pancake mixes;
- Pizza mixes and doughs.

3.5.5 Wet Corn Milling (2046)

This subgroup includes establishments primarily engaged in milling corn or sorghum grain (milo) by the wet process, and producing starch, syrup, oil, sugar, and byproducts such as gluten feed and meal. Also included in this industry are establishments primarily engaged in manufacturing starch from other vegetable sources (e.g., potatoes and wheat). Establishments primarily engaged in manufacturing table syrups from corn syrup and other ingredients, and those manufacturing starch-based dessert powders, are classified in Industry 2099. This subgroup therefore covers

- Corn oil cake and meal;
- Corn starch;
- Corn syrup (including dried), unmixed;
- Dextrine;
- Dextrose;
- Feed, gluten;
- Fructose;
- Glucose;
- High fructose syrup;
- Hydrol;
- Meal, gluten;
- Oil, corn: crude and refined;
- Potato starch;
- Rice starch;
- Starch, instant;
- Starch, liquid;
- Starches, edible and industrial;

- Steepwater concentrate;
- Sugar, corn;
- Tapioca;
- Wheat gluten;
- Wheat starch.

3.5.6 Dog and Cat Food (2047)

Establishments primarily engaged in manufacturing dog and cat food from cereal, meat, and other ingredients are included here. These preparations may be canned, frozen, or dry. Establishments primarily engaged in manufacturing feed for animals other than dogs and cats are classified in Industry 2048. This subgroup thus contains just

- Cat food;
- Dog food.

3.5.7 Prepared Feed and Feed Ingredients for Animals and Fowls, Except Dogs and Cats (2048)

Establishments primarily engaged in manufacturing prepared feeds and feed ingredients and adjuncts for animals and fowls, except dogs and cats, are covered. Included in this industry are poultry and livestock feed and feed ingredients, such as alfalfa meal, feed supplements, and feed concentrates and feed premixes. Also included are establishments primarily engaged in slaughtering animals for animal feed. Establishments primarily engaged in slaughtering animals for human consumption are classified in Industry Group 201. Establishments primarily engaged in manufacturing dog and cat foods are classified in Industry 2047. So, this subgroup contains

- Alfalfa, cubed;
- Alfalfa, prepared as feed for animals;
- Animal feeds, prepared: except dog and cat;
- Bird food, prepared;
- Buttermilk emulsion for animal food;
- Chicken feeds, prepared;
- Citrus seed meal;
- Earthworm food and bedding;
- Feed concentrates;
- Feed premixes;
- Feed supplements;
- Feeds, prepared (including mineral): for animals and fowls;
- Feeds, specialty: mice, guinea pigs, minks, etc.;
- Fish food;
- Hay, cubed;
- Horsemeat, except for human consumption;

- Kelp meal and pellets;
- Livestock feeds, supplements, and concentrates;
- Meal, bone: prepared as feed for animals and fowls;
- Mineral feed supplements;
- Oats: crimped, pulverized, and rolled: except breakfast food;
- Oyster shells, ground: used as feed for animals and fowls;
- Pet food, except dog and cat: canned, frozen, and dry;
- Poultry feeds, supplements, and concentrates;
- Shell crushing for feed;
- Slaughtering of animals, except for human consumption;
- Stock feeds, dry.

3.6 INDUSTRY GROUP 205: BAKERY PRODUCTS

3.6.1 Bread and Other Bakery Products, Except Cookies and Crackers (2051)

Establishments primarily engaged in manufacturing fresh or frozen bread and bread-type rolls and fresh cakes, pies, pastries and other similar "perishable" bakery products are included here. Establishments primarily engaged in producing "dry" bakery products, such as biscuits, crackers, and cookies, are classified in Industry 2052. Establishments primarily engaged in manufacturing frozen bakery products, except bread and bread-type rolls, are classified in Industry 2053. Establishments producing bakery products primarily for direct sale on the premises to household consumers are classified in Retail Trade, Industry 5461. In summary, this subgroup includes

- Bagels;
- Bakery products, fresh: bread, cakes, doughnuts, and pastries;
- Bakery products, partially cooked: except frozen;
- Biscuits, baked: baking powder and raised;
- Bread, brown: boston and other, canned;
- Bread, including frozen;
- Buns, bread-type (e.g., hamburger, hot dog), including frozen;
- Buns, sweet, except frozen;
- Cakes, bakery, except frozen;
- Charlotte Russe (bakery product), except frozen;
- Croissants, except frozen;
- Crullers, except frozen;
- Doughnuts, except frozen;
- Frozen bread and bread-type rolls;
- Knishes, except frozen;
- Pastries, except frozen: e.g., Danish, French;
- Pies, bakery, except frozen;

- Rolls, bread-type, including frozen;
- Rolls, sweet, except frozen;
- Sponge goods, bakery, except frozen.

3.6.2 Cookies and Crackers (2052)

Establishments primarily engaged in manufacturing fresh cookies, crackers, pretzels, and similar "dry" bakery products are included. Establishments primarily engaged in producing other fresh bakery products are classified in Industry 2051. So, this subgroup covers

- Bakery products, dry: e.g., biscuits, crackers, pretzels;
- Biscuits, baked: dry, except baking powder and raised;
- Communion wafers;
- Cones, ice-cream;
- Cookies;
- Cracker meal and crumbs;
- Crackers: e.g., graham, soda;
- Matzoths;
- Pretzels;
- Rusk;
- Saltines;
- Zwieback.

3.6.3 Frozen Bakery Products, Except Bread (2053)

Establishments primarily engaged in manufacturing frozen bakery products, except bread and bread-type rolls, are included. Establishments primarily engaged in manufacturing frozen bread and bread-type rolls are classified in Industry 2051. This subgroup therefore covers

- Bakery products, frozen: except bread and bread-type rolls;
- Cakes, frozen: pound, layer, and cheese;
- Croissants, frozen;
- Doughnuts, frozen;
- Pies, bakery, frozen;
- Sweet yeast goods, frozen.

3.7 INDUSTRY GROUP 206: SUGAR AND CONFECTIONERY PRODUCTS

3.7.1 Cane Sugar, Except Refining (2061)

Establishments primarily engaged in manufacturing raw sugar, syrup, or finished (granulated or clarified) cane sugar from sugarcane are covered in this subgroup. Establishments

primarily engaged in refining sugar from purchased raw cane sugar or sugar syrup are classified in Industry 2062. Included, these, are

- Cane sugar, made from sugarcane;
- Molasses, blackstrap: made from sugarcane;
- Molasses, made from sugarcane;
- Sugar, granulated: made from sugarcane;
- Sugar, invert: made from sugarcane;
- Sugar, powdered: made from sugarcane;
- Sugar, raw: made from sugarcane;
- Syrup, cane: made from sugarcane.

3.7.2 Cane Sugar Refining (2062)

Establishments primarily engaged in refining purchased raw cane sugar and sugar syrup are included here, covering

- Molasses, blackstrap: made from purchased raw cane sugar or sugar;
- Refineries, cane sugar;
- Sugar, granulated: made from purchased raw cane sugar or sugar;
- Sugar, invert: made from purchased raw cane sugar or sugar syrup;
- Sugar, powdered: made from purchased raw cane sugar or sugar;
- Sugar, refined: made from purchased raw cane sugar or sugar syrup;
- Syrup, made from purchased raw cane sugar or sugar syrup.

3.7.3 Beet Sugar (2063)

This subgroup includes establishments primarily engaged in manufacturing sugar from sugar beets, and covers

- Beet pulp, dried;
- Beet sugar, made from sugar beets;
- Molasses beet pulp;
- Molasses, made from sugar beets;
- Sugar, granulated: made from sugar beets;
- Sugar, invert: made from sugar beets;
- Sugar, liquid: made from sugar beets;
- Sugar, powdered: made from sugar beets;
- Syrup, made from sugar beets.

3.7.4 Candy and Other Confectionery Products (2064)

Establishments primarily engaged in manufacturing candy, including chocolate candy, other confections, and related products, are included here. Establishments primarily

engaged in manufacturing solid chocolate bars from cacao beans are classified in Industry 2066; those manufacturing chewing gum are classified in Industry 2067; and those primarily engaged in roasting and salting nuts are classified in Industry 2068. Establishments primarily engaged in manufacturing confectionery for direct sale on the premises to household consumers are classified in Retail Trade, Industry 5441. So, this subgroup covers

- Bars, candy: including chocolate-covered bars;
- Breakfast bars;
- Cake ornaments, confectionery;
- Candy, except solid chocolate;
- Chewing candy, except chewing gum;
- Chocolate bars, from purchased cocoa or chocolate;
- Chocolate candy, except solid chocolate;
- Confectionery;
- Cough drops, except pharmaceutical preparations;
- Dates: chocolate covered, sugared, and stuffed;
- Fruit peel products: candied, glazed, glace, and crystallized;
- Fruits: candied, glazed, and crystallized;
- Fudge (candy);
- Granola bars and clusters;
- Halvah (candy);
- Licorice candy;
- Lozenges, candy: nonmedicated;
- Marshmallows;
- Marzipan (candy);
- Nuts, candy covered;
- Nuts, glace;
- Popcorn balls and candy-covered popcorn products.

3.7.5 Chocolate and Cocoa Products (2066)

Establishments primarily engaged in shelling, roasting, and grinding cacao beans for the purpose of making chocolate liquor, from which cocoa powder and cocoa butter are derived, and in the further manufacture of solid chocolate bars, chocolate coatings, and other chocolate and cocoa products are covered here. Also included is the manufacture of similar products, except candy, from purchased chocolate or cocoa. Establishments primarily engaged in manufacturing candy from purchased cocoa products are classified in Industry 2064. This subgroup therefore includes

- Baking chocolate;
- Bars, candy: solid chocolate;
- Cacao bean products: chocolate, cocoa butter, and cocoa;
- Cacao beans: shelling, roasting, and grinding for making chocolate;
- Candy, solid chocolate;

- Chocolate bars, solid: from cacao beans;
- Chocolate coatings and syrups;
- Chocolate liquor;
- Chocolate syrup;
- Chocolate, instant;
- Chocolate, sweetened or unsweetened;
- Cocoa butter;
- Cocoa mix, instant;
- Cocoa, powdered: mixed with other substances.

3.7.6 Chewing Gum (2067)

This subgroup includes establishments primarily engaged in manufacturing chewing gum or chewing gum base, and covers

- Chewing gum;
- Chewing gum base.

3.7.7 Salted and Roasted Nuts and Seeds (2068)

Establishments primarily engaged in manufacturing salted, roasted, dried, cooked, or canned nuts or in processing grains or seeds in a similar manner for snack purposes are covered in this subgroup. Establishments primarily engaged in manufacturing confectionery-coated nuts are classified in Industry 2064, and those manufacturing peanut butter are classified in Industry 2099. So, this subgroup includes establishment making

- Nuts, dehydrated or dried;
- Nuts: salted, roasted, cooked, or canned;
- Seeds: salted, roasted, cooked, or canned.

3.8 INDUSTRY GROUP 207: FATS AND OILS

3.8.1 Cottonseed Oil Mills (2074)

Establishments primarily engaged in manufacturing cottonseed oil, cake, meal, and linters, or in processing purchased cottonseed oil other than into edible cooking oils are included here. Establishments primarily engaged in refining cottonseed oil into edible cooking oils are classified in Industry 2079. So, this subgroup covers

- Cottonseed oil, cake, and meal: made in cottonseed oil mills;
- Cottonseed oil, deodorized;
- Lecithin, cottonseed.

3.8.2 Soybean Oil Mills (2075)

Included in this subgroup are establishments primarily engaged in manufacturing soybean oil, cake, and meal, and soybean protein isolates and concentrates, or in processing purchased

soybean oil other than into edible cooking oils. Establishments primarily engaged in refining soybean oil into edible cooking oils are classified in Industry 2079. Covered then are

- Lecithin, soybean;
- Soybean flour and grits;
- Soybean oil, cake, and meal;
- Soybean oil, deodorized;
- Soybean protein concentrates;
- Soybean protein isolates.

3.8.3 Vegetable Oil Mills, Except Corn, Cottonseed, and Soybean (2076)

Establishments primarily engaged in manufacturing vegetable oils, cake and meal, except corn, cottonseed, and soybean, or in processing similar purchased oils other than into edible cooking oils, are included here. Establishments primarily engaged in manufacturing corn oil and its byproducts are classified in Industry 2046; those that are refining vegetable oils into edible cooking oils are classified in Industry 2079; and those refining these oils for medicinal purposes are classified in Industry 2833. In summary, this subgroup covers

- Castor oil and pomace;
- Coconut oil;
- Linseed oil, cake, and meal;
- Oils, vegetable: except corn, cottonseed, and soybean;
- Oiticica oil;
- Palm kernel oil;
- Peanut oil, cake, and meal;
- Safflower oil;
- Sunflower seed oil;
- Tallow, vegetable;
- Tung oil;
- Walnut oil.

3.8.4 Animal and Marine Fats and Oils (2077)

Included here are establishments primarily engaged in manufacturing animal oils, including fish oil and other marine animal oils, and fish and animal meal, and those rendering inedible stearin, grease, and tallow from animal fat, bones, and meat scraps. Establishments primarily engaged in manufacturing lard and edible tallow and stearin are classified in Industry Group 201; those refining marine animal oils for medicinal purposes are classified in Industry 2833; and those manufacturing fatty acids are classified in Industry 2899. So, this subgroup covers

- Feather meal;
- Fish liver oils, crude;

- Fish meal;
- Fish oil and fish oil meal;
- Grease rendering, inedible;
- Meal, meat and bone: not prepared as feed;
- Meat and bone meal and tankage;
- Oils, animal;
- Oils, fish and marine animal: e.g., herring, menhaden, whale;
- Rendering plants, inedible grease and tallow;
- Stearin, animal: inedible;
- Tallow rendering, inedible.

3.8.5 Shortening, Table Oils, Margarine, and Other Edible Fats and Oils, Not Elsewhere Classified (2079)

Establishments primarily engaged in manufacturing shortening, table oils, margarine, and other edible fats and oils, not elsewhere classified, are covered here. Establishments primarily engaged in producing corn oil are classified in Industry 2046. This subgroup therefore contains

- Baking and frying fats (shortening);
- Cottonseed cooking and salad oil;
- Margarine oil, except corn;
- Margarine, including imitation;
- Margarine butter blend;
- Nut margarine;
- Oil, hydrogenated: edible;
- Oil, partially hydrogenated: edible;
- Oil, vegetable winter stearin;
- Olive oil;
- Peanut cooking and salad oil;
- Shortenings, compound and vegetable;
- Soybean cooking and salad oil;
- Vegetable cooking and salad oil, except corn oil: refined.

3.9 INDUSTRY GROUP 208: BEVERAGES

3.9.1 Malt Beverages (2082)

Establishments primarily engaged in manufacturing malt beverages are included here. Establishments primarily engaged in bottling purchased malt beverages are classified in Industry 5181. So, this subgroup covers

- Ale;
- Beer (alcoholic beverage);

- Breweries;
- Brewers' grain;
- Liquors, malt;
- Malt extract, liquors, and syrups;
- Near beer;
- Porter (alcoholic beverage).

3.9.2 Malt (2083)

Establishments primarily engaged in manufacturing malt or malt byproducts from barley or other grains are included, covering

- Malt byproducts;
- Malt: barley, rye, wheat, and corn;
- Malthouses;
- Sprouts, made in malthouses.

3.9.3 Wines, Brandy, and Brandy Spirits (2084)

Included here are establishments primarily engaged in manufacturing wines, brandy, and brandy spirits. This industry also includes bonded wine cellars that are engaged in blending wines. Establishments primarily bottling purchased wines, brandy, and brandy spirits, but which do not manufacture wines and brandy, are classified in Wholesale Trade, Industry 5182. So, this subgroup covers

- Brandy;
- Brandy spirits;
- Wine cellars, bonded: engaged in blending wines;
- Wine coolers (beverages);
- Wines.

3.9.4 Distilled and Blended Liquors (2085)

This subgroup covers establishments primarily engaged in manufacturing alcoholic liquors by distillation, and in manufacturing cordials and alcoholic cocktails by blending processes or by mixing liquors and other ingredients. Establishments primarily engaged in manufacturing industrial alcohol are classified in Industry 2869, and those only bottling purchased liquors are classified in Wholesale Trade, Industry 5182. Covered then are

- Applejack;
- Cocktails, alcoholic;
- Cordials, alcoholic;
- Distillers' dried grains and solubles;
- Eggnog, alcoholic;
- Ethyl alcohol for medicinal and beverage purposes;
- Gin (alcoholic beverage);

- Grain alcohol for medicinal and beverage purposes;
- Liquors: distilled and blended, except brandy;
- Rum;
- Spirits, neutral, except fruit for beverage purposes;
- Vodka;
- Whiskey: bourbon, rye, scotch type, and corn.

3.9.5 Bottled and Canned Soft Drinks and Carbonated Waters (2086)

Included here are establishments primarily engaged in manufacturing soft drinks and carbonated waters. Establishments primarily engaged in manufacturing fruit and vegetable juices are classified in Industry Group 203; those manufacturing fruit syrups for flavoring are classified in Industry 2087; and those manufacturing nonalcoholic cider are classified in Industry 2099. Establishments primarily engaged in bottling natural spring waters are classified in Wholesale Trade, Industry 5149. In summary, those products covered here include

- Beer, birch and root: bottled or canned;
- Carbonated beverages, nonalcoholic: bottled or canned;
- Drinks, fruit: bottled, canned, or fresh;
- Ginger ale, bottled or canned;
- Iced tea, bottled or canned;
- Lemonade: bottled, canned, or fresh;
- Mineral water, carbonated: bottled or canned;
- Soft drinks, bottled or canned;
- Tea, iced: bottled or canned;
- Water, pasteurized: bottled or canned.

3.9.6 Flavoring Extracts and Flavoring Syrups, Not Elsewhere Classified (2087)

Establishments primarily engaged in manufacturing flavoring extracts, syrups, powders, and related products, not elsewhere classified, for soda fountain use or for the manufacture of soft drinks, and colors for bakers'; and confectioners' use, are contained here. Establishments primarily engaged in manufacturing chocolate syrup are classified in Industry 2066. So, included here are

- Beverage bases;
- Bitters (flavoring concentrates);
- Burnt sugar (food color);
- Cocktail mixes, nonalcoholic;
- Coffee flavorings and syrups;
- Colors for bakers' and confectioners' use, except synthetic;
- Cordials, nonalcoholic;
- Drink powders and concentrates;
- Flavoring concentrates;

- Flavoring extracts, pastes, powders, and syrups;
- Food colorings, except synthetic;
- Food glace, for glazing foods;
- Fruit juices, concentrated: for fountain use;
- Fruit, crushed: for soda fountain use.

3.10 INDUSTRY GROUP 209: MISCELLANEOUS FOOD PREPARATIONS AND KINDRED

3.10.1 Canned and Cured Fish and Seafoods (2091)

Included here are establishments primarily engaged in cooking and canning fish, shrimp, oysters, clams, crabs, and other seafoods, including soups; and those engaged in smoking, salting, drying, or otherwise curing fish and other seafoods for the trade. Establishments primarily engaged in shucking and packing fresh oysters in nonsealed containers, or in freezing or preparing fresh fish, are classified in Industry 2092. So, this subgroup covers

- Canned fish, crustacea, and mollusks;
- Caviar, canned;
- Chowders, fish and seafood: canned;
- Clam bouillon, broth, chowder, juice: bottled or canned;
- Codfish: smoked, salted, dried, and pickled;
- Crab meat, canned and cured;
- Finnan haddie (smoked haddock);
- Fish and seafood cakes: canned;
- Fish egg bait, canned;
- Fish, canned and cured;
- Fish: cured, dried, pickled, salted, and smoked;
- Herring: smoked, salted, dried, and pickled;
- Mackerel: smoked, salted, dried, and pickled;
- Oysters, canned and cured;
- Salmon: smoked, salted, dried, canned, and pickled;
- Sardines, canned;
- Shellfish, canned and cured;
- Shrimp, canned and cured;
- Soups, fish and seafood: canned;
- Stews, fish and seafood: canned;
- Tuna fish, canned.

3.10.2 Prepared Fresh or Frozen Fish and Seafoods (2092)

This subgroup contains establishments primarily engaged in preparing fresh and raw or cooked frozen fish and other seafoods and seafood preparations, such as soups, stews, chowders, fishcakes, crabcakes, and shrimp cakes. Prepared fresh fish are eviscerated or

processed by removal of heads, fins, or scales. This industry also includes establishments primarily engaged in the shucking and packing of fresh oysters in nonsealed containers. Included, then, are

- Chowders, fish and seafood: frozen;
- Crabcakes, frozen;
- Crabmeat picking;
- Crabmeat, fresh: packed in nonsealed containers;
- Fish and seafood cakes, frozen;
- Fish fillets;
- Fish sticks;
- Fish: fresh and frozen, prepared;
- Oysters, fresh: shucking and packing in nonsealed containers;
- Seafoods, fresh and frozen;
- Shellfish, fresh and frozen;
- Shellfish, fresh: shucked, picked, or packed;
- Shrimp, fresh and frozen;
- Soups, fish and seafood: frozen;
- Stews, fish and seafood: frozen.

3.10.3 Roasted Coffee (2095)

Covered here are establishments primarily engaged in roasting coffee, and in manufacturing coffee concentrates and extracts in powdered, liquid, or frozen form, including freeze-dried. Coffee roasting by wholesale grocers is classified in Wholesale Trade, Industry 5149. So, this subgroup relates to

- Coffee extracts;
- Coffee roasting, except by wholesale grocers;
- Coffee, found: mixed with grain or chicory;
- Coffee, instant and freeze-dried.

3.10.4 Potato Chips, Corn Chips, and Similar Snacks (2096)

Establishments primarily engaged in manufacturing potato chips, corn chips, and similar snacks are included here. Establishments primarily engaged in manufacturing pretzels and crackers are classified in Industry 2052; those manufacturing candy-covered popcorn are classified in Industry 2064; those manufacturing salted, roasted, cooked or canned nuts and seeds are classified in Industry 2068; and those manufacturing packaged unpopped popcorn are classified in Industry 2099. This subgroup therefore contains

- Cheese curls and puffs;
- Corn chips and related corn snacks;
- Popcorn, popped: except candy covered;

- Pork rinds;
- Potato chips and related corn snacks;
- Potato sticks.

3.10.5 Manufactured Ice (2097)

Establishments primarily engaged in manufacturing ice for sale are covered in this subgroup. Establishments primarily engaged in manufacturing dry ice are classified in Industry 2813. So, this subgroup includes

- Block ice;
- Ice cubes;
- Ice plants, operated by public utilities;
- Ice, manufactured or artificial: except dry ice.

3.10.6 Macaroni, Spaghetti, Vermicelli, and Noodles (2098)

Establishments primarily engaged in manufacturing dry macaroni, spaghetti, vermicelli, and noodles are covered here. Establishments primarily engaged in manufacturing canned macaroni and spaghetti are classified in Industry 2032, and those manufacturing fried noodles, such as Chinese noodles, are classified in Industry 2099. Included are

- Macaroni and products, dry: e.g., alphabets, rings, seashells;
- Noodles: egg, plain, and water;
- Spaghetti, dry;
- Vermicelli.

3.10.7 Food Preparations, Not Elsewhere Classified (2099)

Included here are establishments primarily engaged in manufacturing prepared foods and miscellaneous food specialties, not elsewhere classified, such as baking powder, yeast, and other leavening compounds; peanut butter; packaged tea, including instant; ground spices; and vinegar and cider. Also included in this industry are establishments primarily engaged in manufacturing dry preparations, except flour mixes, consisting of pasta, rice, potatoes, textured vegetable protein, and similar products that are packaged with other ingredients to be prepared and cooked by the consumer. Establishments primarily engaged in manufacturing flour mixes are classified in Industry Group 204. This subgroup therefore covers

- Almond pastes;
- Baking powder;
- Bouillon cubes;
- Box lunches for sale off premises;
- Breadcrumbs, not made in bakeries;
- Butter, renovated and processed;
- Cake frosting mixes, dry;
- Chicory root, dried;

- Chili pepper or powder;
- Chinese noodles;
- Cider, nonalcoholic;
- Coconut, desiccated and shredded;
- Cole slaw in bulk;
- Cracker sandwiches made from purchased crackers;
- Desserts, ready-to-mix;
- Dips, except cheese and sour cream based;
- Emulsifiers, food;
- Fillings, cake or pie: except fruits, vegetables, and meat;
- Frosting, prepared;
- Gelatin dessert preparations;
- Gravy mixes, dry;
- Honey, strained and bottled;
- Jelly, corncob (gelatin);
- Leavening compounds, prepared;
- Marshmallow creme;
- Meat seasonings, except sauces;
- Molasses, mixed or blended;
- Noodles, fried (e.g., Chinese);
- Noodles, uncooked: packaged with other ingredients;
- Pancake syrup, blended and mixed;
- Pasta, uncooked: packaged with other ingredients;
- Peanut butter;
- Pectin;
- Pepper;
- Pizza, refrigerated: not frozen;
- Popcorn, packaged: except popped;
- Potatoes, dried: packaged with other ingredients;
- Potatoes, peeled for the trade;
- Rice, uncooked: packaged with other ingredients;
- Salad dressing mixes, dry;
- Salads, fresh or refrigerated;
- Sandwiches, assembled and packaged: for wholesale market;
- Sauce mixes, dry;
- Sorghum, including custom refining;
- Spices, including grinding;
- Sugar grinding;
- Sugar, industrial maple: made in plants producing maple syrup;
- Sugar, powdered;
- Syrups, sweetening: honey, maple syrup, sorghum;

- Tea blending;
- Tofu, except frozen desserts;
- Tortillas, fresh or refrigerated;
- Vegetables peeled for the trade;
- Vinegar;
- Yeast.

This chapter is an introduction to detailed discussions on the technology and use of flavorings in the main branches of the food industry, ranging from beverages, confections, and bakery products to meat and poultry products, sea foods, and variety meals. Thus, in the ensuing chapters, there will be detailed discussions on the use of flavorings in each of several food product segments. The detailed discussion of each product segment becomes necessary because each product group has its own peculiarities, and only few generalizations can be made. This first discussion will therefore focus on a broad review of the principles guiding the technology and use of flavorings in the food industry in general. In addition, there will be a brief review of certain elements of the flavor system, in particular as they affect flavor perception.

Perhaps we can start by stating an obvious fact: the flavor of food is all-important. And there are several reasons for this. First and foremost, many of the foods we eat are lacking in an intrinsic flavor that is satisfying and definite. Diets based on such foods are therefore unattractive and unappetizing without the addition of flavorings. Second, many of the foods we now eat are fabricated or formulated foods. They are formulated from several foodstuffs having widely differing flavors, and a specific flavoring must be added to either confer a definitive character or intensify one of the flavors already present in the food. Third, food preparation has moved progressively from the kitchen to the factory in the last one or two decades. The more intense institutional and/or factory cooking procedures call for adding back the heat-labile and escaped volatile flavor compounds. Fourth, in modern food marketing, the flavor of the food product has become the main selling point in gaining and keeping customer acceptance. Fifth, the introduction of new flavorings is the most frequently explored route, not only in replacement or rejuvenation of existing products with declining sales, and in extension of existing lines to expand sales, but also in repositioning of existing products and in food product development in general. Sixth, of all the three attribute components of food quality, namely color, flavor, and texture, flavor creates the most avenues for offering variety and originality.

It is therefore little surprise that virtually all foods and other consumer goods are now flavored, ranging from bottled water to cigars. One must then justifiably ponder what principles govern the use of the wide array of flavorings employed in the several thousands of products in which they appear. That is basically the task of this chapter.

4.1 CLASSIFICATION OF FOODS BASED ON THEIR NATURAL FLAVOR CHARACTERISTICS

We have already alluded to the fact that many of the foods we eat are lacking in an intrinsic flavor that is both satisfying and quite definite. This needs further clarification here. A distinction needs to be made between natural flavors of foods in their natural state in contradistinction to derived flavors during and after processing. This distinction is fundamental

to an understanding of the basic principles as well as the philosophy for the use of flavorings in foods. It will therefore be helpful to discuss two broad classifications of biological food materials with respect to: (1) Their natural flavor characteristics in the raw state and (2) their derived flavor characteristics during and after processing.

4.1.1 Natural Flavor Characteristics of Foods in Their Raw State

The natural flavor characteristics of food materials in their raw state are important because of the fact that quite a good number of these foods are eaten in the raw state without being cooked. Moreover, such natural flavor characteristics offer a provisional insight into flavoring requirements during processing. It has therefore been quite useful to classify foods generally based on their flavor characteristics in their raw state.

On the basis of the foregoing, it is generally agreed that foods may be classified into three categories (Heath 1978), namely: (1) Low flavor impact, (2) medium flavor impact, and (3) high flavor impact. The characteristics of the three different groups are given in the following.

4.1.1.1 Materials with Low Flavor Impact. The most striking property of foodstuffs in this category is their less than average flavor characteristic. Furthermore, they are highly nutritious. Examples of such low flavor impact foodstuffs, which may require flavoring during processing, include meat, fish, seafoods, fresh milk, cereal grains, and legumes.

4.1.1.2 Materials with Medium Flavor Impact. The foodstuffs in this category are of adequate flavor. Moreover, they are moderately nutritious. Examples of such foodstuffs include fruits, nuts, mushrooms, and aromatic vegetables like onion, garlic, chives, and leeks. Other examples are members of the *Brassicca* species of the cruciferous vegetables like cabbage and cauliflower.

4.1.1.3 Materials with High Flavor Impact. Foodstuffs in this category are extremely flavorful. However, they are of low or no nutritional value. They are therefore useful mainly as flavorings. Examples of such high flavor impact materials include herbs, spices, and vanilla.

4.1.2 Derived Flavor Characteristics of Foods During Processing

The flavor characteristics derived during and after processing are important, especially for processed foods. Such derived flavor characteristics offer a definitive insight into the nature and intensity of flavoring requirements during and after processing. On the basis of the derived flavor, processed foods may be categorized (Heath 1978) as follows: (1) Foods in which the characteristic flavor compounds are not present in the natural product in the raw state, and (2) foods in which the characteristic flavor compounds are present in the natural product in the raw state. The characteristics of the two different groups are as follows:

4.1.2.1 Foods Devoid of Flavor Compounds in Their Natural State. Food materials that are devoid of the characteristic flavors or flavor compounds in their natural state usually contain precursors of such flavor compounds. Such food materials can be further divided on the basis of the mechanism for formation of the flavor

compounds. The two subgroups are as follows: (1) Those in which flavor is developed by fermentation and/or cooking or some form of heat treatment, and (2) those in which flavor is developed by enzymic action in the cold.

Materials in Which Flavor is Developed by Heat. Materials in this group present an interesting case study, especially from the processor's viewpoint. These are materials whose flavor is developed during the processing operation. As such, the unit operations have to be appropriately sequenced such that the developed flavor compounds are not damaged or volatilized in the subsequent unit operations. If there are deleterious effects either on the chemical integrity or concentration of these flavor compounds, then remedial steps must be taken to restore the flavor integrity of the product. This might be in the form of recovery of the flavor compounds, which are then added back, or completely extant flavorings may be employed. Materials in this category range from meat in which the flavor is developed solely by the agency of heat, to such materials like tea, coffee, cocoa, and vanilla, whose flavors are developed by a combination of "fermentation" and heat. Fermentation in this category of foods often refers to the enzymic oxidation of certain compounds.

Materials in Which Flavor is Developed by Enzymic Action in the Cold. Materials in this group also present an interesting case study, similarly from the processor's viewpoint. These are materials whose flavor is developed also during the processing operation by enzymic action, but usually in the cold without the agency of heat. Examples of such materials include pungent spices like mustard and horseradish, as well as some aromatic vegetables like onion and garlic. However, before the reactions leading to flavor formation can be actuated, there has to be some form of cell rupture or comminuting to bring the enzyme into contact with the substrates. Also, the unit operations have to be appropriately sequenced such that the developed flavor compounds are either not damaged, nor volatilize in subsequent processing.

The characteristic flavor in this category of foods comes primarily from the volatile organic sulfur compounds released by the action of some enzymes on certain nonvolatile, odorless amino acid precursors. Leino (1992), Kuo and Ho (1992) and Sinha and others (1992) have discussed extensively the details of the mechanism of flavor release in onion and the other vegetables in this group.

4.1.2.2 Foods Endowed with Flavor Compounds in Their Natural State. Food materials that are endowed with their characteristic flavors or flavor compounds in their natural state present an interesting class of material as far as sourcing for flavoring is concerned. This is due to the fact that the flavor compounds present in the natural product are usually recoverable by chemical and physical means. Examples are the culinary herbs like garden mint, spices like ginger, and umbelliferous fruits such as coriander and caraway.

4.2 USE OF FLAVORINGS IN FOOD PROCESSING

Having discussed the various schemes for the classification of food materials based on their natural flavor characteristics, the ground is set for a thorough examination of the various criteria guiding the use, form of use, and point of introduction of flavorings in processed foods. However, before going into all that, it needs to be pointed out that the

addition of a flavoring (whether natural or synthetic) to a product can result in any of the following three possibilities (Swaine 1972; Heath 1978):

1. The material achieves or assumes the flavor of the added flavoring. Usually this is the case where either a low flavor-impact food or a material that is lacking in intrinsic flavor is involved. A good example is vanilla flavor in ice-cream.
2. The existing flavor of the material is supplemented, fortified, or intensified by that of the added flavoring. This supplementation is usually called for where a substantial portion of the natural flavor has either been lost or destroyed during processing. A ready example is the action of flavor potentiators such as disodium-5′-inosinate and disodium-5′-guanylate, which are usually added to meat and chicken products. A flavor enhancer such as monosodium glutamate (MSG) also works in this way.
3. The flavor of the material is supplanted, masked or covered up by that of the added flavoring. This is usually the case where a material that has an undesirable flavor is involved. Such is the case in the masking of "boar taint" or "sex odor" in the meat of the sexually mature uncastrated male pig or boar with herbs and spices. The occurrences of such species-specific flavors and odors in meats have been thoroughly discussed by Pearson and others (1994).

4.2.1 Criteria for Use of Flavorings

The use of flavorings in processed foods is determined by a number of factors. These factors are not limited to, but generally include (1) a demonstrable need for the flavor, (2) compliance with legal requirements, (3) compatibility with other ingredients, (4) ability to withstand processing, packaging, storage, distribution, and merchandizing conditions, and (5) acceptability to consumers. These criteria will now be examined in detail.

4.2.1.1 Demonstrable Need for the Flavor. The most basic and perhaps the most important criterion for the use of any flavor additive is that there must be a demonstrable need for the flavoring. This is a condition that can be satisfied very easily because this need can be illustrated by a variety of conditions such as the need to make a low flavor-impact food to be more appetizing, the need to give a definitive character to a food that is fabricated from several component materials, the need to restore the integrity of flavors that have been adversely affected by processing conditions, and the need to cover up the unpalatable taste of bitter pharmaceuticals or nutraceuticals. A reason may be a need to make a nutraceutical more appealing; for example, vitamin C and multivitamin tablets that are coated with a sweet taste. "Nutraceutical" is the term often used to refer to a food, dietary supplement, or biologically active compound that improves health and/or well-being (Cardello and Schutz 2003).

The need for the use of flavoring may be further orchestrated either in response to an identified trend in society or in response to changing public preferences and prejudices. In this regard, it is pertinent to point out that consumers are ever looking to food manufacturers for new and innovative flavors to satisfy their sophisticated demands. Also, it is not out of place for market leaders to study societal trends and do some form of forecasting to be able to deliver flavors ahead of customers' demands.

4.2.1.2 Compliance with Legal Requirements. It is important to bear in mind that flavorings are additives and, as such, must meet all legislative guidelines before being used. That is, they must meet all relevant safety regulations discussed in Section 5.2. The other point that needs to be made is that a demonstrable need for an additive is in fact a legislative requirement.

4.2.1.3 Compatibility with Other Ingredients. The compatibility principle is an exacting one, with very wide ramifications. When we say that flavorings intended for use must be compatible with the other ingredients, this is more than a restatement of the legal guidelines highlighted in Section 5.2. According to the guidelines, an additive must not impart any undesirable flavor, odor, color, or texture to the food. Put another way, it must not make the food unacceptable in any way. A more exacting requirement is that it must not be antagonistic to the food. For instance, the additive must not bind to any of the nutrients or make them unavailable to the body.

Beyond these legal requirements of compatibility, there are other unwritten rules that are known to practitioners. For instance, some flavors go hand in hand with some colors. For example citrus flavor goes along with an orange color to give orange identity to carbonated soft drinks, lemon flavor goes along with a very light green color to give lemon identity to carbonated lemon drinks, and strawberry flavor along with a light red color confers a strawberry identity on imitation strawberry drinks.

4.2.1.4 Ability to Withstand Processing Conditions. Any flavoring added to processed foods must be able to withstand the exacting and often adverse processing conditions such as high temperature, ionizing radiation, subatmospheric pressure or vacuum, and superatmospheric pressures. In other words, the flavoring must be stable and still retain its serving properties after processing. More will be said about this in Section 4.3.

4.2.1.5 Acceptability to the Consumer. The acceptability of the flavoring in the end product is vital to the success of the product. As the whole concept of using flavorings in food revolves around stronger consumer preference and acceptability, it is improbable that a flavoring that meets all the previous criteria will be unacceptable to the consumer. However, in situations where this is the case, the processor has to go back to the drawing board to obtain and present to the discriminating consumer what will be acceptable.

4.2.2 Point of Introduction and Form of Use of Flavorings

The twin issues of the point of introduction and form of use of flavorings are so intertwined that it is not so obvious which one takes precedence. Although the issues are interconnected, the factor that receives the prime consideration depends on the peculiar case at hand.

Perhaps we can start by stating that, depending on the peculiarity of the vector material and the processing conditions, most flavorings can usually be obtained in more than one of the following forms: liquids, powders, dispersions, and encapsulated. Within these broad groupings, there are subdivisions. For instance, a liquid flavoring can be dissolved in a wide array of media such as water, alcohol, or oil. The form that will be used will be dictated by the nature of the food material to which the flavoring is to be added. A few examples will illustrate this point.

Encapsulated flavorings are produced by special techniques in which the volatile aromatic compounds are locked up or otherwise protected by a thin film of water-soluble gum, starch, gelatin, or sugar. Such encapsulated forms are suited for use in dry food mixes such as cake mixes and soup mixes for the following reasons: (1) They are dry, free-flowing and nonhygroscopic powders, and they can therefore be readily incorporated into dry food mixes; (2) they are protected from volatile losses and oxidative changes; and (3) when mixed with water, they disintegrate and liberate the flavoring. On the other hand, oil-based flavorings are usually deployed for uses in fat-based products such as shortenings and margarines.

As for the point of introduction of the flavoring, which is also referred to as the mixing sequence, it is to be noted that most food-processing operations consist of a succession of several unit operations. In some cases, the order of succession of such operations cannot be altered without dire consequences. However, there are several other processing operations in which the order of succession can be rearranged. Whenever this rearrangement is possible, the mixing of the flavoring should be done to avoid the most adverse unit operations; that is, adverse with regard to damage to the flavoring. Even in situations where a rearrangement is not possible, the flavoring can still be added towards the end of the processing operation, thus avoiding undue exposure of the added flavorings to damaging conditions.

Finally, it should be emphasized that, by a careful selection of the form of use and the point of introduction of flavorings, the flavoring strength and quality of the added flavor will be retained during processing, packaging, storage, distribution, and merchandizing conditions.

4.3 EFFECT OF PROCESSING CONDITIONS ON FLAVORINGS IN PROCESSED FOOD

In Section 4.2, it was stressed that any flavoring that is to be used in processed foods must be able to withstand the exacting and often adverse processing conditions. Here, we attempt to outline and briefly discuss those factors that may prevent flavorings from being stable and so prevent them from retaining their serving properties after processing. These processing conditions include (1) extremes of temperature (2) irradiation, (3) mixing and contact with air (4) extremes of pressure, (5) mixing sequence, and (6) hydrogen ion concentration or pH.

4.3.1 Extremes of Temperature

Most flavoring materials are volatile in nature and are also subject to thermal decomposition at elevated temperatures. Many flavor compounds such as allyl isothiocyanate, which is the major pungent flavor compound in mustard and Wasabi, are known to be degraded at temperatures as low as 37°C (Chen and Ho 1998). It is therefore advisable to take precautions against undue exposure of particularly themolabile flavorings to high processing temperatures. Some of these precautions have been discussed in Section 4.2 on the use of flavorings, especially with respect to the point of addition and form of use of flavorings. Other precautions include the use of nonthermal processes such as pulsed electric field (PEF) processing to minimize the loss of flavor, color, and nutrients in fruit juices and other foods alike (Dunn 2001; Min and Zhang 2003; Min and others 2003).

It is also important to mention that thermal processing can induce the formation of flavor compounds in a series of reactions known as the Maillard reaction. This reaction occurs when amino acids are heated in the presence of reducing sugars. Alaimo and others (1992) have presented an excellent discussion on some of these and other volatiles formed in the subsequent Amadori rearrangement.

Apart from susceptibility of flavorings to high temperature, the scientific literature is accented with reports on the effects of low temperatures on some volatile flavor compounds. For instance Usai and others (1992) have reported losses in flavors of essential oil of peels of Thompson navel oranges during cold storage and indicted temperatures below 6°C.

4.3.2 Irradiation

Food irradiation refers to the use of ionizing radiation such as gamma rays, from radioactive elements, and electron beams produced in accelerators, for food preservation. They exert this preservative action through their germicidal effects. Although food irradiation is seen primarily as a preservation method, it can also be employed as a more general unit operation to produce specific desirable effects or changes in foods, such as tenderization in irradiated meat. It is also effective for pathogen control in raw meat.

Ionizing radiations are known, however, to induce water radiolysis (Stewart 2001), leading to the formation of hydroxyl radicals ($^{\bullet}OH$), hydrated electrons (e^{-}), hydrogen atoms ($^{\bullet}H$), hydrogen (H_2), hydrogen peroxide (H_2O_2), and hydrated protons (H_3O^{+}). These intermediates are known to react with both organic and inorganic compounds within the food material to produce compounds that are responsible for off-odors in irradiated foods (Ahn and others 2001; Ahn and Lee 2002; Lee and Ahn 2003). Specifically, these intermediates have been implicated in the formation of many distinctive off-flavors in foods, such as "bloody and sweet", "hot fat", and "burnt off" off-odors in meats (Ahn and others 2000), as well as "medicinal" and "cooked off" off-odors in orange juice (Yoo and others 2003). These off-odors impact negatively on the consumer acceptability of these products.

4.3.3 Mixing and Contact with Air

Mixing and, especially high-speed mixing, promotes intimate contact of the food matrix with air, and so predisposes the volatile flavoring in food to oxidation. Losses of flavor volatiles could be appreciable in such high-speed mixing operations. This is especially true in ice-cream making, whipping of eggs, in marshmallows, and to some extent in mechanical dough development during bread making.

Another important unit operation, that promotes aeration of the food material, is the pneumatic or fluidized handling of powders such as soup mixes, cocoa and chocolate beverage powders, cake mixes, and dessert powders. Volatile losses in these products can be minimized through the use of appropriate forms of flavoring, such as encapsulated flavoring.

4.3.4 Extremes of Pressure

Although application of either superatmospheric or subatmospheric pressures can have deleterious effects on the integrity of flavor compounds, negative pressure appears to be implicated more in food processing. This is because negative pressure results in greater losses of volatiles. There are many food processing equipments operating at

subatmospheric pressures, ranging from driers and filters to centrifuges, and many more. Ironically, processing under vacuum is done to mitigate some of the negative consequences of processing at high temperature, including thermal degradation and volatilization of flavor compounds.

4.3.5 Mixing Sequence

In the discussion on the use of flavorings in food processing in Section 4.2.2, we have already highlighted the significance of the point of introduction (also referred to as the mixing sequence) of the flavoring, in avoiding undue exposure of the added flavorings to damaging conditions.

4.3.6 Hydrogen Ion Concentration or pH

Many flavors and flavor compounds are known to be sensitive to fluctuations in pH. In fact, many flavor compounds are known to be more predisposed to chemical transformations, thermal degradation, and other unwanted changes at certain pH ranges or hydrogen ion concentrations. For example, the major pungent flavor compound in mustard, allyl isothiocyanate, is reported to be sensitive to pH. Its decomposition to other compounds having a garlic-like odor in the presence of water at 37°C is known to be accelerated under alkaline conditions (Chen and Ho 1998). Such unfavorable pH conditions should be avoided as much as possible in the processing and handling of such sensitive materials. Furthermore, food-grade buffer systems could be employed where practicable (Turhan and others 2003).

4.4 FLAVOR PERCEPTION AND FLAVOR SYSTEMS

Flavor perception in food systems is built upon the integration of several aroma and oral attributes of the food. The overall flavor is therefore a combination of taste, feeling, and odor on receptors in the oral (mouth and throat) and nasal (nose) cavities. The general flavors discussed in this volume are perceived the way they are because of the influence of certain "silent" elements of the flavor system. A general review of the broad principles guiding the use of flavorings in the food industry will therefore not be complete without a brief on these elements. These silent elements are in fact elements of the stimuli that affect flavor perception, and are generally classified according to the way they affect the particular food or flavor system. They can be listed either as integers, seasoners, enhancers, potentiators, or antioxidants (Sjöström 1972). We shall now discuss each of the elements.

4.4.1 Flavor Integers

Most food matrices consist of water and a rather diverse admixture of other chemical constituents. The major chemical constituents of most foods include carbohydrates, proteins, fats, and their derivatives. In addition, there are inorganic mineral components and a diverse group of organic substances that are present in relatively small quantities. Such organic substances include vitamins, enzymes, emulsifiers, acids, oxidants, antioxidants, pigments, and flavor compounds. These constituents, which have unique arrangements

within each food matrix, give the particular food their peculiar characteristics, such as structure, texture, flavor, color, and nutritive value.

Some of these chemicals combine to produce the stimuli that are then perceived as flavor. Such chemicals that are integral parts of food matrices and at the same time interact to produce flavor sensations are referred to as flavor integers. Sugars, organic acids, and some essential oils are good examples of flavor integers. Many of these integers are present in foods of medium flavor impact like fruits. In many fruits, for instance, and especially the climacteric fruits, ripening is associated with conversion of starch into sugar, which reacts directly on our taste buds to produce the sensation of sweetness. Furthermore, many fruits contain "signature" organic acids such as citric acid in oranges and lemon, tartaric acid in grapes, and malic acid in apples. These organic acids contribute to the peculiar flavor in these fruits, and are therefore invaluable in the formulation of particular imitation fruit drinks. In addition to being flavor enhancers, these acids give the fruits tartness and also slow down bacterial spoilage.

Also, certain essential oils, which are components of essences of many spices, have their individual characters and are powerful flavor factors in their own right. A very good example is eugenol, which accounts for 70–90% of the essential oils of the clove bud, and is generally associated with clove flavor.

4.4.2 Seasoners

Seasoners are so called because they are used for seasoning or altering the aroma and oral attributes of the food in desirable ways. Table salt is undoubtedly the most commonly employed seasoner. It is capable of altering both the aroma as well as the taste of food, and if added to food in high concentrations can also alter the mouth feel.

Other popular seasonings widely used in food processing include the aromatic vegetables of the *Allium* species of the family of Liliaceae. This includes onion, garlic, leeks, chives, scallions, and shallots. The major form of use of these aromatic vegetables in the food industry is the steam distilled flavor or oil.

4.4.3 Enhancers

Flavor enhancers are chemical compounds or materials that are used in very minute quantities to intensify or enhance the flavor that is already present in the food. At the level of parts per thousand, in which they are usually used, they do not add any flavor of their own to the food. The best known of the flavor enhancers is monosodium glutamate (MSG). Other less prominent flavor enhancers, which are similar to MSG, include tricholoric acid and ibotenic acid. These compounds were isolated from some fungi by Japanese scientists.

Monosodium glutamnate is particularly effective in its ability to enhance or intensify the flavor of many high-protein foods. It is not without character. When used in large enough quantities, MSG can contribute a taste of its own, sometimes described as sweet–saline, to the food in which it is added. In such cases, MSG becomes a seasoning.

4.4.4 Potentiators

Potentiation is an action by which a chemical agent by itself and in small quantities has no effect on a biological system, but exaggerates the effects of other chemical reagents on that

system. Flavor potentiators thus work in the same way as flavor enhancers by enhancing or intensifying the flavor of the food to which they are added, without adding any flavor of their own. Flavor potentiators are, however, more intriguing. Prominent flavor potentiators are the 5′-nucleotides such as disodium-5′-inosinate and disodium-5′-guanylate.

Potentiators are different from flavor enhancers in five important respects. (1) Flavor potentiators are much more powerful in that they are effective in concentrations of parts per billion or even much less. (2) At whatever level of use, flavor potentiators do not contribute a taste of their own to the food materials to which they are added. Thus, potentiators can never double as seasoners under any circumstance. (3) The potentiators will consistently intensify certain specific flavor notes regardless of the food to which they are added. (4) The potentiators are stable towards cooking and can be added to food to be cooked. (5) The potentiators are less hygroscopic than enhancers.

From the flavorist's point of view, it is pertinent to point out that there is a specific synergistic action between flavor enhancers and flavor potentiators. This is because the two groups of compounds affect different aroma and oral flavor notes. Flavor potentiators enhance meaty and broth notes, but buttery and sweet notes are not affected. Flavor enhancers intensify mostly attributes of mouth feel such as dryness and astringency. This synergism between the flavor enhancers and flavor potentiators furnishes one of the most important keys to the development of flavor and flavorings in food product development.

4.4.5 Antioxidants

Antioxidants constitute one of the most important but often ignored elements of the flavor system. This is due to the fact that volatile flavor compounds such as aldehydes, ketones, and keto esters are susceptible to oxidation. This, in effect, means that flavorings or food products containing these volatiles lose their flavor during storage. Thus, when an antioxidant like ascorbic acid is added to a food or beverage, it is preferentially oxidized and lost, thereby preserving the major flavor compounds.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

Product development within the context of flavor technology could be construed strictly in terms of creation and development of flavorings. And this will be correct. However, from the wider food industry perspective, it will be apposite to include new flavored food products. Thus, in this chapter, the topic of product development is discussed from the wider food industry perspective, but with special reference to flavor creation.

All flavorings and other food additives, food products, as well as other consumer goods for commercial use, including medicines and cosmetics, are strictly regulated by the enforcement of various legislations and standards. Thus a brief review of the laws and regulations guiding the development, processing and marketing of such food additives, food products, and other consumer goods will be undertaken here.

This review as a prelude to a discussion of the subject matter is important for the simple fact that legislative requirements constitute the most important impediment that tends to slow down innovation and new product development in the consumer industry in general and the food and beverage industry in particular. Thus, due to the strict legal requirements for new additives, the uses of new flavorings are reflected very slowly in end products.

In discussing product development, we shall examine the need for new products in the flavor, as well as the larger food industry. Next, we undertake a discussion of some legislative aspects that have a direct bearing on the success of newly developed products, before finally treating flavor creation and development.

5.1 WHY NEW PRODUCT DEVELOPMENT?

There are many compelling reasons for new product development (Valentas and others 1991). We need to emphasize that the primary purpose of investing capital in plants and equipment for a manufacturing concern is to earn an amount of money that exceeds the investment. In other words, people go into business to make profit. Therefore, one of the most important reasons for new product development is the imperative to constantly replace or rejuvenate existing products that have declining sales. This is with the view of generating new sales volume, meeting projected returns on the investment, and ultimately achieving corporate growth.

In relation to declining sales, it is important to point out that all flavorings, food products, and other consumer goods have a finite life span, just like any living organism. Interestingly, the typical life cycle of any product can be divided into four distinct stages, namely product introduction, market growth, market maturity, and product decline (Albrecht 1981). Suffice it to say that each of these phases has its own characteristic vigor, which is reflected in sales volume and profits. The key point to be made here is that for a flavor manufacturing company or any company for that matter to be successful, it must study the life cycle of its products and know when to introduce new products. Thus, in a fiercely competitive market, new products are what keep companies alive and vital. A company without a viable product-planning profile cannot grow, and will in fact go under sooner rather than later.

Another compelling reason for new product development is the need to take advantage of newer and better technologies. For instance, Blue Pacific Flavors, a leading flavor manufacturing firm in the United States, has developed a new flavor technology, which it refers to as the sun-ripened flavor system (Anonymous 2004a). This system is a proprietary water-soluble, heat-stable matrix that provides intense aroma and taste without the use of traditional solvents like propylene glycol, alcohol, and glycerin. This innovation is bound to create new opportunities in the flavor industry, and before long, similar new

products developed by other firms to take advantage of these new opportunities will start appearing in the market.

Apart from the technology-driven imperative, product development could occur in response to competition from one or more rival products or companies. Usually, whenever a leading manufacturing firm introduces a new product, there is always an upbeat in innovative imitation activities by the other major players in the industry. This phenomenon has been aptly tagged "reverse R&D" (Desrosier and Desrosier 1971). Reverse R&D refers to the efforts of the other manufacturers in trying to create their own imitative equivalents of the innovative products created by the market leaders. Failure of the other manufacturers to make reverse R&D commitments could result in the dipping of their market shares below profitability levels.

Product development could also be in response to identified societal trends and customer needs. This is where the marketing people come in, because they are the ones in contact with the customers and they obtain direct feedback. So, they are in a vantage position to know what the consumers want. Even if the consumers do not voice their opinions, it is part of marketing strategy to feel out the consumer needs and understand the forces that motivate their purchases. In so doing, improvements or innovative products that will sell can be developed and marketed well ahead of the other competitors.

One leading flavor manufacturer who has been responding positively to identified customer needs and emerging trends in the marketplace in the delivery of innovative and custom-designed food flavorings is Flavor Systems International based in Cincinnati, Ohio, in the United States (Anonymous 2004b). The company has responded to the recent damage to the vanilla bean crop in Madagascar and the resultant skyrocketing prices caused by developing vanilla extract replacers. These replacers are suitable for use in ice-creams, alcoholic beverages, and bakery products. Also, it has developed a beef extract replacer consequent upon the recent ban on Brazilian beef imports to the United States and the fear of the dreaded and contagious Bovine Spongiform Encephalopathy (BSE), the so-called "mad cow disease". Lastly, liquid concentrates having the real dark-roasted flavor of coffee have been produced to satisfy the demand for the taste of freshly brewed premium coffee as opposed to the comparatively "stale" flavor of dry instant coffee products presently available in the market.

Another motivating factor could be the expansion of sales by the extension of existing lines. By line extension, we mean building on an existing product by addition of new flavors or features. This option is probably the most common approach to new product development because the brand is retained. This brand that is retained is a symbol carrying with it complex and important significance to customers. Moreover, the meaning of a brand is built up by dint of hard work over several years through advertising and by the success of the product sheltered under its umbrella.

A ready example of a line extension is the one involving Maltina®, a nonalcoholic malt drink, which was recently carried by its manufacturers, the Nigerian Breweries PLC, Lagos. The line extension involved introducing other exotic fruit flavors. The manufacturer simply repackaged the old product by dubbing it as "classic" and strawberry- and pineapple-flavored new products were introduced under the same brand name. Really, a forward-looking manufacturing outfit should constantly be experimenting with new product ideas so that at very short notice, the right things can be done to either modify an old product or reposition it in line with current trends.

Lastly, a motivating factor could be the need to reposition an existing product. In an overwhelming majority of cases, this repositioning is achieved solely through sloganeering or new advertising, marketing, and/or repackaging, usually without any tinkering with

the science or engineering of the product. By portraying an otherwise old product in a new light or making fresh claims for the product, consumers can indeed see the product in a new light. This can boost the demand for the product, thus translating into increased sales volume and a more favorable "bottom line".

Unwittingly, the last factor has thrown up a pertinent question. Does merely repositioning or repackaging of an otherwise old product make it a new product? Or put the other way round, when is a "new" product really new?

5.1.1 When is a New Product Really New?

A product is considered new if it is new in any way, for the company and/or the consuming public and potential customers (Albrecht 1981). Therefore, if a company starts to manufacture a product that is already marketed by other manufacturers, although the product is old in the market, the product marketed newly is considered new because at least the brand name will be different. Also, if the manufacturer succeeds in convincing the consumers of an otherwise old and unchanged product, about the "newness" of the product by making fresh claims or successfully repositioning the product, then the otherwise old product becomes a new product as far as the consumers are concerned. This newness will be reflected in the product experiencing a new lease of life, so to say, by passing through another life cycle. A few examples from the larger food industry will illustrate these points.

Let us begin with a case of a rather peculiar nature. In the past, cookie manufacturers have successfully changed the perception of their product as a dessert to a snack, solely through advertising and marketing. This was achieved in part by seeking different market targets, through marketing in smaller packages, that is, without changes to the physical product. Thus the initial advertising and promotion blitz, followed by the

TABLE 5.1 Some New Flavors and New Flavored Food Products Introduced into the International Market Since 1990.

Product Name and Description	Flavor/New Feature	Manufacturer
Chelsea Teezers (gin blend)	Ginger and other exotic flavors	Continental Distillers, Ikeja, Nigeria
Vegetarian chicken flavor (used in meatless textured proteins)	Vegetarian flavor	Gold Coast Ingredients, Inc., California, USA
Beef extract replacer	Safeguard against mad cow disease	Flavor Systems Int'l., Inc. Cincinnati, USA
Fanta® pineapple (soda)	Pineapple flavor	Coca Cola Canners of S.A (PTY) Ltd., Wadeville, South Africa
Bien® (bottled water)	Apple flavor	Pharma-Deko PLC, Agbara, Nigeria
Drink fit® yogurt (yogurt drink)	Strawberry flavor	DrinkFit GmbH, Schlüchtem, Germany
Fitnesse™ (toasted flakes of rice, wheat and corn — breakfast cereal)	Malt flavor	Nestlé S.A., Vevey, Switzerland
Coco Pops® (toasted rice — breakfast cereal)	Chocolate and malt flavors	Kellog Marketing & Sales Co., Manchester, England
Sugar Puffs (wheat puffs — breakfast cereal)	Honey and brown sugar flavors	Quaker Trading Ltd., Southhall, England
Chocolate Syrup (Sugar syrup)	Chocolate flavor	Fleming Co. Inc., Oklahoma City, USA
Khao Shong™ Nuts (Roasted peanuts)	Coffee flavor	Lily Industry Co. Ltd., Bangkok, Thailand

increased frequency of use as light meals as opposed to its sole use as the final course of meals, caused the product to go through the early stages of the typical product life cycle. Also, in the marketing of orange juice, through extensive promotion, the same physical product was successfully repositioned as orangeade, diet supplements, salad component, garnishing for meat, fish, and seafood, and many other culinary uses.

Apart from repositioning through advertising and marketing, new products are so usually created through improved formulation and packaging. These classes of new products are so evidently new that further pontification appears unnecessary.

To round off the discussion on the need for new products in the flavor, as well as the larger food industry, a list of some new flavors as well as new flavored food products that have been introduced into the international market in the last couple of years are presented in Table 5.1

5.2 AN OVERVIEW OF LEGISLATIVE GUIDELINES ON NEW PRODUCT DEVELOPMENT

As stated in the introductory comments to this chapter, legislative requirements constitute the most important impediment tending to slow down innovation and new product development in the flavor industry in particular, and in the food and consumer industry in general. It is therefore apposite to give a bird's eye view of these regulatory guidelines, with particular reference to those aspects that have a direct bearing on new product development.

The earliest evidence of the existence of food laws appears to be in ancient Egypt (Luckey 1972). Luckey (1972) also cited an Indian law of 300 BC, which prohibited the adulteration of grains, scents, and drugs. However, the earliest records in modern history of food laws can be traced to England in the thirteenth century and later on, to the United States in the nineteenth century. For instance, as early as 1202, King John of England proclaimed the first English food law, which prohibited the adulteration of bread with other nonwheat flours. In the United States, however, serious attempts at food legislation did not commence until around 1880, when the individual states began to pass laws against food adulteration.

The first significant milestone in the checkered history of food legislation in the United States was the signing into law of the original Food and Drugs Act, by President Theodore Roosevelt, in 1906. This act prohibited misbranding and adulteration of foods, drinks, and drugs. Although the original act has been revised through the addition of new provisions (FDA 1966), the basic provisions have been retained. Further information on milestones in the food and drug law history in the United States can be obtained from the Food and Drugs Administration's (FDA) backgrounder (FDA 2002).

In conclusion, it is pertinent to lay emphasis on two important issues. First, there now exist food laws in virtually all countries of the world, and second, food legislation practices in several of these countries have benefited tremendously from the records of modern food laws in England and particularly, the United States. This is because other countries often emulate such laws that a country, especially a developed one, has used to solve a problem with satisfactory results. Thus the provisions in all these food laws are addressing the same central issues relating to marketing standards of identity, misbranding, adulteration, and so forth. Secondly, it is to be noted that the work of international bodies such as the World Health Organization (WHO), Food and Agriculture

Organization (FAO), and the European Union (EU) is assuming increasing prominence over national food laws as a way of harmonizing the diverse national regulatory laws and guidelines in the interest of international trade. The contributions of the international body established by the FAO and WHO to develop international food standards, that is, The Codex Alimentarius Commission, is worthy of note in this regard.

The following is a brief review of the legislative guidelines on new product development, as well as a review of the work of The Codex Alimentarius Commission.

5.2.1 Legislative Guidelines on Food Product Development

Food laws and standards stipulate the exact specifications for items of commerce. The standards establish an authority for the quantity, weight, value, or quality of specific items. They also concern identity, quality, and fill of container. This is generally with a view to promote honesty and fair dealing between the manufacturers and the consumers. Thus, the laws strictly forbid fraudulent practices, especially as regards food additives. Other prohibited acts include adulteration and misbranding.

For the purpose of most food laws, a simple definition of an additive as "a substance or mixture of substances other than the basic food, present in food during production, processing, packaging and storage" (Luckey 1972) will suffice. In this regard, it is to be noted that additives may either be intentionally added to food or may occur by accident. Thus, preservatives may be intentionally added to enhance the keeping quality of foods. On the other hand, residues of pesticides and herbicides used in agricultural production, when not properly removed from the end products, constitute accidental food additives.

Thus several sections of many food laws have guidelines on tolerance for pesticide chemicals, including insecticides, bactericides, fungicides, and mycotics, where tolerances are proposed . Also, there are guidelines on exemption of such pesticides and other agricultural chemicals from the necessity of a tolerance in certain circumstances. For the purpose of our discussion here, we are going to discuss only intentional food additives that are generally used to enhance either the stability or the attribute components of quality of the product. Also, there will be a brief discussion of regulations on adulteration and misbranding.

5.2.1.1 Guidelines on Food Additives. There are general requirements to be satisfied in law with respect to food additives (FAO/WHO 1956). Usually, these requirements vary from one additive to another. However, generally speaking, these guidelines require the following:

1. There must be a demonstrable need for an additive before it is used. This applies mostly to nutritional additives like iodine and vitamins. For instance, the use of iodine is indicated in the case of a population with a high incidence of goiter.
2. A suitable conveyor or vector for the additive must be specified.
3. The keeping quality of the additive must be guaranteed. In other words, it must be scientifically proven that the additive is stable and will not react with the vector.
4. The additive must not impart any undesirable flavor, odor, color, or texture to the food. That is, it must not make the food unacceptable in any way.
5. The additive must be able to retain its serving properties.
6. The safety of the additive must be indicated and ensured.
7. The additive must not be antagonistic to the food. For instance, the additive must not bind to any of the nutrients or make them unavailable to the body.

Furthermore, a processor that intends to use an additive must file a petition with an appropriate authority to establish its safety (FDA 1966). In the petition, the following details must be specified:

1. Name, chemical identity, structure, and composition of the compound.
2. All chemical properties of the compound, including the intermediate compounds that may be formed from the compound. This is because the intermediate compounds may be toxic, although the main compound may not be.
3. Minimum and maximum levels of use. This has to do with the cumulative effect of the additive.
4. Details of toxicological studies and other scientific experiments undertaken to establish the safety of the additive.
5. The methodology of these experiments, which must relate to the proportions of the additive to be used in the food vector.
6. The experimental materials and methods and especially the age of the experimental animals, which must reflect the age group of people for which the additive is intended.
7. Recommended duration of use of the additive.

Suffice it to say that the required details, which must be filed with the appropriate regulatory authority, have been derived largely from the FAO/WHO prescribed guidelines for the international testing of food additives to establish their safety (FAO/WHO 1958). The foregoing notwithstanding, it needs to be pointed out that the prescribed guidelines, being a scientific document, is more detailed than the legislative version of the safety requirements. This is more so especially with regard to the conduct of the toxicological studies. For instance, the FAO/WHO prescriptions require that the design of the experiments be furnished. Also there are guidelines on the number and selection of animal species.

In conclusion, it needs to be pointed out that the successful use of experimental animals depends on careful selection and maintenance of the animals. Secondly, investigation of toxicity should not involve inadequate diets. Lastly, to limit the number of experimental animals, reliance must be based on the ability to observe responses in the majority of animals receiving doses far in excess of the recommended levels for human consumption.

5.2.1.2 Regulations on Adulteration and Misbranding. All food laws forbid fraudulent practices as regards food as an article of trade. Such laws cover the basic offences of adulteration and misbranding. A food is considered adulterated under the following circumstances:

1. If the prepared food contains injurious substances. Such injurious substances may be naturally present, added, or present in the container.
2. If the food has been prepared, packed, or held under insanitary conditions.
3. If the food contain parts of a diseased animal.
4. If it is radiated beyond the prescribed dose.
5. If part of it is omitted for instance in the case of omission of the more expensive part of fabricated foods.
6. If part of the food has been substituted in a fraudulent way.

7. If part of the food is damaged or contains some inferiority, or the inferiority is concealed in same way.
8. If an untypical material has been added to increase bulk.

On the other hand, a food product is deemed misbranded under the following conditions:

1. If it carries a false label or is falsely labeled. A false label refers to the label of a different product and false labeling refers to wrong or false claims on the label.
2. If the required statements are not stipulated. For example, failure to declare that the food contains in part or whole genetically modified organisms (GMOs).
3. If a food product is an imitation and the imitation was done in a fraudulent way.
4. When the standard of quality or fill of the container is tampered with.

5.2.1.3 Labeling of Genetically Modified Foods. In the brief discussion of food regulations in relation to misbranding, only a tepid reference was made to labeling with regard to genetically modified (GM) foods and food ingredients. However, in view of the potential risks involved in their use, and the escalating debate about their safety and mandatory labeling of GM foods (Smyth and Phillips 2003), there is a need to make some clarifications.

First and foremost, it is to be noted that several regulatory bodies have ruled that there is no scientific evidence to suggest that GM foods involve any new or magnified risks. Despite these assurances, many civil society groups and a large portion of consumers are still not convinced about the safety of these foods. Secondly, due to the public concern about the long-term safety of GM foods and food ingredients, the Labeling Committee of the Codex Alimentarius Commission has been meeting for the past ten years in an effort to develop international standards for labeling of GM foods. No definitive guidelines have yet been issued. Thirdly, some national regulatory agencies have issued tentative enactments demanding mandatory labeling of all GM foods and ingredients in the absence of international guidance. Fourth, even in countries that have made these enactments, there is a raging controversy on the appropriate structure of such labeling. Lastly, some food manufacturers, without any compulsion, have taken the initiative to indicate on their labels whether or not their products contain GM foods and ingredients. The last has surely not been heard on the labeling of GM foods.

5.2.2 The Codex Alimentarius Commission

As was pointed out earlier, the work of international bodies such as the World Health Organization (WHO), and the Food and Agriculture Organization (FAO) have assumed prominence over national food laws as a way of harmonizing the diverse national regulatory laws and guidelines in the interest of international trade.

Going down the memory lane, both the FAO and WHO were established in 1945 as specialized agencies within the United Nations (UN) system. The FAO had the mandate to help member governments increase food resources and improve the distribution of food and agricultural products, thereby improving the nutritional level of their people. The WHO on the other hand was mandated to deal with all matters concerning health and general well-being, including nutrition. Because of the linkages and interpenetrations

between food, nutrition, and health, the FAO and WHO have had to form joint expert committees to handle cross-border issues.

The first of such bodies was the WHO/FAO Joint Expert Committee on Food Additives (JECFA), which was formed in 1955. Another of such bodies was the FAO/WHO Codex Alimentarius Commission (CAC), which was formed in 1962. The CAC, with its secretariat at the headquarters of the FAO in Rome, is the main international body concerned with the setting of international food standards. Further information on the statutes, rules, procedures, and membership of the CAC can be obtained from its procedural manual (CAC 1997), and information on the current status of the CAC can be obtained from Jukes (1999).

5.3 FLAVOR CREATION AND NEW PRODUCT DEVELOPMENT

The creation and development of flavorings in food product development cuts across several disciplines. The practitioners are the flavor chemists, flavorists, food technologists, and marketers. For specialized flavors, some specialists, usually within the main groups, may be involved. Generally, a synthetic chemist may be required in addition to the flavor chemist. Also, in addition to the food technologists, nutritionists, dietitians, chefs, home economists, and packaging engineers may be required. The point to be emphasized is that the simplified discussion here is just to illustrate the general principles involved in flavor creation. Nowadays, specialized companies who offer them for sale to food manufacturers develop the flavorings. We can then partition the various tasks involved in flavor creation between the marketer, food techologist, flavorist, and flavor chemist. Figure 5.1 shows the typical roles played by the four professionals in the creation of flavorings in food product development. Let us now examine each of these tasks in greater details.

5.3.1 Generation of New Product Ideas

New product ideas may emanate from the marketing team in the course of their interaction with the public. On the other hand, the idea may emanate from the report of the food technologist on a new flavor from a natural product. It may even emanate from the management. Whichever way the new product ideas are generated, the flavor chemist takes over by isolating, identifying, and synthesizing some of the identified components of the natural flavors to be imitated, when available synthetic compounds are inadequate. The flavorist generally establishes the flavor profile, and then compounds the imitation flavor from synthetic compounds. These and other subsequent roles will now be discussed.

5.3.2 Isolation, Identification, and Synthesis of Flavor Compounds

The task of isolation, identification, and synthesis of flavor compounds in food odor research will be broken down into three stages:

1. Isolation and concentration of volatiles;
2. Identification of compounds; and
3. Synthesis of flavor compounds.

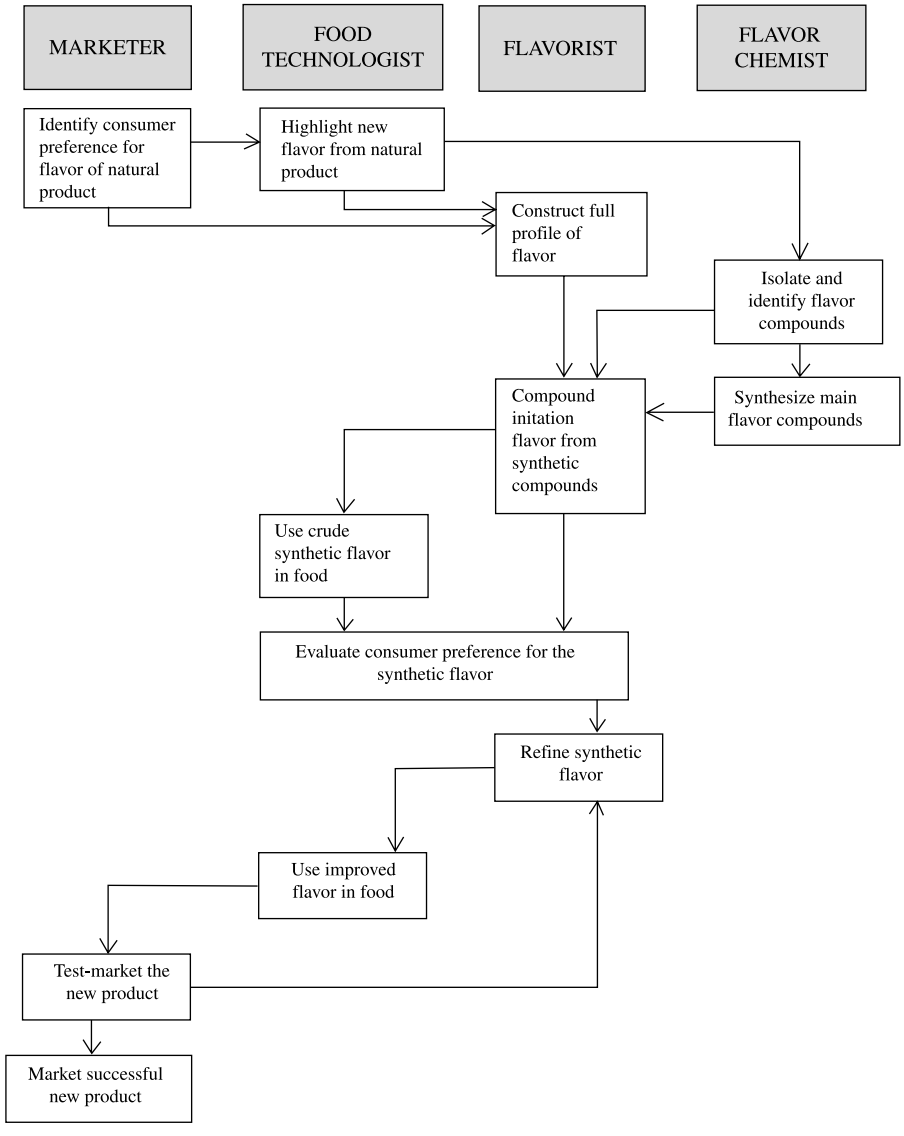

Figure 5.1 *Roles of the marketer, food technologist, flavorist and flavor chemist.*

5.3.2.1 Isolation and Concentration of Volatiles. It must be realized that there are two basic approaches in food odor research. The first involves carrying out direct vapor analysis or headspace vapor analysis. The other approach is to carry out total volatile analysis. Each of the two approaches has its own merits and demerits, which have been discussed by Weurman (1969). The first approach is more straightforward, because the volatiles are already in vapor form and can readily be collected and injected into analytical equipment. So, in effect, the isolation and concentration procedures apply more to the total volatile analysis.

TABLE 5.2 Location of Principal Flavor Compounds in Selected Food and Allied Food Products.

Food and Allied Products	Location of Principal Flavor Compounds
Poultry	Meat (muscle) plus fat under the skin
Fish	Fish oils and fats
Milk and dairy	Milk fat
Potato	Potato fat
Hops	Oleoresin

The process of isolation of the natural flavor compounds entails two steps: (1) Separation of compounds from the original material, and (2) concentration of separated compounds. In order to isolate the volatiles, it is very important to know where flavor compounds reside or, put another way, where they abound in high concentrations in the natural material, before they can be successfully separated. Table 5.2 shows the locations of principal flavor compounds in selected agricultural materials. Generally, when in doubt or when dealing with a new natural product, the fats and oils, that is, the lipid fraction of the material, should be the first suspect.

The first steps in the separation of flavor compounds from the native material generally entail one form of size reduction or another. By this, we mean unit operations such as cutting, grinding, mincing, pressing, or centrifuging. This first step is followed by distillation or solvent extraction, depending on the physicochemical properties of the target compounds. As virtually all flavor or odoriferous substances are volatile in nature, almost invariably the process of choice is distillation.

In this first distillation process where a crude extract is expected, the regular single-plate, total take-off distillation system is often preferred. The other distillation procedures have been reviewed by Weurman (1969) and Parliament (1997). Right from the distillation stage, special precautions are to be taken. For instance, it is essential to work at subzero temperatures under nitrogen, as this prevents chemical and enzymatic side reactions. Following the successful removal of the compounds from the native material, some form of concentration needs to be carried out. The concentration step becomes necessary because very dilute solutions are obtained from the first-step isolation. Concentration of the compounds can be achieved by any of the following methods: (1) Freeze drying; (2) adsorption; (3) extraction; (4) fractional distillation or stripping; and (5) derivative formation. These concentration techniques have been extensively reviewed by Weurman (1969).

5.3.2.2 Identification of Compounds. Identification of the flavor compounds in the concentrates start with their detection using chromatographic techniques. Almost invariably the identification is done by combined gas chromatography/mass spectrometry (GC/MS). Usually, the GC retention times and mass spectra of the volatile compounds are compared with those of reference standards (Garruti and others 2003). Further, the respective structures of the compounds can be confirmed through nuclear magnetic resonance (NMR) and infra red (IR) spectroscopy (Werkhoff, and others 1998). An NMR system is shown in Figure 5.2, and an IR spectrophotometer in Figure 5.3.

5.3.2.3 Synthesis of Flavor Compounds. Usually, the flavorist possesses an intimate knowledge of the aromatic profiles of hundreds of natural and synthetic flavoring components. Thus, following isolation and identification of the natural flavor compounds,

Figure 5.2 *An NMR system.*

there are several hundreds of synthetic compounds available to the flavorist from which the natural flavor compounds can be compounded or recreated synthetically. Both the knowledge and the artistic skill of the flavorist come in handy in performing this delicate task. However, realizing the complex nature of natural flavorings in terms of the large array of volatiles responsible for the flavor of a single natural product and the overbearing influences of those compounds present in seemingly negligible fractions, organic synthesis of some identified flavor compounds with no ready synthetic equivalents become inevitable.

Figure 5.3 *An IR spectrophotometer.*

Organic synthesis of flavor volatiles is the exclusive preserve of the synthetic/flavor chemist. It is a specialized area requiring a lot of skill. The complexities of organic synthesis notwithstanding, there are several excellent works on the syntheses of several components of natural flavorings (Finato and others 1992; Sanders and Seidel 1992; Schmidt and others 1992; De Kimpe and Keppens 1996).

5.3.3 Formulation and Compounding of Synthetic Flavorings

The flavorist executes the formulation and compounding of the synthetic flavorings. In this task, the flavorist is not only adept at, but is in fact first among equals, in the sensory evaluation of flavor and odoriferous compounds. The work of the flavorist in this regard is accomplished in two stages: (1) Characterization or sensory analysis of the flavorings, and (2) compounding of the imitation flavoring.

5.3.3.1 Sensory Analysis of Flavorings. Flavor creation is an iterative process of trial and error. Oftentimes, it necessitates constant assessment of odor and flavor profiles. First, the new flavor from the natural product has to be characterized. Second, several experimental blends of the synthetic flavor have to be characterized progressively and compared with the natural flavor. These comparisons often reflect the direction for improvement or refinement of the crude synthetic flavor. Usually a combination of artistic and scientific tools is employed in the task of sensory evaluation of flavorings and flavor compounds. This task is commonly accomplished through (1) flavor profile analysis, (2) quantitative descriptive analysis, and (3) the spectrum method (Bett and Grimm 1994). All the methods involve teamwork, usually among highly trained panelists or judges. These judges are well experienced in the evaluation of flavor and flavor compounds, especially by sniff testing.

Construction of Flavor Profile. Flavor profile analysis is a way of completely describing all the flavor components of a material. In this method, there is a complete description and recording of the intensity, order, and amplitude of each of the flavor compounds or notes. Thus the product's aroma, flavor, and aftertaste are recorded on a simple universal scale. Normally, about four to six trained judges sniff the material to be evaluated and then they discuss in order to harmonize their judgments and come to a consensus in regard to each character note or descriptor. After reaching a consensus, then the threshold of the flavor compound is recorded on a scale. The scale usually consists of the following: (1) not present or below threshold, (2) threshold, (3) slight, (4) moderate, or (5) strong (Bett and Grimm 1994).

In an overwhelming majority of cases, a detailed flavor profile of a natural flavoring to be imitated has to be constructed prior to the compounding of the synthetic imitation. Also, after the synthetic imitation is compounded, the profile of the synthetic flavor has to be constructed in order to compare how close the imitation or synthetic flavor is to the natural flavor.

Quantitative Descriptive Analysis. In this technique, trained judges are asked to quantify, in order of occurrence, the sensory quality characteristics of a food product. The data obtained from the individuals are used to construct a multidimensional model, which is readily understood in both marketing and research and development environments. A typical model consists of a number of lines corresponding to the flavor

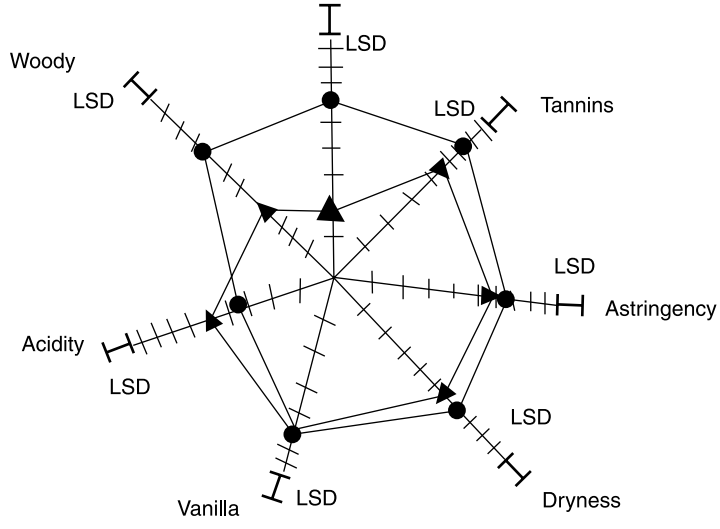

Figure 5.4 *Representation of the flavor of two hypothetical wine samples.*

characteristic to be described. Then the intensity of each flavor note is described on each line with appropriately sized intensity scale. Perez-Preito and others (2003) used this method recently to assess the effect of wood origin, barrel age, and barrel size on the flavor and some other sensory characteristics of red wine. A typical pictorial representation of the flavor of two hypothetical wine samples is presented in Figure 5.4.

This method is different from the previous one in some respects. Although the flavor descriptors are arrived at through a consensus of opinion as in the previous method, that is where the consensus building ends. The individual judges do the scoring of the flavor intensities. Thus, multiple evaluations on each sample are obtained. The multiple scores are then subjected to statistical analysis to improve on the accuracy as well as reliability of the results.

Spectrum Method. The spectrum method separates the overall flavor impression into descriptors just as in the two previous methods. Also, a panel of trained judges derives the descriptors. The judges ensure that the descriptors describe succinctly the flavor notes for which specific standards or references are provided, thus minimizing to the barest minimum the conflict between the descriptors and evaluation of the flavor intensities. Specifically, reference-point intensities are calibrated against specific flavors in commercially available foods, thus reducing the error due to the judges. Therefore, the data can be compared across time and between products, because the effects are due solely to the treatments.

5.3.3.2 Compounding of Imitation Flavoring. The formulation and compounding of the synthetic flavorings is the exclusive preserve of the flavorist. Traditionally, the flavorist creates imitation flavors by using chemicals whose odor and flavor are reminiscent of the natural flavor to be imitated. This is purely an art, which is done by a process of mental association. This task is facilitated by an intimate knowledge of the aromatic

profiles of hundreds of natural and synthetic flavor compounds. The flavorist therefore has hundreds of synthetic volatiles at his/her fingertips, from which to select several permutations and combinations of small groups of synthetic compounds to simulate the natural flavor.

The synthetic flavor need not comprise the wide array of volatile compounds usually associated with natural flavors. The identities of the volatiles need not even be identical with those of the natural flavor, but the formulation must be capable of sensorial simulation of the natural flavor. Further, the flavorist must ensure that the synthetic flavoring will be stable during processing such that it has an acceptable strength in the end product despite the adverse processing conditions.

5.3.4 Trial Use of Synthetic Flavorings

Usually, several experimental blends of the synthetic flavor are produced in the course of the compounding and refinement of the synthetic flavor. At convenient intervals, the food technologist is routinely called upon to creatively use the progressively refined synthetic flavor in selected food vectors so that a preliminary estimation of the consumer preference for the newly created flavoring may be obtained. The food technologist is also well trained to employ different sensory evaluation techniques and appropriate statistical tools to (1) test if there are statistically significant differences between the synthetic and natural flavors; (2) test if one of the flavors is significantly preferred to the other(s); (3) quantify the extent of differences and/or preferences between the test products; and (4) obtain an initial estimate of consumer acceptability of the new flavors. These evaluations often reflect the direction for improvement or refinement of the synthetic flavor under development.

At the final stages of the development, the marketer may be called upon to test-market the product incorporating the newly created flavoring. Marketers are able to obtain an estimate of the consumer reaction to the product through the use of questionnaires and also through interviews.

5.3.5 Marketing of the New Product

Finally, the marketer markets the new product. The new product in this case may either be a newly created flavoring or the new food product in which the newly created flavoring is employed.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

6.1 INTRODUCTION

Extraction is a process of great importance for flavor compounds, because it enables the separation or concentration of a variety of substances from natural feedstock. Presently, the amount of solvent used by industries in conventional extractive processes is estimated as about one million tons per year. The development of extraction techniques can reduce the amount of solvent used and also improve product quality. Thus, there is space, not only to update conventional techniques, but also to take into account the commercial application of new techniques that are studied and used by research groups.

The majority of essential oils are obtained by distillation. This subject, as well as drying methods, will be discussed in Chapter 7. This chapter will focus on other techniques for flavor extraction.

6.2 EXTRACTION TECHNIQUES

Extraction techniques vary according to where the flavor compound is located in a plant. Simões and Spitzer (2003) have cited various methods of extraction, treatment, and conservation applied in the recovery of essential oils and flavor compounds. The most common are presented here.

6.2.1 Enfleurage

This method is only used by perfumery industries, when plants have a small amount of oil with a high commercial value. It is used to extract volatile oil from flower petals. The principle of the method is simple. Every jasmine and tuberose flower resembles a small factory, continually emitting minute quantities of perfume. Fat possesses a high absorption power and, if in contact with fragrant flowers, readily absorbs the perfume emitted. This principle, methodically applied on a large scale, constitutes enfleurage. Petals are placed on a fat layer at room temperature for a period of time. The physiological activities of these flowers continue for 24 h or longer after harvesting. During this period, the fat absorbs the perfume emitted by these flowers. Exhausted petals are exchanged with new ones. Later, the saturated fat is treated with alcohol. The volatile oil is then obtained by distillation of the alcoholic mixture at low temperatures.

In the Grasse region of Southern France, flowers had been processed by this method for a long time until the modern method of extraction with volatile solvents was introduced. In the early days of perfumery, flower scents were extracted with fats and the alcoholic washings of the perfumed fats represented the so-called floral extracts. Despite the introduction of the modern extraction process with volatile solvents, the old-fashioned method of enfleurage, as passed on from father to son through generations, still plays an important role.

Enfleurage on a large scale is today carried out only in the Grasse region, with the possible exception of isolated places in India where the process remains primitive. Every enfleurage building is equipped with thousands of chassis, which serve as vehicles for holding the fat during the process. A chassis consists of a rectangular wooden frame about 2 in high, 20 in long, and 16 in wide. The frame holds a glass plate where the fat is applied at the beginning of the process.

6.2.2 Extraction with Hot Fat (Maceration)

Before the modern process of extraction with volatile solvents was introduced, the perfume of roses, orange blossoms, violets, acacia, mimosa, and others flowers in which the physiological activity stops after picking had been obtained by treating the flowers with hot fat. The principle of this process involves immersion of the flowers in hot fat. In sequence, the same batch of hot fat is placed in direct contact with several batches of fresh flowers, until the fat becomes saturated with the flower perfume. The fragrant fat is then washed with alcohol, as the extract obtained from cold extraction in enfleurage.

The process of maceration is analogous to that of enfleurage, with two fundamental differences. In the case of maceration, hot fat is employed, and the time of contact between fat and fresh flowers is much smaller. Fifty years ago, orange blossoms, if not distilled, were treated by maceration; acacia blossoms, which do not lend themselves to steam distillation, had to be processed exclusively by maceration. Today, the process of maceration is seldom employed. Its products, especially those from orange blossoms, find application only in a few old-fashioned perfume formulas.

6.2.3 Stripping Using Water Vapor

Volatile oils have vapor pressures higher than water; therefore, they can be stripped by water vapor. On a small scale, a Clevenger apparatus, a traditional apparatus used in hydrodistillation, can be used. The distilled volatile oil, after separation from water, must be dried using anhydrous sodium sulfate. In this classical procedure, the formation of new compounds via degradation is possible, because of the high temperatures used during the stripping or water separation stages. This technique is preferentially used to extract oils from fresh plants in flavor extraction.

Using batch or continuous operation, this process can be used in the deodorization of vegetable oils on a large scale, in which the stripping is accomplished using water vapor under vacuum conditions and elevated temperatures (Heldman and Hartel 1999). The objective is the removal of volatile fatty acids from the oil; therefore, the vapor stream is not the main product as in flavor extraction from plants.

6.2.4 Distillation

Distillation is widely used in the chemical processing industry for the separation of components with different volatilities. It is mainly used for the separation of volatile components, like flavors, in the food and cosmetic industries. Hydrodistillation (steam distillation) is a common type of distillation in flavor extraction. Its main feature is that the matrix containing the substances to be extracted must be immersed in boiling water. Distillation processes are described in more detail in Chapter 7.

6.2.5 Extraction with Organic Solvents

Robiquet first applied the extraction with organic solvents to flowers in 1835. Buchner, in 1836, and Favrot, in 1838, investigated the use of diethyl ether as a solvent. During the nineteenth century, several solvents were applied and patents pertaining to the process and its main extraction products were registered in several countries of Europe. Gradually,

the method attracted the attention of the manufacturers, and industrial workers conducted large-scale experiments independently. Finally, some processors were forced to adopt the volatile solvents, and special extraction plants were constructed in addition to their existing enfleurage buildings.

Volatile oils are extracted preferentially with nonpolar solvents, such as ether, petroleum ether, or dichloromethane. However, these solvents extract other lipophylic compounds besides the volatile oils, and these compounds decrease the commercial value of the oils. The undesired extraction of other compounds is difficult to prevent.

The principle of extraction is simple. Components present in a solid raw material are extracted by dissolving them in a liquid solvent. This process is called leaching or solid–liquid extraction. The raw material is placed in specially constructed extractors where its contact with carefully purified solvent, usually petroleum ether, is promoted at room temperature. The solvent penetrates the raw material and dissolves the natural flavor components along with some waxes and albuminous and coloring matter. The solution obtained is removed from the extractor and pumped into an evaporator to be concentrated at a temperature that is as low as possible. After the solvent is completely removed, a concentrated flavor is obtained. Temperatures applied along the entire process are lower than those used in distillation. Compared with distilled oils, the essential oil obtained by solvent extraction, generally, has a flavor that better represents the original flavor present in the raw materials.

Despite its advantages, solvent extraction cannot entirely replace steam distillation, which remains the principal method for the isolation of essential oils. Steam distillation can be carried out in remote and primitive parts of the world, whereas solvent extraction needs complicated and expensive apparatus and well-trained workers. In solvent extraction, running expenses are comparatively high. Therefore, a mistake in the operation can be costly. Extraction with solvents can be applied advantageously to higher priced materials, like the extraction of essential oils present in flowers. The products of solvent extraction possess one main advantage: their true-to-nature odor. In addition, certain types of flowers, such as jasmine, acacia, mimosa, and violet, do not yield their volatile oil in steam distillation.

Two factors must be investigated and carefully defined to guarantee the success of solvent extraction: the selection of the solvent and the extraction unit. Currently, the solvent selection must be made in accordance with legislation governing the use of the extract (food, cosmetics, or perfumery), as well as with client specifications, which can be more restrictive than the legislation itself. The selected solvent influences the composition of the extract (different solubility parameters), its sensory quality, and the extraction yield (Danisco 2001).

6.2.6 Extraction with Supercritical Carbon Dioxide

This technique allows the recovery of different kinds of natural flavors and volatile oils with high efficiency. If the costs and technical problems involving high-pressure operation could be solved, it would be the preferred method to be applied in the industrial extraction of volatile oils. No trace of solvent remains in the final product, which represents a higher degree of purity when compared with those obtained by other techniques.

In the extraction, the solvent, carbon dioxide, is pressurized to at least 73 bar (critical pressure) at a temperature higher than 31°C (critical temperature). Above these critical values, the carbon dioxide reaches the "supercritical state". In this state, the viscosity is

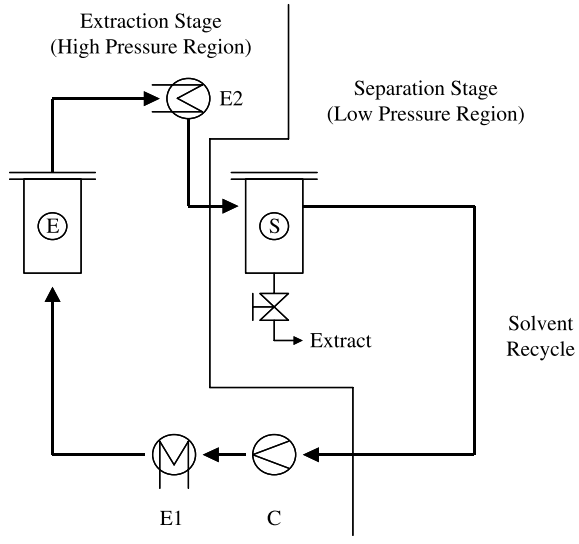

Figure 6.1 *Typical supercritical extraction process.*

similar to that of a gas, facilitating its penetration into the solid matrix, and its capacity of dissolution is similar to that of a liquid. After extraction, the solvent is separated from the extract by lowering its pressure, causing the carbon dioxide to convert to the gaseous phase and to lose its high dissolution capacity. The product can be completely separated from the solvent, which is again compressed and recycled into the process.

Solvent extraction from solids typically consists of two main stages: extraction and separation. A schematic description of a typical supercritical extraction process can be seen in Figure 6.1. In the extraction stage, the supercritical solvent flows through a fixed bed of solid particles and dissolves the extractable components. The direction of the solvent flow through the fixed bed can be upward or downward. At high solvent ratios (ratio of supercritical solvent flow to the amount of solid), the influence of gravity is negligible. The geometry of the fixed bed should also be considered an important parameter in the process design.

The temperature and the pressure inside the extraction unit define the relevant physical properties of the carbon dioxide (namely density, viscosity, and mass diffusivity) that change significantly with small changes in temperature and pressure near the critical point. This behavior causes changes in the solvent dissolving capacity, which makes it possible to define a specific set of compounds to be extracted. On the other hand, it makes it difficult to control the extraction unit operationally. The typical values of these operational parameters are 1.01 to 1.10 for reduced temperature (ratio between operational and critical temperature) and 1.01 to 1.50 for reduced pressure (ratio between operational and critical pressure).

The solid material will be depleted from the extractable material in the direction of the flow. Therefore, the concentration of the extracted components increases in the direction of the flow in the supercritical solvent and in the solid material. This behavior is a function of the operational conditions, of the kinetic extraction properties in the solid matrix, and of the solvent power of the supercritical solvent (Brunner 1994).

In the separation stage, the solution that exits from the extraction unit is expanded in a low-pressure vessel. The carbon dioxide vaporizes and the extract is collected by gravity or by entrainment through a porous media.

Supercritical fluid extraction using carbon dioxide has found commercial application in decaffeination of coffee beans, extraction of essential oils, removal of coloring agents, and concentration/purification of flavor components (Moyler 1993; Hawthorne and others 1993; Ayala and Luque de Castro 2001; Bernardo-Gil and others 2003).

Some solvents, such as water (critical temperature and pressure 374°C and 220 bar, respectively), have a higher critical pressure and temperature then carbon dioxide. Thus, extraction in a supercritical condition would require more severe conditions, which would result in higher costs and technological difficulties. There is also the possibility of degradation of thermolabile substances. Therefore, it is usual to adopt operational conditions below the solvent critical point, even with carbon dioxide. An example is the continuous subcritical water extraction process (CSWE), tested by Jiménez-Carmona and others (1999) in the recovering of flavor compounds from marjoram essential oils.

6.2.7 Cold Pressing

During cold pressing, the fluids entrained inside the raw material are removed by expression. This method is used to extract volatile oils from citric fruits. The pericarp of the fruits are pressed and the fluid, which contains the volatile oil, is separated. Water can be used to enhance oil removal from the solid residue. The oil is separated from the emulsion by gravity, centrifugation, or fractionated distillation.

6.2.8 Solid-Phase Micro Extraction

Solid-phase micro extraction (SPME) is a technique that started in the 1990s with applications not yet consolidated, even from a theoretical point of view. The initial studies were on laboratory applications, exploiting fundamental aspects of the method.

SPME is a process involving a multiphase equilibrium. It is a micro technique, in which the process of extraction of the analytes takes place at an unusual scale. The basic device consists of a thin slapstick of optical fiber of fused silica with 10 mm of one of its ends recovered with a thin film of polymer. SPME consists of two basic steps: partition of the analytes between the fiber and the sample (matrix), and desorption of the concentrated extract in an analytical instrument (gas chromatograph). The sample consists of an aqueous solution with solid particles in suspension that has several interactions of adsorption with the analytes besides the gas phase. The desorption time depends on several parameters, the most important of which are the volatility of the chemical compounds, the kind of injector, and the temperature (Zhu and others 1999; Cai and others 2001; Tellez and others 2004). The great advantage of the method is the extraction with the direct quantification of flavor compounds present in different matrices – gas, liquid and solid.

6.3 ENHANCEMENT TECHNIQUES

A procedure that can be used to increase the extraction potential is the previous freezing of vegetable raw material. Freezing causes rupture of the cell wall, facilitating the action of the solvent on the products of cellular metabolism. Moreover, conventional extraction

methods can have their yields enhanced by ultrasonic waves, which improve the interaction between the solvent and the analyte molecules.

Extraction using microwaves is a process in which the solvent, in contact with the raw material, is heated by radiation in the microwave range to improve the dissolution of desired substances from the natural matrix into a solvent. Since 1985, application of microwave heating in extraction processes from solid matrices has demonstrated good efficiency. Solvent extraction enhanced by microwave radiation has been used on a large scale to obtain essential oils from various vegetable raw materials. The advantages are its simplicity and the short period of extraction. The first publications about extraction using solvent and microwave involved yeast, hop, broad beans, corn, and chestnut. Solvents like methanol and a mixture of hexane and water have been used, and the extraction yields obtained using microwave are much better than without it.

Ganzler and Salgo (1990) described the use of microwave to improve the extraction of organic substances from solid matrices such as soil, seeds, and food. These researchers used a conventional microwave oven to irradiate the solid matrix with the solvent seven times, for 30 s each time. The extraction assisted by microwave was more efficient for polar substances than extraction using a Soxhlet apparatus.

Comparative measurements were performed using a Soxhlet extractor (conventional extraction technique) and extractions assisted by sonic waves and microwave. The extraction with microwave was a more feasible alternative than the Soxhlet technique or the use of sonic waves. Furthermore, it used a smaller amount of organic solvent, reduced extraction time to less than 10 min, and allowed extraction of several samples simultaneously (Lacerda 1999).

6.4 EXTRACTS TREATMENT

Often it is necessary to clarify, to neutralize, or to rectify the extracted volatile oils. Rectification, drying, or low-pressure water vapor jet utilization allows the extraction of irritant or unpleasant flavor compounds, leading to final products with higher aggregated value. Deterpenation, which is a special kind of rectification, aims at the reduction of monoterpenes in the oil. The use of chromatographic techniques, in particular exclusion chromatography, allows the separation of the volatile oils from other lipophylic nonvolatile compounds. A partial fractionation allows the separation of the original solution into a fraction rich in monoterpenes and another rich in sesquiterpenes.

6.5 GENERAL COMMENTS

Extraction processes can be applied to selectively obtain a more specific and standardized product, with a higher degree of purity. Extraction of volatile substances is still performed using adequate solvents and applying different physical processes. The disadvantages are the possibility of chemical alteration of the substances, the degradation of thermolabile compounds, and the occurrence of undesired reactions caused by an eventual need for higher extraction temperatures to obtain better yields. After extraction, solvent separation from the final product is another point of difficulty. For example, when using hydrodistillation, besides heating, there is the inconvenience of direct contact of the material with hot water, which can cause hydrolysis of some substances. Extracts obtained from organic solvent extraction often contain a solvent residue that could be seen, in many situations,

as a contamination that must comply with a maximum level defined by legislation. The lower the limit, the more difficult and more expensive the process of solvent separation.

Due to differences among separation methods, it is common to find in the literature studies comparing the performance of new methods with the traditional ones, mainly hydrodistillation. Foods, essential oils, and medicinal plants are raw materials often used in these studies. Some of these results are described below.

Ondarza and Sanchez (1990) compared steam distillation (hydrodistillation) and supercritical fluid extraction for the isolation, separation, and purification of some compounds from spices. The use of supercritical CO_2 extraction presented a commercial advantage because of the fact that the oils obtained were constituted mainly of oxygenated hydrocarbons and had a low content of monoterpenes that could mask the natural flavor of the essential oil.

Blanch and others (1993a,b) investigated factors affecting the simultaneous steam distillation and solvent extraction of volatile components from foods using solvents with many densities. A new apparatus was developed in order to minimize losses of the most volatile compounds. The cooling surface was enlarged by the introduction of a cooled jacket at the end of the condenser. The jacket acted as a second cooling system.

Jiménez-Carmona and others (1999) compared continuous subcritical water extraction (CSWE) with hydrodistillation in the recovery of flavor compounds from marjoram essential oil. CSWE was faster (15 min compared to 3 h) than hydrodistillation, and provided a more valuable essential oil (with higher amounts of oxygenated compounds and no significant presence of terpenes). CSWE allowed substantial cost savings in terms of both energy and raw material. Its extraction efficiency was about five times higher than that of hydrodistillation.

Gámiz-Garcia and Luque de Castro (2000) reported the use of CSWE in the extraction of essential oils from a medicinal plant and compared its performance with hydrodistillation. The advantages observed were shorter extraction time (50 min instead of 4 h for hydrodistillation), lower energy cost than for hydrodistillation, and the possibility of controlling the composition of the oil by changing the extraction parameters (temperature, fluid flow rate, and static extraction time). Another advantage of CSWE was that the design of automated and controlled plants is more feasible.

Sarrazin and others (2000) compared five different extraction methods to determine which provided the most representative coffee flavor extract, including supercritical extraction with CO_2, extractive distillation, oil recovery under pressure, and vacuum steam-stripping with water or organic solvent. The vacuum steam-stripping with water provided the most representative flavor extraction, followed by stripping with methylene chloride. About two-thirds of the flavor was recovered in solvent extraction, and approximately 5% was lost in the concentration step.

Padukka and others (2000) studied five different extraction methods, among them hydrodistillation, solvent extraction using hexane, diethyl ether and chloroform, and supercritical CO_2 extraction, to obtain lemon oil from a complex of cyclodextrin and lemon oil. Volatile flavor components were successfully extracted by hydrodistillation under carefully controlled conditions. All three solvents tested could be used; however, hexane was more efficient and easier to handle, with the organic phase readily separated. Chloroform was less efficient in terms of phase separation. Supercritical fluid extraction was not successful and extracted only 33% of the total encapsulated oil after 7 h at 45°C. The profiles of the flavor compounds of the oil extracted by the different solvents were similar.

Kondo and others (2002) studied the supercritical fluid extraction of cold-pressed lemon oil carried out in semibatch and continuous countercurrent modes. Continuous operation at a linear temperature gradient from 313 to 333 K at 8.8 MPa showed the highest selectivity, which increased with an increase in the solvent-to-feed ratio. Operation with a linear temperature gradient allowed a more selective separation of oxygenated compounds than that obtained with a uniform temperature along the column.

Diaz-Maroto and others (2002) compared hydrodistillation and solvent extraction with supercritical CO_2 to recuperate the volatiles from spices (oregano, basil, and mint). The extracts obtained using the two methods were very similar in composition. Supercritical CO_2 extraction required less extraction time, did not allow thermal degradation and solvent contamination of the samples, and preserved the natural character of the fresh product.

6.6 FINAL REMARKS

After analyzing the available methods to extract and to concentrate flavor compounds, some final remarks can be made.

- Hydrodistillation: Not all oils can be processed by hydrodistillation, because boiling water and steam can have a deteriorating influence upon delicate flavor substances. Moreover, certain raw materials yield no oil during hydrodistillation.
- Enfleurage (extraction with cold fat): This method is carried out on a commercial scale only in France, and on a smaller scale than in the past. It is restricted to plants that, after harvesting, continue their physiological activities, forming and emitting flavors. Enfleurage gives a higher yield of oil than other methods. It has been replaced by extraction with solvents because it is a very delicate and time-consuming process, requiring experience and labor.
- Maceration (extraction with hot fat): This is applied to raw materials that give a low yield of oil when distillation or enfleurage are used. It has been almost entirely substituted by the organic solvent extraction process.
- Solvent extraction: This is applied to many different raw materials and is carried out in many countries. It is technically the most modern process in comparison to hydrodistillation, enfleurage, and maceration, yielding alcohol-soluble compounds.
- Supercritical solvent extraction: This technology can be applied to different raw materials and has the advantages of the absence of solvent residues in the extract and the use of lower temperatures. Moreover, it is less time-consuming when compared with the other techniques. At present, its main disadvantage is its high production cost, because of the pressures used.

7.1 DISTILLATION

7.1.1 General Aspects

Distillation is the most common and best known separation technique. It is widely used in chemical processing industries for the separation of components with different volatilities. It involves the creation of two or more coexisting phases, generally two – vapor and liquid – which differ in composition at the same temperature and pressure. These characteristics

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

are used for the separation of the substances. Its costs may comprise more than 50% of a plant's operating costs.

According to Seader and Henley (1998), the art of distillation dates back at least to the first century A.D., when it was used to produce alcoholic beverages. As discussed by Heldman and Hartel (1998), distillation is used in the food industry for the separation of volatile components, including flavors from different matrices. For example, in the processing of orange juice, vapors coming off the evaporator contain a significant amount of volatile components that are separated from the condensed vapors in a distillation column.

Optimization of the distillation process is important. The control of distillation columns to reduce operating costs, to decrease energy consumption, and to improve the efficiency of separation is necessary. Up to the eleventh century, distillation consisted of a process in which the liquid to be separated was placed in a vessel to which heat was applied, causing part of the liquid to evaporate. The vapors from the heated vessel were condensed in another chamber, producing the distillate (Seader and Henley 1998). Today, distillation can be defined as an operation in which a mixture of substances, liquid and/or vapor, called feed, is separated into components of desired quality using heat as the separation agent. The separation is based on differences in the boiling point of the substances. The vapor phase becomes richer in components that have lower boiling points, and the liquid phase will become richer in the components that have higher boiling points. Many texts on the principles, operation, and mathematical modeling of distillation can be found in the literature (Coulson and Richardson 1991; McCabe and others 1993). For a more detailed approach, the book by King (1980) may be consulted.

Distillation columns and/or distillation operations can be classified according to many aspects. Focusing on the operation mode, batch or continuous operation can be performed. In batch operations, the column is charged with a determined amount of feed and, when the desired task is achieved, the column is opened, cleaned, and again charged with feed to start a new operational cycle. Each operational cycle is called a batch. In continuous operation (continuous columns), the feed stream flows continuously into the column, and the products are continuously withdrawn. In the continuous operation mode, distillation columns can process a large amount of materials, but in batch operation mode, only smaller amounts of materials are permitted. As a function of the number of components in the feed, there exist binary columns, where the feed contains two components, and multicomponent columns, where the feed contains more than two components. Multiproduct columns are those with more than two product streams. Based on the type of internal components in a column that promote contact between phases, the columns can be divided into two major types: tray (or plate) columns and packed columns. In tray columns, the liquid–vapor contact is promoted by bubbling the vapor phase through a liquid layer above each tray inside the column. There are several tray designs to better promote the liquid hold up and the vapor–liquid contact. In packed columns, the vapor–liquid contact occurs all along the column, and this contact is usually enhanced by filling the column with specially designed small objects that are dumped randomly into the column or with structured packings having an ordered geometry. It is known that, in principle, more theoretical trays might be obtained by removing the trays and replacing them with packing. In fact, more and more frequently, additional distillation capacity is being achieved with existing tray towers by replacing all or some of the trays with sections of packing. Packed columns have a higher surface area for liquid–vapor equilibrium to occur and provide more efficient separations, but with a lower throughput rate.

The separation of components with nearly the same boiling points is difficult by simple distillation. In such systems the separation can be improved by adding a third component.

In extractive distillation, the new component, with a higher boiling point and greater interaction with one of the original components in the liquid phase, enhances the separation by increasing the amount of this component in the bottom stream. In azeotropic distillation, the third component forms an azeotrope with one of the original components, resulting in a higher concentration of this component in the top stream. The stream containing the third component is an independent column feed. In extractive distillation, this extra feed is at the bottom of the column, and in azeotropic distillation, at the top of the column.

Distillation columns are made of several devices, each of which is used either to transfer heat energy or enhance material transfer. A typical distillation column contains several major devices: a vertical shell where the separation of liquid components is performed, internal column components such as trays/plates and/or packings, which are used to enhance component separations, a reboiler to provide the necessary vaporization for the distillation process, a condenser to cool and condense the vapor from the top of the column, and a reflux drum to hold the condensed vapor from the top of the column so that liquid (reflux) can be recycled back to the column. The vertical shell houses the internal column components and, together with the condenser and reboiler, constitutes a distillation column (also denominated a fractionator or still) (Tham 1997). A schematic representation of a conventional distillation column can be seen in Figure 7.1.

The feed material that is to be separated into fractions is usually introduced somewhere near the middle of the column to a tray known as the feed tray or at other points along the column shell. The feed tray divides the column into a top (enrichment or rectification) section and a bottom (stripping) section. The feed flows down the column, where it is collected at the bottom in the reboiler. Heat is supplied to the reboiler to generate vapor. The source of heat input can be any suitable fluid, although, in most chemical plants, it is usually steam. The vapor produced in the reboiler is reintroduced into the unit at the bottom of the column. The liquid removed from the reboiler is known as the bottoms product or residue, or simply bottoms. The vapor moves up the column, and, as it exits the top of the unit, it is cooled by a condenser. The condensed liquid is stored in a holding vessel known as the reflux drum. Some of this liquid is recycled back to the top of the column and is called the reflux. The condensed liquid that is removed from the system is known as the distillate or top product. Thus, there are internal flows of vapor and liquid within the column, as well as separation of components from a feed

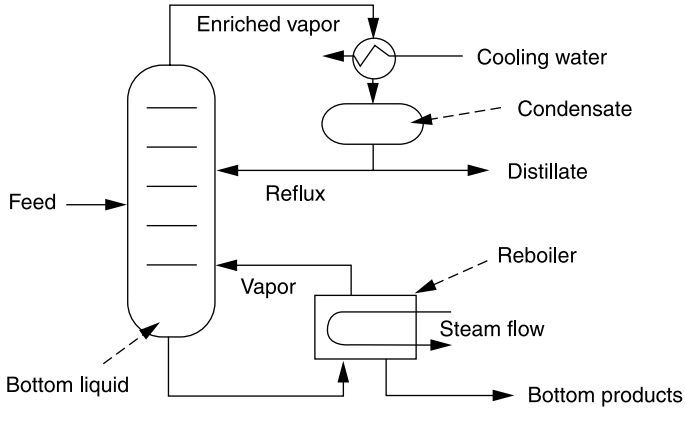

Figure 7.1 *Schematic of a conventional distillation column.*

mixture via distillation. The separation depends on the differences in boiling points of the individual components. In addition, the boiling point of the feed mixture will depend on the relative concentrations of the components. The distillation process depends on the vapor pressure characteristics of the liquid mixtures.

The design of distillation columns is based on the boiling-point properties of the components in the mixtures being separated. Thus the dimensions, particularly the height, of distillation columns are determined by the vapor–liquid equilibrium (VLE) data for the external flows of feeds and product streams into and out of the column, respectively.

Distillation involves the transfer of material from one phase to another. Often the residence time and intimacy of contact of the two phases in a separation device are not sufficient for the two phases to come to thermodynamic equilibrium with each other. The rate of mass transfer across the phase interface will govern the extent to which the phases equilibrate. Mass transfer rates between phases reflect the phenomenon of diffusion coupled with convective flow, turbulence, and gross mixing. The transferring component(s) must travel from the original phase to the interface and then from the interface to the new phase. For any real separation device, it will be necessary to correct an analysis based upon product equilibrium or ideal separation factors for the effects of entrainment, mixing, charging sequence, flow configuration, and mass and heat transfer limitations (King 1980). The most common way of correcting for these effects is to use the actual separation factor (which can be called column efficiency) that relates actual product compositions with the compositions based on the phase equilibrium.

7.1.2 Hydrodistillation

Distillation using water vapor is called steam distillation. Steam distillation can be used when the material to be distilled has a high boiling point and/or decomposition might occur if direct distillation were employed. The liquid is added to the still, and steam is passed through it. The solubility of steam in the liquid must be very low. Superheated steam that provides sufficient heat to vaporize the material concerned without condensing may be used. Otherwise, some of the steam may condense, producing a liquid water phase, as mentioned by Coulson and Richardson (1991).

Most essential oils have been obtained by steam distillation, or, in the more general sense, by hydrodistillation (first used by von Rechenberg as referring to codistillation with water vapor). The practical problems connected with distillation of aromatic plants are, therefore, of utmost importance to the actual producer of essential oils.

Essential, volatile, or ethereal oils are mixtures composed of a variety of volatile, liquid, or solid compounds that vary widely in concentration and boiling points. They are present in the interstices of vegetable tissues and can be extracted by hydrodistillation or by pressing. If extraction by pressing is used, the liquid mixture obtained usually has to pass through a separation process in order to remove undesired substances. At present, the most common process employed in this case is also hydrodistillation. Normally, these substances have a very low vapor pressure because they are high boiling substances. The intensity of the odor can be considered a manifestation of the volatility (related to the boiling point and vapor pressure) of the substance. Of course, there are many exceptions.

Little investigation has been undertaken on the process by which steam actually isolates the flavors present in the essential oils. It is commonly assumed that the steam penetrates the plant tissue and vaporizes all the volatile substances. If this assumption were

true, the isolation of oil from plants by hydrodistillation would appear to be a rather simple process, merely requiring a sufficient quantity of steam. However, this model is not always able to describe the extraction step in the process, and the complete prediction of the hydrodistillation process from a solid matrix by mathematical models is not possible even in a context of many theoretical models available for phase equilibrium of the substances involved.

Considering the manner in which the contact between water and the original matrix is promoted, a terminology that distinguishes three types of hydrodistillation has been developed: water distillation, steam distillation, and direct steam distillation. When the first method is employed, the material to be distilled comes in direct contact with boiling water. In the second method, the material is supported on a perforated grid or screen held some distance above the bottom of the still. In this case, low-pressure, saturated, wet steam rises through the material. The typical features of this method are that the steam is always fully saturated, wet, and never superheated, and the material is only in contact with steam, and not with boiling water. The last type of hydrodistillation, direct steam distillation, resembles the preceding type, except no water is kept in the bottom of the still, but live steam, saturated or superheated, is passed through the sample, and the process is frequently maintained at higher-than-atmospheric pressures.

Hydrolysis of certain components of the essential oils and decomposition caused by heat always occur in the hydrodistillation process. Although it is an inevitable reaction, the intensity of hydrolysis is typically low under the conditions normally used. The process temperature is determined entirely by the operating pressure, and its value is around 100°C at atmospheric pressure. At this temperature, decomposition by degradation of some substances occurs, and the decomposition products can cause interference in the odor of the oil. Considering these aspects, the temperatures used to extract essential oils by hydrodistillation should be kept as low as possible, and the contact between water and the original matrix should be minimized.

Hydrodistillation at high and reduced pressures and with superheated steam may be used for certain plant materials. Orris root, sandalwood, cloves, caraway seed, and pine needles, for example, are occasionally distilled with steam at a pressure that is higher than atmospheric pressure to obtain a more favorable ratio of oil to water in the distillate. The use of high-pressure steam for the rectification of volatile oils *per se* is not advisable, nor is it necessary, because superheated steam gives better results. Distillation of plant material with high-pressure steam should not be made a general practice, as it will increase the quantity of decomposition products in the plant material and in the oil. The degree of decomposition is influenced by temperature and the length of the distillation process. That is, steam distillation of plant material at high pressure is not advisable, because the higher temperature of the steam gives rise to decomposition products that impart an unpleasant odor to the oil. Nor is there any appreciable gain in the ratio of oil to water in the distillate, except perhaps in cases where the previous distillation under atmospheric pressure has been carried out inefficiently.

Steam distillation of plant material at reduced pressure may be subdivided into two types: steam distillation at slightly reduced pressure, which often shortens the length of the distillation process, and vacuum steam distillation at such a low pressure that the temperature remains just sufficiently above that of the cooling water so as to allow adequate condensation of the steam/oil vapors. The principal advantage of vacuum steam distillation consists in the purity of the flavor of the volatile oil obtained. It will be free from any off-flavor caused by decomposition, which accompanies most oils distilled above 70°C.

Because distillation is a very important separation process, much effort has been expended to increase the performance of existing distillation equipment and to develop new devices for facilitating vapor–liquid contact (Henley and Seader 1981). This effort can also be applied to more recently developed separation processes such as supercritical fluid extraction.

There are advantages and disadvantages for the methods for processing natural essential oils to concentrate aromatic components and for steam distillation of volatile oils. Some oils cannot be processed by hydrodistillation, because boiling water and steam have a deteriorating influence upon the rather delicate flavoring constituents. Certain raw materials yield no oil at all when distilled, and, hence, must be processed by methods other than distillation.

7.2 DRYING

Drying a solid generally refers to the removal of relatively small amounts of water or other liquid to reduce its final content from an initial value to some acceptable low value. The reduction in water or liquid content from solids can be achieved by mechanical (centrifugation or pressing) or thermal methods (vaporization). Often the mechanical removal of liquids from solids is performed before the thermal process, as it is less expensive and easier to use than thermal methods (Perry and others 1997; Sonaglio and others 1999). Mechanical methods for separating a liquid from a solid are not strictly considered drying, although they often precede a drying operation. This chapter is restricted to drying by thermal vaporization. In this case, the feed material is moist solids, the separating agent is heat, and the products are dried solid and water vapor. The solids to be dried may be in different forms, such as flakes, granules, crystals, powders, slabs, or sheets. The liquid to be dried may be on the surface of the solid, entirely inside the solid, or partly internal and partly external (McCabe and others 1993). Consequently, there are many types of dryers, differing basically in the way the solid is moved through the drying zone and in the way the heat is transferred. The choice of dryer is based on many factors, including characteristics of the material being dried (liquid, solid, particulate), economy of a particular dryer, capital cost of the dryer, and so on (Heldman and Hartel 1998). The drying operation always reduces the weight and volume and facilitates the milling of the materials (Mentz and Bordignon 1999).

In many cases, the drying of materials is the final operation in a manufacturing process, carried out immediately prior to packing or dispatching, and it often follows evaporation, filtration, or crystallization. In some cases, drying is an essential part of the manufacturing process, but, in the majority of the processing industries, according to Coulson and Richardson (1991), drying is performed for one or more reasons: (1) to reduce the cost of transport; (2) to make a material more suitable for handling; (3) to provide definite properties, such as maintaining the free flowing nature of salt; and (4) to remove moisture that may otherwise lead to corrosion. With some products, some care has to be taken. For example, it is essential that the crystals not be damaged during drying of a crystalline product; contamination of a pharmaceutical product must be avoided; and the loss of flavor from a fruit must also be prevented. Almost all the drying processes involve the removal of water by vaporization, requiring the addition of heat, and the major consideration is the effective utilization of that heat.

The moisture content of a material is usually expressed as a percentage of the mass of the dried material. If the material is exposed to air at a given temperature and humidity, the material will either lose or gain water until an equilibrium condition is established. This equilibrium moisture content varies widely with the moisture content and the temperature of the air. The moisture may be present in two forms:

1. *Bound Moisture* – this is water retained in such a way that it exerts a vapor pressure less than that of free water at the same temperature. Such water may be retained in small capillaries, adsorbed on surfaces, or as a solution in cell walls.
2. *Free Moisture* – this is water that is in excess of the equilibrium moisture content (Coulson and Richardson 1991).

The ability of air or hot gases to absorb the water liberated by evaporation will be determined by their temperatures and relative humidities.

The drying of natural raw materials is a complex phenomenon involving momentum, heat and mass transfer, the physical properties of the materials, air and water vapor mixtures, and the macro- and microstructure of the materials (Rizvi and Mittal 1992). There are many possible drying mechanisms, but those that control the drying of a particular product depend on its structure and the drying parameters, such as drying conditions, moisture content, dimensions, surface transfer rates, and equilibrium moisture content. These mechanisms fall into three classes: evaporation from a surface, flow as a liquid in capillaries, and diffusion as a liquid or a vapor (Rao and Rizvi 1995).

The mechanisms of internal flow are determined by the structure of the solid. The flow can be caused by gravity, by a sequence of vaporization–condensation, by shrinkage and pressure gradients, by capillary flow in granular and porous solids, and by diffusion in continuous, homogeneous solids. During drying, one mechanism predominates at any given time in a solid, but different mechanisms can predominate at different times during the drying cycle. According to Rao and Rizvi (1995), in the case of capillary-porous materials, water transport can take place by liquid diffusion caused by concentration gradients, liquid transport due to capillary forces, vapor diffusion due to partial vapor pressure gradients and liquid or vapor transport resulting from the difference in total pressure caused by external pressure and temperature, evaporation and condensation effects, surface diffusion, and liquid transport due to gravity.

In the typical dryer, moist solids are placed inside and heated by circulating air, heated walls, radiation, or microwave radiation. Heat must pass from the heat source to the particle surface and through the particle to wherever evaporation of water occurs. The water vapor generated must then travel to the surface of the particle and from the particle surface to a moisture sink, which may be a condenser, a desiccant, an exhaust of humid air, and so on (King 1980).

The application of the basic principles to the project for the dryer equipment is not direct. Variations in the drying conditions throughout the dryer, in the difference between the thermal and the mass transfer areas, in the configuration of the gas flow, in the effect of the operational conditions, and in the choice of the equipment according to the desired conditions of the dried products are among the difficulties encountered in the prediction of the drying velocity profiles. The selection of the dryer is usually based on preliminary tests, where the material is dried under the same conditions to be used in production.

The classification of dryers is not a simple task because of the very wide range of dryer designs available. Two steps are of primary importance for selecting a dryer for a

particular application: (1) Listing of the dryers that are capable of handling the material to be dried and (2) eliminating the more costly alternatives on the basis of annual costs (capital and operating costs). According to Perry and others (1997), dryers can be classified as direct or indirect. Direct dryers have the following characteristics:

1. Direct contact of hot gases with the solids is used for heating of solids and vapor removal.
2. Drying temperatures range up to 1000 K, the limiting temperature for most common structural metals. At the higher temperatures, radiation becomes an important heat-transfer mechanism, but it can cause degradation of the flavor compounds.
3. At gas temperatures below the boiling point, the vapor content of the gas influences the rate of drying and the final moisture content of the solid; with gas temperatures above the boiling point throughout, the vapor content of the gas has only a slight retarding effect on the drying rate and final moisture content (thus, superheated vapors of the liquid being removed can be used for drying).
4. For low-temperature drying, dehumidification of the drying air may be required when atmospheric humidities are excessively high.
5. A direct dryer consumes more fuel per pound of water evaporated and the lower the final moisture content, the greater the amount of fuel consumed.
6. The efficiency increases with an increase in the inlet-gas temperature for a constant exhaust temperature.
7. Because large amounts of gas are required to supply all the heat for drying, dust-recovery equipment may be very large and expensive when drying very small particles.

The indirect dryers differ from direct dryers with respect to heat transfer and vapor removal.

1. Heat is transferred to the wet material by conduction from an external medium such as condensing steam, usually through a metal surface with which the solid is in contact.
2. Surface temperatures may range from below freezing in the case of freeze dryers to above 800 K in the case of indirect dryers heated by combustion products.
3. Indirect dryers are suited to drying under reduced pressures and inert atmospheres to permit the recovery of solvents and to prevent the formation of explosive mixtures or the oxidation of easily decomposed materials.
4. Indirect dryers using condensing fluids as the heating medium are generally economical from the standpoint of heat consumption, as they furnish heat only in accordance with the demand made by the material being dried.
5. Dust recovery and dusty materials can be handled more satisfactorily in indirect dryers than in direct dryers.

As cited by Heldman and Hartel (1998), direct-contact dryers may be classified as fixed-bed or moving-bed. In fixed-bed dryers, the product is placed in the dryer, hot air is blown across the product to cause drying, and the product is removed when a certain moisture content is reached. Sun dryers, bin dryers, kiln dryers, or tray (cabinet or tunnel) dryers, which are typically batch dryers, are examples of this type of dryer. Moving-bed dryers, such as belt or conveyor dryers, belt-trough dryers, fluidized-bed dryers (Fig. 7.2), or rotary air dryers are continuous process dryers in which wet feed is

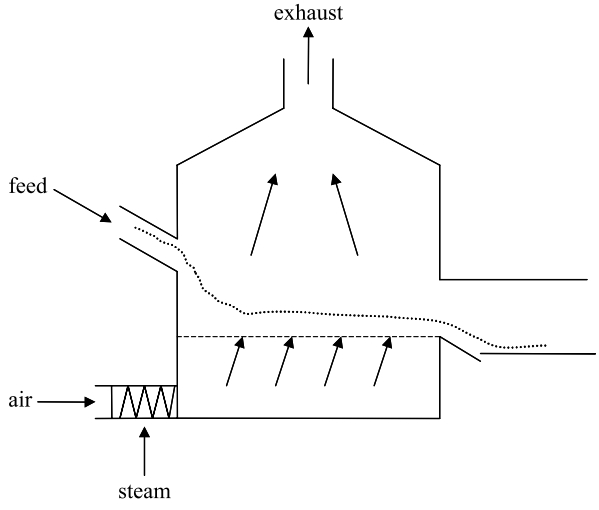

Figure 7.2 *Fluidized-bed dryer.*

input to the dryer and the final dried product is removed at the outlet. In the case of indirect-contact dryers, where heat is indirectly transferred from an external medium to the product through a heat-transfer surface, there is one common example, the drum dryer. The infrared contact dryer, where heat transfer occurs through a secondary mechanism, is another type of dryer. In each category, dryers can be operated either at ambient pressures or under vacuum to enhance vaporization at reduced temperatures. A final category of drying technology is freeze drying, where moisture is removed by a solid–vapor transition (sublimation) enhanced by low pressure.

There is no single theory of drying that covers all materials and dryer types. Many types of commercial equipment are available, with differences depending on variations in shape and size of stock, moisture equilibrium, mechanism of moisture flow through the solid, and method of providing the heat required for vaporization (McCabe and others 1993). The preliminary selection of dryers can be achieved by considering the following factors:

1. Properties of the material being handled (physical characteristics when wet and dry, corrosiveness, toxicity, particle size, abrasiveness);
2. Drying characteristics of the material (type of moisture, initial moisture content, maximum final moisture content, permissible drying temperature, probable drying time for different dryers);
3. Flow of material to and from the dryer (quantity to be handled per hour, continuous or batch operation, processing prior to drying, processing subsequent to drying);
4. Product qualities (shrinkage, contamination, uniformity of final moisture content, decomposition of product, over-drying, state of subdivision, product temperature, bulk density);
5. Recovery problems (dust recovery, solvent recovery);
6. Facilities available at the proposed site of installation (space, temperature, humidity, cleanliness of air, available fuels, available electric power, permissible noise, vibration, dust, heat losses, source of wet feed, exhaust-gas outlets).

7.2.1 Drying Effects

At the moment of harvest, an enzymatic degradation process begins in the plant that leads to degradation of the active principles. The incidence sunlight on the plants also accelerates the degradation of the substances present. A drying process that uses solar radiation promotes the degradation of the active principles, rapid drying of the edge of the vegetable tissue, and creation of an impermeable crust in these regions. In a relatively short time, the external surface of the material has a dried appearance, but its interior has a wet appearance.

The use of temperatures above room temperature is of extreme importance. For the drying of flowers and leaves, the temperature must be around 38°C. For barks and roots, temperatures up to 60°C are acceptable. The contact time varies around seven days at these temperatures (Mentz and Bordignon 1999). Temperatures over these limits accelerate the drying process, but promote the degradation of many volatile components (active principles). The drying of the plants must be achieved individually to avoid mixing the volatile components from each plant (Reis and others 1999).

The drying process will be faster if the material is present in small particles because of the greater surface area available for evaporation. For this same reason, the vegetable material must be placed in thin layers to optimize the drying process by facilitating transfer of moisture from the solid material to the environment (Mentz and Bordignon 1999). This procedure will allow greater efficiency and control of the operational conditions.

Hot-air greenhouses equipped with a thermostat may be used for drying, as the maintenance of a constant temperature during the desired period is guaranteed. It is also desirable to allow the air from the greenhouse to escape to prevent its saturation with the water vapor released from the drying material. The speed with which air circulates in the greenhouse has a great importance in the drying procedure. The use of greenhouse models provided with a system of forced air circulation is more efficient. The forced circulation provokes the constant renewal of air, removing the moisture-saturated air and facilitating the drying process.

Most liquid food flavorings are volatile and chemically unstable in the presence of air, light, moisture, and high temperatures. This is the case for most essential oils (Beristain and others 2001). The effect of drying on the compositions of the essential oils has been extensively studied. Mendes and others (2003) investigated the effect of natural and artificial drying on the composition of the essential oil of citronella and concluded that, in particular for this plant, the drying operation did not negatively influence the composition of the volatile compounds. In the case of the essential oil of lemongrass, Mendes and others (2004) observed large differences in the compositions of the essential oils obtained from dry and fresh leaves.

The perception of flavor in a food depends on the composition of its matrix. It has been shown that macromolecules, such as proteins, are involved in the retention of flavor compounds. The drying time may affect the retention of aroma; for example, the results obtained by Andriot and others (2004) have shown that the percentage of retention decreases significantly with the increase in freeze-drying time. Other studies are found in the literature with the same objective due to the fact that some plants and seeds are dried before they are processed (Radünz and others 2002).

Radünz and others (2003) studied the effect of temperature on the air drying of the extracted essential oil from guaco (*Mikania glomerata* Spengel) at 40, 55, and 70°C. It was observed that a temperature of 55°C did not influence the quantity of essential oil extracted and enabled a higher efficiency of extraction from the fresh plant in comparison to temperatures of 40 and 70°C.

The temperatures of 30, 40, 50, 60, and 70°C were investigated in the drying of citronella (*Cymbopogon winterianus*) plants (Rocha and others 2000). The results indicated that air drying at 60°C was best because of the shorter drying time and the higher efficiency of the essential oil extraction. This temperature did not affect the chromatographic profile or the quality of the essential oil.

Balladin and Headley (1999) studied the effects of drying methods using a wire basket solar dryer (temperatures not exceeding 50°C for 2 days) and an oven dryer (50°C for 2 h) on the composition of the essential oil of thyme (*Thymus vulgaris* Linné) herbs. The percentage of the essential oil was 0.5% using oven drying and 0.6% for the wire basket solar dryer method. The density of the extracted essential oil was lower than that of water. The difference was a result of the continuous heating in the oven for 2 h. In this case, some of the essential oils were lost. The authors suggested that the maximized use of supercritical extraction (using liquefied carbon dioxide) can yield higher concentrations of the volatile essential oils without thermal degradation.

A spray-dryer can be used to produce emulsions of essential oils using a gum as an encapsulating agent. Beristain and others (2001) studied the encapsulation of cardamom (*Elettaria cardamomum*) essential oil using this method. The conclusion of the work was that cardamom-based oil microcapsules were successfully produced by spray-drying using a gum. High flavor retention (83.6%) was attained during micro-encapsulation when a ratio of gum to oil equal to 4 was used.

Bos and others (2002) compared the volatile components present in both fresh and dried leaf and root material of *Anthriscus sylvestris* (L.) Hoffm. The essential oils were obtained through hydrodistillation and by extraction with dichloromethane, and the plants were submitted to air- and freeze-drying (lyophilization). Lyophilization resulted in more loss of volatile constituents than drying at room temperature. There were also quantitative differences between these extracts. In addition, air-drying and freeze-drying resulted in a significant loss of volatile constituents as compared to the fresh material.

Jerkovic and Mastelic (2003) have isolated volatile components from fresh and air-dried leaf buds of *Populus nigra* L. (Salicaceae). Forty-eight components were identified. Fresh buds contained 0.27% essential oil, and dried buds contained 0.12%. The authors concluded that the reduction in the amounts of volatile substances during the drying process depended on the volatility (physical–chemical properties) and the botanical structure of the particles that store the essential oil. Although the leaf buds contained numerous nonpolar compounds (waxes and lipids), a significant loss of volatile compounds was noted in dried leaf buds. Air-drying moderately effected the qualitative and quantitative composition of polar bud volatiles. It is well known that drying plant material could also have an effect on glycosides, as the enzymes are still active for some time after plant collection and could catalyze hydrolysis.

As drying is a unit operation that affects the composition of some essential oils, affecting the quality and characteristics, operational conditions such as temperature and velocity of the air-drying must be controlled. Thus, drying is necessary to reduce the moisture content, but more studies have to be made to better control the processes involving plants, seeds, and so on, without damaging the flavoring compounds.

8.1 INTRODUCTION

The knowledge that bacteria and viruses have genes that could mutate gave rise, in the 1940s, to the discovery of the genetic information present in DNA molecules. Interdisciplinary applications of very different novel research strategies explain the rapid progress in life sciences in the middle of the twentieth century.

The rising popularity of natural products during recent decades has triggered significant research activities in the use of bioprocesses for the production of flavor compounds. Products derived from bioprocesses starting with natural substrates are defined as natural if they have already been identified in plants or other natural sources. Natural flavors extracted from plant materials are often either too scarce or too expensive for

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

commercial use. Commercial exploitation of biotechnology in this area relies not only on technical advances, but also on satisfying certain regulatory considerations.

The flavor industries worldwide are expected to expand at an increased rate. Natural flavors and their ingredients are the largest growing sector of this market. Biotechnological production of flavor compounds can be carried out through a number of different processes, among them plant cell and tissue culture, biocatalysis and biotransformation with microorganisms, or *de novo* synthesis (Marasco and Dannert 2003).

This chapter focuses on the application of genetic engineering for the synthesis of natural flavor compounds. The intention is to present some examples of bioprocesses currently used or under investigation.

8.2 GENETICS AND MOLECULAR GENETICS IN VEGETABLES FOR FLAVOR PRODUCTION

Terpenoids comprise a diverse class of natural products from which several commercial flavors, fragrances, and medicines are derived. These compounds give our foods their wonderful aromas and tastes, and many of our cleaning reagents their fresh scents. These products are commonly isolated from plants, microorganisms, and marine organisms. Because these compounds are naturally produced in small quantities, purification from biological material results in low yields and consumption of large amounts of natural resources.

Terpenes and sterols are complex molecules synthesized by equally complex biosynthetic pathways. Plants are known to accumulate a diverse range of sterols and triterpenes, and there has been considerable effort to unravel terpene metabolism in plants. Biologically, the terpenes are very important compounds for plants. They provide unique means acting as hormones in plants, orchestrating development programs. Impressive progress in understanding these complex biochemistries has opened up opportunities to use genetic engineering to alter terpene metabolism for industrial applications.

The isoprenoid or terpene biosynthetic pathway in plants is probably one of the most complex and elaborate. It consists of two pathways operating independently of each other and localized in separate intracellular compartments. To simplify, the mevalonate pathway (MEP) provides a good route to manipulate the synthesis of these compounds in plants using the tools of genetic engineering.

Although there has been some success in manipulating the cytosolic mevalonate pathway, recent progress by Lewinsohn and others (2001) and Mahmoud and Croteau (2001) represents strides forward in manipulating the MEP (Fig. 8.1). The work of these groups addresses a broader conceptual issue of how the flux of carbon down the MEP is controlled or regulated.

The challenge in manipulating flavors and fragrances is not to divert too much of the carbon entering the MEP, but just enough to produce sufficient flavor molecules, allowing their detection by the olfactory senses.

Lewinsohn and others (2001) argued that even when only a small amount of geranyl pyrophosphate (GPP) is available in developing tomato fruits, a properly engineered monoterpene synthase might be able to siphon away enough carbon from the MEP pathway for the production of volatile monoterpenes. These investigators fused a linalool synthase gene from *Clarkia breweri* that had been well characterized previously to the E8 promoter element known to direct gene expression during fruit development. They could

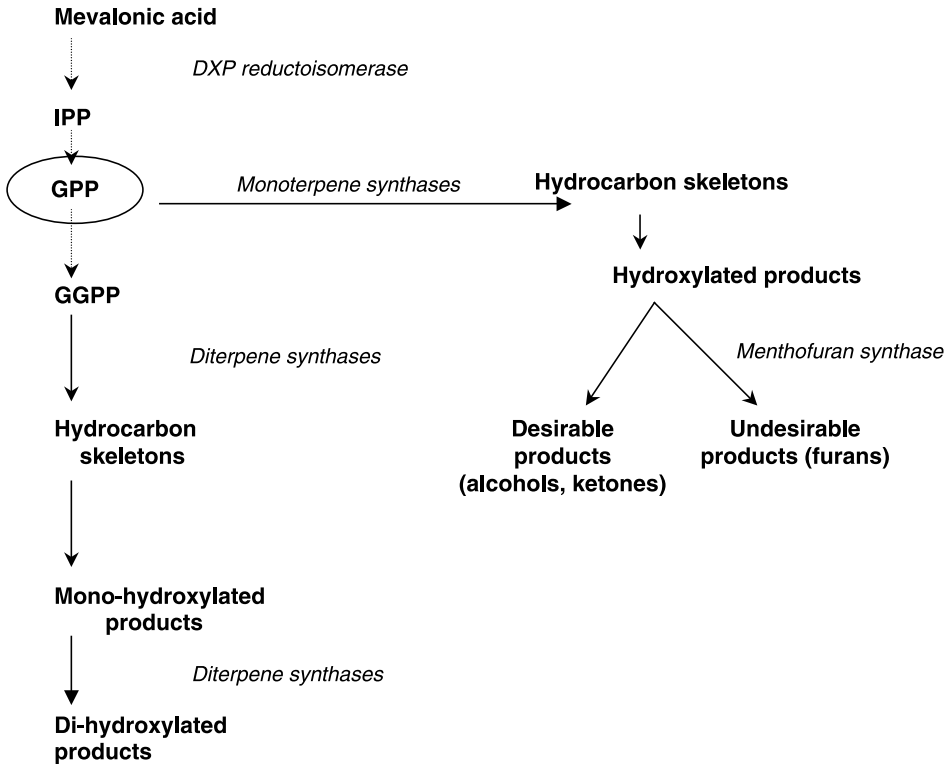

Figure 8.1 *The mevalonate pathway.*

observe that the transgenic fruits not only accumulated linalool during ripening, but also a hydroxylated derivative of linalool at 25–50% of the linalool present.

Mahmoud and Croteau (2001) introduced the gene encoding 1-deoxy-D-xylulose-5-phosphate (DXP) reductoisomerase into peppermint under the control of a strong constitutive promoter, and examined the complete terpene profile resulting from these transgenic lines. This gene limited an early step in the MEP that resulted in a 30% increase in the total content without changing the monoterpene profile. These investigators also demonstrated the feasibility of a new approach to enhance the quality of peppermint oil. Monoterpene hydrocarbons derived from the action of monoterpene synthases can be modified in different ways. In peppermint, menthofuran is derived from such modification of monoterpenes and is considered undesirable because it alters the flavor and color characteristics of the oil. Upon expressing an antisense form of the menthofuran synthase gene in transgenic peppermint, these authors observed a reduction of 50% in the menthofuran content, without any alteration in the terpene profile of the oil.

8.3 GENETIC ENGINEERING OF MICROORGANISMS AND FLAVOR

As for every bioprocess, the screening of suitable microorganisms, the adjustment of a full set of chemical and physical parameters, the design of the reactor, and a reliable online monitoring must be considered (Krings and Berger 1998).

Recombinant DNA technology has allowed low-cost production of flavor compounds. Genetic engineering of recombinant microorganisms is useful for improving the industrial production of flavor from microbial biotechnology. Functional expression of newly discovered flavor-generating plant enzymes in bacteria or yeasts constitutes a potential starting point for a bioprocess-oriented optimization.

Lactones are important flavor components of foods, responsible for the pleasant flavor of a variety of fruits and fermented foods. Lactones have been described as fruity, coconut-like, buttery, sweet, or nutty. A variety of microorganisms can perform *de novo* biosynthesis.

In the case of γ-decalactone (DECA), which has a peachy and creamy flavor, the basic process involves the biodegradation of ricinoleic acid using *Yarrowia lipolytica*, as indicated in Figure 8.2. However, other lactones have no sensorial properties or exhibit

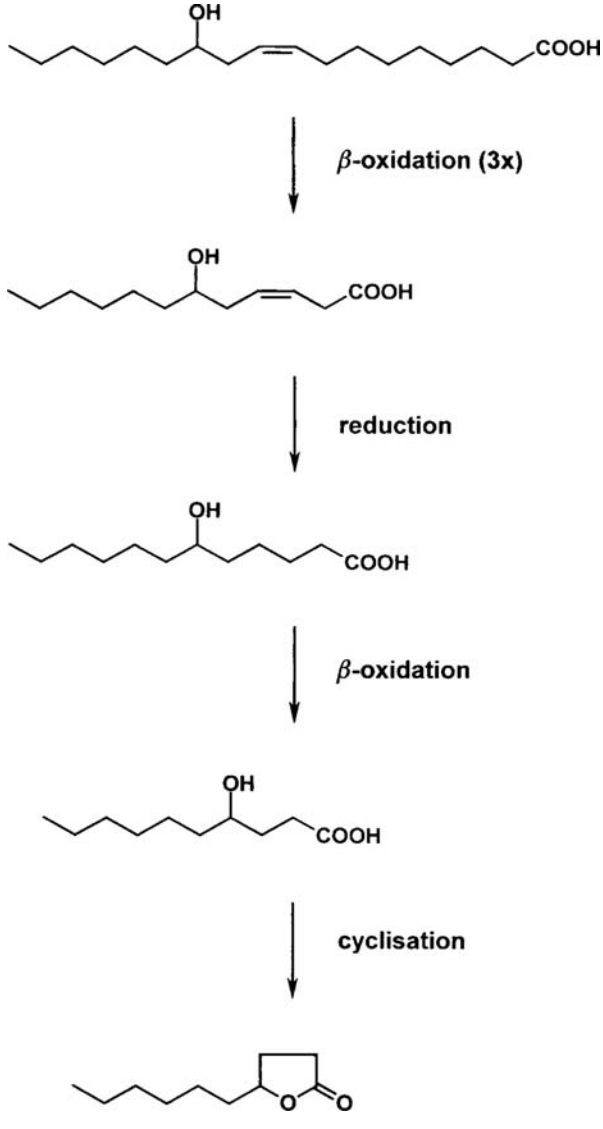

Figure 8.2 *The biodegradation of ricinoleic acid.*

mushroom or fruity notes. Furthermore, these lactones are produced at a higher rate and complicate the extraction of DECA.

The yeast *Y. lipolytica* possesses a five-gene family coding for acyl-CoA oxidase coding for acyl-CA oxidase (Aox1 to Aox5), the first enzyme of the pathway that is generally considered as catalyzing the rate-limiting step. It is possible to optimize the β-oxidation pathway of *Y. lipolytica* for production of DECA by modifying the genotype of the yeast to block β-oxidation at the C10 Aox level (Wache and others 2002). A strain not capable of degrading C10 was constructed so as to accumulate the precursor of DECA. Twice the amount of DECA was obtained from the mutant strain. Although this strain was efficient for lactone production, it was not growing as rapidly as the wild type on fatty acids. Using genetic engineering, it was possible to construct a yeast strain growing at a good rate and able to produce DECA by blocking the activity of Aox4. It produced 10 times more lactone in 48 h compared to the wild type, and this amount did not significantly decreased in 250 h (Groguenin and others 2004).

Citrus fruits possess unique flavors rarely found in other fruit species. Fruit flavor is a complex combination of soluble and volatile compounds. Several low-abundance sequiterpenes, such as valencene, nootkatone, and alpha- and beta-sinensal, are important flavor and aroma compounds in citrus (Sharon-Asa and others 2003).

D-Limonene (4-isopropenyl-1-methylcyclohexene) is one of the most widely distributed monoterpenes and is biosynthesized by more than 300 different plants (Menendez and others 2002). D-Limonene is the major component of peel oil in orange and lemon. Because of its low cost and extensive availability from citrus waste, this monoterpene is a very convenient starting material for bioconversions to higher value flavor and fragrance constituents.

Some microorganisms are able to convert limonene to chemicals of interest, including α-terpineol, carvone, and perillyl aldehyde and alcohol. *Bacillus stearothermophilus* can utilize D-limonene as the only carbon source for growth. Usually, aerobic thermophilic bacteria have rapid growth rates, broad metabolism, and resistance to chemical toxicity (Gurajeyalakshmi and Oriel 1989). The capability of *B. stearothermophilus* to grow on limonene may result in the production of monoterpenes of interest. The cultivation of *B. stearothermophilus* BR388 on minimal medium supplemented with 0.0125% yeast extract and limonene resulted in the formation of multiple metabolites such as perillyl alcohol, α-terpineol, perillyl aldehyde, and cyclohexanol (Chang and Oriel 1994).

To better understand the limonene pathway and the enzymes participating in monoterpene metabolism, the pathway encoding limonene metabolism was cloned as a 9.6 Kb chromosomal fragment from *B. stearothermophilus* BR388 into *Escherichia coli* (Chang and Oriel 1994). Limonene was the only carbon source. It resulted in the bioproduction of α-terpineol, perillyl alcohol, and perillyl aldeyde.

Studies on how to improve the bioconversion of limonene into special flavor compounds show the importance of limonene hydroxylase. This enzyme proved to be capable of limonene hydroxylation into a mixture of carveol and perillyl alcohol as well as dehydrogenation of these products to carvone and perillyl aldehyde.

A chromosomal DNA fragment of 3.6 Kb from *B. stearothermophillus* BR388 into *E. coli* has been sequenced, revealing a single open reading frame encoding a single subunit of limonene hydroxylase containing 444 amino acid residues. Using *E. coli* cells overexpressing limonene hydroxylase resulted in perillyl alcohol and carvone as principal products (Cheong and Oriel 2000).

Bioindustries are discovering the importance of biooxidation in fermentation processes. It allows the introduction of oxygen into nonactivated carbon atoms in a sterically and optically selective way.

Cytochrome P-450 monooxygenases can be isolated from bacteria, yeasts, insects, mammalian tissues, and plants. They play an essential role in the biosynthesis of numerous secondary metabolites and they can be efficiently expressed in *E. coli* cells. All microbial P450 monooxygenases that are expressed keep their activity during production and isolation (Urlacher and others 2004). The cytochrome P450 from *Pseudomonas putida*, which is a camphor-hydroxylating enzyme, was engineered to enhance activity towards α-pinene. The resulting products were (+)*cis*-verbenol and (+)verbenone, which are natural fragrances and flavors (Bell and others 2003).

Carotenoids form a large group of structurally diverse higher terpene pigments, widespread in plants and microorganisms. Potent flavor compounds are derived from carotenoids. These diverse compounds are the result of the oxidative cleavage reactions of carotenoid compounds into the corresponding aldehydes. Volatiles such as β-ionone, α-ionone, dihydroactinidiolide, damascenol, and β-cyclocitral are obtained from the cleavage of 9–13 carbon carotenoids (Glória and others 1993). The ionones are found in many fruits, such as raspberry, blackberry, peach, melon, and tomato.

Recently, Zorn and others (2003) performed a screening of potential β-carotene degrading strains. Four strains produced dihydroactinidiolide, and three others produced β-ionone as the main product, along with β-cyclocitral, dihydroactinidiolide, and 2-hydroxy-2,6,6-trimethylcyclohexanone.

The increasing amount of genome sequence data gives access to new enzymes including those playing key roles in plant flavor biosynthesis. The construction of microbial host vector systems simplifies the functional expression and molecular biochemical characterization of these enzymes. Isolation, cloning, and expression of plant genes into microbial hosts may be the key to natural flavor production.

8.4 ADVANCES IN BEER FLAVOR USING GENETIC TOOLS

Volatile substances such as alcohols, esters, sulfur compounds, and phenols are important for beer quality and in controlling the formation of the volatile flavor profile. To achieve effective control, the mechanism of production of these compounds should be understood. Two major areas are in development: the first is the physicochemical methodology used to determine and quantify flavor components during the fermentation process, and the second is yeast genetic engineering (Hammond 1995). As a result, more than 530 beer flavor compounds have been identified (Maarse and Visscher 1998).

Although raw material such as hop and malt are important factors for beer flavor development, there is a general agreement that flavor compounds are mostly produced by yeasts during fermentation. For the moment, none of the genetically engineered brewer's yeasts is in use because of problems in obtaining public acceptance and lack of governmental regulations. In the following paragraphs some examples of yeast genetic engineering modification to improve beer flavor are discussed.

Diacetyl is an off-flavor easily found in beer. The diacetyl pathway is shown in Figure 8.3. Diacetyl is formed from acetolactate, an intermediate in the synthesis of the amino acids isoleucine and valine (Inoue and others 1968; Inoue and Yamamoto 1970). Most of the acetolactate is converted into valine, but a part is converted into diacetyl by

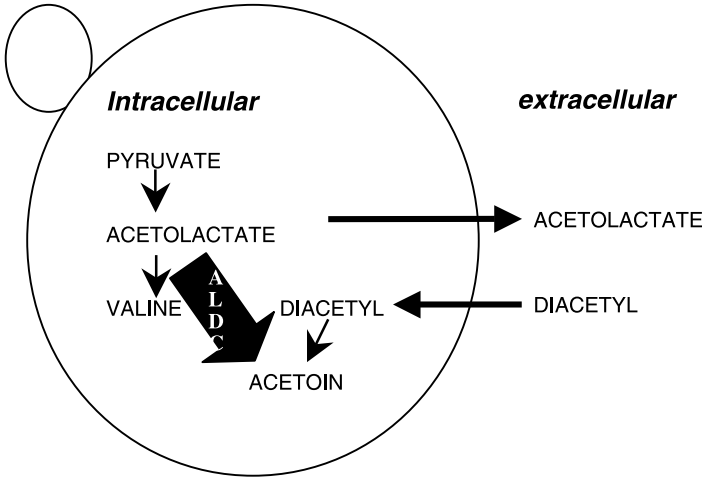

Figure 8.3 *The diacetyl pathway.*

nonenzymatic oxidation. Diacetyl is reduced by yeasts to acetoin by diacetyl reductase during maturation. Acetoin has no effect on beer flavor. There are several approaches to alter the concentration of acetolactate in the fermentation process (Hansen and Brandt 1996). The conversion of acetolactate to diacetyl and subsequently to acetoin can be limited by a shorter maturation period.

The enzyme acetolactate decarboxylase (ALDC) converts acetolactate directly to acetoin. ALDC is found in some microorganisms, but not in yeasts. This enzyme was introduced into brewer's yeast to accelerate beer maturation and to reduce the acetolactate concentration in young beer (Sone and others 1999). The ALDC gene was cloned from *Acetobacter aceti*, which is used in vinegar production (Yamano and others 1994). The gene was linked to the promoter and terminator of the *Saccharomyces cerevisae* phosphoglycerate kinase gene for expression. In that way, the ALDC expression cassette was integrated into the genome of commercial brewer's yeast. The fermentation performances of the parent yeast and the transformant were almost identical in terms of sugar consumption and flavor volatile production. However, diacetyl formation by the transformant was reduced to 10–20% of that produced by the parent. Other tests confirmed that the beer produced by the transformant had the same flavor and quality (Tada and others 1995). A similar result was obtained using the *Enterobacter* ALDC gene (Sone and others 1988; Suihko and others 1989). These results indicate that genetic engineering of brewer's yeast is an effective tool to improve beer flavor and quality.

Besides the reduction of the formation of a flavor compound, it is also possible to modify the metabolism to increase the formation of certain compounds. Higher alcohols and esters are formed by the yeast during wort degradation, and some of these compounds contribute significantly to the taste and flavor of beer. Isoamyl and isobutyl alcohol and their acetate esters are especially important flavor constituents in beer. These alcohols are formed from the corresponding keto-acids α-ketosivalerate and α-ketoisocaproate by addition of α-keto acid dehydrogenase. These keto acids may be formed either through branched-chain amino-acid biosynthesis or through deamination of valine and leucine. There are different approaches to increase the formation of the isoamyl esters

in beer. One of them is by controlling the esterase activity to increase the level of esters. Watanabe and others (1993) induced in mutants of sake yeast resistance to isoamyl monofluoroacetate, which resulted in an 85% reduction of esterase activity and 1.5–2.0 times increase in formation of isoamyl and isobutyl acetate.

8.5 FUTURE PROSPECTS

Innovative strategies for biocatalytic flavor generation will certainly take advantage of the emerging fields of functional genomics, proteomics, protein and metabolic engineering. Genetic engineering in flavor biosynthesis will become the most useful way to obtain natural flavors. As an increasing amount of genome sequence data becomes available, the improved genomic and proteomic methodologies provide access to new enzymes, including those playing key roles in plant flavor biosynthesis.

Operation under mild conditions to protect unstable products, that is, green processes, and functionalization of complex precursor molecules in a highly specific way (chemo-, regio-, and stereospecific) are important factors allowing biocatalysis to outplay chemical approaches in certain cases. Research exploiting these advantages of flavor biocatalysis will certainly be intensified in the future.

Finally, the industrial application of novel biocatalysis strategies will depend upon a less prejudiced and more balanced public perception of the use of genetic engineering for improved food quality and more environmentally friendly production processes (Schrader and others 2004).

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

9.1 INTRODUCTION

Microorganisms play an important role in the generation of natural compounds, particularly in the field of food flavors. For a long time, plants were the sole sources of flavor compounds and most of them were isolated from essential oils. However, active compounds are present in low concentrations, which makes their isolation difficult. Another disadvantage of plants as a source of flavors is the dependence on factors that are difficult to control such as the weather and the risk of plant diseases. The production of flavor compounds by biotechnological methods has been an interesting alternative due to consumers' preference for natural ingredients. Microbial processes seem to be the most promising methods for the production of natural flavors.

9.2 MAIN TECHNOLOGIES

Many microorganisms are capable of synthesizing flavor compounds when growing on a culture media. They have the ability to perform conversions that would require multiple chemicals steps. Microorganisms are used to catalyze specific steps. They are also an economical source of enzymes, which can be utilized to enhance or alter the flavors of many food products (Kempler 1983). In this way, biotechnological processes involved in the production of flavor compounds can be divided into two groups: microbiological and enzymatic. Microbiological methods are subdivided into biosynthesis and biotransformation. The first is the production of chemical compounds by cells (fermentation or secondary metabolism). The second refers to the use of microbial cells in the specific modification of chemical structures (Welsh and others 1989).

In fermentation, the production of flavors starts from cheap and simple sources such as sugars and amino acids. The product is generated by the complex metabolism of the microorganism. When microorganisms are used in order to catalyze specific conversions of precursors and intermediates, the process is called biotransformation. Although fermentation requires C and N sources, a specific substrate is necessary for microbial transformation. The enzymatic catalysis precedes a simple and specific transformation of the substrate molecule. The substrate does not have to be "natural"; according to Schreier (1989) "non-natural" substrates can also be biotransformed.

It is important to distinguish research with the purpose of obtaining complex products with natural characteristics from those that try to obtain isolated molecules. The first consists in the experience of nature imitation and in developing a process with one or more microorganisms and enzymes. The second tries to obtain a higher yield of the characteristic components. The choice between them determines the methodology, which will be employed *in vivo* or *in vitro*, through biosynthesis or bioconversions (Delest 1995).

9.3 HOW TO OBTAIN FLAVORS

9.3.1 Flavor from Fermented Foods

The sensory properties of fermented foods are one of the key parameters in distinguishing these products from foods that have undergone undesirable spoilage. The organoleptic properties of fermented foods usually differ from those of the unfermented substrate

and are dependant upon the biochemical activities of the associated microorganisms (Cook 1994).

Fermentation has been practiced for the production of food since ancient times. It has become an effective technology for the production of organic acids, flavor compounds, and other biologically important chemicals. New aroma and flavors includes acids, alcohols, carbonyl compounds, esters, and pyrazines.

The use of microorganisms in the production of food has been practiced for a long time to improve the sensory quality of the food. Products such as beer, wine, distilled beverages, bakery, vinegar, fermented vegetables, milk, soybean, and meat are preserved, modified, and flavored using microorganisms. The flavor compounds of traditionally fermented foods originate from a complex microflora that acts in the chemical precursors of a food matrix (Berger 1995).

Lactic acid and alcoholic fermentations are the two important processes responsible for fermented food flavors. However, in some cases, the flavor is formed by specific fermentations (Joshi and Pandey 1999). The creation of new fermented products can result in the development of novel flavors and textures.

9.3.1.1 Dairy Products. Cheese flavors find application in snacks, sauces, baked goods, and several other products. Yogurt and buttermilk flavors are also useful. The cheese flavor results from the action of microorganisms and enzymes on milk's proteins, fats, and carbohydrates. Numerous breakdown products are formed, among them, short-chain fatty acids, acetic and lactic acids, alcohols, aldehydes, ketones, esters, sulfur and nitrogen compounds (Sharpell 1985). Marilley and Casey (2004) have reported that the use of bacteria strains for cheese ripening with enhanced flavor production is promising. They also mentioned that the catabolism of amino acids is presumably the origin of some major flavor compounds.

The starter cultures used in dairy technology are mainly prokaryotes like *Lactococci*, *Lactobacilli*, *Leuconostocs*, *Bifidobacteria*, *Propionibacteria*, *Streptococci*, and *Brevibacterium linens*.

Yeasts, such as *Kluyveromyces*, *Debaromyces*, *Candida* or *Trichosporon* are present in many manufactured milk products. These microorganisms modify the sensory characteristics of the products by synthesizing or assimilating volatile nitrogen and sulfur compounds.

Several chemical reactions take place in the surface of ripened cheeses such as Camembert and Brie during maturation due to fungi growth. The Fungal mycelium of *Penicillium roqueforti* grows rapidly and the resulting products are used directly for flavoring foods with a blue cheese-type flavor.

9.3.1.2 Alcoholic Beverages. Flavor compounds are produced as byproducts of yeast metabolism during alcoholic fermentation. Many flavor compounds have been identified in alcoholic beverages. The main compounds are listed in Table 9.1.

During alcoholic fermentation, yeasts transform sugars (glucose, fructose, and sucrose) into ethanol and carbon dioxide by the Embden–Meyrhof–Parmas pathway. This is the main bioreaction, but not the only one and, at the same time, several secondary byproducts are formed. Higher alcohols, organic acids, and esters are the main flavor compounds.

Higher alcohols, which contain more than two carbons, are also called fusel alcohols. They constitute the major portion of the secondary products of yeast metabolism. They

TABLE 9.1 Compounds Produced by Yeasts During Alcoholic Fermentation.

Class	Compounds
Esters	Amylacetate, butyl acetate, ethyl acetate, ethyl butyrate, ethyl lactate, ethyl benzoate, ethyl hexanoate, ethyl guaiacol, ethyl-2-methyl butyrate, ethyl-3-methyl butyrate, ethyl octanoate, ethyl octenoate, ethyl decanoate, ethyl dodecanoate, diethyl succinate, 3-methyl propionate
Alcohols	Ethanol, 2-methyl butan-1-ol (amyl alcohol), methyl butan-1-ol (isoamyl alcohol), heptanol, hexan-1-ol, 2-phenyl ethanol, 2-methyl propanol, glycerol, 2,3-butanediol, n-propanol
Carbonyls	Decalactona, decan-2-one, acetaldehyde, butyraldehyde, hexanal, nonanal diacetyl benzaldehyde
Acids	Acetate, butyrate, lactate, malate, succinate, hexanoate, nonanoate, octanoate
Sulfur derivatives	Methionol, ethanetiol, methylthioacetate, dimethyl disulfide, ethyl methyl disulfide, diethyl disulfide, 3-methylthiopropyl acetate, 2-mercaptoethanol, *cis*- and *trans*-2-methylthiophanol
Phenolic compounds	Vinyl phenol, ethyl phenol, ethyl guaiacol, vinyl guaiacol

include n-propanol, isobutyl alcohol, 2-methyl butanol, amyl alcohol, isoamyl alcohol, and 2-phenyl ethanol. Isoamyl alcohol accounts for more than 50% of the total concentration of higher alcohols.

Esters at appropriate concentrations impart flowery and fruity flavors. They are formed by esterification of fatty acyl-CoA or of organic acid by alcohols. Esters are present in very low amounts, near their threshold level. However, ethyl acetate has been found in wine in high concentrations.

Beer. Acetaldehyde, the most important aldehyde in beer, is formed as a metabolic branch point in the pathway from carbohydrate to ethanol. Its level varies during fermentation and ageing of beers, reaching 2–20 mg/L. At concentrations of 20–25 mg/L, acetaldehyde causes "green" or "vegetable" flavor.

Diacetyl and pentane-2,3-dione (vicinal diketones) have a characteristic flavor described as "buttery", "honey" or "toffee-like". They have a very high off-flavor potential, dependent on the fermentation temperature. The threshold for diacetyl in lager-type beers is 0.10–0.14 mg/L. At levels above 1 mg/L, it becomes increasingly "cheese-like" and sharp.

Volatile acids are usually present in beer at concentrations of 20–150 mg/L. Butyric and iso-butyric acids in concentrations of 6 mg/L cause a "butyric" or "rancid" flavor. Valeric and iso-valeric acids cause an "old-hop" and "cheesy" flavor. Fatty acids with 6 to 12 carbon fatty acids give the characteristic flavor of "cheesy", "goaty", or "sweaty" (Smogrovicová and Dömény 1999).

Wine. The chemical composition of wine is determined by many factors, among them grape variety, geographical and viticultural conditions, microbial ecology of the grape, fermentation processes, and winemaking practices. Microorganisms affect the quality of the grape before harvest and during fermentation. They metabolize sugars and other components into ethanol, carbon dioxide, and hundreds of secondary products that contribute to the characteristic flavor of wine (Fleet 2003).

9.3.1.3 Bakery Products. Although *Candida* yeast has occasionally been used for baking and some *Saccharomyces carlsbergensis* strains have been patented for use as baker's yeast, pure strains of *Saccharomyces cerevisae* are almost universally employed.

9.3.1.4 Mushroom Flavors. The commercially important mushrooms belong to the orders *Ascomycetes* and *Basidiomycetes*. Truffles (*Tuber* sp.) and morels (*Morchella* sp.) represent the *Ascomycetes*. *Basidiomycetes* are represented by *Agaricus bisporus*, *A. bitorquis*, *Lentinus edodes* (Shiitake), *Volvariella volvacea*, *Pleurotus* sp., and *Flammulina velutipes*. The main chemical compound responsible for the mushroom flavor is 1-octen-3-ol, although several others, including glutamic acid and 5′-guanylic acid, can modify the flavor, giving each mushroom species its distinctive characteristic. There is interest in growing mushroom mycelium in submerged culture and then utilizing the dried mycelium as a flavor compound (Sharpell 1985).

9.3.2 Biosynthesis of Flavor Compounds

Biochemical reactions as well as several nonenzymatic reactions involving sugars, fatty acids, and amino acids give rise to flavor during fermentation. Several reports and reviews have been published on the production of volatile compounds by microorganisms (Janssens and others 1988, 1992; Berger 1995; Jiang 1995; Christen and others 1997; Bramorski and others 1998; Soares and others 2000; Medeiros and others 2001). Although several bacteria, yeasts, and fungi have been reported to produce flavor compounds, a few species of yeasts and fungi are often preferred. However, only a few of them find application in the food industries due to their GRAS (Generally Recognized As Safe) status.

Flavor compounds derived from microorganisms are often produced in low concentrations. These compounds have low thresholds and can be detected by chromatographic methods in parts per million (ppm, μL/L). The amount and type of compounds secreted by microorganisms depend on the strain, with its enzyme-specific action, chemical composition of the culture medium, pH and temperature control, age of inoculum, and water activity of the substrate.

Flavor compounds produced by *Trichoderma viride, Penicillium roqueforti*, and *Penicillium decumbens* have been detected during the phases of growth or sporulation, depending on the culture medium (Latrasse and others 1985).

Singhal and Kulkarni (1999) presented a schematic representation of the flavor compounds produced by microorganisms (Fig. 9.1). Some examples of flavor compounds produced by microorganisms are also indicated in Table 9.2.

9.3.2.1 Esters. Esters are a very important class of flavor compounds of fresh fruits and fermented foods, which are found in concentrations between 1 and 100 ppm (Janssens and others 1992). The production of the ester ethyl acetate by the yeast *Candida utilis* from glucose is observed when the yeast grows on a medium containing a specific initial ethanol concentration.

Esters of low molecular weight are responsible for fruity odors and consist of acids and their derived compounds such as acetates, propionates, and butyrates. Some examples are ethyl butyrate and isoamyl acetate, which are found in strawberry and banana (Macedo and Pastore 1997).

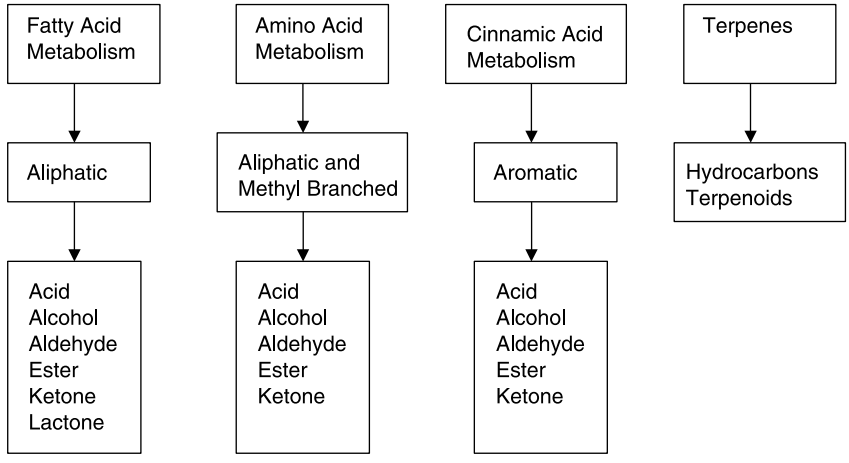

Figure 9.1 *Flavor compounds produced by microorganisms.*

The presence of esters such as ethyl acetate and butyric acetate in the culture medium can eventually describe a detoxification mechanism by which the microorganism avoids the accumulation of toxic compounds. The production of acetates occurs in order to detoxify the medium by converting acetic acid and high alcohols (Latrasse and others 1985).

TABLE 9.2 Microbial Production of Flavor Compounds.

Compounds	Microorganism
Diacetyl	*Saccharomyces lactis, Leuconostoc dextranicum*
Esters	
Geranyl acetate	*Ceratocystis virescens,C. variospora*
Ethyl butyrate and ethyl hexanoate	*Pseudomonas fragi*, *Streptococcus lactis*, *S. cremoris* *S. diacetylactis*, *L. casei*
Ethyl isovalerate	*Pseudomonas fragi*
2-Phenyl ethanol	*Erwinia carotovora*
Lactones	
α-Decalactone	*C. moniliformis*
t-Decalactone	*Sporobolomyces odorus*
s-Decalactone	*Saccharomyces cereviseae*, *Candida pseudotropicali*, *Sarcina lutea*
L-Menthol from menthyl esters	*Saccharomyces*, *Bacillus*, *Trichoderma*, *Candida*, *Rhizopus*
Pyrazynes	
2-Methoxy-3-isopropyl pyrazine	*Pseudomonas perolenes*, *Streptomyces*, *Streptococcus lactis*
Tetramethyl pyrazine	*B. subtilis*, *Corynebacterium glutanicum*
Terpenes	
Linalool	*Ceratocystic variospora*, *C. moniliformis*, *Phellinus igniarus*, *Kluveromyces lactis*, *Asocoidea, Lentinus lepidus*
Citronellol	*Ceratocystic variospora*, *C. moniliformis*, *K. lactis*, *Trametes odorate*
Geranyl acetate	*Ceratocystic virescens*
Citronemmyl acetate	*Ceratocystic coarulescens*

Source: Modified from Berger (1995) and Singhal and Kulkarni (1999).

Two metabolic pathways can be followed in the formation of esters: alcoholysis of acyl-CoA compounds and the direct esterification of an organic acid. Yeasts follow predominantly the first pathway, and filamentous fungi and bacteria prefer the second (Welsh and others 1989).

Some ramified amino acids are important precursors of flavor compounds and are related to fruit maturation. The initial reaction is called the enzymatic Strecker degradation. Several microorganisms including yeasts and bacteria such as *Streptococcus lactis* can modify the majority of the amino acid structures. Even if alcohols are related to fruit maturation, esters have a dominant role. Ethyl acetate comprises, with other compounds, banana flavor. 2-Methyl-ethyl-butyrate has a great impact on characteristic apple flavor (Fennema 1993).

Janssens and others (1987) found and quantified the fruity banana flavor produced by the yeast *Hansenula mrakii* and by the fungus *Geotrichum penicilliatum* in submerged fermentation using a synthetic medium. In the study using the yeast it was concluded that the fruity aroma occurred due to the biosynthesis of esters and alcohols. Seventeen compounds were identified in concentrations greater than 50 μL/L, including ethanol, ethyl acetate, isobutanol, ethyl propionate, isobutyl acetate, and isopenthyl acetate. Alcohols were formed in the exponential growth phase, but the esters were formed in the stationary phase. Ethyl acetate was the main product. In both studies, some precursors of fruity esters were added, such as vanillin, leucine, isoleucine, and phenylalanine. Thirty-three compounds were identified in concentrations greater than 50 μL/L: ethanol, ethyl acetate, ethyl propionate, and others. Ethyl acetate was produced in the highest concentrations (9924.1 μL/L).

Inoue and others (1994) reported the tolerance of *Hansenula mrakii* to ethyl acetate, which can be used as a sole carbon source. In this study, the esters formed during the production of sake by *Hansenula mrakii* and *Saccharomyces cerevisae*, were compared. Ethyl acetate, isobutyl acetate, and isoamyl acetate were preferably formed, determining the beverage quality. The formation of these compounds was catalyzed by the enzyme acetyl transferase from isoamylic acid and acetyl CoA.

Ethyl acetate, ethanol, acetic acid, and acetaldehyde were also produced by submerged fermentation and identified in the glucose metabolism of *Hansenula anomala*. In this case, the production of ethyl acetate was recognized as an aerobic process (Davies and others 1951).

Strains of *Ceratocystis* were also identified as ester producers. Lanza and others (1976) studied the production of acetates with different carbon (glucose, galactose, and glycerol) and nitrogen (urea and leucine) sources. They concluded that the type of flavor compounds produced depended on both sources (carbon and nitrogen), which is different for other microorganisms such as *Trichoderma viride*.

Collins and Morgan (1961) identified esters synthesized by different species of *Ceratocystis* (*C. moliniformis*, *C. major*, *C. coerulescens*, and *C. fimbriata*) during submerged fermentation in a dextrose potato medium. Ethyl acetate and ethanol were found in higher concentrations, except for *C. fimbriata*, which had isobutanol as the main compound. A strong banana flavor was detected when using dextrose and urea due to the presence of isoamyl acetate, which was also identified in leucine- or isoleucine-based media. For the combination galactose–urea, the main flavor was citric due to the formation of terpenes.

The yeast *Kluyveromyces marxianus* produced some compounds with characteristic fruity flavor, with ethyl acetate found in higher concentrations in solid-state fermentation

of different agro-industrial residues such as cassava bagasse (Medeiros and others 2000, 2001).

Banana flavor has also been identified in some plants when microorganisms (*Erwinia caratovora* ssp atroseptica) infected them. Spinnler and Dijian (1991) identified the volatiles formed in a synthetic medium, similar to the ones in the infected plant. From 13 isolated microorganisms with capacity to produce esters and alcohols, several compounds were identified; including ethyl acetate, 2-methyl-1-propanol, and propyl acetate. In this study, different media were tested with different nitrogen and carbon sources. Better results were found with glucose, fructose, sucrose, and asparagine. The addition of leucine led to the production of isoamyl acetate, corresponding to the degradation of the amino acid following the Erlich route.

Beiju is made of naturally fermented cassava, with fruity characteristics. It was used by the indians in Maranhão, North of Brazil, in order to produce a typical alcoholic beverage, *tiquira*. The microbiological population was identified and quantified by Park and others (1982), with counts between 6×10^5 and 1.9×10^6 CFU, as being predominantly *Aspergillus niger* and *Pecylomyces* sp.

Yoshizawa and others (1988) identified some volatiles produced by a strain of *Neurospora*, isolated by Park and others (1982), in submerged fermentation. These include ethanol, ethyl acetate, isoamyl acetate, ethyl hexanoate, and acetoine.

9.3.2.2 Aldehydes. Aliphatic, aromatic, and terpenoid aldehydes are important contributors to the flavor of fermented dairy products. They are synthesized by microorganisms as intermediates in the formation of alcohols from keto acids. An example is the bioconversion of ethanol to acetaldehyde by *Candida utilis.*

Flavor production using immobilized lipase from the yeast *Candida cylindracea* in a nonaqueous system has been studied for producing a broad range of esters including ethyl butyrate, isoamyl acetate, and isobutyl acetate. Ethyl butyrate has a pineapple–banana flavor, which has a large market demand, and sells at a price of US$150/kg upwards. This process has shown a great stability of the enzyme (more than a month) if kept hydrated intermittently (Singhal and Kulkarni 1999).

9.3.2.3 Alcohols. Alcohols do not contribute as a flavor component unless present in high concentration. They are formed as a primary metabolite from microorganisms' activity or due to the reduction of a carbonyl. Fusel alcohols can be formed from either carbohydrate or amino-acid metabolism and are the predominant volatiles of all fermented beverages, in addition to ethanol.

Different alcohols can be found in the culture of yeasts such as ethanol, propanol, isobutanol, and phenyl ethyl alcohol. In filamentous fungi it is possible to find methyl-3-buthanol, butanol, isobutanol, pentanol, hexanol, octanol-3, and phenyl ethanol from the metabolism of amino acids such as leucine, valine, isoleucine, and phenylalanine (Welsh and others 1989).

9.3.2.4 Carbonyls. Among the ketones, odd-numbered 2-alkanones from five to eleven carbons, along with free fatty acids and 2-alkanols, determine the flavor of *Penicillium*-ripened cheese and have received much attention. Bacteria such as *Aureobasidium*, yeasts, and higher fungi produce 2-alkanones, but only *Penicillium* has been used industrially.

9.3.2.5 Terpenes. Terpenes are the most important natural components of essential oils to be used as flavors. Microorganisms are able not only to synthesize but also to degrade or transform terpenes. Fungi are the main microorganisms responsible for terpene production, but bacteria are capable of synthesizing a few volatile terpenoids, such as geosmin and cadin-4-ene-1-ol (Berger 1995).

The synthesis of monoterpenes by *Ceratocystis variospora* has been studied by Collins and Halim (1972). Numerous other microorganisms are able to synthesize monoterpenes, among them *Ceratocystis moniliformis*, *Kluyveromyces lactis*, *Sporobolomyces odorus*, *Trametes odorata* and *Trichoderma viridae*.

Microbial bioconversion of terpenes has been studied by several authors. Monoterpenoid compounds like citronellal, citral, limonene, and menthol (acetates) can be biotransformed in citronellol, geranic acid, carveol and 1-menthol, respectively.

Valencene is a sesquiterpenoid available from orange oil and has little commercial use. Some bacteria are capable of transforming valencene to nootkatone, a main flavoring component of grapefruit.

From the economic point of view, the development of biotechnological processes for the production of terpenes is not viable due to the low yields obtained and the abundance of vegetable sources available. The real meaning of these studies is the understanding of the steps of the catabolism of terpenes.

9.3.2.6 Lactones. Lactones are associated with fruity, coconut, buttery, sweet, or nutty flavors. *Trichoderma viridae*, a soil fungus, generates a characteristic coconut flavor due to the production of 6-pentyl-2-pyrone. The main component of peach flavor, 4-decalactone, can be synthesized by *Sporobolomyces odorus. Aspergillus niger* can transform β-ionone into a complex mixture resembling tobacco flavor. Lactones make a significant contribution to the flavor of several fermented foods like dairy products and alcoholic beverages.

Some microorganisms such as *Ceratocystic moniliformis*, *Trichoderma viride*, *Sporobolomyces odorus*, and some species of *Candida* have been reported as lactone producers. However, the production is not very significant and has low yields (mg/L), except for the *in situ* production of lactones from dairy products.

Lee and Chou (1994) verified that the addition of 3% castor oil to the culture medium raised the production of lactones by *Sporobolomyces odorus*, with a yield of 8.62 mg/L.

Among lactones, 6-pentyl-α-pyrone (6-PP) presents the most interesting flavor properties. It is a molecule with a strong coconut flavor and is also present in the aroma of peaches and nectarines. The production of 6-PP by *Trichoderma harzanium* with sugar cane bagasse by solid-state fermentation was studied by Sarhy-Bagnon (1999) as an alternative for the production by submerged fermentation, giving a six fold raise in concentration.

9.3.2.7 Pyrazines. Pyrazines are typical flavor components of heated foodstuffs. They give the roasted or nutty flavors characteristic of roasted nuts, coffee, and cocoa beans, and baked and meat products. Microwave foods need the addition of pyrazines because they do not develop a characteristic nonenzymatic browning flavor during cooking. *Bacillus subtilis* was the first organism found to produce pyrazine. Pyrazines were also identified in cultures of *Septoria nodorum* and *Aspergillus parasiticus*.

9.3.3 Enzymatic Technology

Enzymatic processes that are used to obtain flavors can be described by the hydrolysis of some compounds without microbial growth. The majority of the enzymes used in food processing are hydrolases, such as amylases, proteases, pectinases, cellulases, pentonases, invertase, and lactase. They are used, for example, in cheesemaking (lipases, proteases), wine and juice production (pectinases), lactose reduction (lactase). Immobilization techniques, such as gel inclusion, microcapsules entrapment, and covalent or adsorptive binding onto solid supports has improved technical aspects such as handling, recycling, and long-term stability. Microbial enzymes have become an integrated part of processes in the food industry, So it is natural to see their use for the generation of flavor compounds (Whitaker 1991).

Filamentous fungi are capable of producing enzymes that are used to hydrolyze plant cell wall and liberate its content. However, the enzymatic extraction needs a thermal treatment, which sometimes can destroy or change flavor compounds.

Pectinase, cellulase, and hemicellulase of *Aspergillus*, *Penicillium*, *Rhizopus*, and *Trichoderma* are enzymes more commonly used to increase extraction efficiency during fruit, vegetable, cereal, or juice processing (Armstrong and others 1989).

Lipases often show complex patterns after isoeletric focusing, but this heterogeneity is due to the varying degrees and positions of glycosilation of the protein core. Pre-pro-lipase and pro-peptides are now studied in detail by genetic engineering (Berger 1995).

Microbial hydrolases have been reported to improve the sensory quality of food by the synergistic action of mono-, oligo-, and poly-glucanases. Various carbohydrases have been purified and characterized, among them, β-glucosidase from *Aspergillus niger* and α-glucosidase, with maltase properties from banana pulp. Carbohydrases have contributed to the assessment of the identity and origin of plant products, to the understanding of changes during processing and maturation, and to the selection of flavor-rich cultivars. Stability and selectivity data will be decisive for sensory changes in a food and thus for the future application of new enzymes in food processing (Berger 1995). Smaller peptides and free amino acids, which are end products of various proteases, contribute to the non-volatile flavor fraction and act as precursors of volatiles.

Cheese treated with enzymes to enhance flavor, or a significant portion of the flavor profile, is considered to be enzyme-modified cheese (EMC). It provides the food manufacturer with a strong cheese note in a cost-effective, nutritious, and natural way (Moskowitz and Noelck 1987). Such EMCs are ideal in frozen cheese, because proteins from natural cheese tend to coagulate and produce a grainy texture, but the proteins in EMCs have been hydrolyzed to more soluble peptides and amino acids, overcoming these problems (Missel 1996).

EMC flavors available commercially include Cheddar, Muzzarela, Romano, Provolone, Feta, Parmesan, Blue, Gouda, Swiss, Emmental, Gruyere, Colby, and Brick. These cheese flavors have a wide range of applications in salad dressings, dips, soups, sauces, snacks, crisps, pasta products, cheese analogs, frozen foods, microwave meals, ready-made meals, canned foods, crackers, cake mixes, biscuits, quiches, gratins, cheese spreads, low-fat and no-fat cheese products, and cheese substitutes (Buhler 1996).

The basis of EMC technology is the use of specific enzymes acting at optimum conditions to produce typical cheese flavors from suitable substrates. These enzymes consist of proteinases, peptidases, lipases, and esterases. EMCs can be used in food recipes to fulfill several roles, for example, as the sole source of cheese flavor in a product, to

intensify an existing cheesy taste, or to give a specific cheese character to a more bland-tasting cheese product (Anon 1993). They have approximately 15 to 30 times the flavor intensity of natural cheese and are available as pastes or spray-dried powders (Freund 1995). The production of EMC is an important industrial activity, which has grown due to a greater demand for convenience foods, together with the health-related concerns regarding the amounts of fat, cholesterol, and cholesterol-producing saturated fat in traditional dairy products. EMC has been included in no-fat and low-fat products, replacing the functional and flavor characteristics of fats previously derived from natural cheese (Anon 1993; Freund 1995). The addition of EMC creates the desired flavor without increasing fat content. It can be added at levels of 0.1% (w/w) and contribute less than 0.07% fat or 2.28 calories per 100 g. Most new applications are targeted at texture and provide rich mellow tones, pleasant flavor-enhancing effects, fatty mouth-feel, flavor masking, rounding-off of sharp spicy notes, and harmonization of other flavor ingredients (Buhler 1996).

10.1 INTRODUCTION

Microbial fermentation is a promising biotechnological technique for the production of natural flavors. Although many biotechnological processes have been reported, most have not yet been applied in industrial production. The major reason for this is the low yield. Microbial flavors are often present in low concentrations in fermentation broths,

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

resulting in high costs for downstream processing. This is compensated by the price of the naturally produced compounds, which is 10 to 100 times higher than that of synthetic ones. It is estimated that around 100 flavor compounds are produced industrially by microbial fermentation (Janssens and others 1992).

The aim of current research is the development of low-cost processes with high yields. In order to achieve that, it is necessary to control the metabolic pathway and to develop alternative production techniques, such as the use of solid-state fermentation, immobilized cells, or genetically modified organisms.

10.2 FERMENTATION SYSTEMS

Any bioprocess is designed according to the microbial growth pattern and by the selection of the fermentation technique in which the desired product is produced by the microorganism. The bioprocess technique takes into account the physiological and morphological characteristics of the microorganisms and the properties of the products (Drawert 1987).

There are many factors that should be considered for the establishment of a fermentation process. These include the screening of suitable microorganism and substrate, optimization and adjustment of process parameters, design of the bioreactor, and downstreaming of the flavor compounds produced (Pandey 2003).

10.2.1 Effect of Environmental Conditions on Flavor Production

Physical, chemical, biological, physiological, and genetic factors can affect flavor production, among them pH, temperature, medium composition, inoculums' size, and strain selection.

10.2.1.1 Biological Factors. Desired microorganisms have to be present in the culture medium in sufficient amounts to carry out fermentation at an economical rate. In practice, it is achieved by applying a sterilization method, which eliminates undesirable microorganisms (Nigam and Singh 1999).

10.2.1.2 pH. Generally, the pH of the medium changes as a result of the microorganism's metabolism and growth. As carbohydrates are metabolized, organic acids are formed and the pH decreases significantly. Therefore, it is important to control the pH of the medium, as it affects microorganism growth, fermentation rates, and byproduct formation. Furthermore, in low-pH media there is no contamination (Pandey 1999).

Ceratocystis fimbriata cultivated on coffee husk achieved its best flavor yields at an initial pH of 6.0. Different medium pH resulted in lower levels of the fruity characteristic flavor (Soares and others 2000a; Medeiros 2003).

10.2.1.3 Temperature. Microbial growth and product formation are the result of many chemical reactions. The temperature influences them all. As microorganism growth and metabolism produce heat, cooling may be necessary to maintain the desired temperature. Temperature should be controlled, especially when volatile flavors are produced (Nigam and Singh 1999).

Optimal temperatures for growth and product formation are often different and have to be examined separately. It is important in particular for secondary metabolites, like many

flavor compounds. There is a need to determine the temperature at which growth rate is adequate and product formation is maximized. In the case of a secondary metabolite, it is interesting to maintain growth at low rates (Nigam and Singh 1999).

Sarhy-Bagnon (1999) studied the production of 6-pentyl-α-pyrone by the fungus *Trichoderma harzanium*, which has a characteristic coconut flavor. The best flavor production was reached at 25°C. However, 30°C was found to be the optimal temperature for growth.

Yeast metabolism makes an important contribution to beer flavor. Higher temperatures increase yeast metabolism, but the temperature will affect differently each biochemical reaction, changing the balance of flavor compounds. Bottom-fermented beer is produced at lower temperatures due to the fact that fermentation above 14°C results in a product with significantly poorer flavor and aroma (Smogrovicová and Dömény 1999).

10.2.1.4 Nutrients. Nutrients are substances used in the biosynthesis and energy production required for microbial growth and product formation. The nutrients may be classified as macronutrients (C, H, O, and N) and micronutrients (P, K, S, and Mg). The requirement for trace elements in the medium is a qualitative factor. In general, their concentration is arbitrary and they have to be present in sufficient amounts to avoid deficient growth of the microorganism (Pandey 1999).

Carbon Sources. The nature of the carbon source is another factor that affects flavor quality. This fact was verified by Hubball and Collins (1978) with cultures of *C. variospora* in the presence of many combinations of sugars and acids. When combining glucose, fructose, and arabinose with acetic acid, there is production of banana, strawberry, and lemon flavors, respectively.

Bramorski and others (1998a) investigated the possibility to improve the sensory properties of solid agricultural substrates through the synthesis of volatile compounds by the edible fungus *Rhizopus oryzae*. Cassava bagasse, soybean meal, and apple pomace were used in various proportions to study the influence of the C/N (carbon to nitrogen) ratio on the production of volatile metabolites. The volatile production was strongly dependent on the medium composition, as indicated in Table 10.1.

TABLE 10.1 Total Volatile Compounds Produced by *Rhizopus oryzae* at Different Solid Substrate Compositions.

Substrate (w/w)	C/N	Odor Detected	Total Volatile (μmol/L)
Cassava bagasse + soybean (8 : 2)	29.3	Mild, pleasant	13.5
Cassava bagasse + soybean (2 : 8)	10.8	Slightly ammoniacal	15.1
Cassava bagasse + soybean (5 : 5)	20.5	Mild, pleasant	23.0

Nitrogen Sources. In general, the concentration of nitrogen compounds in the environment is low and, therefore, cells that grow fast in low N concentrations have an important competitive advantage.

Ceratocystis fimbriata is recognized as a fungus that can generate fruity flavors. Christen and others (1994) tested the influence of six nitrogen sources (leucine, urea, ammonium sulfate, asparagine, casein peptone, and fish hydrolyzate) on the nature and intensity of the flavors produced. They observed that leucine, urea, asparagine, and ammonium sulfate, to a lesser extent, were adequate for producing fruity notes. Leucine is known as a precursor of isoamyl alcohol and isoamyl acetate, which are major constituents of banana flavor. High amounts of metabolites were produced with those sources due to the maximum biomass concentrations.

Different nitrogen sources were tested for the production of coconut flavor by *Trichoderma viride* (Yong and others 1985). It was shown that a variation of the nitrogen source affected the quantity of 6-pentyl-α-pyrone produced, this being the lactone responsible for the characteristic flavor, but the flavor quality of the culture was the same for any nitrogen source.

10.2.1.5 Water Activity. In fermentation processes the water requirement is expressed in terms of water activity, which is the partial vapor pressure of water in the air in relation to the vapor pressure of pure water at the same temperature. Water is important to the microbial cell, not only because it represents about 80% of the cell's weight, but also as it is a reactant (as in hydrolysis reactions) and a product. In addition, water provides the most common environment for microbial growth. All living organisms need water for their growth and metabolism (Doelle 1985). The moisture content should be optimal. The moisture in solid-state fermentation exists in absorbed or associated form within the solid matrix, which can be more advantageous for growth because of the more efficient oxygen transfer process.

10.2.1.6 Aeration. In solid-state fermentation, the water content is quite low and the microorganism is almost in contact with air oxygen, unlike in the case of submerged fermentation. The low volume of water present in the media per unit mass of substrate can substantially reduce the volume of the fermentor without severely sacrificing yield. Aeration and mixing requirements may also be easily met (Raghavarao and others 2003). In submerged fermentation, the transfer of oxygen to microorganisms is the major difficulty (Durand 2003).

10.2.2 Types of Fermentation Processes

10.2.2.1 Liquid Fermentation. Most industrial fermentations are carried out in liquid media, also called submerged fermentation (SmF), in which microorganisms are dispersed into a nutrient liquid using a bioreactor. Brewing industries have used this kind of fermentation. The reactor, a stirred or nonstirred tank, could run as batch or continuous (Nigam and Singh 1999).

There are a number of flavors compounds produced by the liquid fermentation technique on an industrial scale. An example is the production of (R)-δ-dodecanolide, a lactone applied as a butter flavor in margarine. The bioconversion of 5-ketododecanoic acid takes place on a 30,000-L fermentor using baker's yeasts (Janssens and others 1992). The production of peach aroma (4-decalactone) involves the conversion of ricinoleic acid, an oil obtained from the

seeds of *Ricinus communis*, known as castor oil. The yeast *Yarrowia lipolytica* converts the oil into 4-hydroxydecanoic acid, which is easily lactonized. A yield of 6 g/L can be reached (Janssens and others 1992). *Clostridium butyricum* produces butyric acid from glucose in concentrations that reach 1–2% in the fermentation broth. Butyric acid can be applied as a natural cheese flavor and its esterification with ethanol gives rise to ethyl butyrate, an important fruity flavor (Janssens and others 1992).

Another example of the liquid fermentation process is the production of vanillin, which is widely used as a flavoring agent in a wide range of foods and fragrances. The use of biotechnological methods involving fungi to produce vanillin is being developed (Lomascolo and others 1999). Ferulic acid, a constituent of various grasses and crops, is a product of the microbial oxidation of lignin, particularly by white-rot basidiomycetes. This compound has been used as a direct precursor in bioconversions to vanillin. However, its recovery as a pure compound is difficult. Besides, low conversion yields are obtained due to numerous side reactions. An alternative for the production of vanillin is the use of solid-state fermentation. Some agro-industrial residues, which often contain ferulic acid in cell walls, may be used as substrates (Feron and others 1996).

10.2.2.2 Solid-State Fermentation. Solid-state fermentation (SSF) can be defined as a method to cultivate microbial cells in which organisms are grown on solid substrates or supports in the absence of free water. The moisture content is just sufficient to assure growth and metabolism of the microorganism (Pandey and others 2001).

Due to a low level of water activity, SSF processes have advantages in comparison with submerged liquid fermentation. These include high volumetric productivity, low capital investment and energy requirements, the possibility of using alternative substrates (e.g., solid residues) without pretreatments, less wastewater output, and easier product recovery. However, there are some disadvantages, such as the difficulty in removing excessive heat generated, problems in fermentation control, sterilization, and contamination (Feron and others 1996). They are more difficult to control due to the lack of adequate sensors and efficient solid handling techniques, especially for continuous operations. Furthermore, SSF processes are slower than liquid fermentations due to the additional barrier from the bulk solid (Raghavarao and others 2003).

Agro-industrial residues such as sugarcane and cassava bagasse, apple pomace, and coffee husk and pulp have been used efficiently in several bioprocesses. Not only does the application of agro-industrial residues provide alternative substrates for SSF, but it also helps in solving pollution problems (Soccol and Vandenberghe 2003).

Cassava and sugarcane bagasse, apple pomace, giant palm bran, and coffee husk have been used as substrates for flavor production in SSF (Bramorski and others 1998a, 1998b; Soares and others 2000a, 2000b; Medeiros and others 2000, 2001). Fruity flavors were detected in cultures of *Ceratocystis fimbriata* using coffee husk as substrate. In Table 10.2, Soares and others (2000a) have shown results of SSF under different experimental conditions. It was found that the flavor detected in the headspace of the culture depended on the amount of glucose added to the medium. Increased levels of glucose decreased flavor intensity. According to the authors, glucose concentration seemed to have a direct effect on metabolic pathways and thus on the nature of the volatile compounds produced (Fig. 10.1*a*). Among the compounds produced, ethanol and ethyl acetate were the most abundant.

Soares and others (2000a) investigated the influence of the addition of salt solution, soybean oil, and leucine on flavor production. According to Figure 10.1*b*, salt solution,

TABLE 10.2 Sensory Evaluation of the Headspace from *Ceratocystis fimbriata* Grown on Coffee Husk in Different Conditions.

Glucose (g/100 g)	Addition	Flavor and Intensity*	Total Volatile (mmol/L.g)
20	—	Pineapple +++	6.58
35	—	Fruity, pineapple +++	5.24
46	—	Banana, sweet +	1.13
35	Salt solution	Banana +	2.71
35	Soybean oil	Banana ++	5.7
35	Leucine	Banana +++	8.29

*Intensity: +++: strong; ++: medium; +: weak.

which was added to determine if the substrate lacked some minerals, caused a strong negative effect on flavor production (run 35.S). Addition of soybean oil (run 35.O) did not affect flavor production when compared to control (run 35).

10.2.3 Bioreactors

A suitable bioreactor design includes heat and mass transfer effects and easy diffusion and extraction of metabolites. Maximization of the rate of formation and yield of product within the bioreactor is a key part of optimizing the production process. In contrast to SmF systems, the development of an SSF bioreactor has some problems, such as poor mixing and heat transfer characteristics and material handling (Pandey 2003).

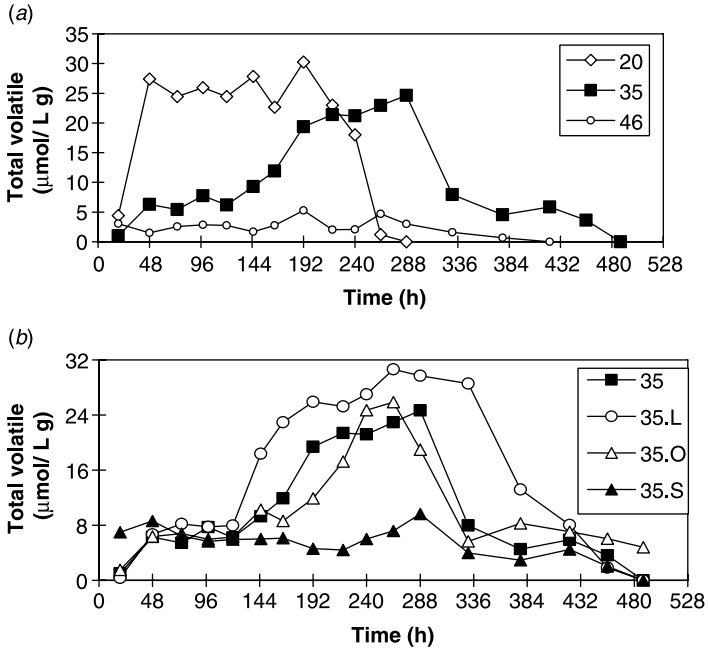

Figure 10.1 *Dynamics of total volatile compounds in the culture of* C. fimbriata *in coffee husk supplemented with (a) different glucose concentrations and (b) different compounds (L, leucine; O, soybean oil; S, salt solution).*

Most of the flavor-producing microorganisms are oxygen dependent. Therefore, a subdivision of the usual bioreactor is done according to the mode of gas supply. The oxygen can be supplied by using moving assemblies or pumps. Reactors with a turbulent layer are frequently used for yeasts and higher fungi, which can be propagated in submerged culture as well as in surface reactors (Drawert 1987).

A large number of patents and publications are available on how to design, operate, and scale-up SSF bioreactors. As SSF is more applicable for filamentous fungi, the process in most of the cases is aerobic (Pandey 2003). The main bioreactors used for SSF can be classified as tray, packed-bed, rotating drum, gas–solid fluidized-bed, stirred aerated bed, and rocking-drum bioreactors.

SSF processes can be operated in batch, fed-batch, or continuous modes, although batch processes are the most common. Some important aspects have to be considered during the construction of a bioreactor, among them the sensitivity of the substrate and/or the microorganism to the shear forces generated by agitation. Rotating-drum bioreactors operating at high rotation speeds damage the substrates and the hyphae of the fungus due to shear. Another aspect that occurs in the case of microbial degradable substrates is the shrinking of the substrate bed. This might result in an undesirable channeling of air through the gaps between the bed and the walls. This could be avoided by using an inert support or a natural substrate in which the solid structure is not attacked by the microorganism (Raghavarao and others 2003).

Some recent developments in automated bioreactors include operations such as the sterilization of the substrate, inoculation, control of fermentation conditions, extraction of the product from the substrate, and poststerilization of the substrate.

Medeiros and others (2001) produced flavor compounds with fruity characteristic in an SSF system. Cassava bagasse was used as the substrate and was inoculated with a GRAS (generally recognized as safe) strain of the yeast *Kluyveromyces marxianus*. The SSF was carried out by packing pre-inoculated solid medium (20 g cassava bagasse) into glass columns (4 cm diameter and 20 cm length). Figure 10.2 shows the schematic set-up of the fermentation system. The fermentation temperature was maintained at 28°C and the columns were connected with an air distributor. The authors studied the influence of different aeration rates on volatile production. It was found that ca. 7 μmol/L/g of esters were produced by the yeast at a low aeration rate (0.06 L/h/g).

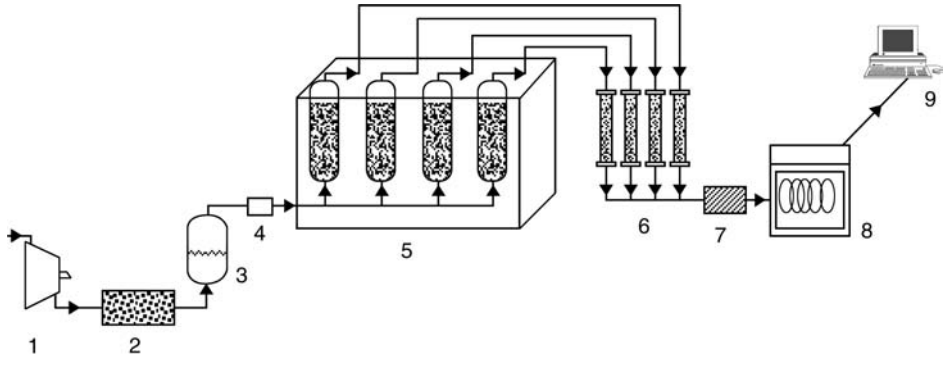

Figure 10.2 *Schematic set-up of packed-bed bioreactor system (1: air pump; 2: air filter; 3: air moisturizing unit; 4: air distributor; 5: bioreactor columns in water bath; 6: silica gel columns; 7: auto gas sampler; 8: gas chromatograph; 9: computer).*

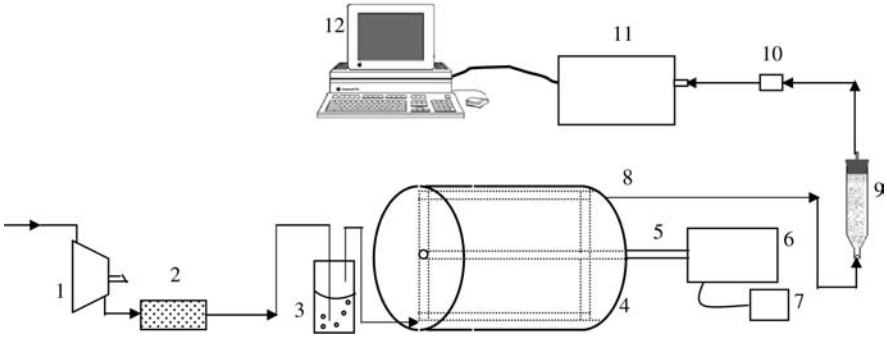

Figure 10.3 *Schematic set-up of a bioreactor system for flavor production by SSF (1: air pump; 2: air filter; 3: air moisturizing unit; 4: bioreactor; 5: paddle; 6: agitation motor; 7: rpm controller; 8: gas outlet; 9: silica gel columns; 10: auto gas sampler; 11: gas chromatograph; 12: computer).*

A stainless steel cylinder bioreactor (Fig. 10.3) connected with an air distributor was used to produce flavor compounds using *Ceratocystis fimbriata* (Medeiros 2003). Experiments were carried out using 3 kg of coffee husk as substrate. The volatile metabolites released by the culture were collected by connecting adsorbent tubes at the outlet of the bioreactor. The adsorbent tubes were made of glass and were packed with granular activated carbon (Ultraporous 6–8 mm, FBC Brazil); Tenax (Tenax TA, 60–80, Supelco); or Amberlite XAD-2 (Aldrich). The adsorbed volatile compounds were eluted with solvent and the concentrated solution of volatiles obtained was ready to be analyzed by gas chromatography.

10.3 EXTRACTION OF FLAVOR COMPOUNDS

Product recovery is often a difficult step in bioprocesses, especially for flavor compounds because of their volatility and low solubility. It is also necessary to keep the concentration of volatile compounds on the fermentation medium below a certain level due to their inhibitory effect in microbial growth. There are many on- and off-line technologies that can enable the extraction and concentration of flavor compounds (Bluemke and Schrader 2001).

To maximize the efficiency of the bioprocess, production of flavors should be maximized and the production of new cells minimized. In the case of cultures with a high cell density, integrated systems based on ultrafiltration and microfiltration techniques have been studied. Another technique is cellular immobilization. Senemaud (1988) immobilized cells of *C. moniliformis* in alginate beads to control the production of esters, alcohols, and monoterpenic alcohols.

As the toxicity of the hydrophobic flavor compounds leads to inhibitory effects on microorganisms, the efficiency of biosynthesis improves with the recovery of the compounds from the culture medium. One of the most used methods to remove organic compounds from fermentation media involves solvent extraction, separation on specific membranes, and adsorption on activated carbon and porous hydrophobic polymers. The two last methods have been used for the concentration of aroma compounds. Activated carbon has a high adsorption capacity which allows the use of small amounts of material; however, desorption is not always complete. Porous polymers commonly used include Tenax GC (Supelco), Porapak Q (Interchim); Chromosorb 105 (Altech Associated); and Amberlite XAD-2 and XAD-4 (Prolabo) (Souchon and others 1995).

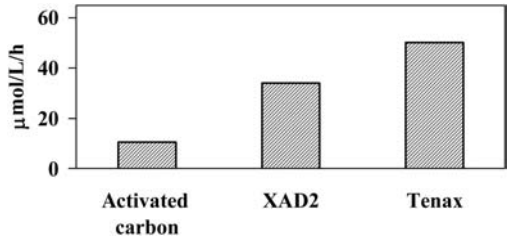

Figure 10.4 *Adsorption of volatile compounds produced by* C. fimbriata *cultivated on coffee husk using different adsorbent materials.*

There are numerous reports on the adsorption of flavor compounds. Sorption on activated carbon and porous hydrophobic polymers is a suitable method to extract and concentrate γ-decalactone from aqueous media. Solid sorbents were used in an on-line extraction of γ-decalactone during a bioconversion process (Souchon and others 1996). The sorbents tested were activated carbon and three porous polystyrene-type polymers [Porapak Q (Interchim); Chromosorb 105 (Altech Associated); and Amberlite XAD-2 and XAD-4 (Prolabo)]. *Sporidioolus salmonicolor* was cultivated on a fermentation broth. Adsorbents were added to the culture medium at 20 g/L and 30 g/L. γ-Decalactone was extracted from the adsorbents using hexane. The presence of adsorbents in the bioconversion medium allowed a very low concentration of the lactone in the liquid medium; as a consequence, it limited the toxicity of the flavor compound to the yeast. Carbon activated and porous resins (Amberlite XAD-2 and Tenax) were used to collect the flavor compounds released by the solid-state culture. The adsorbent columns were attached to the end of the bioreactor-type column fermentation. The advantage of Amberlite XAD-2 (Aldrich) and Tenax (Tenax TA, 60–80, Supelco) over activated carbon in collecting flavor compounds is shown in Figure 10.4 (Medeiros 2003). The hydrophobic character of the resins allows higher efficiency compared to activated carbon.

Spray-drying has been widely used for micro-encapsulation of volatile materials. The water is removed by vaporization, and substances that are more volatile than water, for example, organic compounds, are retained. Food flavors are highly volatile and may be easily lost during drying. The retention of volatiles in spray-drying can still be improved if a high concentration of dissolved solids builds up on the surface of drops early in the drying process (Ré 1998).

Flavor compounds produced in SSF by *C. fimbriata* were encapsulated in a blend of maltodextrin and arabic gum and the emulsion obtained was spray-dried. The powder was suspended in water in order to analyze whether micro-encapsulation was effective in the recovery of flavor compounds (Medeiros 2003). According to Table 10.3, the main compounds produced during fermentation were efficiently recovered.

TABLE 10.3 Flavor Compounds Obtained by Micro-encapsulation Using Spray-Dryer.

Compound	Concentration (μmol/L)
Acetaldehyde	0.34
Ethanol	0.05
Ethyl acetate	0.44

The advantage of flavor compounds obtained as a spray-dried powder is their stability. The flavor components do not have direct contact with the hot air, which prevents oxidation and losses by evaporation (Ré 1998). In order to prevent losses during drying, processing conditions should be optimized. It was estimated that only 34% of the total volatile produced during SSF is recovered by micro-encapsulation during fermentation.

Pervaporation is a membrane process consiststing of partial vaporization of a liquid mixture through a nonporous permselective membrane (Souchon and others 1995; Karlsson and Trägárdh 1996). The technique allows potential applications in the food industry: for wine or beer dealcoholization, juice concentration, and extraction of substances produced by microorganisms. Flavor compounds can often be enriched several hundred times using this technique (Karlson and Trägárdh 1994). Lamer and others (1996) used pervaporation to extract benzaldehyde produced by *Bjerkandera adusta* in a 7-L glass fermentor. A system for continuous extraction of benzaldehyde was used. The performance of the process was studied using different parameters.

In situ product removal is an interesting tool for overcoming inhibitory effects on a microorganism's growth and production of flavor compounds. Some benefits are minimization of the interaction's products-producing cells, smaller product losses during cultivation, and reduction of subsequent downstream processing steps. An integrated bioprocess consisting of a bioreactor and a downstream unit was set up by Bluemke and Schrader (2001). A pervaporation membrane module was interlinked with a bioreactor for production of flavor compounds by *Ceratocystis moniliformis*. The product concentration in the bioreactor decreased and microbial growth rates increased. The yield of flavor compounds produced was higher than for batch fermentation.

11.1 INTRODUCTION

All living creatures on this planet spend a lot of time and energy trying to survive. Finding food to sustain their biological needs surely represents a major aspect of their life. Human beings are not really that different, but because of their level of complexity they are, by far, the most prone to making feeding more than just a necessary biological part of their existence. Apart from a few exceptions, humans are the only species that can modify their food resources by using cooking, fermentation, and other presentation techniques. One main reason for this habit is the quest for a higher level of satisfaction, which takes them way beyond the simple need to absorb all the necessary nutrients to have their body work properly. Let us face it, humans have become experts in looking for pleasure and food has certainly, and has for eons, represented one of the few aspects of their lives that can generate that sensation. Humans can eat almost anything, and if you travel a little bit around this planet, you will realize what anything really means. For one, you have to take into consideration what type of nutrient is available at any given time and location, and also the benefit this brings to the survival aspect of all living creatures. Humans are very adaptable. Combined with the ability to change their environment, it is no surprise they have spread around Earth to the extent they have.

Changing natural raw ingredients most certainly dates as far back as the mastering of fire. This essential capability has triggered a drastic change in human feeding habits. One benefit of cooking is obviously the possibility to develop chemical compounds that are not present in the raw product as explained in other chapters of this book. The other important side effect of cooking is to make food safer. One can reasonably assume that using fire for cooking has also contributed to humans increasing their curiosity as to other ways to modify their food. For example, the use of controlled fermentation has brought us beer and wine, which can definitely increase our satisfaction level, as well as milk derivatives such as yogurt. Another way has been to add other natural ingredients to the primary food product so as to complement its performance towards the ultimate satisfaction of Mankind. In this category we can include salt and of course herbs and spices.

The following paragraphs will try to give some clarification about what can be considered a spice or herb and also why their usage is important to modify the taste of our food. I would also like to stress that the title of this chapter (Herbs, Spices, and Essential Oils) may bring some confusion; these are not totally independent sections. We will also discuss the Spice trade, from its humble origin to its modern highly sophisticated situation. We will also evaluate the benefit that such products can bring to our ever-changing food habits.

11.2 DEFINITION

When looking at dictionaries, the definition of spices usually appears vague, if not redundant. The general consensus would be to define spices as aromatic or pungent botanical

products used to flavor food. Add the definition of flavor as being a mixed sensation of smell and taste, and you may understand why any interpretation would be as good as the next one. The definition of taste is somehow left to the reader's imagination and usually confines it to the sensation caused by aromatic or pungent compounds in the mouth. There is a lot more to it and the different aspects of taste help to understand why and how we can use these vegetable substances to modify our food. Spices and herbs belong to the angiosperms, plants where the reproductive organs are concentrated in a flower and whose seeds are locked in a fruit. This family is divided between monocotyledons and dicotyledons and represents more than 230,000 species around the globe.

11.2.1 Spices

The Codex Classification, Section 028, gives a good baseline for our understanding: "Spices are dried aromatic seeds, buds, roots, bark, pods, berries or other fruits from a variety of plants, which are used in relatively small quantities as seasoning, flavoring, or imparting aroma in food. They are consumed in the dried form after being added to or sprinkled on foods". "Dried" and "small quantities" are clearly important words here, and the Codex obviously leaves the fresh herbs and some aromatic vegetables on the side. A good reason is that fresh products may be of limited and even uncertain use. I have also recently read a proposal by the Codex Committee on pesticide residues that is a little more restrictive. The definition does not include plants that have been traditionally regarded as vegetables or fruits. The use of the word "traditionally" is not as innocent as it may seem when related to the taste concept. However, the article proposed an interesting sorting of the different species depending on the general Codex guidelines.

We can all grow a few culinary herbs in our back yard, but it would certainly become a challenge to use them for international trade. Fresh products spoil quickly, both in term of safety and quality, and until reliable transportation and conservation modes became available all around the globe, it was pretty difficult to maintain fresh products in a palatable form, and therefore use them for trade. Fresh spices were then consumed locally around their native growing location, and the dried products were the only form used to be sent to other parts of the world that were showing an increasing urge for them.

Traditional spices, understood as commonly used, come from a wide array of plants as shown in Table 11.1. In our occidental culture, we also apply an exotic connotation to the plants we refer to as spices. They historically come from regions of the world that have been out of reach for centuries and their availability has been subject to secrecy and even myths. We should not forget that each spice will in fact present several, and sometimes hundreds of subspecies, so that the name refers in fact to all cultivars. Each specific cultivar presents variations that can translate into color, shape, aroma, or taste changes, from subtle to very significant differences. Each subspecies presents variations in what contributes the most to taste and aroma, that is, the level and composition of the essential oil or pungent compounds they may contain. All these aspects tend to complicate classification, but extend our understanding that such a simple word as "spice" covers in fact so many botanical varieties. Mother Nature really offers what seem unlimited palatable options to Mankind.

Spices generally originated in warm and humid climates, mainly India and South-east Asia, and their availability was therefore limited in the past to those parts of the world. They all started in being collected from the wild until it became possible to apply agricultural techniques, which would transform picking into something more productive, and

TABLE 11.1 Classification of Some Usual Spices and Herbs.

Family	Common Name	Part of Plant
	Angiosperms	
DICOTYLEDON		
Solanaceae	Chili, paprika, red pepper	Fruit
Pedaliaceae	Sesame	Seeds
Piperaceae	Pepper, long pepper	Berries
Myristicaceae	Nutmeg, mace	Aril
Lauraceae	Cinnamon, cassia	Barks
	Bay leaf, laurel	Leaf
Cruciferae	Mustard	Seeds
	Horse radish	Root
Myrtaceae	Clove	Buds
	Allspice	Berries
Lamiaceae	Mint, basil, oregano, rosemary, sage, thyme	Leaf, twig, terminal, shoot
Umbelliferae	Anise, caraway, coriander, cumin, fennel, coriander, celery	Seeds, fruit
	Chervil, dill, parsley	Leaf
MONOCOTYLEDON		
Liliaceae	Garlic, onion	Bulbs
	Chive	Leaf
Iridaceae	Saffron	Pistil
Zingiberaceae	Ginger, turmeric	Rhizomes
	Cardamom	Fruit, seed
Orchidaceae	Vanilla	Fruit (pod)

mass transportation. As long as the supply could meet the needs of a slow-growing population, collecting and limited trade was good enough. The extraordinary expansion of European countries that started at the end of the fifteenth century changed the situation dramatically.

Spices have been around Mankind long enough, mostly used in their dried form for trade, such that their definition may vary around the globe. Each spice may also be referred to under local names. This has contributed, in the past, to maintaining trade secrets. Like any classification, there are always borderline situations and it is not rare to come across arguments about whether or not a given product would (or would not) qualify as a spice, given the wide array of definitions. Garlic, onion, or shallots are a good example. Many of us think of them as vegetables. Very aromatic indeed, but do they really qualify as a spice? As fresh products probably not, but very large volumes are traded as dry, diced, or ground product, and I would say they do indeed bring a lot of flavor to any dish, so let's include them in the spice category.

11.2.2 Herbs

In this category, and because of the Codex definition, it is intuitive to group together all plants where leaves are used for their aromatic properties. Herbs can be used fresh in our own kitchen or at a restaurant, where their highly delicate aromatic character is best preserved, but the vast majority of the trade is based on dried herbs. Herbs mainly relate to the Lamiaceae and Umbelliferae families as shown in Table 11.1. Their

growth does not require the same type of hot and humid climate as do the spices in general, which explains why they have been known and used without interruption for thousands of years around the Mediterranean Sea. There is a general consensus that there are two main categories of herbs: fresh and aromatic.

11.2.2.1 Fresh Herbs. Fresh herbs are also referred to as culinary herbs. They have a high water content and their aromatic character is really at its best when fresh. Some herbs, like parsley, chervil, or chives, withstand freezing nicely when chopped (color and aroma), so we can extend their domestic use throughout the winter. However, their industrial usage remains limited to restaurants. If dried, they tend to lose their aroma and their taste quickly evolves to hay. Freeze-drying herbs allows a very good preservation of the original green color, and prevents mold, and their industrial use is limited to provide a pleasant visual aspect in seasonings. The aroma contribution is negligible.

11.2.2.2 Aromatic Herbs. Herbs such as thyme, oregano, marjoram, rosemary, or laurel offer a more attractive industrial usage because of a much lower water content and higher aromatic compound level. The drying process maintains the aromatic character a lot better than what can be achieved with the fresh herbs, making them valuable trade goods. They also contain a wide range of functional compounds such as antioxidants, which has energized their value in the past few years.

11.2.3 Essential Oils and Sapid Compounds

Modern botanical studies and analytical techniques have helped us identify and classify species that have been known for thousands of years. We are also in a better position to understand what gives each spice or herb its character because we can identify their molecular constituents. Their properties have been known for ages as food or medicinal additives. They can be separated into two main groups: essential oils and sapid compounds.

11.2.3.1 Essential Oils. Spices and herbs are not the only botanical species that contain an essential oil (EO). The term "oil" is also commonly used in the flavor industry and should not be mistaken with just vegetable oil (triglycerides). Every plant produces some, but it may not always be of real value; either the quantitative level is too low to be beneficial in a food product, or the overall sensation it produces is not considered appealing by humans. It some cases, it can even be somehow toxic due to the presence of certain chemicals. Rue oil, for example, contains several aliphatic ketones. It has been known for centuries to be a rather effective abortive when the leaves were used in decoctions provided by medicine men or sorcerers. I should add that the frequency of use of rue oil in food flavoring is close to nothing.

Essential oils contain a very wide range of chemicals created as byproducts by plant cells during their regular photosynthesis and respiratory cycles. These molecules have a high vapor pressure that allows them to be considered as volatile at atmospheric pressure and room temperature, in the sense they can be detected by olfaction, which usually represents our first contact with the spice and is a very important part of our relation to food. Their influence on our perception of taste is also critical. Essential oils also have a significant antimicrobial activity; this is an additional benefit of using spices in food. Without any knowledge of the mechanisms, our ancestors had discovered this interesting property and used spices to preserve delicate food, along with salt. The composition of each

essential oil is characteristic of a plant, and their analysis by modern analytical chemistry equipment, such as gas chromatography and mass spectrometry, reveals the presence of the following components:

- Terpenes, general formula $C_{10}H_{16}$, such as limonene, α and β pinene, myrcene;
- Sesquiterpenes, general formula $C_{15}H_{24}$; such as β-caryophyllene, curcumene;
- Aldehydes (cinnamaldehyde);
- Alcohols (linalool, terpineols, eugenol, menthol);
- Esters (linalyl and terpenyl acetate);
- Ketones;
- O-ethers and S-ethers;
- carboxylic acids.

This list is by no means exhaustive, as continuous researches identify new molecules almost every day. The relative proportions of such molecular compounds play a major role in the final aromatic character of an oil. However, it is not only the proportion that is critical – the molecular conformation also plays a role, for example, as in isomers like estragole and anethole (Figs 11.1 and 11.2). Both have an anise-like aroma, but the overall taste is somehow vaguely different. Estragole is present in tarragon or bitter fennel oils and anethole in anise or sweet fennel. The difference can also be based on the stereo conformation, as in the case of carvone (Fig. 11.3). The D-carvone is the main component of caraway or dill oil, and the L-carvone may represent 80% of spearmint oil. There is no doubt that this difference would be clearly identified by aroma and taste. We can relate these changes to the influence of stereochemistry in pharmaceutical molecule activities.

It is important to remember that the composition of an essential oil varies between subspecies and is widely dependent on the plant phenotype, geographical origin, climatic

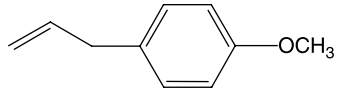

Figure 11.1 *Estragole.*

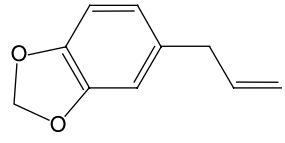

Figure 11.6 *Safrole.*

conditions, and even time of harvest. The composition may also vary between parts of the same plant, which makes some spices so valuable. The bark of the cinnamon tree produces an oil rich in cinnamic aldehyde, and the oil extracted from the leaves has eugenol as a main constituent (Figs 11.4 and 11.5).

The nutmeg–mace case represents the ultimate variation, because mace is the external envelope of the nutmeg fruit. Safrole (Fig. 11.6) is a major constituent of mace oil, but nutmeg oil has very little of it. Safrole is now considered carcinogenic and nutmeg fruits must be stripped of their external layer for trade. Safrole is also a major component of the sassafras root oil once used to make root beer or widely used in Cajun dishes.

The quantitative level of oil may vary from a fraction of a percent (herbs) to several percent (clove buds). It is therefore understandable why our perception would be affected so much. For more information on oil compositions, I cannot recommend enough that students and food chemists alike refer to what some of us call the "Dr Brian Lawrence's bible", in reality the best published review on essential oils composition (Lawrence 1979, 1981, 1989, 1993, 1995, 2003). There is no doubt in my mind it is a "must have" reference book for any chemist in the food and flavor industry.

Essential oils are not only consumed as part of the plant, but they are also extracted to be used in aromatic composition because this is where the taste and aroma is concentrated. Oils are then used to supplement low-quality natural products, or bring a typical character to a seasoning blend where the use of the straight spice or herb may represent a composition challenge. The following oil extraction methods have traditionally been used:

- Steam distillation (may induce oxidation) followed by decantation;
- Maceration in vegetable oil (old but simple technique that can still be used in the kitchen);
- Cold press (a must for citrus and any highly oxidation-sensitive oil).

11.2.3.2 Sapid Compounds. Apart from the volatile essential oil, plants, and more specifically spices, also generate some other highly interesting molecules. These are not present in the essential oil and because of their low vapor pressure we do not detect then by olfaction, but their importance on the taste is by no means negligible. The main attractions are the pungent compounds. Would black pepper be of any interest without piperine (Fig. 11.7)? And why would we use chili pepper if it was not for the presence of capsaicin (Fig. 11.8)?

Although these sapid compounds are present in the whole spice, the industry has rapidly developed specific extracts that concentrate those molecules in a form that facilitates their dispersion in a food product. As we discussed for the essential oil, we will not forget to mention the oleo-resins (commonly referred to as OR). Historically they have been obtained using solvent extraction of spices or herbs. The main solvent remains ethanol, but in some instances, acetone, ethyl acetate, or water may be of assistance. The solvent extraction concentrates the spice or herb aromatic compounds, both volatile and sapid. The final extract is usually stabilized with some oils (mono- and diglycerides) and is also standardized to a volatile oil (VO) content using the related essential oil. As an example, a commercial black pepper OR contains 40–42% piperine and has a minimum 20% VO content.

Another interesting category of sapid compounds contains the functional molecules. Their application in food has been more recent than it has been for pharmaceutical purposes. A very interesting category is the natural antioxidant, generally found in herbs such as sage, oregano, or rosemary. Their recent application to food is becoming a craze as consumers see a health benefit in moving away from more traditional (artificial) solutions. Their industrial importance also relies in the labeling benefit for food manufacturers, because they fall under the natural extract section. There is no doubt that more research will unveil other functional molecules that will represent future benefits for food.

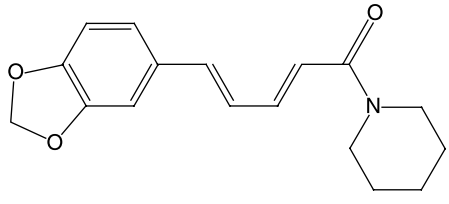

Figure 11.7 *Piperine.*

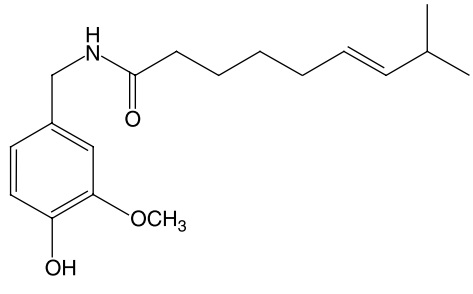

Figure 11.8 *Capsaicin.*

The knowledge of the chemical compositions of spices or herbs is very helpful for the food technologist to combine products and create appealing products. It also helps to understand the origin of a spice so as to maintain the authenticity and the quality of supplies, which in time will ensure the consistency of our food products.

11.3 THE SPICE TRADE

Spices and herbs have been available to humans for a very long time. Some recent archeological findings in the Swiss Jura mountains have unearthed fennel seeds dating back to the Neolithic age (5000 B.C.). Obviously, Homo sapiens tried whatever was available around them, and started to develop food habits. No-one will ever know how much deception or pain these attempts may have produced, and our knowledge will probably remain very vague. Apart from inhabitants fortunate enough to live in subtropical regions where spices grew naturally, others would yet have to discover them. For the European populations, such discovery would bring interest, then greed and the urge to conquer new territories.

As humans settled and started civilizations, their ability and urge to discover led them to trade. As time went by, trade routes emerged, expanded, and brought new knowledge, techniques, and products. Spices quickly became one form of goods that was highly prized. In ancient Egypt, spices such as cinnamon, anise, and cumin were used to embalm the dead. No doubt the essential oil they contain performed well to protect the tissues from decaying by stopping microbiological growth. In addition, their aroma surely helped cover the stench that probably surrounded the priests during the ceremony, and, in turn, spices received some kind of spiritual attribute, which definitely conferred them a special place in society: high value. Trade was made through Arabic merchants that had connections all the way to India and islands that are now Malaysia and Indonesia, and they maintained such a high level of secrecy and mythology that nobody really challenged them. In the 5th century B.C., the Greek historian Herodotus relates stories he gathered from Arabic merchants of large birds that jealously kept the spices on top of high mountains. The cover up worked so well that it kept people away and preserved the Arabic monopoly. Supplies had to come by land, using caravans that would take months of travel, through dangerous areas so that no-one else had the real capability to dominate the trade in the long term.

By the mid-4th century B.C., Alexander the Great would send expeditions east. I doubt this was just for glory, but also for an attempt to control what was an already lucrative business. Greeks were known as fierce merchants and their domination over the eastern part of the Mediterranean Sea was already complete. His armies reached the Indus River and the control of the spice trade was within grasp. Unfortunately, he died young and his efforts were abandoned quickly. In those days, and for centuries to come, such imperialistic efforts remained too dependent on individuals to translate into long-lasting political or economic systems.

Kingdoms evolved to empires and armies pushed their conquests ever further. Then the Romans took over the entire Mediterranean region and, by the end of the third century A.D., their Empire extended so far east it had nearly reached India. Trade routes were solid and supplies arrived to Rome where the rich population could enjoy a very wide array of foreign goods. Spices such as cinnamon, clove, pepper, or cardamom were plentiful for the few families that ruled the Empire, and their use in food, beverages, and

toiletries reached levels that would make us quiver. There are some documents, books or plays, that describe some "delicacies", and it would be quite an experience to try them today. No place for delicate combinations, but a rather constant quest to surprise and stun guests. Banquets were not so much a time for feeding and partying than a clear statement of wealth and power. As spices were expensive, they ideally served that purpose.

The demise of the Roman Empire by the fifth century A.D. would almost bring Western civilization to a stop and draw a curtain between the two sides of the Eurasian continent. Western European kingdoms would lose almost all their trade routes, apart from those maintained by the cities of Venice and Genoa in Italy; navigation and exploration would become a definite hazard when not considered a heresy. This period is sometimes called the Dark Age of Western civilization. It will last almost 900 years. The cost of spices, along with other imported goods, would skyrocket and become a luxury enjoyed by the wealthiest caste of ruling feudal societies. When in 1194 the king of Scotland paid a visit to his fellow monarch Richard I of England, he received, among other proofs of hospitality, daily allotments of 2 pounds of pepper and 4 pounds of cinnamon, obviously more than one person could consume. Spices had a ceremonial as well as a culinary function in the Middle Ages; the two were closely connected. Besides being used in food, spices were presented as gifts, like jewels, and collected like precious objects.

At the end of the fifteenth century, pushed by the Renaissance new ideas and awareness of some fragmented stories from the ancient days and the almost mythical Polo journey to China (1271–1295), a few adventurers were to force Europe to emerge from its long sleep. As we all know, Christopher Columbus sailed west to reach China as to avoid the Arabic route and found a new world instead. Among other things, his followers would discover "red pepper", a brand new pungent plant. Those daring men travelled to find new lands, gold, gems, new souls to be converted, but the desire to re-open and control the old spice trade routes must have played a significant role. After all, those expeditions had to be funded somehow. Political and spiritual blessing from kings was necessary, but in the end the money came from merchants and bankers, who had achieved an undisputed economical if not political strength by then.

When, in May 1498, the Portuguese Vasco de Gama set foot in the Indian city of Calicut (known today as Kozhikode), on the Oman sea, the long awaited time to control the spice trade had arrived. Western civilization was now in a better shape to maintain that control because of its new naval capabilities. It would not take long to erase the Arabic domination and develop all necessary economical, technological, and military tools to maintain that trade. Europe was to enjoy those goods so much that it would once again be a symbol of power. The spice trade would shape European countries and is certainly the point of origin for guilds, companies, and our modern capitalist system. It would also result in fierce competition between European countries. Portugal, until it was annexed by Spain in 1580, would dominate during the fifteenth and sixteenth centuries, and then the Dutch would take over during the seventeenth century. Naval domination took turns and whoever had the best battleships would surely win the domination. During the eighteenth and nineteenth centuries, England and France would fight over the southeast and Caribbean worlds alike, until spice seeds and plants were exported and cultivated all around the world.

The twentieth century would witness the creation of organizations such as ASTA (American Spice Trade Association) and ESA (European Spice Association) to regulate (and therefore set up necessary quality standards) a trade that represents hundreds of millions of dollars. Accurate numbers are difficult to obtain as there is still a great deal

of secrecy about costing. To this day, black pepper remains the king of spices and represents a good third of the international spice trade. In spite of multiple growing regions, the best quality remains its Indian ancestral location. Spices have now lost a large part of their traditional luxury or magical connotations and have become more of a commodity. As such, their price can vary dramatically, depending on climatic conditions, political turmoil, or just speculations from brokers or producers, and it takes a lot of experience and networking for any purchasing agent to keep up with any news that may affect pricing and availability. There are opportunities to obtain good deals, but also to end up empty-handed and have to pay premium dollars to get supplies in and on time, and you still may receive substandard quality.

11.4 QUALITY ASPECTS FOR HERBS, SPICES, AND RELATED EXTRACTS

An old saying states that you always get what you pay for, but you still want to make sure you really get what you have ordered. Within the spice industry, a close relationship between purchasing and their quality departments, brokers and local producers of spices have become the norm. What is at stake here is building trust between all parties. There have been, even recently, amazing stories of grossly adulterated shipments and malevolence and greed were not always out of the equation. The different trades associations have slowly developed rules to maintain quality and make sure that the final consumer is protected.

11.4.1 Authenticity

Because there are so many variants of each spice, the botanical subspecies must be understood by all parties, and specifications should clearly reflect them. Spices, herbs, and essential oils may be contaminated, either by accident or through malevolence. Adulteration has plagued this industry probably for as long as trade has been around. It is the chemist's duty to make sure the supplies meet specifications. To illustrate the possible mishaps we can face sometimes, let me relate the incident we had a few years back when one of our seasoning blends containing fennel seeds was rejected by a customer. The rejection was motivated by the president of that company, who had found their finished meat product did "not taste as it used to be". This gentleman had been in charge for decades and maybe some people would have argued about his tasting capabilities not being at their best by then. The problem was investigated, however, and we discovered the old gentleman was right after all. There had been a lot of fennel seeds that had contained a different variety of fennel; the one we had purchased was to contain estragole as the major ingredient in the oil, and the other one had anethole instead. Both were fennel seeds, but from different species. The difference was not dramatic, but it was noticeable. Different techniques from GC/MS to SNIF/NMR (site specific isotopic abundance) allow us to detect anomalies and adulteration.

11.4.2 Cleanliness

This measures the amount of extraneous matter, from dirt and wood to metal and insect fragments or rodent excreta. Cleaning works best on the whole product (before any grinding) and different methods have been put in place at the production level to eliminate

those contaminants, for example, air separators, destoners, indent and spiral separators. Control methods are either visual, under a microscope, or using screens on ground products to validate the cleanliness. This aspect has become a major concern worldwide as our concerns about food safety have increased dramatically since September 2001. Trade associations allow a certain amount of extraneous matter (small stones for example) and I am not sure this will not need to be revisited soon. Food manufacturers have improved their detection equipment, or acquired some (X-ray detectors), and the spice industry will have to react soon because the trend will be to have zero tolerance, not so much because of safety, but rather because of quality issues in direct connection with consumer feelings.

11.4.3 Ash Level

This measures the level of mineral residues after burning all carbon-based material at a usual 550°C temperature. It helps prove the effectiveness of the cleaning steps.

11.4.4 Volatile Oil (VO)

This test will determine the good organoleptic quality of the product and prevent accepting old or previously spent material. The oil is separated from the ground spice sample by steam distillation and read off in a volume proportional to the mass of the product under test. Each spice or herb has its own acceptable VO range.

11.4.5 Moisture Content and Available Water

This is an important measure as it directly pertains to the overall cost of a shipment. A 12% maximum value is usually accepted. A level of available water (Aw) of 0.6 has also been used in recent years to define a safe level under which microbial activity would be contained.

11.4.6 Bulk Density

This would mostly affect filling retail containers and applies to chopped, crushed, or ground products. This determination is fundamental when dealing with packaging design.

11.4.7 Particle Size

Most spices and herbs are usually ground to provide better dispersion in the final food product, which in turn helps the dispersion of the aromatic compounds. The particle size specification is maintained by means of metal screens (sieves). The aperture is characterized in microns or millimeters. The older method or mesh size (still widely used in the United States) relates to the number of holes per inch. As an example, a 25 mesh U.S. is equivalent to a 500 micron aperture. Conversion tables have been developed.

11.4.8 Heavy Metals

Spices, like any other plant material, contain heavy metals and their levels would usually meet the usual international or national standards for food products. Given the relatively low level of daily consumption, the health risk remains limited.

11.4.9 Pathogens

Depending on the treatment they undergo at the original production site, and the nature of the spice itself, pathogen contamination may happen. Spices and herbs have traditionally been dried outside, on the ground, and it is impossible to prevent contamination. Although Good Manufacturing Procedures (GMPs) tend to be implemented everywhere, a complete guaranty is impossible. Counts of over 1,000,000 (TPC) are not rare on some spices, and it is believed that 10% of consignments may contain such pathogens as Salmonella. Spices and herbs may then need to be treated. Different methods have been used, from ethylene oxide (ETO) fumigation to more modern irradiation or steam treatment. Ethylene oxide has now been banned because of potentially harmful residue concerns, and in some countries irradiation is not possible, or needs to be added on the label. Although irradiation is very efficient, in most cases, pressure from the consumer and a lack of sufficient technical skills may tend to limit its usage. Noncondensing steam has also been introduced in the past few years, and I have recently seen a unit in Italy. Its effectiveness is certain; it works in about 20 minutes and does not require the level of protection needed for irradiation. However, it does not really work well on fine ground products, just because there is not enough empty space between particles.

11.4.10 Pesticide Residues

This subject has been discussed many times within the different trade associations. There is still no firm stance on the matter. I guess that, just as for heavy metals, there has not been a major pressure from consumers and administrations to regulate and issue maximum levels. The most efficient identification methods would be gas or liquid chromatography associated with mass spectrometry.

11.4.11 Mycotoxins

Mycotoxins, especially aflatoxin and ochratoxin, have been of recent concern. Legislations have set maximum levels at 10 ppb in Europe and 20 ppb in the United States. Although aflatoxin has more of a tropical occurrence, ochratoxins have proven to be found in more temperate climates and most countries are in fact affected. They were first discovered in cereals, mainly during long storage in silos, but it is reasonable to see their extension into other plants. Cleanliness seem to be a way to eliminate problems, but their detection still remains a challenge because it is very much dependent on the sampling techniques used.

11.4.12 Other Specific Quality Tests

Piperine levels in pepper, color values (ASTA color value) and capsaicin level in capsicums, and curcumin content in turmeric represent standard determinations in the industry to ensure the quality of supplies. Prices would be based on specific levels, and rugged methods have been developed by the trade associations and prevail worldwide.

11.5 SPICES AND HERBS IN THE FOOD INDUSTRY

In our occidental civilization, and especially in the United States, the food industry has taken over our food habits. It is important, however, to remember that the vast majority

of the planet's population does not follow the same drastic changes and millions if not billions of people still spend time preparing meals, at home, usually following recipes that have been passed down through generations. The world population has many cultures, hence various food histories.

Our relation to food results, in fact, from a synthetic approach among our different senses. First we see a food product, then smell its aroma, long before it enters our mouth; through mastication, its components will finally reach our taste buds. All of our senses generate stimuli that are conveyed to our brain for a final interpretation. At this point we must not forget how important our past experience is. I was about to use the word "training", less noble maybe, but so much closer to reality. Our interpretation of all the visual, olfactive, and taste stimuli relies on years of learning, pleasurable or not. We are used to some products, from the day we were born (and maybe even before that) because of the place we live, the influence of our parents, social pressure, and even religious beliefs. The products we have not been used to would most certainly fall in the dislike category. Each part of the world, sometimes limited to a region, has developed food habits over many centuries. Ironically, they now tend to be referred to as "ethnic food", which in itself carries some kind of exotic connotation, when in fact they could very well be classified as "not what I know", not comparable to what I have been "trained" to like. These aspects need to be remembered when planning any product development. For example, the usual U.S. pickle seasoning, based on dill weed and a touch of cassia (sweetening effect) would not draw much interest in France where the same type of product composition relies on vinegar with tarragon, onion, and pepper for flavor. The opposite situation would certainly bring the same consumer reaction. Humans are prone to follow habits, without realizing they would become more susceptible to boredom. There lies the final threat and history has taught us the high price we may pay for it.

Designing food products involves the active participation of the food chemist, who uses ingredients, just the same way a musician would use notes or the painter colors, to create a combination of sensations to affect as many senses as possible, with the exception of touch and hearing. The goal is to attract the consumer's attention: our attention. Apart from those fortunate enough to enjoy vegetables from the garden, fruits picked just at the right time, meat from animals raised in the open and naturally fed, or fresh seafood from the ocean, the modern-life reality forces the majority of us to feed on products that lack good organoleptic character. The need to supplement that mediocrity with other ingredients is constantly increasing. Luckily enough, Nature helps us in our quest for sensations; spices and herbs bring us what we need, and the spice industry has developed a very diverse line of products to bring flavor to our dishes.

11.5.1 Whole Spices

At the consumer level, spices are sold in small jars, very attractive and also expensive. If you have ever tried to buy saffron (and I mean real), you know what I mean. This activity requires good quality products. As many spices may be sold as such, cleanliness and good visual aspect are a must. It requires extensive sorting capabilities, which will increase the overall cost. Some whole spices such as cinnamon sticks or star anise suffer during transportation. Broken spices may of course be re-worked into ground forms. On the consumer side their usage requires a good knowledge of culinary art and some curiosity, and, above all, time (and inclination) to prepare meals, all becoming rare in today's American society.

11.5.2 Spice Blends

Instead of maintaining stocks of several ingredients, we have seen the development of ready-to-use-blends, in fancy packaging with an alluring name, which we use to sprinkle on all dishes, from meat to soups or vegetables. These blends combine several different spices and herbs for a specific use. It is not a surprise that most contain a sizable amount of pepper, as it has been a world favorite for so long. Blends should also use visual attributes to grab attention, and the freeze-dried herbs, as well as dried vegetable pieces such as bell pepper or carrot, play an essential role. Their contribution to the final taste is limited, but they do bring a nice look. Crushed chilies, with their bright yellow and red flakes, not to mention their pungency, are also a big favorite. The different ingredients may be used in whole, crushed, cracked, diced, or ground forms. The physical aspect would condition both the visual final aspect and their ability to deliver the aromatic constituents that make them valuable. Such blends generally use salt as a carrier (or filler), which allows low pricing. The trend to reduce salt intake has pushed the development of blends without salt. The elaboration of spice blends can easily become an industrial nightmare because of the very wide range of apparent densities in complex blends. Mixing those different ingredients must prevent the breaking up of the most delicate parts (parsley flakes for example), but still ensure a homogeneous mixing and avoid segregation. Overblending is as disastrous as underblending. The packaging steps add more challenges. Transfers and vibrations will rearrange the different ingredients and the final little shaker on the shelf of some convenience store in Nevada may not be quite as the original design intended it to be.

11.5.3 Seasoning Blends

These blends are more complex and include more functional ingredients such as gums, starches, and acids, along with spices, herbs, spices extractives, flavors, and colors. Their main usage is certainly in the meat industry (sausages, patties), but they are also commonly used for snacks, salad dressings, marinades, sauces, and exotic (ethnic) applications. They include spices, along with soluble spice preparations, herbs, and vegetables (onion, garlic), and are added during the final stage of preparation of the food product. The prices of these blends must be low as most industrial users require to save every penny (or fraction of) in their highly competitive market. Duplication of existing blends is the game, as users will switch suppliers when presented with savings. Spices are usually used ground so as to facilitate blending with the more functional ingredients, but cracked pepper or crushed chilies can be of interest for topical applications (an Italian sausage must show pieces of crushed chilies). Some other visual contributors would be herbs flakes for snacks or dips. Spices can also be used in more unconventional associations, like red berries and chili for marinades.

11.6 CONCLUSION

When elaborating a food product, the chemist will naturally turn to ways of making a difference to his composition. In recent years, we have seen a rapid succession of new trends, new health-conscious meals, low-fat, no cholesterol, low sugar, and so on. The new “low-carb” craze is the flavor of the month. How long will it last? Probably until

another high profile "guru" makes his way to the top of the chart. As we remove all the "bad" things from our food, it seems we also take away the fun from it and we are just so lucky that Mother Nature is still around to offer its treasures. Spices and herbs will remain a valuable way to preserve our interest in food.

Today's U.S. food market is also evolving towards constantly more spicy ("hot") food. When walking around the aisles in any grocery store you realize how many spicy products have surfaced in recent years. It almost seems like the intent is to strike the consumer as much as possible, and maybe make him forget the basic taste of the food. Looking back at history, it appears that the Romans tried it some 2000 years ago – I am not so sure this is such a new concept after all. The saturation of the taste induced by high levels of spices, especially pungent varieties, is comparable to looking at a flash, and certainly leads to neuronal pain. Is it still a pleasure? I will leave it to you to decide.

Maybe some of you will decide to embrace a career in the food industry, become a food chemist, create new seasonings or spice blends, carry on the exciting quest for pleasure in food. Why not? You are more than welcome. Working in the spice world is more than a job – it is a passion!

REFERENCES

It is simply quite impossible to mention the thousands of articles, books, theses, and Internet links dedicated to spices and herbs. From personal experience I would suggest some of the following, which contain more information on composition, processing techniques, and applications.

12.1 INTRODUCTION

Nearly 25 years ago, the United States Food and Drug Administration (FDA) started the approach of using umbrella regulations to help the food industries to produce wholesome food as required by the Federal Food, Drug, Cosmetic Act (the Act). In 1986, the FDA promulgated the first umbrella regulations under the title of Good Manufacturing Practice (GMP) regulations (GMPR). Since then, many aspects of the regulations have been revised (FDA).

Traditionally, industry and regulators have depended on spot-checks of manufacturing conditions and random sampling of final products to ensure safe food. The Current Good Manufacturing Practice Regulations (CGMPR) form the basis on which the FDA will inform the food manufacturer about deficiencies in its operations. This approach, however, tends to be reactive, rather than preventive, and can definitely be improved.

For more than 30 years, FDA has been regulating the low acid canned food (LACF) industries with a special set of regulations, many of which are preventive in nature. This action aims at preventing botulism. In the last 30 years, threats from other biological pathogens have increased tremendously. Between 1980 and 1995, FDA has been studying the approach of using Hazard Analysis and Critical Control Points (HACCP). For this approach, FDA uses the LACF regulations as a partial guide. Since 1995, FDA has issued HACCP regulations (HACCPR) (FDA) for the manufacture or production of several types of food products. These include the processing of seafood and fruit/vegetable juices.

Since 1938, when the Act was first passed by Congress, FDA and State regulatory agencies have worked hard to reach a uniform set of codes for the national regulation of food manufacturing industries and state regulation of retail industries associated with food, for example, groceries, restaurants, catering, and so on. In 1993, the first document, titled *Food Code*, was issued jointly by the FDA and state agencies. It has been revised twice since then. This chapter discusses CGMPR, HACCPR, and the *Food Code*.

12.2 CURRENT GOOD MANUFACTURING PRACTICE REGULATIONS (CGMPR)

The Current Good Manufacturing Practice Regulations (CGMPR) cover the topics listed in Table 12.1. These regulations are discussed in detail here. Please note that the word "shall" in a legal document means mandatory and is used routinely in FDA regulations published in the U.S. Code of Federal Regulations (CFR). In this chapter, the words "should" and "must" are used to make for smoother reading. However, this in no way diminishes the legal impact of the original regulations.

TABLE 12.1 Contents of the Current Good Manufacturing Regulations (CGMPR).

21 CFR 110.3	Definitions
21 CFR 110.5	Current good manufacturing practice
21 CFR 110.10	Personnel
21 CFR 110.19	Exclusions
21 CFR 110.20	Plant and grounds
21 CFR 110.35	Sanitary operations
21 CFR 110.37	Sanitary facilities and controls
21 CFR 110.40	Equipment and utensils
21 CFR 110.80	Processes and controls
21 CFR 110.93	Warehousing and distribution

12.2.1 Definitions (21 CFR 110.3)

FDA has provided the following definitions and interpretations for several important terms.

1. *Acid food* or *acidified food* means foods that have an equilibrium pH of 4.6 or below.
2. *Batter* means a semifluid substance, usually composed of flour and other ingredients, into which principal components of food are dipped or with which they are coated, or which may be used directly to form bakery foods.
3. *Blanching*, except for tree nuts and peanuts, means a prepackaging heat treatment of foodstuffs for a sufficient time and at a sufficient temperature to partially or completely inactivate the naturally occurring enzymes and to effect other physical or biochemical changes in the food.
4. *Critical control point* means a point in a food process where there is a high probability that improper control may cause a hazard or filth in the final food or decomposition of the final food.
5. *Food* includes raw materials and ingredients.
6. *Food-contact surfaces* are those surfaces that contact human food and those surfaces from which drainage onto the food or onto surfaces that contact the food ordinarily occurs during the normal course of operations. *Food-contact surfaces* include utensils and food-contact surfaces of equipment.
7. *Lot* means the food produced during a period of time indicated by a specific code.
8. *Microorganisms* means yeasts, molds, bacteria, and viruses and includes, but is not limited to, species having public health significance. The term *undesirable microorganisms* includes those microorganisms that are of public health significance, that promote decomposition of food, or that indicate that food is contaminated with filth.
9. *Pest* refers to any objectionable animals or insects including, but not limited to, birds, rodents, flies, and insect larvae.
10. *Plant* means the building or facility used for the manufacturing, packaging, labeling, or holding of human food.
11. *Quality control operation* means a planned and systematic procedure for taking all actions necessary to prevent food from being adulterated.

12. *Rework* means clean, unadulterated food that has been removed from processing for reasons other than insanitary conditions or that has been successfully reconditioned by reprocessing and that is suitable for use as food.
13. *Safe moisture level* is a level of moisture low enough to prevent the growth of undesirable microorganisms in the finished product under the intended conditions of manufacturing, storage, and distribution. The maximum safe moisture level for a food is based on its water activity, a_w. An a_w will be considered safe for a food if adequate data are available that demonstrate that the food at or below the given a_w will not support the growth of undesirable microorganisms.
14. *Sanitize* means to adequately treat food-contact surfaces by a process that is effective in destroying vegetative cells of microorganisms of public health significance, and in substantially reducing numbers of other undesirable microorganisms, but without adversely affecting the product or its safety for the consumer.
15. *Water activity* (a_w) is a measure of the free moisture in a food and is the quotient of the water vapor pressure of the substance divided by the vapor pressure of pure water at the same temperature.

12.2.2 Personnel (21 CFR 110.10)

Plant management should take all reasonable measures and precautions to ensure compliance with the following regulations.

1. *Disease Control.* Any person who, by medical examination or supervisory observation, is shown to have an illness, open lesion, including boils, sores, or infected wounds, by which there is a reasonable possibility of food, food-contact surfaces, or food-packaging materials becoming contaminated, should be excluded from any operations which may be expected to result in such contamination until the condition is corrected. Personnel should be instructed to report such health conditions to their supervisors.
2. *Cleanliness.* All persons working in direct contact with food, food-contact surfaces, and food-packaging materials should conform to hygienic practices while on duty. The methods for maintaining cleanliness include, but are not limited to, the following:
   a. Wearing outer garments suitable to the operation to protect against the contamination of food, food-contact surfaces, or food-packaging materials.
   b. Maintaining adequate personal cleanliness.
   c. Washing hands thoroughly (and sanitizing if necessary to protect against contamination with undesirable microorganisms) in an adequate hand-washing facility before starting work, after each absence from the work station, and at any other time when the hands may have become soiled or contaminated.
   d. Removing all unsecured jewelry and other objects that might fall into food, equipment, or containers, and removing hand jewelry that cannot be adequately sanitized during periods in which food is manipulated by hand. If such hand jewelry cannot be removed, it may be covered by material which can be maintained in an intact, clean, and sanitary condition and which effectively protects against their contamination of the food, food-contact surfaces, or food-packaging materials.
   e. Maintaining gloves, if they are used in food handling, in an intact, clean, and sanitary condition. The gloves should be of an impermeable material.

f. Wearing, where appropriate, hairnets, headbands, caps, beard covers, or other effective hair restraints.
g. Storing clothing or other personal belongings in areas other than where food is exposed or where equipment or utensils are washed.
h. Confining the following personal practices to areas other than where food may be exposed or where equipment or utensils are washed: eating food, chewing gum, drinking beverages, or using tobacco.
i. Taking any other necessary precautions to protect against contamination of food, food-contact surfaces, or food-packaging materials with microorganisms or foreign substances including, but not limited to, perspiration, hair, cosmetics, tobacco, chemicals, and medicines applied to the skin.

3. *Education and Training*. Personnel responsible for identifying sanitation failures or food contamination should have a background of education or experience, to provide a level of competency necessary for production of clean and safe food. Food handlers and supervisors should receive appropriate training in proper food handling techniques and food-protection principles and should be informed of the danger of poor personal hygiene and insanitary practices.
4. *Supervision*. Responsibility for assuring compliance by all personnel with all legal requirements should be clearly assigned to competent supervisory personnel.

12.2.3 Plant and Grounds (21 CFR 110.20)

1. *Grounds*. The grounds surrounding a food plant that are under the control of the plant manager should be kept in a condition that will protect against the contamination of food. The methods for adequate maintenance of grounds include, but are not limited to, the following.
   a. Properly storing equipment, removing litter and waste, and cutting weeds or grass within the immediate vicinity of the plant buildings or structures that may constitute an attractant, breeding place or harborage for pests.
   b. Maintaining roads, yards, and parking lots so that they do not constitute a source of contamination in areas where food is exposed.
   c. Adequately draining areas that may contribute contamination to food by seepage or foot-borne filth, or by providing a breeding place for pests.
   d. Operating systems for waste treatment and disposal in an adequate manner so that they do not constitute a source of contamination in areas where food is exposed. If the plant grounds are bordered by grounds not under the operator's control and not maintained in an acceptable manner, steps must be taken to exclude pests, dirt, and filth that may be a source of food contamination. Implement inspection, extermination, or other countermeasures.
2. *Plant Construction and Design*. Plant buildings and structures should be suitable in size, construction, and design to facilitate maintenance and sanitary operations for food-manufacturing purposes. The plant and facilities should:
   a. Provide sufficient space for such placement of equipment and storage of materials as is necessary for the maintenance of sanitary operations and the production of safe food.

b. Take proper precautions to reduce the potential for contamination of food, food-contact surfaces, or food-packaging materials with microorganisms, chemicals, filth, or other extraneous material. The potential for contamination may be reduced by adequate food safety controls and operating practices or effective design, including the separation of operations in which contamination is likely to occur, by one or more of the following means: location, time, partition, air flow, enclosed systems, or other effective means.
c. Take proper precautions to protect food in outdoor bulk fermentation vessels by any effective means, including:
   – Using protective coverings,
   – Controlling areas over and around the vessels to eliminate harborages for pests,
   – Checking on a regular basis for pests and pest infestation,
   – Skimming the fermentation vessels, as necessary,
d. Be constructed in such a manner that floors, walls, and ceilings may be adequately cleaned and kept clean and kept in good repair; that drip or condensate from fixtures, ducts and pipes does not contaminate food, food-contact surfaces, or food-packaging materials; and that aisles or working spaces are provided between equipment and walls and are adequately unobstructed and of adequate width to permit employees to perform their duties and to protect against contaminating food or food-contact surfaces with clothing or personal contact.
e. Provide adequate lighting in hand-washing areas, dressing and locker rooms, and toilet rooms and in all areas where food is examined, processed, or stored and where equipment or utensils are cleaned; and provide safety-type light bulbs, fixtures, skylights, or other glass suspended over exposed food in any step of preparation or otherwise protect against food contamination in case of glass breakage.
f. Provide adequate ventilation or control equipment to minimize odors and vapors (including steam and noxious fumes) in areas where they may contaminate food; and locate and operate fans and other air-blowing equipment in a manner that minimizes the potential for contaminating food, food-packaging materials, and food-contact surfaces.
g. Provide, where necessary, adequate screening or other protection against pests.

12.2.4 Sanitary Operations (21 CFR 110.35)

1. *General Maintenance*. Buildings, fixtures, and other physical facilities of the plant should be maintained in a sanitary condition and should be kept in repair sufficient to prevent food from becoming adulterated within the meaning of the Act. Cleaning and sanitizing of utensils and equipment should be conducted in a manner that protects against contamination of food, food-contact surfaces, or food-packaging materials.
2. *Substances Used in Cleaning and Sanitizing; Storage of Toxic Materials*.
   a. Cleaning compounds and sanitizing agents used in cleaning and sanitizing procedures should be free from undesirable microorganisms and should be safe and adequate under the conditions of use. Compliance with this requirement may be

verified by any effective means including purchase of these substances under a supplier's guarantee or certification, or examination of these substances for contamination. Only the following toxic materials may be used or stored in a plant where food is processed or exposed:

- Those required to maintain clean and sanitary conditions;
- Those necessary for use in laboratory testing procedures;
- Those necessary for plant and equipment maintenance and operation; and
- Those necessary for use in the plant's operations.

b. Toxic cleaning compounds, sanitizing agents, and pesticide chemicals should be identified, held, and stored in a manner that protects against contamination of food, food-contact surfaces, or food-packaging materials.

3. *Pest Control.* No pests should be allowed in any area of a food plant. Guard or guide dogs may be allowed in some areas of a plant if the presence of the dogs is unlikely to result in contamination of food, food-contact surfaces, or food-packaging materials. Effective measures should be taken to exclude pests from the processing areas and to protect against the contamination of food on the premises by pests. The use of insecticides or rodenticides is permitted only under precautions and restrictions that will protect against the contamination of food, food-contact surfaces, and food-packaging materials.
4. *Sanitation of Food-Contact Surfaces.* All food-contact surfaces, including utensils and food-contact surfaces of equipment, should be cleaned as frequently as necessary to protect against contamination of food.
   a. Food-contact surfaces used for manufacturing or holding low-moisture food should be in a dry, sanitary condition at the time of use. When the surfaces are wet-cleaned, they should, when necessary, be sanitized and thoroughly dried before subsequent use.
   b. In wet processing, when cleaning is necessary to protect against the introduction of microorganisms into food, all food-contact surfaces should be cleaned and sanitized before use and after any interruption during which the food-contact surfaces may have become contaminated. Where equipment and utensils are used in a continuous production operation, the utensils and food-contact surfaces of the equipment should be cleaned and sanitized as necessary.
   c. Non-food-contact surfaces of equipment used in the operation of food plants should be cleaned as frequently as necessary to protect against contamination of food.
   d. Single-service articles (such as utensils intended for one-time use, paper cups, and paper towels) should be stored in appropriate containers and should be handled, dispensed, used, and disposed of in a manner that protects against contamination of food or food-contact surfaces.
   e. Sanitizing agents should be adequate and safe under conditions of use. Any facility, procedure, or machine is acceptable for cleaning and sanitizing equipment and utensils if it is established that the facility, procedure, or machine will routinely render equipment and utensils clean and provide adequate cleaning and sanitizing treatment.

5. *Storage and Handling of Cleaned Portable Equipment and Utensils*. Cleaned and sanitized portable equipment with food-contact surfaces and utensils should be stored in a location and manner that protects food-contact surfaces from contamination.

12.2.5 Sanitary Facilities and Controls (21 CFR 110.37)

Each plant should be equipped with adequate sanitary facilities and accommodations including, but not limited to the following.

1. *Water Supply*. The water supply should be sufficient for the operations intended and should be derived from an adequate source. Any water that contacts food or food-contact surfaces should be safe and of adequate sanitary quality. Running water at a suitable temperature, and under pressure as needed, should be provided in all areas where required for the processing of food, for the cleaning of equipment, utensils, and food-packaging materials, or for employee sanitary facilities.
2. *Plumbing*. Plumbing should be of adequate size and design and adequately installed and maintained to
   a. Carry sufficient quantities of water to required locations throughout the plant;
   b. Properly convey sewage and liquid disposable waste from the plant;
   c. Avoid constituting a source of contamination to food, water supplies, equipment, or utensils or creating an unsanitary condition;
   d. Provide adequate floor drainage in all areas where floors are subject to flooding-type cleaning or where normal operations release or discharge water or other liquid waste on the floor; and
   e. Provide that there is no backflow from, or cross-connection between, piping systems that discharge wastewater or sewage and piping systems that carry water for food or food manufacturing.
3. *Sewage Disposal*. Sewage disposal should be made into an adequate sewerage system or disposed of through other adequate means.
4. *Toilet Facilities*. Each plant should provide its employees with adequate, readily accessible toilet facilities. Compliance with this requirement may be accomplished by
   a. Maintaining the facilities in a sanitary condition;
   b. Keeping the facilities in good repair at all times;
   c. Providing self-closing doors;
   d. Providing doors that do not open into areas where food is exposed to airborne contamination, except where alternate means have been taken to protect against such contamination (such as double doors or positive air-flow systems).
5. *Hand-Washing Facilities*. Hand-washing facilities should be adequate and convenient and be furnished with running water at a suitable temperature. Compliance with this requirement may be accomplished by providing the following.
   a. Hand-washing and, where appropriate, hand-sanitizing facilities at each location in the plant where good sanitary practices require employees to wash and/or sanitize their hands.
   b. Effective hand-cleaning and sanitizing preparations.

c. Sanitary towel service or suitable drying devices.
d. Devices or fixtures, such as water control valves, so designed and constructed to protect against recontamination of clean, sanitized hands.
e. Readily understandable signs directing employees handling unprotected food, unprotected food-packaging materials, of food-contact surfaces to wash and, where appropriate, sanitize their hands before they start work, after each absence from post of duty, and when their hands may have become soiled or contaminated. These signs may be posted in the processing room(s) and in all other areas where employees may handle such food, materials, or surfaces.
f. Refuse receptacles that are constructed and maintained in a manner that protects against contamination of food.

6. *Rubbish and Offal Disposal*. Rubbish and any offal should be so conveyed, stored, and disposed of as to minimize the development of odor, minimize the potential for the waste becoming an attractant and harborage or breeding place for pests, and protect against contamination of food, food-contact surfaces, water supplies, and ground surfaces.

12.2.6 Equipment and Utensils (21 CFR 110.40)

1. All plant equipment and utensils should be so designed and of such material and workmanship as to be adequately cleanable, and should be properly maintained. The design, construction, and use of equipment and utensils should preclude the adulteration of food with lubricants, fuel, metal fragments, contaminated water, or any other contaminants. All equipment should be so installed and maintained as to facilitate the cleaning of the equipment and of all adjacent spaces. Food-contact surfaces should be corrosion-resistant when in contact with food. They should be made of nontoxic materials and designed to withstand the environment of their intended use and the action of food, and, if applicable, cleaning compounds and sanitizing agents. Food-contact surfaces should be maintained to protect food from being contaminated by any source, including unlawful indirect food additives.
2. Seams on food-contact surfaces should be smoothly bonded or maintained so as to minimize accumulation of food particles, dirt, and organic matter and thus minimize the opportunity for growth of microorganisms.
3. Equipment that is in the manufacturing or food-handling area and that does not come into contact with food should be so constructed that it can be kept in a clean condition.
4. Holding, conveying, and manufacturing systems, including gravimetric, pneumatic, closed, and automated systems, should be of a design and construction that enables them to be maintained in an appropriate sanitary condition.
5. Each freezer and cold storage compartment used to store and hold food capable of supporting growth of microorganisms should be fitted with an indicating thermometer, temperature-measuring device, or temperature-recording device so installed as to show the temperature accurately within the compartment, and should be fitted with an automatic control for regulating temperature or with an automatic alarm system to indicate a significant temperature change in a manual operation.

6. Instruments and controls used for measuring, regulating, or recording temperatures, pH, acidity, water activity, or other conditions that control or prevent the growth of undesirable microorganisms in food should be accurate and adequately maintained, and adequate in number for their designated uses.
7. Compressed air or other gases mechanically introduced into food or used to clean food-contact surfaces or equipment should be treated in such a way that food is not contaminated with unlawful indirect food additives.

12.2.7 Processes and Controls (21 CFR 110.80)

All operations in the receiving, inspecting, transporting, segregating, preparing, manufacturing, packaging, and storing of food should be conducted in accordance with adequate sanitation principles. Appropriate quality control operations should be employed to ensure that food is suitable for human consumption and that food-packaging materials are safe and suitable. Overall sanitation of the plant should be under the supervision of one or more competent individuals assigned responsibility for this function. All reasonable precautions should be taken to ensure that production procedures do not contribute contamination from any source. Chemical, microbial, or extraneous material testing procedures should be used where necessary to identify sanitation failures or possible food contamination. All food that has become contaminated to the extent that it is adulterated within the meaning of the Act should be rejected, or if permissible, treated or processed to eliminate the contamination.

1. *Raw Materials and Other Ingredients.*
   a. Raw materials and other ingredients should be inspected and segregated or otherwise handled as necessary to ascertain that they are clean and suitable for processing into food and should be stored under conditions that will protect against contamination and minimize deterioration. Raw materials should be washed or cleaned as necessary to remove soil or other contamination. Water used for washing, rinsing, or conveying food should be safe and of adequate sanitary quality. Water may be reused for washing, rinsing, or conveying food if it does not increase the level of contamination of the food. Containers and carriers of raw materials should be inspected on receipt to ensure that their condition has not contributed to the contamination or deterioration of food.
   b. Raw materials and other ingredients should either not contain levels of microorganisms that may produce food poisoning or other disease in humans, or they should be pasteurized or otherwise treated during manufacturing operations so that they no longer contain levels that would cause the product to be adulterated within the meaning of the act. Compliance with this requirement may be verified by any effective means, including purchasing raw materials and other ingredients under a supplier's guarantee or certification.
   c. Raw materials and other ingredients susceptible to contamination with aflatoxin or other natural toxins should comply with current FDA regulations, guidelines, and action levels for poisonous or deleterious substances before these materials or ingredients are incorporated into finished food. Compliance with this requirement may be accomplished by purchasing raw materials and other ingredients

under a supplier's guarantee or certification, or may be verified by analyzing these materials and ingredients for aflatoxins and other natural toxins.

d. Raw materials, other ingredients, and rework susceptible to contamination with pests, undesirable microorganisms, or extraneous material should comply with applicable FDA regulations, guidelines, and defect action levels for natural or unavoidable defects if a manufacturer wishes to use the materials in manufacturing food. Compliance with this requirement may be verified by any effective means, including purchasing the materials under a supplier's guarantee or certification, or examination of these materials for contamination.

e. Raw materials, other ingredients, and rework should be held in bulk, or in containers designed and constructed so as to protect against contamination and should be held at such temperature and relative humidity as to prevent the food from becoming adulterated. Material scheduled for rework should be identified as such.

f. Frozen raw materials and other ingredients should be kept frozen. If thawing is required prior to use, it should be done in a manner that prevents the raw materials and other ingredients from becoming adulterated.

g. Liquid or dry raw materials and other ingredients received and stored in bulk form should be held in a manner that protects against contamination.

2. *Manufacturing operations.*

a. Equipment and utensils and finished food containers should be maintained in an acceptable condition through appropriate cleaning and sanitizing, as necessary. Insofar as necessary, equipment should be taken apart for thorough cleaning.

b. All food manufacturing, including packaging and storage, should be conducted under such conditions and controls as are necessary to minimize the potential for the growth of microorganisms, or for the contamination of food. One way to comply with this requirement is careful monitoring of physical factors such as time, temperature, humidity, a_w, pH, pressure, flow rate, and manufacturing operations such as freezing, dehydration, heat processing, acidification, and refrigeration to ensure that mechanical breakdowns, time delays, temperature fluctuations, and other factors do not contribute to the decomposition or contamination of food.

c. Food that can support the rapid growth of undesirable microorganisms, particularly those of public health significance, should be held in a manner that prevents the food from becoming contaminated. Compliance with this requirement may be accomplished by any effective means, including:

   – Maintaining refrigerated foods at 41°F (5°C) or below as appropriate for the particular food involved;
   – Maintaining frozen foods in a frozen state;
   – Maintaining hot foods at 140°F (60°C) or above;
   – Heat treating acid or acidified foods to destroy mesophilic microorganisms when those foods are to be held in hermetically sealed containers at ambient temperatures.

d. Measures such as sterilizing, irradiating, pasteurizing, freezing, refrigerating, controlling pH, or controlling a_w that are taken to destroy or prevent the growth of undesirable microorganisms, particularly those of public health

significance, should be adequate under the conditions of manufacture, handling, and distribution to prevent food from being adulterated.

e. Work-in-process should be handled in a manner that protects against contamination.

f. Effective measures should be taken to protect finished food from contamination by raw materials, other ingredients, or refuse. When raw materials, other ingredients, or refuse are unprotected, they should not be handled simultaneously in a receiving, loading, or shipping area if that handling could result in contaminated food. Food transported by conveyor should be protected against contamination as necessary.

g. Equipment, containers, and utensils used to convey, hold, or store raw materials, work-in-process, rework, or food should be constructed, handled, and maintained during manufacturing or storage in a manner that protects against contamination.

h. Effective measures should be taken to protect against the inclusion of metal or other extraneous material in food. Compliance with this requirement may be accomplished by using sieves, traps, magnets, electronic metal detectors, or other suitable effective means.

i. Food, raw materials, and other ingredients that are adulterated should be disposed of in a manner that protects against the contamination of other food. If the adulterated food is capable of being reconditioned, it should be reconditioned using a method that has been proven to be effective or it should be reexamined and found not to be adulterated before being incorporated into other food.

j. Mechanical manufacturing steps such as washing, peeling, trimming, cutting, sorting and inspecting, mashing, dewatering, cooling, shredding, extruding, drying, whipping, defatting, and forming should be performed so as to protect food against contamination. Compliance with this requirement may be accomplished by providing adequate physical protection of food from contaminants that may drip, drain, or be drawn into the food. Protection may be provided by adequate cleaning and sanitizing of all food-contact surfaces, and by using time and temperature controls at and between each manufacturing step.

k. Heat blanching, when required in the preparation of food, should be effected by heating the food to the required temperature, holding it at this temperature for the required time, and then either rapidly cooling the food or passing it to subsequent manufacturing without delay. Thermophilic growth and contamination in blanchers should be minimized by the use of adequate operating temperatures and by periodic cleaning. Where the blanched food is washed prior to filling, water used should be safe and of adequate sanitary quality.

l. Batters, breading, sauces, gravies, dressings, and other similar preparations should be treated or maintained in such a manner that they are protected against contamination. Compliance with this requirement may be accomplished by any effective means, including one or more of the following:
   - Using ingredients free of contamination;
   - Employing adequate heat processes where applicable;
   - Using adequate time and temperature controls;
   - Providing adequate physical protection of components from contaminants that may drip, drain, or be drawn into them;

- Cooling to an adequate temperature during manufacturing;
- Disposing of batters at appropriate intervals to protect against the growth of microorganisms.

m. Filling, assembling, packaging, and other operations should be performed in such a way that the food is protected against contamination. Compliance with this requirement may be accomplished by any effective means, including:
   - Use of a quality control operation in which the critical control points are identified and controlled during manufacturing;
   - Adequate cleaning and sanitizing of all food-contact surfaces and food containers;
   - Using materials for food containers and food-packaging materials that are safe and suitable;
   - Providing physical protection from contamination, particularly airborne contamination;
   - Using sanitary handling procedures.

n. Food such as, but not limited to, dry mixes, nuts, intermediate-moisture food, and dehydrated food, that relies on the control of a_w for preventing the growth of undesirable microorganisms should be processed to and maintained at a safe moisture level. Compliance with this requirement may be accomplished by any effective means, including employment of one or more of the following practices:
   - Monitoring the a_w of food;
   - Controlling the soluble solids/water ratio in finished food;
   - Protecting finished food from moisture pickup, by use of a moisture barrier or by other means, so that the a_w of the food does not increase to an unsafe level.

o. Food, such as, but not limited to, acid and acidified food, which relies principally on the control of pH for preventing the growth of undesirable microorganisms should be monitored and maintained at a pH of 4.6 or below. Compliance with this requirement may be accomplished by any effective means, including employment of one or more of the following practices:
   - Monitoring the pH of raw materials, food-in-process, and finished food;
   - Controlling the amount of acid or acidified food added to low-acid food.

p. When ice is used in contact with food, it should be made from water that is safe and of adequate sanitary quality, and should be used only if it has been manufactured in accordance with current good manufacturing practice.

q. Food-manufacturing areas and equipment used for manufacturing human food should not be used to manufacture nonhuman-food-grade animal feed or inedible products, unless there is no reasonable possibility for the contamination of the human food.

12.2.8 Warehousing and Distribution (21 CFR 110.93)

Storage and transportation of finished food should be under conditions that will protect food against physical, chemical, and microbial contamination as well as against deterioration of the food and the container.

12.2.9 Natural or Unavoidable Defects in Food for Human Use that Present no Health Hazard (21 CFR 110.110)

1. Some foods, even when produced under current good manufacturing practice, contain natural or unavoidable defects that at low levels are not hazardous to health. FDA establishes maximum levels for these defects in foods produced under current good manufacturing practice and uses these levels in deciding whether to recommend regulatory action.
2. Defect action levels are established for foods whenever it is necessary and feasible to do so. These levels are subject to change upon the development of new technology or the availability of new information.
3. The mixing of a food containing defects above the current defect action level with another lot of food is not permitted and renders the final food adulterated within the meaning of the Act, regardless of the defect level of the final food.
4. A compilation of the current defect action levels for natural or unavoidable defects in food for human use that present no health hazard may be obtained from the FDA for printed or electronic versions.

12.3 HAZARD ANALYSIS CRITICAL CONTROL POINTS REGULATIONS (HACCPR)

In 1997, FDA adopted a food safety program that was developed nearly 30 years ago for astronauts, and is now applying it to seafood, and fruit and vegetable juices. The agency intends to eventually use it for much of the U.S. food supply. The program for astronauts focuses on preventing hazards that could cause foodborne illnesses by applying science-based controls, from raw material to finished products. FDA's new system will do the same.

Many principles of this new system, now called Hazard Analysis and Critical Control Points (HACCP), are already in place in the FDA-regulated low-acid canned food industry. Since 1997, FDA has mandated HACCP for the processing of seafood, fruit juices, and vegetable juices. Also, FDA has incorporated HACCP into its *Food Code*, a document that gives guidance to and serves as model legislation for state and territorial agencies that license and inspect food service establishments, retail food stores, and food vending operations in the United States.

FDA is now considering developing regulations that would establish HACCP as the food safety standard throughout other areas of the food industry, including both domestic and imported food products. HACCP has been endorsed by the National Academy of Sciences, the Codex Alimentarius Commission (an international, standard-setting organization), and the National Advisory Committee on Microbiological Criteria for Foods. Several U.S. food companies already use the system in their manufacturing processes, and it is in use in other countries, including Canada.

12.3.1 What is HACCP?

HACCP involves seven principles.

1. *Analyze Hazards*. Potential hazards associated with a food and measures to control those hazards are identified. The hazard could be biological, such as a

microbe; chemical, such as a toxin; or physical, such as ground glass or metal fragments.

2. *Identify Critical Control Points*. These are points in a food's production – from its raw state through processing and shipping to consumption by the consumer – at which the potential hazard can be controlled or eliminated. Examples are cooking, cooling, packaging, and metal detection.
3. *Establish Preventive Measures with Critical Limits for Each Control Point*. For a cooked food, for example, this might include setting the minimum cooking temperature and time required to ensure the elimination of any harmful microbes.
4. *Establish Procedures to Monitor the Critical Control Points*. Such procedures might include determining how and by whom cooking time and temperature should be monitored.
5. *Establish Corrective Actions* to be taken when monitoring shows that a critical limit has not been met – for example, reprocessing or disposing of food if the minimum cooking temperature is not met.
6. *Establish Procedures to Verify that the System is Working Properly* – for example, testing time-and-temperature recording devices to verify that a cooking unit is working properly.
7. *Establish Effective Record Keeping* to document the HACCP system. This would include records of hazards and their control methods, the monitoring of safety requirements and action taken to correct potential problems.

Each of these principles must be backed by sound scientific knowledge such as published microbiological studies on time and temperature factors for controlling foodborne pathogens.

12.3.2 Need for HACCP

New challenges to the U.S. food supply have prompted FDA to consider adopting a HACCP-based food safety system on a wider basis. One of the most important challenges is the increasing number of new food pathogens. For example, between 1973 and 1988, bacteria not previously recognized as important causes of foodborne illness such as *Escherichia coli* O157:H7 and *Salmonella enteritidis* became more widespread. There is also increasing public health concerns about chemical contamination of food: for example, the effects of lead in food on the nervous system.

Another important factor is the fact that the size of the food industry and the diversity of products and processes have grown tremendously – in the amount of domestic food manufactured and the number and kinds of foods imported. At the same time, FDA and state and local agencies have the same limited level of resources to ensure food safety. The need for HACCP in the United States, particularly in the seafood industry, is further fueled by the growing trend in international trade for worldwide equivalence of food products and the Codex Alimentarius Commission's adoption of HACCP as the international standard for food safety.

12.3.3 Advantages and Plans

HACCP offers a number of advantages over previous systems. Most importantly, HACCP

1. Focuses on identifying and preventing hazards from contaminating food;
2. Is based on sound science;

3. Permits more efficient and effective government oversight, primarily because the record keeping allows investigators to see how well a firm is complying with food safety laws over a period rather than how well it is doing on any given day;
4. Places responsibility for ensuring food safety appropriately on the food manufacturer or distributor;
5. Helps food companies compete more effectively in the world market; and
6. Reduces barriers to international trade.

The following are the seven steps used in HACCP plan development.

1. Preliminary steps:
   a. General information;
   b. Describe the food;
   c. Describe the method of distribution and storage;
   d. Identify the intended use and consumer;
   e. Develop a flow diagram.
2. Hazard Analysis Worksheet:
   a. Set up the Hazard Analysis Worksheet;
   b. Identify the potential species-related hazards;
   c. Identify the potential process-related hazards;
   d. Complete the Hazard Analysis Worksheet;
   e. Understand the potential hazard;
   f. Determine if the potential hazard is significant;
   g. Identify the critical control points (CCP).
3. HACCP Plan Form:
   a. Complete the HACCP Plan Form;
   b. Set the critical limits (CL).
4. Establish monitoring procedures:
   a. What;
   b. How;
   c. Frequency;
   d. Who.
5. Establish corrective action procedures.
6. Establish a record keeping system.
7. Establish verification procedures.

It is important to remember that, apart from the HACCPR promulgated for seafood and juices, the implementation of HACCP by other categories of food processing is voluntary. However, the FDA and various types of food processors are working together so that eventually HACCPR will become available for many other food processing systems under FDA jurisdiction. Using the HACCPR for seafood processing as a guide, the following

discussion for a HACCP plan applies to all categories of food products being processed in United States.

12.3.4 Hazard Analysis

Every processor should conduct a hazard analysis to determine whether there are food safety hazards that are reasonably likely to occur for each kind of product processed by that processor and to identify the preventive measures that the processor can apply to control those hazards. Such food safety hazards can be introduced both within and outside the processing plant environment, including food safety hazards that can occur before, during, and after harvest. A food safety hazard that is reasonably likely to occur is one for which a prudent processor would establish controls because experience, illness data, scientific reports, or other information provide a basis to conclude that there is a reasonable possibility that it will occur in the particular type of product being processed in the absence of those controls.

12.3.5 The HACCP Plan

Every processor should have and implement a written HACCP plan whenever a hazard analysis reveals one or more food safety hazards that are reasonably likely to occur. A HACCP plan should be specific to:

1. Each location where products are processed by that processor; and
2. Each kind of product processed by the processor.

The plan may group kinds of products together, or group kinds of production methods together, if the food safety hazards, critical control points, critical limits, and procedures required to be identified and performed are identical for all products so grouped or for all production methods so grouped.

12.3.5.1 The Contents of the HACCP Plan. The HACCP plan should, at a minimum do the following.

1. List the food safety hazards that are reasonably likely to occur, as identified, and that thus must be controlled for each product. Consideration should be given to whether any food safety hazards are reasonably likely to occur as a result of the following: natural toxins; microbiological contamination; chemical contamination; pesticides; drug residues; decomposition in products where a food safety hazard has been associated with decomposition; parasites, where the processor has knowledge that the parasite-containing product will be consumed without a process sufficient to kill the parasites; unapproved use of direct or indirect food or color additives; and physical hazards.
2. List the critical control points for each of the identified food safety hazards, including as appropriate: critical control points designed to control food safety hazards that could be introduced in the processing plant environment; and critical control points designed to control food safety hazards introduced outside the processing plant environment, including food safety hazards that occur before, during, and after harvest.

3. List the critical limits that must be met at each of the critical control points.
4. List the procedures, and frequency thereof, that will be used to monitor each of the critical control points to ensure compliance with the critical limits.
5. Include any corrective action plans that have been developed to be followed in response to deviations from critical limits at critical control points.
6. List the verification procedures, and frequency thereof, that the processor will use.
7. Provide for a record keeping system that documents the monitoring of the critical control points. The records should contain the actual values and observations obtained during monitoring.

12.3.5.2 Signing and Dating the HACCP Plan. The HACCP plan should be signed and dated

- Either by the most responsible individual on site at the processing facility or by a higher-level official of the processor – this signature should signify that the HACCP plan has been accepted for implementation by the firm;
- Upon initial acceptance; upon any modification; and upon verification of the plan.

12.3.6 Sanitation

Sanitation controls (FDA) may be included in the HACCP plan. However, to the extent that they are otherwise monitored, they need not be included in the HACCP plan.

12.3.7 Implementation

This book is not the proper forum to discuss in detail the implementation of HACCPR. Readers interested in additional information on HACCP should visit the FDA HACCP website at http://vm.cfsan.fda.gov/, which lists all the currently available documents on the subject.

12.4 FDA FOOD CODE

The FDA *Food Code* (the Code) (FDA) is an essential reference that guides retail outlets such as restaurants and grocery stores and institutions such as nursing homes on how to prevent foodborne illness. Local, state, and federal regulators use the FDA *Food Code* as a model to help develop or update their own food safety rules and to be consistent with national food regulatory policy. Also, many of the over one million retail food establishments apply *Food Code* provisions to their own operations. The *Food Code* is updated every two years, to coincide with the biennial meeting of the Conference for Food Protection. The conference is a group of representatives from regulatory agencies at all levels of government, the food industry, academia, and consumer organizations that works to improve food safety at the retail level (FDA). A brief discussion of the Code is provided below. Further information may be obtained from the FDA.

The Code establishes definitions; sets standards for management and personnel, food operations, and equipment and facilities; and provides for food establishment plan review, permit issuance, inspection, employee restriction, and permit suspension. The

Code discusses the good manufacturing practices for equipment, utensils, linens, water, plumbing, waste, physical facilities, poisonous or toxic materials, compliance, and enforcement. The Code also provides guidelines on food establishment inspection, HACCP guidelines, food processing criteria, model forms, guides, and other aids.

Although this guide is designed for retail food protection, more than half of the data included are directly applicable to food processing plants, for example, equipment design (cleanability), CIP system, detergents and sanitizers, refrigeration and freezing storage parameters, water requirements, precautions against "backflow" (air, valve, etc.), personnel health and hygiene, rest rooms and accessories, pest control, storage of toxic chemicals, inspection forms, inspection procedures, and many more.

The Code consists of eight chapters and seven annexes. The annex that covers inspection of a food establishment applies equally as well to both retail food protection and to sanitation in food processing. According to the Code, the components of an inspection would usually include the following elements:

- Introduction;
- Program planning;
- Staff training;
- Conducting the inspection;
- Inspection documentation;
- Inspection report;
- Administrative procedures by the state/local authorities;
- Temperature-measuring devices;
- Calibration procedures;
- HACCP inspection data form;
- Food establishment inspection report;
- FDA electronic inspection system;
- Establishment scoring.

Details of these items will not be discussed here; some are further explored in various chapters in this book (please consult the index for specific topics). Instead, the next two sections trace the history and practices of food establishment inspection and how basic sanitation controls are slowly evolving into the prerequisites for HACCP plans in both retail food protection *and* food processing plants.

12.4.1 Purpose

A principal goal to be achieved by a food establishment inspection is to prevent foodborne disease. Inspection is the primary tool a regulatory agency has for detecting procedures and practices that may be hazardous and for taking actions to correct deficiencies. Laws and ordinances based on the *Food Code* provide inspectors with science-based rules for food safety. The *Food Code* provides regulatory agencies with guidance on planning, scheduling, conducting, and evaluating inspections. It supports programs by providing recommendations for training and equipping the inspection staff, and attempts to enhance the effectiveness of inspections by stressing the importance of communication

and information exchange during regulatory visits. Inspections aid the food-service industry in the following ways.

1. Serving as educational sessions on specific Code requirements as they apply to an establishment and its operation;
2. Conveying new food safety information to establishment management and providing an opportunity for management to ask questions about general food safety matters; and
3. Providing a written report to the establishment's permit holder or person in charge so that the responsible person can bring the establishment into conformance with the Code.

12.4.2 Current Applications of HACCP

Inspections have been a part of food safety regulatory activities since the earliest days of public health. Traditionally, inspections have focused primarily on sanitation. Each inspection is unique in terms of the establishment's management, personnel, menu, recipes, operations, size, population served, and many other considerations.

Changes to the traditional inspection process were first suggested in the 1970s. The terms "traditional" or "routine" inspection have been used to describe periodic inspections conducted as part of an ongoing regulatory scheme. A full range of approaches was tried and many were successful in managing a transition to a new inspection philosophy and format. During the 1980s, many progressive jurisdictions started employing the HACCP approach to refocus their inspections. The term "HACCP approach" inspection is used to describe an inspection using the "Hazard Analysis and Critical Control Point" concept. Food safety is the primary focus of a HACCP approach inspection. One lesson learned was that good communication skills on the part of the person conducting an inspection are essential.

FDA has taught thousands of state and local inspectors the principles and applications of HACCP since the 1980s. The State Training Branch and the FDA Regional Food Specialists have provided two-day to week-long courses on the scientific principles on which HACCP is based, the practical application of these principles including field exercises, and reviews of case studies. State and local jurisdictions have also offered many training opportunities for HACCP.

A recent review of state and local retail food protection agencies shows that HACCP is being applied in the following ways.

1. *Formal Studies* – An inspector is trained in HACCP and is using the concepts to study food hazards in establishments. These studies actually follow foods from delivery to service and involve the write-up of data obtained (flow charts, cooling curves, etc.).
2. *Routine Use* – State has personnel trained in HACCP and is using the hazard analysis concepts to more effectively discover hazards during routine inspections.
3. *Consultation* – HACCP-trained personnel are consulting with industry and assisting them in designing and implementing internal HACCP systems and plans.
4. *Alternative Use* – Jurisdiction has used HACCP to change inspection forms or regulations.

5. *Risk-Based* – Jurisdiction has prioritized the inventory of establishments and set inspection frequency using a hazard assessment.
6. *Training* – Jurisdiction is in the active process of training inspectors in the HACCP concepts.

Personnel of every sort of food establishment should have one or several copies of the *Food Code* readily available for frequent consultation.

12.5 APPLICATIONS

The sanitary requirements in the CGMPR and the *Food Code* serve as the framework for the chapters in this book. The HACCPR will be touched on when they help to clarify the discussion. Essentially, this book shows how to implement the umbrella regulations provided under the CGMPR. Each chapter handles one aspect of these complicated regulations. Most chapters discuss the regulations applicable to all types of food products being processed. Several chapters concentrate on the sanitary requirements from the perspectives of the processing of a specific category of food.

13.1 INTRODUCTION

All information in this chapter has been modified from several public documents available at the website of the U.S. Food and Drug Administration (FDA). The discussion resembles the format of teacher–student. The supervisor is describing the procedures to the inspection personnel. The objective of the presentation in this chapter is to assist the plant operation manager of a food company to become familiar with a food processing establishment inspection routinely conducted by the federal agency, FDA.

Food plant inspections are conducted to evaluate the methods, facilities, and controls used in manufacturing, storage, and distribution of foods. The general approach is as follows. Before undertaking an inspection some preparation should be carried out.

13.1.1 Preparation

1. Review the files of the firm to be inspected and acquaint yourself with the firm's history, related firms, trade marks, practices, and products. The review will identify products difficult to manufacture, that require special handling, special processes, or techniques, and hours of operation, which is especially important in bacteriological inspections. Remove, for subsequent investigations and discussion with management, Complaint/Injury Reports, which are marked for follow-up during the next inspection.
2. Become familiar with current programs relating to the particular food or industry involved.
3. Review and become familiar with the various parts of 21 CFR pertaining to foods, especially those of special significance to the firms being inspected.

13.1.2 Food Registration

The Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (the Bioterrorism Act) requires most domestic and foreign facilities that manufacture/process, pack, or hold food for human or animal consumption in the United States to register with the FDA. The Bioterrorism Act covers both interstate and intrastate firms. The regulations are codified at 21 CFR 1 Subpart H–Registration of Food Facilities. Registrations will be maintained in the FDA Unified Registration and Listing System (FURLS). Facilities are not considered to be registered until their information is entered into FURLS.

13.2 PERSONNEL

Obtain the full name and titles of the following individuals:

1. Owners, partners, or officers;
2. Other management officials or individuals supplying information;
3. Individuals refusing to supply information or permit inspection;
4. Individuals with whom inspectional findings were discussed or recommendations made.

Regulations require that plant management take all reasonable measures and precautions to assure control of communicable disease, employee cleanliness, appropriate training of key personnel, and compliance by all personnel with all requirements of FDA.

Determine if adequate supervision is provided for critical operations where violations are likely to occur if tasks are improperly performed.

13.2.1 Employees

Improper employee habits may contribute to violative practices in an otherwise satisfactory plant. Do the following:

1. Observe the attitude and actions of employees during all phases of the inspection.
2. Observe employees at their work stations and determine their duties or work functions.
3. Note whether employees are neatly and cleanly dressed and whether they wear head coverings that properly cover their hair.
4. Determine if employees working with the product have obvious colds, or infected sores, cuts, and so on. Under no circumstance should you swab a sore, touch, or remove a bandage from an employee in an attempt to obtain bacteriological data. To do so is a violation of personal privacy, possibly hazardous to you and/or the employee, and usually provides few useful data.
5. Note whether employees eat while on duty.
6. Observe and record insanitary employee practices or actions showing employees handling or touching unsanitized or dirty surfaces and then contacting food products or direct food-contact surfaces. Such practices might include employees spitting, handling garbage, placing their hands in or near their mouths, cleaning drains, handling dirty containers, and so on, and then handling food product without washing and sanitizing their hands.
7. Observe whether employees comply with plant rules such as, "No smoking", "Keep doors closed", "Wash hands before returning to work", and so on.
8. Be alert to employees handling insanitary objects, then quickly dipping their hands in sanitizing solutions without first washing them. Depending upon the amount and type of filth deposited on the hands during the handling of insanitary objects, such attempts at sanitizing are questionable at best. Sanitizers work most effectively on hands that have first been cleaned by washing with soap and water.
9. Conversations with employees doing work may provide information on both current and past objectionable practices, conditions, and circumstances. These should be recorded in your notes.
10. Where appropriate, determine employee education and training. Also determine type, duration, and adequacy of firm's training programs, if any, to prepare employees for their positions and to maintain their skills.

13.3 PLANTS AND GROUNDS

13.3.1 Environment

Observe the general nature of the neighborhood in which the firm is located. Environmental factors such as proximity to swamps, rivers, wharves, city dumps, and so on, may contribute to rodent, bird, insect, or other sanitation problems.

13.3.2 Plant Construction, Design, and Maintenance

Determine the approximate size and type of building housing the firm and whether it is suitable in size, construction, and design to facilitate maintenance and sanitary operations. Check placement of equipment, storage of materials, lighting, ventilation, and placement of partitions and screening to eliminate product contamination by bacteria, birds, vermin, and so on. Determine any construction defects or other conditions such as broken windows, cracked floor boards, sagging doors, and so on, which may permit animal entry or harborage.

Determine who is responsible for buildings and grounds maintenance. Many facilities such as docks, wharves, or other premises are owned and maintained by other firms, municipalities, or individuals for lease for manufacturing operations. Determine who is legally responsible for repairs, maintenance, rodent proofing, screening, and so on. Evaluate the firm's attitude toward maintenance and cleaning operations.

Inspect toilet facilities for cleanliness, adequate supplies of toilet paper, soap, towels, hot and cold water, and hand-washing signs. Check if hand-washing facilities are hidden, or if they are located where supervisory personnel can police hand washing.

13.3.3 Waste Disposal

Waste and garbage disposal poses a problem in all food plants depending upon plant location and municipal facilities available.

Check the effectiveness of waste disposal on the premises and ensure it does not cause violative conditions or contribute toward contamination of the finished products. Check for in-plant contamination of equipment and/or product, and whether its water is supplied from nearby streams, springs, lakes, or wells. Suspected dumping of sewage effluent into nearby streams, lakes, or bay waters near water intakes can be documented by color photographs and water-soluble fluorescein sodium of dye. Place approximately two ounces of dye, which yields a yellowish red color, into the firm's waste system and/or toilets, as applicable, and flush the system. The discharge area of the effluent becomes readily visible by a yellowish-red color on the surface of the water as the dye reaches it. Color photographs should be taken.

Determine collecting or flushing methods used to remove waste from operating areas. If water is used, determine if it is recirculated and thus may contaminate equipment or materials. Determine the disposition of waste materials that should not be used as human food, such as rancid nuts, juice from decomposed tomatoes. Determine the disposition of waste, garbage, and so on, that contain pesticide residues. Determine how this is segregated from waste material that contains no residues and that may be used for animal feed.

13.3.4 Plant Services

If applicable, check steam generators for capacity and demand. Demand may reach or exceed the rated capacity, which could effect adequacy of the process. Check boiler water additives if steam comes into direct contact with foods. Check central compressed air supply for effective removal of moisture (condensate) and oil. Determine if any undrained loops in the supply line exist where condensate can accumulate and become contaminated with foreign material or microorganisms.

13.4 RAW MATERIALS

General observations:

1. List in a general way the nature of raw materials on hand. Itemize and describe those that are unusual to you, or are involved in a suspected violation (copy quantity of contents and ingredient statements, codes, name of manufacturer or distributor, and so on).
2. Be alert for additives and preservatives.
3. Evaluate the storage of materials.
4. Determine the general storage pattern, stock rotation, and general housekeeping. Materials should be stored so they are accessible for inspection. Thoroughly check ceilings, walls, ledges, and floors in raw material storage areas for evidence of rodent of insect infestation, water dripping, or other adverse conditions.

Study the firm's handling procedure as follows:

1. Determine if growing conditions relative to disease, insects, and weather are affecting the raw material.
2. Check measures taken for protection against insect or rodent damage.
3. Raw materials may be susceptible to decomposition, bruising, or damage, for example, soft vegetables and fruits delivered in truckload lots. Determine the holding times of materials subject to progressive decomposition.
4. Evaluate the firm's acceptance examination and inspection practices, including washing and disposition of rejected lots. Where indicated, examine rejected lots and collect appropriate samples and report consignees.
5. Determine the general acceptability of raw materials for their intended use and their effect on the finished product. Raw stocks of fruits or vegetables may contribute decomposed or filthy material to the finished product.
6. Be alert for use of low-quality or salvage raw materials.
7. Check bags, bales, cases, and other types of raw material containers to determine signs of abnormal conditions, indicating presence of filthy, putrid, or decomposed items.
8. Check any indication of gnawed or otherwise damaged containers, to ascertain if material is violative.
9. Be alert to contamination of raw materials by infested or contaminated railroad cars or other carriers.
10. Document by photographs, exhibits, or sketches any instances where insanitary storage or handling conditions exist.
11. Determine whether the firm is aware of this publication and whether or not they comply.

13.5 EQUIPMENT AND UTENSILS

By arriving before processing begins, you are able to evaluate conditions and practices not otherwise observable before plant start-up. This includes adequacy of clean-up, where and how equipment is stored while not in use, how hand sanitizing solutions and food batches

are prepared, and if personnel sanitize their hands and equipment before beginning work. The following are some guidelines.

1. Dirty or improperly cleaned equipment and utensils may be the focal point for filth or bacterial contamination of the finished product. Examine all equipment for suitability and accessibility for cleaning. Determine if equipment is constructed or covered to protect contents from dust and environmental contamination. Open inspection ports to check inside only when this can be done safely. Notice whether inspection ports have been painted over or permanently sealed.
2. Observe the firm's filtering systems and evaluate the cleaning methods (or replacement intervals of disposable filters) and schedules. Check types of filters used. There have been instances where firms have relied on household-furnace-type-filters.
3. Check the sanitary condition of all machinery. Determine if equipment is cleaned prior to each use and the method of cleaning. If the firm rents or leases equipment on a short-term basis, report prior cleaning procedures. Equipment may have been used for pesticides, chemicals, drugs, and so on, prior to being installed, and could therefore be a source of cross-contamination.
4. Inspect conveyor belts for build-up of residual materials and pockets of residue in corners and under belts. Look in inspection ports and hard-to-reach places inside, around, underneath, and behind equipment and machinery for evidence of filth, insects, and/or rodent contamination. Chutes and conveyor ducts may appear satisfactory, but a rap on them with the heel of your hand or a rubber mallet may dislodge static material, which can be examined. Review procedure on taking in-line sample subs.
5. Determine how brushes, scrapers, brooms, and other items used during processing or on product contact surfaces are cleaned, sanitized, and stored. Evaluate the effectiveness of the practices observed.
6. Be alert for improper placement or inadequately protected mercury switches, mercury thermometers, or electric bulbs. Breakage of these could spray mercury and glass particles onto materials or into processing machinery.
7. If firm is using UV lamps for bacteria control, check if it has and uses any method or meters to check the strength of UV emissions. If so, obtain methods, procedures, type of equipment used, and schedule for replacement of weak UV bulbs.
8. In plants where chlorine solution is piped, check on the type of pipe used. Fiberglass reinforced epoxy pipe has been observed to erode inside through the action of the chlorine solution. This poses a threat of contamination from exposed glass fibers. Pipes made with polyester resin do not deteriorate from this solution.
9. Observe sanitizing practices throughout the plant and evaluate their effectiveness, degree of supervision exercised, strength, time, and methods of use of sanitizing agents. Determine the use, or absence of, sanitizing solutions both for sanitizing equipment and utensils as well as for hand dipping. If chlorine is used, 50–200 ppm should be used for equipment and utensils; a 100 ppm solution will suffice for hand-dipping solutions. Sanitizing solutions rapidly lose strength with the addition of organic material. The strength of the solution should be checked several times during the inspection.

13.6 MANUFACTURING PROCESS

Where helpful, to describe equipment and processes, draw flow plans or diagrams to show movement of materials through the plant. Generally, a brief description of each step in the process is sufficient. List all quality control activities for each step in the process and identify Critical Control Points. Provide a full description when necessary to describe and document objectionable conditions, or where the assignment specifically requests it.

Observe whether hands and equipment are washed or sanitized after contact with unsanitized surfaces, for example; in the following situations:

1. Workers do general work, then handle the product;
2. Containers contact the floor, then are nested or otherwise contact product or table surfaces;
3. Workers use common or dirty cloths or clothing for wiping hands;
4. Product falls on a dirty floor or a floor subject to outside foot traffic and is returned to the production line.

Be alert for optimum moisture, time, and temperature conditions conducive to bacterial growth. In industries where scrap portions of the product are reused or reworked into the process (e.g., candy and macaroni products), observe the methods used in the reworking and evaluate from a bacteriological standpoint. Reworking procedures such as soaking of macaroni or noodle scrap to soften, or hand kneading of scrap material, offers an excellent seeding medium for bacteria.

When a product is processed in a manner that destroys microorganisms, note whether there are any routes of recontamination from the "raw" to the processed product (e.g., dusts, common equipment, hands, flies, and so on).

13.6.1 Ingredient Handling

Use the following guide lines:

1. Observe the method of adding ingredients to the process. Filth may be added into the process stream from dust, rodent excreta pellets, debris, and so on, adhering to the surface of ingredient containers.
2. Evaluate the effectiveness of cleaning and inspectional operations performed on the materials prior to or while adding to the process.
3. Determine specific trimming or sorting operations on low-quality or questionable material.
4. Observe and report any significant lags during the process or between completion of final process and final shipping. For example, excessive delay between packing and freezing may be a factor in production of a violative product.

13.6.2 Formulas

Laws and regulations do not specifically require management to furnish formula information in food manufacturing, except for infant formulas. Nonetheless, they should be

requested particularly when necessary to document violations of standards, labeling, or color and food additives. Management may provide the qualitative formula but refuse the quantitative formula.

If formula information is refused, attempt to reconstruct the formula by observing:

1. Product in production;
2. Batch cards or formula sheets;
3. Raw materials and their location.

13.6.3 Food Additives

Be familiar with FDA's food additives program for instructions on conducting establishment inspections of firms manufacturing food additive chemicals. When making food plant inspections, direct your evaluation of food additives only to those instances of significant violation or gross misuse. Routine inspectional coverage will be directed primarily to the following two types of additives:

1. Unauthorized and illegal as listed in the FDA's Food Additives Status List (safrole, thiourea, and so on); and
2. Restricted as to amount in finished food.

Because of special problems, exclude the following additives from coverage during routine inspections:

1. Packaging materials;
2. Waxes and chemicals applied to fresh fruit and vegetables;
3. Synthetic flavors and flavoring components except those banned by regulations or policy statements (these products will be covered under other programs); and
4. Food additives in feeds (these products will be covered under other programs).

The Food Additives Status List (FASL) contains an alphabetical listing of substances that may be added directly to foods or feeds and their status under the Food Additives Amendment and Food Standards. In addition, a few unauthorized or illegal substances are included. Review this document. You may encounter substances not included in FASL. Such substances will include

1. Obviously safe substances not on the list of items generally recognized as safe (GRAS) that are not published in the regulations, for example, salt, cane sugar, corn syrup, vinegar;
2. Synthetic flavoring substances, because of their indefinite status;
3. Substances pending administrative determination;
4. Substances granted prior sanction for specific use prior to enactment of the Food Additives Amendment.

Give primary attention to unauthorized substances. Document and calculate levels of restricted-use additives in finished food only where gross misuse or program violations are suspected.

1. List ingredients, which may be restricted substances or food additives, and determine their status by referring to the current FASL. Report complete labeling on containers of these substances.
2. Obtain the quantitative formula for the finished product in question.
3. Determine the total batch weight by converting all ingredients to common units.
4. Calculate the theoretical levels in the final product of all restricted or unauthorized ingredients from the formula by using the Food Additives Nomographs.
5. Determine the probable level of restricted ingredients by observing the weight of each ingredient actually put into the batch.

13.6.4 Color Additives

Evaluate the status of all colors observed during each food establishment inspection by using FDA's Color Additives Status List (CASL). The list provides the current status and use limitations of most colors likely to be found in food, drug, device, or cosmetic establishments. Review the document.

Stocks of delisted and uncertified colors may be found in the possession of manufacturers where there is no evidence of misuse. Advise the firm of the status of these colors. If management wishes to voluntarily destroy such colors, witness the destruction. If the firm declines to destroy the colors, determine what disposition is planned, for example, use in nonfood products.

Where decertified or restricted-use colors are used in manufacturing food products, proceed as follows:

1. Collect an Official Sample consisting of the color and the article in which it is being used. Make every effort to collect interstate shipments of the adulterated product before attempting to develop a case for the court. When regulatory action is an alternative, obtain sufficient interstate records to cover both the color and the basic ingredients of the manufactured product. Refer to "Sampling Schedule for Color Containing Products" for guidance.
2. Document the use of decertified colors after the decertifying date. Documentation should include batch formula cards, employee statements, code marks indicating date of manufacture, color certification number, and so on. The presence of color in the finished product will be confirmed by your servicing laboratory.

13.6.5 Quality Control

The objective of quality control is to ensure the maintenance of proper standards in manufactured goods, especially by periodic random inspection of the product. Your inspection should determine if the firm's quality control system accomplishes its intended purpose. Establish responsibility for specific operations in the control system. Determine which controls are critical for the safety of the finished product.

13.6.5.1 Inspection System

1. Determine what inspectional control is exercised over both raw materials and the processing steps. Such inspection may vary from simple visual or other organoleptic examination to elaborate mechanical manipulation.
2. Determine what inspection equipment is used, that is, inspection belts, sorting belts, grading tables, ultraviolet lights, and so on. Ascertain its effectiveness, maintenance, or adjustment schedules.
3. Where indicated, determine the name of the manufacturer of any mechanical inspection device and the principles of its operation.
4. Evaluate the effectiveness of the personnel assigned to inspection operations. Determine if the inspection belts or pick-out stations are adequately staffed and supervised.
5. Determine the disposition of waste materials that are unfit for food or feed purposes.

13.6.5.2 Laboratory Tests

1. Describe routine tests or examinations performed by the firm's laboratory and the records maintained by the firm.
2. Determine what equipment is available in the laboratory and if it is adequate for the purpose intended. If the firm uses a consulting laboratory, determine what tests are performed and how often.
3. Review laboratory records for the period immediately preceding the inspection.

13.6.5.3 Manufacturing Code System

1. Obtain a complete description of the coding system with any necessary keys for interpretation.
2. Provide an example by illustrating the code being used at the time of the inspection (see 21 CFR 113.60(c) and 114.80(b)).
3. Report coding systems that require the use of UV light for visibility.
4. Hermetically sealed containers of low-acid processed food must be coded in a manner clearly visible (see 21 CFR 113.60).
5. Check 21 CFR 113 and 114 for regulations on coding for the type of plant you are inspecting.

13.6.6 Packaging and Labeling

1. Evaluate storage of packaging materials including protection from contamination by rodents, insects, toxic chemicals, or other materials.
2. Appraise the manner in which containers are handled and delivered to the filling areas.
3. Determine if there is likelihood of chipping of glass or denting, puncturing, tearing, and so on, of packaging materials.
4. Observe the preparation of containers prior to filling. Consider any washing, steaming, or other cleaning process for effectiveness.
5. Determine, in detail, the use of air pressure or other cleaning devices.

13.6.6.1 Quantity of Contents. If slack fill is suspected, weigh a representative number of finished packages. See guidelines for net weight procedure. Sets of official weights are available in the servicing laboratory. These may be used to check the accuracy of a firm's weighing equipment.

13.6.6.2 Labeling

1. Check the sanitary condition of labelers and equipment feeding cans to, and away from, the labeler. Determine if old product is present on any equipment that touches the can end seams, in the presence of moisture carryover from the can cooling operation.
2. Check availability of floor drains in the labeling area. Absence of floor drains could indicate infrequent cleaning of the equipment unless it is physically moved to another area for cleaning.
3. Determine what labels are used and what labeling is prepared or used to accompany or promote the product. Obtain specimens of representative labels and labeling including pamphlets, booklets, and other promotional material.

13.6.6.3 Nutritional Labeling. See document "Guide to Nutritional Labeling and Education Act (NLEA) Requirements" for guidance.

14.1 INTRODUCTION

In the food manufacturing industries, the baking industry is one of the most stable sectors (Liberopoulos and Tsarouhas 2005). Bread and bakery product development has a long history. The most recent archeological discovery indicated that baking might date back to as early as around 21,000 B.C. (Piperno and others 2004), when people knew wheat and learned to mix wheatgrain meal with water and bake it on stones heated by fire – the first flat bread. During the period 2600 to 3000 B.C., yeast was used by ancient Egyptians to make fermented bread. Due to the high cost of milling, wholewheat and wholegrain bread was generally consumed. White bread was also available, but limited only to groups of rich people. Since the 1900s, white bread has become common for everyone. However, there has recently been a reverse trend, where wholewheat and wholegrain bread has become more expensive than white bread, due to health concerns. Meanwhile, technological advances have enabled wholemeal bread to be developed to become both nutritious and tasty (www.breadinfo.com/history.shtml). Cake, meanwhile, has been developed since the discovery of flour. At the beginning, yeast was used as a raising agent for cake. It was then replaced by eggs in the middle of the eighteenth century (whatscookingamerica.net/History/CakeHistory.htm; www.themediadrome.com/content/articles/food_articles/cake_ history.htm). Conventionally, cake was defined as a flour-based sweet food, whereas bread was defined as flour-based nonsweet food. In addition, the word "cake" was used for small bread. Cake was normally made from expensive ingredients, therefore it was specially made for certain occasions (whatscookingamerica.net/History/CakeHistory.htm). From culinary historians, we learn that cake batter was once used for the purpose of oven temperature testing. As a result, a new product was created and called "biscuit" (in the United Kingdom) or "cookie" (in the United States). That is why biscuit was originally described as a flour-based sweet cake. It can be either crispy or soft. Around 1600, people started traveling to discover the world. As biscuit has a much longer shelf-life, it was ideal for use as a food for travelers (whatscookingamerica.net/History/CookieHistory.htm).

In earlier days, the bakery business started in small bakeries with large varieties of products in every village. Later, the small bakeries were replaced with industrial mono-production, particularly for bread. This was mainly because bread could then be produced efficiently. Therefore, the key for success is productivity (Decock and Cappelle 2005). Typically, a modern-day production line is composed of several workstations integrated into an automatic system using common transfer mechanisms and control systems. The nominal production rate can be determined from the bottleneck workstation, which is almost always a baking oven (Liberopoulos and Tsarouhas 2005). Decock and Cappelle (2005) found that the consequence of evolution of the bakery business was a decreased interest in bread flavor from a long fermentation process. In contrast, artisan bakeries and specialty bread from all over the world became more interesting to consumers. Moreover, issues related to health have become

more of a concern. The effect of information on dietary fiber has been studied. In Australia, it was found that the likelihood of the consumption of white products including bread and English muffins could be enhanced by a label claiming "high in fiber" (Mialon and others 2002). According to an annual survey of manufacturers in 2001, the total value of the manufacturing of bread and bakery products in the United States was US$31.2 billion including retail bakeries (US$2.5 billion), commercial bakeries (US$25.7 billion), and frozen products and other pastries (US$3.0 billion) (Liberopoulos and Tsarouhas 2005). Meanwhile, according to the Euromonitor International sources, the total global market value of bread and bakery products stood at US$311.1 billion in 2005, representing a 7.32% increase from 2004.

14.2 PRODUCT CHARACTERISTICS

14.2.1 Bread

Bread is a product consisting of two distinctly different parts: crust and crumb. Crust is a dry and crispy surface layer, and the crumb inside bread loaves or buns is soft. To produce a soft and fine crumb, bread dough requires the proper development of a gluten network during dough mixing. Varieties of bread differ in size, shape, color, texture, and flavor. They contain different ingredients and may also be baked under significantly different conditions. Bread can either be broadly classified as leavened and unleavened, depending on the present or absence of leavening agents in dough, or be classified as yeast bread and quick bread (Zhou and Therdthai 2006).

Sourdough bread is a traditional bread with natural flavor developed by yeast (commercially *Saccharomyces cerevisiae*) and lactic acid bacteria (mostly *Lactobacillus* genus). It has an acidic sharp taste. Compared to normal bread, the addition of lactic acid bacteria can slow down the staling rate during bread storage (Gul and others 2005). The ratio of lactic acid to acetic acid is also an important factor. Corsetti and others (1998) found that a high ratio of lactic acid to acetic acid could reduce the staling rate as well as increase volume expansion. To obtain the highest quality sourdough, the interaction between yeast and lactic acid bacteria therefore has to be clearly understood. Gul and others (2005) found that a mixture of 1.5% *Saccharomyces cerevisiae* and 1.5% *Lactobacillus amylophilus* could produce dough and bread with the best quality attributes including yield, specific volume, and harness. However, a sensory evaluation revealed that consumers preferred sourdough bread made from a mixture of 1.5% *Saccharomyces cerevisiae* and 1.5% *Lactobacillus sake*.

14.2.2 Cake

Cake is made by the formation of a batter, which is a complex emulsion and foam system with an appreciable amount of bubbles inside. The required ingredients are similar to bread dough, except weak wheat flour is needed. A gluten network is not required for cake because it would make the cake firmer and chewier. The ratio of water to flour to make a cake batter is high, compared to that in bread dough. Therefore, one of the important rheological properties of cake batter is its low viscosity.

Eggs are normally among the ingredients for cake, and the egg protein acts as a surface active agent to form a protective film around air bubbles. This helps to keep the air bubbles in the batter during mixing. The mixing process is ended when there are enough air bubbles kept in the batter and the density of the batter reaches its minimum. To keep the product fresh for longer, oil or fat solid is needed. With the addition of oil/fat, the

batter becomes an oil-in-water emulsion system. Due to the positive effect of soluble solids on the starch gelatinization temperature, the ratio of water to soluble solids, especially sucrose, is one of the key factors for cake making. Recently, computer programs have been introduced for designing balanced ingredients to create different cake recipes (Cauvain and Young 2000).

14.2.3 Biscuit

Biscuit is a low-moisture bakery product. According to the information provided by various manufacturers, its moisture content varies widely, because of the variation in its thickness and weight during forming and shaping (Cronin and Preis 2000). Typically, the moisture content of biscuit after baking is below 10%. Therefore, water addition to biscuit dough is lower compared to other bakery products. The size of the biscuit after baking is affected by the rheological properties of the dough. For sweet biscuit that contains high levels of sugar and fat, the dough has good cohesiveness and plasticity without the formation of a gluten network (Gallagher and others 2003a). Therefore, short dough can be made from soft wheat flour with a high amount of sugar (25–55%) and shortening (20–60%) (Baltsavias and others 1999).

Using the preference mapping technique, Martinez and others (2002) found that four characteristics are mainly responsible for the consumer acceptance of the cracker type of biscuits, including appearance, aroma and flavor, texture and overall acceptability.

A typical defect of biscuit is cracking or checking, as a result of the moisture gradient in the product after baking. The moisture content of freshly baked biscuit is high in the center and low at the edge. Therefore, moisture migrates from the centre to the edge, which causes an expansion at the edge, but a contraction at the centre. Subsequently, stress is developed and when it exceeds a critical level, crack may occur (Saleem and others 2005).

14.2.4 Others

Besides the major bakery products described above, there are also numerous other types of bakery products, including pastries, pizzas, breakfast cereals, and so on. Other than wheat flour, many bakery products are also made from other cereal flours, such as barley, rye, corn, soy, rice, and oats.

Pastry products are characteristically flaky, tender, crisp, and slightly browned. Pastry can be classified into two types: plain pastry and puff pastry. Plain pastry is used mainly for pie crust, and puff pastry is primarily found in desserts such as Napoleons, patty shells, tarts, and cream horns. The proportion of fat is probably the most important determinant of quality in pastry, especially in creating flakiness. As little water as possible should be added to the pastry dough, because too much water will cause shrinkage and a tougher crust from excess gluten development (Brown 2004).

Breakfast cereals in today's context are ready-to-eat (RTE) cereals. They are cereal grains processed in ways that make them suitable for human consumption. They are made from various grains and in many forms, including flakes, shredded shapes, gun puffed shapes, extruded shapes, and so on. The products are often fortified with vitamins and minerals. In making breakfast cereals, slurry, rather than dough, is often made first by blending the dry ingredients with liquid ingredients, followed by cooking, drying/roasting (i.e., baking), tempering, and forming (Fast 2001). It is worth noting that baking might not be part of the process for making some breakfast cereals, therefore it may not be appropriate to classify all breakfast cereals as bakery products.

14.3 INGREDIENTS AND THEIR IMPACT ON PRODUCT QUALITY

14.3.1 Flour

The major constituents of wheat flour are starch (65–75%) and proteins (7–16%). Starch consists of mainly amylose and amylopectin. In dough, starch is present as semicrystalline granules that absorb a significant amount of water and may act as filler in the continuous protein network, or may form a complex network with the proteins. During baking, the starch granules gelatinize, which is a major part of the solidification process of the dough. The gelatinization starts at 55°C and finishes at 85°C when water evaporation at the surface dominates (Engelsen and others 2001). A series of processes at a molecular scale include swelling, melting, disruption of starch granules, and exudation of amylose. In bread, as a result of starch gelatinization, the partially swollen granules can be stretched into elongated forms to allow gas cells to expand. Therefore, texture and structure of the product is dependent on starch gelatinization (Therdthai and Zhou 2003).

Quality of flour in terms of protein content has been found to be a key factor influencing bakery product quality. Wheat flour contains some specific proteins such as glutenins, and gliadins, which can absorb water and form gluten. Sliwinski and others (2004) found a positive correlation between gluten, content and bread volume, due to the gluten's key role in building up a dough structure to retain gas inside the dough. Gas retention capacity varies depending on the rheological properties of dough, such as viscosity and extensibility (Kokelaar and others 1996). For uniaxial extension, wheat flour with higher protein content had higher elongation extensibility. High dough viscosity could prevent ascent of gas cells, whereas high extensibility could prevent coalescence and thereby premature fracture of membranes between gas cells. With high dough strength, the expansion of gas cells during proving and baking could be limited (Sliwinski and others 2004). Freeze-dried gluten could increase water addition, dough resistance, and water-holding capacity, as well as reduce the firmness of the bread bun. Wet, freshly extracted gluten could improve the texture of bread, but the extraction needs to be carried out every time the gluten is needed, which is necessary for keeping the gluten's good functional characteristics including the rate of water absorption and the degree of viscoelasticity (Esteller and others 2005).

14.3.2 Water

Water is one of the main ingredients of bakery products. It influences the formation of dough and batter and therefore the textural properties of baked products. Water is needed for hydrating the proteins, therefore developing the gluten, gelatinizing the starch, making the leavening agents function, activating the enzymes, dissolving sugar and salt, as well as acting as a major heat transfer mechanism during bread baking through evaporation and condensation.

The optimum amount of water addition is dependant on the required viscosity and product characteristics. Sliwinski and others (2004) stated that puff pastry dough requires lower water addition than bread dough. For baguette, high water addition is needed together with soft dough consistency to develop an open cell structure. In general, too little water addition leads to high viscosity, therefore the dough shape is not flexible during dividing and molding. On the other hand, too much water makes viscosity low, and dough might not be able to retain its shape during proving. However, the problem is not significant with pan-proving dough. In addition to product characteristics, dough-making process also varies the requirement on water addition. For a bread dough-making process with 1 h bulk

fermentation, 57% water may be added. When the fermentation becomes longer, at 4 h, the water addition should be reduced to 55%. For the no-time dough making in the Chorleywood Breadmaking Process (CBP), water can be added up to 60%. Extra 2% water may be added when partial vacuum is applied during mixing (Cauvain and Young 2000).

14.3.3 Fat

Fat functions to reduce dough viscosity and relaxation time, through coating the flour particles and preventing the formation of gluten. This provides a shortness character to the products, that is, a soft, pleasant, and crumbly texture.

Biscuit with a high fat content has a friable structure (Maache-Rezzoug and others 1998a). In addition, Chevallier and others (2000) stated that fat could delay the effect of chemical leavening agents. In cake batter, addition of oil or fat decreases the foam-stabilizing properties of egg and hydration of flour protein (Cauvain and Young 2000). To reduce the fat content in bakery products, protein-based fat replacers (e.g., Simplesse®) can be used (Gallagher and others 2003a).

14.3.4 Sugar

Similarly to fat, sugar also functions to reduce dough viscosity and relaxation time (Maache-Rezzoug and others 1998a), as well as to delay the effect of chemical leavening agents during baking (Chevallier and others 2000). Biscuit with a high sugar content contains a cohesive structure and crisp texture (Maache-Rezzoug and others 1998a). Moreover, sugar could increase the temperature of the starch phase transition (Chevallier and others 2000). To reduce the sugar content in bakery products, sugar replacers might be used. Gallagher and others (2003b) found that fructooligosaccharide could replace sugar at low (20%) and medium levels (25%) but still maintain the snapping characteristics of short dough biscuits.

14.3.5 Salt

Salt is added into dough not only to be a seasoning or flavor enhancer, but also to strengthen the gluten structure. However, it also inhibits yeast growth. It can be used for controlling fermentation (Gisslen 1994). Gianotti and others (1997) found that salt could be used to control the growth rate of both lactic acid bacteria and yeast. Increasing the salt content can slow down the fermentation, therefore the proving process, whereas decreasing the salt content may cause an overfermentation. In the case of overfermentation, a large amount of sugar would have been used for the yeast growth. As a result, the crust color may not be brown enough (Gisslen 1994).

14.4 PROCESSING STEPS

Generally, the production of bread and bakery products consists of several common steps, including weighing, mixing, proving, baking, cooling, and packaging. Each step plays an important role in achieving high and consistent product quality. In industrial bakeries, flour is stored in silos and transferred to production lines. In production lines, flour and other ingredients are mixed and kneaded to make dough or batter. Then the dough/batter is divided and molded. Some of the bakery products require a fermentation step to develop unique flavor and/or texture prior to the baking step at 180–300°C. The products are then cooled down before packing and delivery. Baking trays and molds are normally cleaned in hot water at 40°C (Kannan and Boie 2003).

14.4.1 Dough Making

All ingredients, including mainly flour, water, leavening agent, fat, and sugar, are weighed in hoppers before being released sequentially into a mixer. Mixing is a process that uses the mechanical action of kneaders and the corresponding energy to mix all ingredients to form a coherent material, that is, dough. There are several dough-making techniques used to modify the rheological characteristics of dough to optimize its gas-retaining properties (Cauvain 1998). During mixing, there is a gradual uptake of water by flour (composed mainly of protein and starch), that is, hydration. During hydration, the protein changes from a hard glassy material to a soft rubbery material through a glass transition. At room temperature (20°C), the glass transition for gluten occurs at about 16% moisture content. The moisture content at which the glass transition occurs increases when temperature decreases. However, it is still within the typical range of the water to flour ratio for breadmaking. Decreasing the dough temperature at the end of mixing produces a firmer dough with less oxidation. Some additional water is needed to adjust the dough consistency. Increasing the dough temperature would speed up the enzymatic activity, yeast fermentation, and proving rate. Moreover, the dough texture becomes softer and less resistant to deformation. A dough-making process with a period of bulk fermentation typically has a dough temperature of 23–26°C, whereas a no-time dough-making process may have a dough temperature of 28–31°C. In order to obtain a suitable dough temperature at the end of mixing, the temperature of the added water has to be controlled (Cauvain and Young 2000).

To increase the rheological characteristics of dough, including elastic recovery, cohesiveness, and/or adhesiveness, the mixing time should be extended. In contrast, the apparent biaxial extensional viscosity and consistency can be increased by shortening the mixing time. According to Sliwinski and others (2004), increasing the mixing time could increase the volume of puff pastry. However, there was no correlation between the mixing time and product volume in the case of bread. For biscuit, increasing the mixing time could soften the dough, reduce the relaxation time, increase the product length, and decrease the product weight (Maache-Rezzoug and others 1998b). Manohar and Rao (1997) found that a long mixing time of 300 s produced biscuit with a dense structure, low crispness, and high breaking and compression strength values. However, a short mixing time of 90 s resulted in a wrinkled surface. Compared to the mixings of 300 s and 90 s, a mixing time of 180 s produced a superior biscuit.

In addition to mixing time, the sequence of ingredients to mix is also important. The arrangement of the sequence may affect the flour hydration behavior and therefore the dough texture. In bread, Cauvain and Young (2000) suggested that salt should be added later in mixing, particularly when a low-speed mixer is used, because salt reduces the amount of water available to hydration and gluten development. In biscuit, the creaming technique (i.e., all ingredients excluding flour and nuts are mixed together first) is used to make a cream mixture for blending with flour at the end of the mixing process. This results in significantly less gluten development, and therefore a soft dough. Maache-Rezzoug and others (1998b) found that dough could be softened by mixing sugar with liquid ingredients before mixing with other dry ingredients, because sugar prevented the hydration of the flour constituents by reducing the water activity of the dough during mixing and therefore inhibited gluten formation.

In the CBP, where the mixing is carried out using a fixed amount of energy input, partial vacuum can be applied towards the end of mixing in order to increase dough water addition. As vacuum makes a dough firmer and drier, extra water is required to maintain the dough consistency (Cauvain and Young 2000). Moreover, the applied vacuum may decrease the average size of bubbles (Cauvain 1998) and the amount of bubble gas by 50% (Marsh 1998) in the dough. Figure 14.1 shows the interior of a Tweedy mixer that is typically used in the CBP.

Figure 14.1 *Interior of a Tweedy mixer (as typically used in the CBP). (Courtesy of APV Baker.)*

14.4.2 Proving

Proving is an important step for bread and other yeasted bakery products that use yeast to produce carbon dioxide through fermentation to increase the dough volume. After the dough-making step, dough is normally proved at 38°C, as yeast is most active within the temperature range of 25–40°C. Proving time is dependent on the yeast level, proving temperature, and humidity. Increasing the yeast level is likely to speed up the proving process (Anon. 1995). Yeast uses sugar as a carbon source for growth. However, too much sugar will damage yeast by an osmotic dehydration mechanism. This is why volume expansion is always a problem for sweet bread bun. Similarly, salt can inhibit yeast growth as described earlier, and too much salt will slow down the proving process. Generally, the yeast used in bakery products is *Saccharomyces cerevisiae*. Various yeast strains have been developed to have different tolerances to osmotic dehydration and therefore suit different types of bread (Linko and others 1997). To achieve the correct relative humidity, steam or hot water can be used to increase the humidity in a proving chamber in order to speed up the process.

14.4.3 Baking

Baking is a complex unit operation involving simultaneous heat and mass transfer mechanisms. Heat is supplied to the dough through radiation, convection, and conduction. Thermal reactions including starch gelatinization and protein denaturation are activated. When temperature increases and protein is denatured, water originally held in the protein network during proving is released. Starch uses this water to form a gel. The physicochemical properties of dough are changed and, as a result, dough is changed and, to a baked product with a porous and rigid structure.

The volume expansion of bakery products during baking is through two different mechanisms. Taking bread as an example, at the early stage of a baking process, the dough volume is expanded mainly due to yeast fermentation. When temperature is increased to around 55°C, yeast would be killed. Once the temperature reaches 60°C, any volume expansion is mainly due to vapor pressure (Fan and others 1999). During baking, heat

from the oven penetrates to the product core by the combined mechanism of conduction, water vapor evaporation, diffusion, and condensation, and water migrates from the product core to the surface by combined evaporation, vapor diffusion, and condensation, as well as liquid diffusion (Therdthai and Zhou 2003). The product volume keeps increasing until a rigid structure is formed and restricts the expansion. The developed crust becomes the main resistance to heat and mass transfer. At the surface of the dry crust, water vapor is transferred by convection under the gradient of pressure (Lostie and others 2002).

In addition to textural and structural changes, color and flavor are developed during baking. When the surface temperature reaches 150°C, browning reactions are activated and therefore the crust color becomes darker. For flavor, volatile compounds are formed and released, which gives the bakery products a uniquely good smell after baking.

To maintain product uniformity and quality consistency, it is necessary to adjust the oven operation from time to time. Such adjustments result in higher cost in terms of time and raw materials. Several researches have been conducted to develop reliable models for simulating the various phenomena during baking (Therdthai and others 2003, 2004a). The simulation can predict the consequence of any change in the operating condition, which may be used to establish the optimal operation conditions for different product varieties. For designing effective process control systems, on-line sensors are needed to collect data and inform a controller in order to regulate the baking condition at a set level. For biscuit baking, color can be monitored from the top of biscuits using a Colorex sensor. The reflection of a light source (D65) is analyzed and converted into an electrical signal (Perrot and others 1996).

A conventional baking oven typically consists of baking chambers and heating elements. Heat is transferred, either directly or indirectly, to dough/bread, through radiation, convection, and conduction. Figure 14.2 shows a direct heating oven. However, new baking ovens have been developed to improve product quality as well as process efficiency. For example, microwave has been introduced to baking ovens to speed up the baking process. Dough is heated up rapidly by the movement of water molecules under the influence of the microwaves. Therefore, the ambient temperature of a microwave baking oven is lower than that of a conventional baking oven. Not only can it save energy, but it also helps to maintain the nutritional value of the baked products. However, surface color might not be fully developed, because the surface temperature is too low and the baking time is too short to complete

Figure 14.2 *A direct heating over. (Courtesy of C. H. Babb Co., Inc.)*

the Maillard browning reactions. Similar problems can occur with starch gelatinization and flavor development (Sumnu 2001). However, these problems may be reduced by integrating conventional baking ovens with microwave (Verboven and others 2003). Recently, impingement ovens have been introduced to industrial baking. Due to the very high velocity in the oven, baking time can be significantly shortened. However, product loss tends to be increased as well (Wählby and others 2000).

14.4.4 Cooling

Baked products have to be cooled down to room temperature in order to avoid condensation after packaging. The most common method for cooling is natural cooling using room air or chilled air. Figure 14.3 shows a natural cooling system. A cooling process can take from a few minutes to a few hours depending on the product characteristics and cooling methods. Using room air, some products such as panetonni, a fermented Italian cake, may need 24 h for cooling. To shorten the cooling process, a vacuum cooler can be used, which cools panetonni within 4 min. This also applies to some other products such as breadsticks, meat pies, sausage rolls, pastries, and cakes, which can be cooled in between 1 and 3 h by conventional cooling, but within only 30 s to 5 min by vacuum cooling (Anon. 1978). With regard to weight loss during cooling, Everington (1993) found 6.8% loss after cooling from 98°C to 30°C by vacuum cooling, but cooling using an air blast cooler caused just 3–5% loss. However, vacuum cooling can cause structural changes due to the build-up of vapor pressure in areas of low vapor permeability. Modulated vacuum coolers may be used to alleviate this problem by modulating pressure, instead of continuous pressure, resulting in controlled vacuum during cooling (Sun and Zheng 2006).

14.5 PACKAGING AND SHELF-LIFE

In terms of shelf-life, bakery products can be divided into two groups: low- and intermediate-moisture products, and high moisture products. Normally, the shelf-life of

Figure 14.3 *A natural cooling system. (Courtesy of Baking Technology Systems, Inc.)*

low- and intermediate-moisture products is limited by physical or chemical spoilage (Smith and others 2004). For low-moisture products such as biscuits, moisture absorption is the main problem, resulting in a product texture changed from crispy to soft. It is affected by the equilibrium of water activity and mass transfer mechanism (Labuza and Hyman 1998). For intermediate moisture products such as bread and cake, the physico-chemical change is normally associated with starch retrogradation. Water distribution among the high-molecular-weight substances such as protein and starch causes the water to transform from strongly bound to weakly bound. Therefore, staling can be observed (Schiraldi and others 1996). Baeva and Panchev (2005) found 16% reduction of bound water in a dietetic sucrose-free cake after storage for 6 days.

The shelf-life of high-moisture products is limited by microbiological spoilage, mainly by yeast and mold. Moreover, some foodborne microbes including *Salmonella* spp., *Listeria monocytogenes*, and *Bacillus cereus* are of concern (Smith and others 2004). Bailey and von Holy (1993) studied *Bacillus* spore contamination on a brown bread production line in a commercial bakery in South Africa. High counts of *Bacillus* spores were obtained mainly from yeast, crumbs of broken loaves, and premix. The spore counts after mixing, baking, and 3 days storage was 2.6 log cfu/g, 2.1 log cfu/g, and 6.4 log cfu/g, respectively. To detect spoilage before it becomes visible, an electronic nose can be applied, which as differentiate spoilage by microorganisms from that by lipoxygenase enzymes (Needham and others 2005).

To prolong the shelf-life of bakery products, modified atmosphere package (MAP) can be used. A combination of gases plays the most important role in maintaining product quality during MAP storage. To prevent the growth of mold and provide the greatest stagnancy, carbon dioxide and nitrogen gases should be used in ranges of 20–50% and 80–50%, respectively (Kotsianis and others 2002). However, spoilage by *Clostridium botulinum* has to be of concern when MAP is used (Smith and others 2004).

In addition to MAP, edible films can be used to cover products. Baeva and Panchev (2005) used a pectin-containing edible film to cover a dietetic sucrose-free cake. The uncovered cake exhibited quicker crumb aging compared to a sucrose-sweetened cake. After storage for 6 days, the cake covered with the film had 1.5 times higher amount of strongly bound water, compared with the uncovered cake. This indicated a slower rate of retrogradation, therefore slower aging, in the film-covered cake. Moreover, shrinkage was found after 5 days of storage, and slight changes in crumb yellow color were also observed.

Utilization of preservatives is another method to prolong the shelf-life of bakery products. To prevent fungi spoilage in intermediate-moisture products, weak acid preservatives, especially propionic, sorbic, and benzoic acids, can be used. Propionic acid is used for the inhibition of mold and *Bacillus* spores. Sorbic acid is used for the inhibition of mold and yeast. It can be used in combination with benzoic acid. Due to a better solubility in aqueous solutions, the preservative acids are used normally in the form of salts.

Acidity plays an important role in the effectiveness of preservatives. When products have high acidity (pH 4.4–4.8) and high water activity (a_w, 0.94–0.97), 0.3% propionate can inhibit fungal growth (except *Pencillium roqueforti*, *Penicillium commune*, and *Eurotium rubrum*) for 2 weeks (Suhr and Nielsen 2004). Guynot and others (2005a) utilized the hurdle technology (hurdle technology is on combining several preservation techniques of mild degree to make the overall process effective to ensure microbiological safety and stability of a food), including weak acid preservatives (0–0.3%), water activity (0.80–0.90), and pH (4.5–5.5) for the inhibition of mold. It was found that 0.3%

potassium sorbate was effective at 0.90 water activity and pH 4.5. However, it became less effective at pH 5.5. To make calcium propionate and sodium benzoate effective, water activity had to be kept at a low level (0.80). The relationship between fungal growth and storage parameters including potassium sorbate concentration, water activity, and pH could be described by polynomial models having 10 terms (Guynot and others 2005b). At higher water activity (a_w, 0.93–0.97), combining potassium sorbate with calcium propionate could be used to inhibit fungal growth when the acidity was kept at 4.5 (Arroyo and others 2005).

At higher pH (6.0 and above), potassium sorbate and sodium benzoate were more effective than calcium propionate (Suhr and Nielsen 2004). Among the weak acid preservatives, potassium sorbate was the most effective (Guynot and others 2002). However, at near neutral pH, 0.1% sorbate presented little antifungal effect. When the concentration was increased to 0.2%, sorbate could inhibit the growth of mold effectively under some conditions of water activity and storage temperature (Marin and others 2003). Guynot and others (2002) stated that 0.3% sorbate was effective under the conditions pH 6.0 and an a_w of 0.80–0.85.

For bakery products with an unbaked filling, contamination from equipment could be very easy. To delay the growth rate of pathogenic microorganisms, the pH of the filling has to be reduced by addition of acids such as acetic acid, citric acid, and so on. Bakery products with a filling made of fruits are possibly more stable because of their lower pH (Leitenberger and Rocken 1998).

Without preservatives, water activity and storage temperature have to be optimized to prevent any fungal growth in intermediate moisture products. In the case of a sponge cake, Abellana and others (2001) concluded that the water activity had to be lower than 0.85 for storing the product at a temperature above 15°C.

14.6 PROCESS MODELING FOR TECHNOLOGY IMPROVEMENT

Modeling has been carried out for describing all events throughout the bakery process. For product formulation, the impact of ingredients on product quality can be expressed by mathematical models. Based on the models, various recipes can be designed (Young and others 1998). Furthermore, a Convected Maxwell Model was used to simulate the stress–time curves during mixing (Maache-Rezzoug and others 1998b). During baking, heat distribution has been described using mathematical models (Fahloul and others 1995; Sablani and others 1998) and computational fluid dynamics (CFD) (De Vries and others 1995; Therdthai and others 2003, 2004a). Using artificial neural networks, the thermal conductivity of bakery products can be modeled as a function of moisture content, temperature, and apparent density (Sablani and others 2002). Moisture diffusion and transfer in biscuits during baking can be simulated using mathematical models based on Fick's second law (Guillard and others 2004). The effect of baking profiles on the quality (Therdthai and others 2002) and cost (Dingstad and others 2004) of bread may be described using empirical models. Variations in material properties can be used to simulate cracking in biscuits using finite element modeling (Saleem and others 2005). Reactions in bread such as gelatinization and browning have been estimated using first-order kinetic models (Zanoni and others 1995a, 1995b). To facilitate designing the optimal operating condition for a bread-baking process, several models could be integrated to predict the product quality resulting from various baking conditions or process

modifications (Therdthai and others 2004b). During cooling, the effect of air temperature, initial product temperature, and air velocity on the cooling rate should be evaluated, and empirical models can be established directly based on the industrial data. As described earlier, the shelf-life of intermediate-moisture bakery products after packaging could be estimated using polynomial models with 10 terms (Guynot and others 2005b). Patterns in the product acceptance of biscuit crackers have been studied using the mapping technique (Martinez and others 2002).

Recently there have been several commercial computing programs introduced to the baking industry, such as the CCFRA Cake Expert System by the Campden and Chorleywood Food Research Association (CCFRA), Food Processor by ESHA Research, Balance by CCFRA, and SolidWorks ® by SolidWorks Corporation (Otles and Onal 2004). These software all use modeling approaches to compute/design the optimum formulation and process. Such an approach can improve bakery manufacturing with an economic design of product and process.

14.7 CURRENT TRENDS

As mentioned earlier in the introduction section, the rising health consciousness of today's consumers has been constantly shaping trends in bakery products. Although the low-carb craziness might well be over, other issues such as high-fiber multigrains have been among the major market drivers. Well in line with the global functional food trend, new varieties of bread products, sometimes called functional breads, have been developed and released, particularly those enriched or fortified with particular grains or other ingredients (Anon. 2006).

Recently, there has been considerable interest in plant polyphenols and phytosterols, as many of them are strong antioxidants and/or cholesterol-reducing substances. Incorporating these active components into traditional bakery products would turn the products into modern functional food items. However, recent studies on incorporating tea catechins into bread have revealed that, although the tea antioxidants might be stable enough so that most of them can survive the bread-making process, they may impose significant negative effects on the quality of bread in terms of volume and texture, depending on the dose level (Wang and Zhou 2004; Wang and others 2006). In another study, phytosterol esters have been incorporated into croissants and muffins, together with α-tocopherol and β-carotene, and the products were given to normocholesterolemic and habitual consumers, respectively, to provide 3.2 g/day of the phytosterol esters. It was found that the total and LDL cholesterols decreased in those consuming the products for 8 weeks (Quilez and others 2003). A subsequent sensory evaluation indicated that no difference was detected between the products with and without phytosterols at the dose level (Quilez and others 2006).

With regard to bakery production method, the increasing popularity of frozen dough and frozen par-baked bakery products has been driven mainly by the economic advantage of a centralized manufacturing and distribution process as well as the standardization of product quality. These products, bread in particular, do not demand specialized workers and offer the possibility of making "fresh" products available at any time of the day.

The quality of bread made out of frozen dough is influenced by dough formulation, as well as process parameters such as dough mixing time, freezing rate, storage duration, and thawing rate. These factors may act either independently or synergistically to reduce yeast

activity, which results in reduced carbon dioxide production or in damage to the gluten network, which in turn results in poor CO_2 retention and poor baking performance (Lucas and others 2005). The inclusion of improvers in bread formulation, such as emulsifiers and hydrocolloids, may overcome such problems associated with frozen dough. Selomulyo and Zhou (2007) provide a comprehensive review of the effects of freezing storage and dough improvers on the quality of frozen bread dough and the corresponding bread.

On baking equipment, automation and optimal control systems of the bakery making processes are among the major focuses of new development. However, to successfully design an advanced process control system for a bakery making process heavily depends on a good understanding of the process, its responses to the operation conditions and their interactions. This understanding needs to be quantitative. In other words, a good model, particularly a good dynamic model of the process, needs to be established. Bakery making involves complicated transformations from raw ingredients to dough and further to the final product. This makes it very hard to establish a high-quality model. However, there have been persistent efforts and progresses towards modeling the various stages of bakery making using advanced modeling techniques, as described in the previous section.

14.8 SUMMARY

Bread and bakery products are among the popular food items with a long history of development. Varieties of bakery products have been produced with regard to technology development and consumer preference. The main ingredients for bakery products include flour, water, sugar, fat, and salt. Each ingredient imparts a different effect on the quality of the final product. The ingredients should be formulated in accordance with the required rheological properties of dough and batter. The degree of gluten development seems to play the most important role in achieving the desired product characteristics. In addition to formulation, processes including dough making, proving, baking, cooling, and packaging are all among the important steps in delivering a high-quality end product. Different process operating methods and conditions are required to produce different product varieties. To obtain a longer shelf-life, packaging has to be carefully designed. Mathematical modeling could be an effective tool in optimizing both product formation and manufacturing process.

15.1 MUFFINS

15.1.1 Background Information

15.1.1.1 History of Muffins. English muffins originating in London were made from yeast dough, in contrast to the quick-bread muffins served in early America. Muffins are described as a quick bread because "quick-acting" chemical leavening agents are used instead of yeast, a "longer acting" biological leavening agent. Muffins have become increasingly popular as a hot bread served with meals or eaten as a snack. Freshly baked muffins are served in restaurants and bakeries, and consumers can buy packaged ready-to-eat muffins from grocery stores and vending machines. With the availability of dry mixes, frozen muffin batter, and predeposited frozen muffins available on the wholesale market, it is possible for restaurants and small bakeries to serve a muffin of a consistently high quality. Muffin mixes that are lower in fat, carbohydrates, and calories are available for home and institutional use for individuals with cardiovascular disease and diabetes.

15.1.1.2 Health Concerns. The economic burden of chronic disease is a worldwide problem. Chronic diseases contributed to 60% of the deaths worldwide in 2001 (WHO 2003a). The increasing rate of obesity and the aging of the population are expected to impact the burden of chronic disease. Those with obesity are at greater risk and have an earlier onset of the chronic diseases of diabetes, cardiovascular disease, cancer, and stroke. Aging increases the risk for all chronic diseases. Nearly one-quarter of the population in developed countries is made up of those over 60 years of age, with expectations for the numbers to increase to one-third of the population by 2025 (WHO 2002a).

The problems of overweight and obesity are growing rapidly around the world and coexist with malnutrition in developing countries (WHO 2003a). Surveys of U.S. adults carried out in 1999–2000 showed that 64% of adults were overweight and 30% were obese (Flegal and others 2002). The percentage of children and adolescents in the United States who are overweight has tripled in the past 30 years, with 15% of 6- to 19-year-olds being overweight in 1999–2000 (Ogden and others 2002). Obesity rates have increased threefold or more in some parts of North America, Eastern Europe, the Middle East, the Pacific Islands, Australasia, and China since 1980 (WHO 2002b). The prevalence rates of overweight and obesity are growing rapidly in children and adults in such countries as Brazil and Mexico, where malnutrition and obesity coexist in the same households (Chopra 2002). Countries with the highest percentage (5–10%) of overweight preschool children are from the Middle East (Qatar), North Africa (Algeria, Egypt, and Morocco), and Latin America and the Caribbean (Argentina, Chile, Bolivia, Peru, Uruguay, Costa Rica, and Jamaica) (de Onis and Blossner 2000).

Globalization of food and the availability of energy-dense snacks and "fast foods" have had a significant impact on dietary patterns and the incidence of chronic disease in both

developing and developed countries (Hawkes 2002). For example, Coca-cola and Pepsi soft drinks and McDonald's, Pizza Hut, and Kentucky Fried Chicken fast foods are now available worldwide (Hawkes 2002). Changes in dietary patterns combined with a sedentary life-style have increased the rates of obesity and chronic disease. Dietary factors related to chronic disease are excessive intakes of calories, fat (especially saturated fat), and sodium, and low intakes of fruits and vegetables and wholegrain breads and cereals (WHO 2004). National dietary guidelines recommend limiting intakes of total fat, saturated fat, trans fat, cholesterol, free sugars, and sodium, and they promote dietary fiber from wholegrain breads and cereals, fruits, and vegetables (WHO 2003b). In 2002, consumers in the United States reported making food choices in an effort to avoid fat, sugar, calories, and sodium, and to increase fiber intake (NMI 2003). Consumers chose fat-free foods or foods low in fat 74–80% of the time and selected low-calorie foods and low-sodium foods 76–67% of the time, respectively. High-fiber foods were chosen 75% of the time, and 40% of consumers reported using organic foods (NMI 2003).

The food industry has responded to concerns of consumers and public health officials by developing "healthy" food products, lower in saturated fat, trans fat, cholesterol, sodium, sugar, and calories. New ingredients have been developed by food scientists in the government and industry to use as fat and sugar replacers in preparing baked products that are lower in calories and saturated and trans fats (Tables 15.1 and 15.2).

TABLE 15.1 Ingredients Used as Fat Replacers in Baked Products.

Brand Name	Composition	Supplier
	Carbohydrate-Based	
Beta-Trim™	Beta-glucan and oat amylodextrin	Rhodia USA, Cranbury, NJ
Fruitrim®	Dried plum and apple puree	Advanced Ingredients, Capitola, CA
Just Like Shorten™	Prune and apple puree	PlumLife division of TreeTop, Selah, WA
LighterBake™	Fruit juice, dextrins	Sunsweet, Yuma City, CA
Oatrim®	Oat maltodextrin	Quaker Oats, Chicago, IL
Paselli FP	Potato maltodextrin	AVEBE America, Inc., Princeton, NJ
Z-Trim	Multiple grain fibers	U.S. Department of Agriculture
	Low- and Noncaloric-Lipid Based	
Enova™	Diglycerides	Archer Daniels Midland/Kao LLC, Decatur, IL
Benefat® Salatrim/ Caprenin	Triglycerides modified by substituting short- or medium-chain fatty acids	Danisco Culter, New Century, KS Proctor and Gamble, Cincinnati, OH
Olestra/Olean®	Sucrose polyester	Proctor and Gamble, Cincinnati, OH

TABLE 15.2 Ingredients Used as Sugar Replacements in Baked Products.

Sweetener	Brand Name	Sweetness Compared to Sucrose	Supplier
Acesulfame-K	Sunett®	200% sweeter	Nutrinova, Somerset, NJ
Sucralose	Splenda®	600% sweeter	Splenda, Inc., Ft. Washington, PA

TABLE 15.3 Ingredients Marketed for Specific Health Benefits.

Brand Name	Composition	Health Benefit	Supplier
Caromax™ Carob fiber	Carob fruit fiber; soluble fiber, tannins, polyphenols, lignan	Lower serum cholesterol	National Starch and Chemical, Bridgewater, NJ
FenuPure™	Fenugreek seed concentrate; galactomannan	Regulate blood glucose; Lower serum cholesterol	Schouten USA, Inc., Minneapolis, MN
Fibrex®	Sugar beet fiber; soluble fiber, lignan	Lower serum cholesterol Regulate blood glucose	Danisco Sugar, Malmo, Sweden
MultOil	Diglycerides &+ phytosterols	Lower serum cholesterol	Enzymotec, Migdal HaEmeq, Israel
Nextra™	Decholesterolized tallow and corn oil; free of trans fat	Reduce the risk for coronary heart disease	Source Food Technology, Durham, NC
Novelose 240	Corn fiber; high amylose, resistant fiber	Reduce risk for colon cancer	National Starch and Chemical, Bridgewater, NJ
Nutrifood®	Fruit and vegetable liquid concentrates; source of antioxidants: carotenoids, anthocyanins, polyphenols	Reduce risk for chronic diseases: cancer, diabetes, and cardiovascular disease	GNT USA, Inc., Tarrytown, NY GNT Germany, Aachen, Germany
OatVantage™	Beta-glucans, a soluble fiber	Lower serum cholesterol	Nurture, Inc., Devon, PA
Tonalin® CLA	Conjugated linoleic acid made from sunflower oil	Weight management	Cognix Corp. USA, Cincinnati, OH
Vegapure® Sterol Esters	Sitosterol, campersterol, and stigmasterol esterified with sunflower oil fatty acids	Lower serum cholesterol	Cognis Corp. USD, Cincinnati, OH

The newest category of ingredients is concentrated bioactive compounds with specific health benefits (Table 15.3) (Pszczola 2002a). These ingredients are added to formulations during food processing to enhance the health benefits of specific food products or to develop "functional foods". Individual foods, such as apples, blueberries, oats, tomatoes, and soybeans, are being marketed as functional foods because of the health benefits of components of these foods. For example, diets that include oat fiber and soy protein lower serum cholesterol, and lycopene in tomatoes reduces the risk of prostate cancer. Apples and blueberries contain unique antioxidants shown to reduce the risk for cancer (Pszczola 2001). Examples of bioactive ingredients available to the baking industry are OatVantage™ (Nature Inc., Devon, Pennsylvania), a concentrated source of soluble fiber, and FenuPure™ (Schouter USA, Minneapolis, Minnesota), a concentrated source of antioxidants from fruits and vegetables.

15.1.1.3 Food Labeling and Health Claims. The Nutrition Labeling and Education Act (NLEA), issued by the Food and Drug Administration (FDA) in the United States in 1990, to be effective in 1994, required food labels to include nutrition content on all packaged foods (FDA/CFSAN 1994). Information required on the Nutrition Facts portion of the food label are the serving size and the amount per serving of calories, protein, fat, saturated fat, cholesterol, carbohydrates, fiber, sodium, calcium, vitamins A and C, and iron. A 1993 amendment to the NLEA authorized food manufacturers to add health claims related to specific food components (Federal Register 2003) (Table 15.4). However, for many "functional foods", the scientific evidence to meet FDA criteria to make health claims is lacking (Wahlqvist and Wattanapenpaiboon 2002). A 2003 amendment to NLEA requires that trans fatty acids be listed under saturated fat on the Food Facts label (DHHS/FDA 2003). The Codex Alimentarius Commission of the Food and Agriculture Organization of the United Nations World Health Organization (FAO/WHO) Codex Guidelines on Nutrition Labeling adopted in 1985 are similar to the NLEA implemented by the FDA in 1994 (Hawkes 2004). The Codex Alimentarius Commission adopted the Codex Guidelines for the use of Nutrition Claims on food labels in 1997 (Hawkes 2004). Codex standards are voluntary, and each country within the United Nations is free to adopt food-labeling standards. The European Union, which includes 25 member states in Europe, also sets guidelines for nutrition labeling and nutrition claims, subject to the requirements of the individual member states.

The Food Standards Agency of the United Kingdom was established in 2000 as the regulatory agency to set policy for food labeling in Great Britain and Northern Ireland (FSA 2005). Food Standards Australia and New Zealand (FSANZ 2005) specifies the requirements for food labeling in these countries. Health Canada published new food labeling regulations on January 1, 2003, making nutrition labeling mandatory for most foods and allowing diet-related health claims on food labels for the first time (Health Canada 2005).

TABLE 15.4 Health Claims Approved for Food Labeling in the United States.

Food Component	Health Claim
Calcium	Osteoporosis
Dietary fat	Cancer
Dietary sugar alcohol	Dental caries
Dietary saturated fat and cholesterol	Coronary heart disease
Fiber-containing grain products, fruits, and vegetables	Cancer
Folate	Neural tube defects
Fruits and vegetables	Cancer
Fruits, vegetables, and grain products that contain fiber, particularly soluble fiber	Coronary heart disease
Plant sterols/stanol esters	Coronary heart disease
Potassium	High blood pressure and stroke
Sodium	Hypertension
Soy protein	Coronary heart disease
Wholegrain foods	Heart disease and certain cancers

15.1.1.4 Food Labeling Standards for Organically Grown Foods. The Organic Foods Production Act of 1990 passed by the U.S. Congress required the U.S. Department of Agriculture to develop certification standards for organically produced agricultural products (AMS/USDA 2003). Producers who meet the standards may specify the percentage of the product that is organic on the food label if 70% or more of the ingredients in the product are organically grown (AMS/USDA 2003). The Codex Alimentarius Commission has also published standards for labeling organically grown foods (FAO/WHO 2001). Organic fruits and vegetables are produced without using conventional pesticides, petroleum-based fertilizers, or sewage-sludge-based fertilizers. Animal products identified as organic come from animals that are given organic feed but are not given antibiotics or growth hormones. Food products that have been developed through genetic modification cannot be labeled as organically grown foods (FAO/WHO 2001; AMS/USDA 2003).

15.1.1.5 Ingredient Labeling for Possible Allergens. The Codex Alimentarius Commission of FAO/WHO and FDA/CFSAN require that food labels list all ingredients known to cause adverse responses in those with food allergies or sensitivities (FDA/ORA 2001; Hawkes 2004). The FDA requires listing of ingredients from eight foods that account for 90% of all food allergies. These foods are peanuts, soybeans, milk, eggs, fish (e.g., bass, flounder, or cod), crustacean shellfish (e.g., crab, lobster, or shrimp), tree nuts (almonds, pecans, or walnuts), and wheat (FDA/ORA 2001). A proposed rule to define and permit food labels to use the term gluten-free is a part of the Food Allergen Labeling and Consumer Protection Act of 2004 (FDA/CFSAN 2004a). Food manufacturers in the United States are required to list foods from these eight major allergens on the food label (FDA 2005). Codex standards require listing ingredients from these same eight foods plus all cereals that contain gluten (rye, barley, oats, and spelt), lactose, and sulfite in concentrations of 10 mg/kg or more (Hawkes 2004). Gluten, lactose, and sulfite are listed on food labels because these substances cause distress for some consumers, even though these substances are not considered allergens. Individuals with celiac disease or gluten intolerance eliminate all sources of gluten from the diet. A small percentage of individuals lack lactase, the enzyme needed to digest lactose, and avoid dairy products and all other foods with lactose additives.

Food processing plants are required to follow Good Manufacturing Practices (GMPs) to avoid possible cross-contamination with trace amounts of allergens during processing. An example of possible cross-contamination is using the same plant equipment to prepare nut-free muffins after the equipment has been used to prepare muffins with nuts (Taylor and Hefle 2001). An example of GMP is dedicating food processing plants to the production of allergen-free foods (Taylor and Hefle 2001).

Small bakeries (defined by the number of employees or annual gross sales) and restaurants are exempt from the FDA food labeling requirements. Food labeling to identify foods that have been genetically modified through bioengineering (GM) is voluntary (FDA/CFSAN 2001). However, because of consumer concerns about GM foods, managers of bakeries may choose to include a statement on the ingredient label such as, "We do not use ingredients produced by biotechnology", (FDA/CFSAN 2001). Consumers with food allergies have learned to read the lists of ingredients on food labels to identify any possible sources of allergens. Managers of small bakeries that use nuts or soy flour in their operations, but are unable to follow GMPs because of the added cost, may choose to alert consumers with a statement on the ingredient label such as, "This product was made on equipment

TABLE 15.5 Muffin Formulas Listed by Baker's Percent and Weight.

Total	303.75	3037	361.70	3615

Specifications

Mixer: Hobart N-50 with 5-quart bowl and paddle agitator.

Directions for basic cake muffin formula:

- Blend dry ingredients together by mixing for 1 min at low speed
- Add shortening and eggs and mix for 1 min at low speed
- Add water and mix for 1 min at low speed
- Scaling weight: 2 and a 1/2 oz. batter
- Yield: 3 dozen muffins
- Bake at 205°C for 19–21 min in a gas-fired reel oven

Directions for bran muffin formula:

- Blend dry ingredients and mix for 1 min at low speed
- Add shortening, eggs, honey, molasses and 50% (500 g) of the water and mix for 1 min at medium low speed
- Add the remaining water and mix for 1 min at low speed
- Add raisins and mix at low speed for 3 min or until raisins are dispersed
- Scaling weight: 3 oz. batter
- Yield: 3 dozen muffins
- Bake at 193°C for 20–25 min in a gas-fired reel oven.

Sources: Benson (1988), Doerry (1995).

that also makes products containing tree nuts". Making a decision to sell bakery products made with organic ingredients requires assessing the market for these products, the availability of organic ingredients, and the expected income from the operation.

15.1.2 Preparation of Cake-Type Muffins

15.1.2.1 Selection and Scaling of Ingredients. Muffins made by large commercial bakeries are more cakelike, and those made in the home or small institutions tend

to be more breadlike. The differences between cakelike and breadlike muffins are that cakelike muffins are higher in fat and sugar and use soft wheat flours. A common problem encountered in bread-type muffins is tunnel formation resulting from overdevelopment of gluten. However, this problem is avoided in cake-type muffins, because sugar, fat, and soft wheat flours interfere with gluten development and prevent tunnel formation. Bread-type muffins contain 12% of both fat and sugar compared with 18–40% fat and 50–70% sugar in cake-type muffins (Benson 1988).

Formulas for a standard cake-type muffin and a bran muffin are shown in Table 15.5. Ingredient formulas used by commercial bakeries are based on the weight of flour at 100% (Gisslen 2000). The amounts of other ingredients are a percentage of flour weight (Baker's percent). For example,

$$\frac{w_{\mathrm{i}}}{w_{\mathrm{ref}}} \times 100 = \text{baker's } \% \quad \text{(of the specific ingredient)}$$

where w_{i} is the weight of the specific ingredient, and w_{ref} is the total weight of the wheat flour. Therefore, if the weight of another ingredient is the same weight as the flour, the baker's percent for that ingredient is also 100. The advantage of using baker's percent is that batch sizes can be easily increased or decreased by multiplying the baker's percent for each ingredient by the same factor. Weighing all ingredients, including liquids, is faster and more accurate than using volumetric measurements, especially in large commercial bakeries.

Flour. Flour is the primary ingredient in baked products. Flour represents 30–40% of the total batter weight in most cake-type muffins (Benson 1988). Most muffin formulas contain either a blend of cake or pastry flour and a higher protein flour such as bread flour, or all bread flour (Willyard 2000). The protein in flour is needed to provide structure in quick breads made with limited amounts of sugar. Flour contains starch and the proteins glutenin and gliadin, which hold other ingredients together to provide structure to the final baked product. Hydration and heat promote gelatinization of starch, a process that breaks hydrogen bonds, resulting in swelling of the starch granule, which gives the batter a more rigid structure (McWilliams 2001e). Substituting wholewheat flour, wheat germ, rolled oats, or bran for part of the flour is an excellent way to increase fiber. Other types of flour used in muffins include cornmeal, soy, oat, potato, and peanut. An acceptable product is possible when cowpea or peanut flours are substituted for 25% or when wholewheat flour or cornmeal is substituted for 50% of all-purpose flour (Holt and McWatters 1992). Acceptable muffins have been prepared when soy flour was substituted for 10–20% (Sim and Tam 2001) or 100% of all-purpose flour (Bordi and others 2001). None of these flours contains glutenin or gliadin except the wholewheat flour, and large pieces of bran in wholewheat flour cut and weaken gluten strands. Thus, there is minimal gluten development when these flours are used; however, the muffins tend to be crumbly and compact unless other modifications are made in the formula.

Sugar. Amounts of sugar in muffins range from 50 to 70%, based on flour at 100% (Benson 1988). Sugar contributes tenderness, crust color, and moisture retention in addition to a sweet taste. Sucrose promotes tenderness by inhibiting hydration of flour proteins and starch gelatinization. Sugar is hygroscopic (attracts water) and maintains freshness. Corn syrup, molasses, maple sugar, fruit juice concentrates, and honey are used as sweeteners for flavor variety. Honey or molasses is often used as a sweetener in wholewheat or bran muffins to cover the bitter flavor of the bran (Willyard 2000). The quantity of liquid will need to be decreased if these sweeteners are used instead of sucrose because

of the high water content in these syrups. Chemical changes in sugars during baking contribute characteristic flavors and browning. Caramelization of sugar is responsible for the brown crust of muffins. Caramelization involves dehydration and polymerization (condensation) of sucrose (McWilliams 2001c). Reducing sugars such as dextrose, corn syrup, or high-fructose corn syrup are often added to muffins at levels of 1–3% to increase crust color (Willyard 2000). Reducing sugars react with amino acids in flour, milk, and eggs to form a complex that is responsible for the flavor and brown crust of muffins. The reaction between the aldehyde or ketone groups in reducing sugars and the amino acids in protein is described as the Maillard reaction (McWilliams 2001e). The Maillard reaction, together with caramelization, contributes to the characteristic flavor and color of the crust of a baked muffin. Crust temperatures reach 100°C and above, which lowers water activity. Both the high temperature and low water activity are necessary for the Maillard reaction to occur (McWilliams 2001f). Sugar replacers such as acesulfame-K and sucralose (see Table 15.2) can be substituted for all or part of the sugar. These sugar replacers, however, do not contribute to tenderness, browning, or moisture retention; thus, other formula modifications are necessary for an acceptable product. For example, a small amount of molasses or cocoa may be added to substitute for color from the caramelization of sucrose. The shelf-life of muffins prepared without sugar would be very limited.

Fat. Muffins contain 18–40% fat, based on flour at 100% (Benson 1988). Fat contributes to the eating qualities of tenderness, flavor, texture, and a characteristic mouthfeel. Fat keeps the crumb and crust soft and helps retain moisture, and thus contributes to keeping qualities or shelf-life (McWilliams 2001d). Fat enhances the flavor of baked products because flavor components dissolve in fat. Both shortening and vegetable oils are used in muffins.

To meet the demands of the consumer, muffin formulas are being modified to reduce total fat, saturated fat, trans fat, and calories and to increase the amount of monounsaturated and polyunsaturated fat. Canola oil and flaxseed meal are being added to muffins to increase the proportion of monounsaturated fat. Muffins made with reduced fat and polyunsaturated fatty acids (13% safflower oil) were comparable in sensory and physical characteristics to the standard muffin made with shortening at 20% (Berglund and Hertsgaard 1986).

Low-fat and fat-free muffins are available ready to eat and as frozen batters or dry mixes for bake-off. Various fat replacers have been classified by their macronutrient base (see Table 15.1). Carbohydrate- and lipid-based fat replacers can be used to prepare muffins acceptable to the consumer. Lipid-based fat replacers that have the same chemical and physical characteristics as triglycerides are described as fat substitutes (Akoh 1998). These products provide the same characteristics as fat but with fewer calories.

Monoglycerides, diglycerides, and modified triglycerides are examples of fat substitutes that replicate the mouthfeel and sensory qualities of baked products made with shortening. Enova™ (Archer Daniels Midland KAO LLC, Decatur, Illinois) is an example of a diglyceride that is lower in calories than other oils and is being marketed as beneficial in weight management (Pszczola 2003). Benefat® (Danisco Culter, New Century, Kansas) and Caprenin (Proctor and Gamble, Cincinnati, Ohio) are examples of triglycerides modified by substituting shorter-chain fatty acids (Akoh 1998). Sucrose polyesters of six to eight fatty acids are marketed as Olean® (Procter and Gamble, Cincinnati, Ohio), a fat substitute with the same physical qualities as shortening but without the calories, because sucrose polyesters are not digested or absorbed in the human intestinal tract. A commercial shortening product (Nextra™) (Source Food Technology, Durham, North Carolina) made from decholesterolized tallow and corn oil is being marketed to the baking industry as a trans-free fat to replace shortening (Pszczola 2002b). Other methods used by the food

industry to decrease the amount of trans fat are (1) blending hydrogenated fat high in stearic acid with unhydrogenated oils, and (2) interesterfying (rearranging) unhydrogenated oils with saturated-fat-based oils (Hunter 2002).

Carbohydrate-based fat replacers are described as fat mimetics; for example, cellulose, corn syrup, dextrins, fiber, gum, maltodextrins, polydextrose, starches, and fruit-based purees. Z-trim, developed by a U.S. Department of Agriculture Scientist, is a mixture of plant fibers (Inglett 1997). Fat mimetics replicate the mouthfeel and texture of fat in baked products and extend the shelf-life by binding water and trapping air (American Dietetic Association 2005). Acceptable low-fat cake muffins (5% fat) use 2% pregelatinized dull waxy starch and corn syrup (3.6%) to replace fat (Hippleheuser and others 1995).

Fruit purees or pastes of one or more fruits – apples, dates, figs, grapes, plums, prunes, and raisins – are being promoted as fat replacers. Just Like Shorten™ is a mixture of dried prunes and apples. The fruit purees have humectant properties, promote tenderness and moistness, increase shelf-life, and can replace some of the sugar and/or fat in muffins and cakes. Formulas will need to be developed based on adjustments in ingredients when fat replacers are substituted for all or part of the fat in the formula. New formulas need to be prepared and the muffins evaluated using the muffin scorecard (Table 15.6),

TABLE 15.6 Scorecard for Muffins.

Evaluator:

and the shelf-life also needs to be evaluated. Several formula adjustments may be necessary before an acceptable muffin is developed.

Leavening Agents. The amount of baking powder used in muffins varies between 2 and 6%, based on flour at 100%, with lower amounts in muffins with ingredients that increase acid (Benson 1988). Gases released by a leavening agent influence volume and cell structure. During baking, heat increases gas volume and pressure to expand cell size until proteins are coagulated (McWilliams 2001c). Stretching of the cell walls during baking improves texture and promotes tenderness (McWilliams 2001c). The quantity of leavening used in a baked product depends on the choice of leavening agent as well as other ingredients. Formulation of baking powders considers the amount of leavening acids needed to neutralize baking soda or sodium bicarbonate, an alkaline salt. Double-acting baking powder (most commonly used in muffins) contains both slow- and fast-acting acids (McWilliams 2001e). Fast-acting acids are readily soluble at room temperature, but slow-acting acids are less soluble and require heat over an extended period of time to release carbon dioxide. Formulations of slow- and fast-acting acid leavening agents control the reaction time and optimize volume (Borowski 2000). An example of a formulation to neutralize sodium bicarbonate is a mixture of slow- and fast-acting acids – monocalcium phosphate monohydrate (a fast-acting acid) combined with sodium aluminum sulfate (a slow-acting acid). Development of baking powder requires consideration of the unique neutralizing value (NV) and the rate of reaction (ROR), or the percent of carbon dioxide released during the reaction of sodium bicarbonate with a leavening acid during the first 8 min of baking (Borowski 2000).

Baking soda is used in addition to double-acting baking powder when muffins contain acidic ingredients such as sour cream, yogurt, buttermilk, light sour cream, molasses, and some fruits and fruit juices (McWilliams 2001e). Baking soda in the amount of 2–3% is added to acidic batters (Benson 1988).

Sodium carbonate is a product of an incomplete reaction in formulas with excess sodium bicarbonate. Excess sodium carbonate results in a muffin with a soapy, bitter flavor and a yellow color because of the effect of an alkaline medium on the anthoxanthin pigments of flour (McWilliams 2001f). Also, formulas with too much baking powder or soda result in a muffin with a coarse texture and low volume because of an overexpansion of gas, which causes the cell structure to weaken and collapse during baking. Inadequate amounts of baking powder will result in a compact muffin with low volume. Figures 15.1 and 15.2 show different chemical reactions for fast-acting and slow-acting baking powders (McWilliams 2001e).

Whole Eggs. Liquid egg contributions to muffin batter are 10–30%, based on flour at 100%, and dried egg powder contributions are 5–10% (Benson 1988). Eggs provide flavor, color, and a source of liquid. Upon baking, the protein in egg white coagulates to provide structure. Adding egg whites to muffin batter provides structure to the finished product and produces a muffin that is easily broken without excessive crumbling (Stauffer 2002). Substituting egg whites for whole eggs, however, will result in a dry, tough muffin

unless the formula is adjusted to increase the amount of fat (Stauffer 2002). Fat in the yolk acts as an emulsifier and contributes to mouth-feel and keeping qualities.

Nonfat Dry Milk Powder. Milk powder contributions to muffin batter are 5–12%, based on flour at 100% (Benson 1988). Milk powder is added to dry ingredients, and water or fruit juice is used for liquid in muffin formulas. Milk powder binds flour protein to provide strength, body, and resilience – qualities that are helpful in reducing damage during packing and shipping (Willyard 2000). In addition, milk powder adds flavor and retains moisture. The aldehyde group in lactose in milk combines with the amino group in protein upon heating, contributing to Maillard browning.

Sodium Chloride. The amount of salt in muffins is 1.5–2%, based on flour at 100% (Benson 1988). The function of sodium chloride is to enhance the flavor of other ingredients. Sodium chloride may be omitted from the formula without compromising flavor, if other ingredients such as dried fruit or spices are added for flavor.

Liquids. Liquids perform several functions in baked products (Benson 1988). These include dissolving dry ingredients, gelatinization of starch, and providing moistness in the final baked product. Insufficient liquid results in incomplete gelatinization of the starch and a muffin without the structure to support expansion of air volume. The muffins will have nonuniform cell structure, overly crumbly texture, low volume, and a dip or "M" fault in the top.

Additional Ingredients. Other ingredients are often added to muffins to provide variety in flavor, texture, and color and to increase specific nutrients or health components such as fiber, vitamins and minerals, or antioxidants from fruit and vegetable extracts. Part of the flour may be replaced with cornmeal, bran, or wholewheat, oat, or other flours to increase the fiber content. Adjustments in the amount of water in the formula are necessary when wholewheat flour, bran, or other concentrated sources of fiber are added, because fiber absorbs a great deal of water (Willyard 2000). An example of a concentrated

source of fiber is Caromax™ (National Starch and Chemical, Bridgewater, New Jersey) (Pszczola 2001). Nutrifood® (GNT USA, Tarrytown, New York), a liquid concentrate marketed as a blend of the antioxidants carotenoids, anthocyanins, and polyphenols, is an example of a bioactive ingredient (Pszczola 2002a).

Other ingredients can be substituted for part of the liquid; for example, applesauce, bananas, shredded carrots, or zucchini. Variations in texture are achieved by adding fresh fruits such as apples or blueberries, or dried fruits such as dates, raisins, or apricots. Nuts and poppy seeds complement the flavor of sweet muffins, and grated cheese, whole-kernel corn, green peppers, chopped ham, and bacon add interest to corn muffins. Added flavorings include cinnamon, nutmeg, allspice, cloves, and orange or lemon zest. Topping mixtures such as chopped nuts, cinnamon, and sugar are added to the batter after depositing.

15.1.2.2 Processing

Stage 1 — Mixing. There are two primary methods for mixing muffins – the cake method and the muffin method. The cake method involves creaming sugar and shortening together, followed by addition of liquid ingredients and the final addition of dry ingredients. The muffin method of mixing involves two to three steps. First, dry ingredients are mixed together; second, shortening or oil and other liquids are mixed together; and third, the liquids are added to the dry ingredients and mixed until the dry ingredients are moistened. Additional ingredients are added at the end of the mixing cycle or after depositing the muffin batter. Institutional or commercial bakeries use a mixer on slow speed for 3–5 min. Inadequate mixing results in a muffin with a low volume, as some of the baking powder will be too dry to react completely.

Stage 2 — Depositing. The traditional size of muffins is 2 ounces, although today muffins are marketed in a wide range of sizes from 1/2-ounce mini muffins to muffins 5 ounces or larger in size (Willyard 2000). For institutions or bakeries, small batter depositors are available that will deposit four muffins at a time. Also available are large piston-type depositors that maintain accurate flow of the batter (Benson 1988).

Stage 3 — Baking. Many physical and chemical changes occur in the presence of heat to transform a liquid batter into a final baked muffin. Solubilization and activation of the leavening agent generate carbon dioxide, which expands to increase the volume of the muffin. Gelatinization of starch and coagulation of proteins provide permanent cell structure and crumb development. Caramelization of sugars and Maillard browning of proteins and reducing sugars promote browning of the crust. Reduced water activity facilitates Maillard browning as well as crust hardening (McWilliams 2001f). The choice of oven, baking pans, and baking temperature influences the final baked product (Benson 1988). A good flow of heat onto the bottom of the pan is necessary to produce a good product. Muffin tins are usually placed directly on the shelf or baking surface. The appropriate oven temperature is related to scaling and the type of oven. Standard 2-ounce muffins are baked at 204°C or slightly higher in a deck oven.

Deck ovens may be stacked and are often used in small retail bakeries, because these are less expensive and easier to maintain than reel or rotary ovens. Reel ovens consist of an insulated cubic compartment 6 or 7 feet high. A Ferris wheel-type mechanism inside the chamber moves four to eight shelves in a circle, allowing each shelf to be brought to the door for adding or removing muffin tins from the shelves (Matz 1988). Retail bakers often

prefer the reel oven as several hundred to several thousand pounds of batter can be baked each day. Rack ovens may be stationary, or the racks may be rotated during baking.

Stage 4 — Cooling. Products should be cooled prior to wrapping. This allows the structure to "set" and reduces the formation of moisture condensation within the package. Condensed moisture creates an undesirable medium that promotes yeast, mold, and bacterial growth and spoilage.

Stage 5 — Packaging. Muffins may be wrapped individually, in the tray in which they are baked, or transferred into plastic form trays for merchandizing (Benson 1988). The shelf-life of muffins is 3–5 days for wrapped muffins, and 4–7 days for those packaged in foil or plastic wrap. The storage life of muffins is significantly influenced by exposure to oxygen and moisture (Rice 2002). Cake-type muffins have a longer shelf-life than bread-type muffins because of their high sugar content and lower water activity (Willyard 2000). Added ingredients such as cheese, ham, and dried fruits, which are high in sodium or sugar content, reduce water activity and may increase shelf-life.

15.1.3 Finished Product

A muffin fresh out of the oven will vary in appearance based on the formula (whether the formula is for a cake- or bread-type muffin), the size of the muffin (mini muffin or mega muffin), and the desired shape, from flat or mushroom-shaped tops to the traditional bell-shaped muffin (Willyard 2000). In general, a desirable muffin product has a symmetrical shape, a rounded top that is golden brown in color, cells that are uniform and moderate in size, and a sweet flavor and pleasant aroma. It should be tender and moist, be easily broken apart, and be easy to chew with a pleasant aftertaste.

15.1.4 Muffin Evaluation

During the process of developing or modifying muffin formulas, bakers can use Table 15.6, Scorecard for Muffins, to evaluate muffins. Large commercial bakeries may use sophisticated methods to evaluate bakery products, for example, gas chromatography to evaluate flavor components.

15.1.4.1 Volume. Compact muffins with small cells or large muffins with peaked tops and tunnels are undesirable in all types of muffins. Diameter is a more important criterion than volume for evaluating mushroom and flat-topped muffins. For bell-shaped muffins, volume can be evaluated objectively by measuring the height and width of the muffin and calculating the volume ($\pi[r^2] \times$ height). To determine the height and width, measure the height of the muffin at the highest point, then slice off the top of the muffin and measure the diameter of the muffin. The volume also can be directly measured by Rapeseed displacement using a special volume meter (National Mfg., Lincoln, Nebraska).

15.1.4.2 Contour of the Surface. The muffin should be rounded and golden brown in color with a pebbled surface.

15.1.4.3 Color of Crust. Crust color should be a pleasing golden brown, not pale or burnt.

15.1.4.4 Interior Color. Crumb color should be a pleasant creamy color, not white and not too yellow. Crumb color will be darker with wholegrain flour or when added ingredients such as nuts, dried fruits, or spices are used.

15.1.4.5 Cell Uniformity and Size. Cell structure can be evaluated by making a vertical cut in the muffin to form two equal halves and then making an ink print or photo copy (McWilliams 2001b). A desirable muffin should have a uniform cell structure without tunnels.

15.1.4.6 Thickness of Cell Walls. Uniform thick-walled cells are desirable. Coarseness, thin cell walls, uneven cell size, and tunnels indicate poor grain.

15.1.4.7 Texture. Texture depends on the physical condition of the crumb and is influenced by the grain. A desirable muffin should be easily broken and slightly crumbly. Extreme crumbling, and toughness with lack of crumbling, are undesirable characteristics.

15.1.4.8 Flavor. An acceptable muffin should have a pleasingly sweet flavor. Flat, foreign, salty, soda, sour, or bitter tastes are undesirable.

15.1.4.9 Aftertaste. An acceptable muffin should have a pleasant, sweet aftertaste, not bitter or foreign.

15.1.4.10 Aroma. Aroma is recognized by the sense of smell. The aroma may be sweet, rich, musty, or flat. The ideal aroma should be pleasant, fresh, sweet, and natural. Sharp, bitter, or foreign aromas are undesirable.

15.1.4.11 Mouthfeel. Mouthfeel refers to the textural qualities perceived in the mouth. Characteristics can be described as gritty, hard, tough, tender, light, or moist. A desirable muffin is tender, light, and moist and requires minimal chewing.

15.2 BAGELS

15.2.1 History of Bagels

Bagels originated in southern Germany in the 1600s to honor the successful campaign of the Polish King Jan Cobleskill and his Christian horsemen against the Turkish invasion of Vienna, Austria. Dough used to make hard rolls was formed into the shape of a stirrup by pulling the dough around to form a half circle. The word bagel was derived from the Yiddish and German word for a round loaf of bread, bugel, and from the German word for stirrup, buegel (Meloan and Doerry 1988).

Bagels were developed by Jewish bakers in Eastern Europe and were sold by street vendors in small towns in Poland. Because of the circular shape, bagels symbolized the eternal circle of life and a protection against evil spirits (Roden 1996). Bagels followed Jewish immigration in the early 1900s from Eastern to Western Europe, Canada, and the United States.

TABLE 15.7 Bagel Formulas Listed by Baker's Percent and Weight.

	Basic Bagel Formula (Baker's %)	Weight (g)	Oregon Hazelnut Bagel Formula (Baker's %)	Weight (g)
	Ingredients			
Bread flour (11% protein)	95.2	2856	–	–
Vital wheat gluten	4.8	144	–	–
High-gluten wheat flour	–	–	100	4540
Sugar	3	90	–	–
Salt	2	60	2.0	80
Vegetable shortening	3	90	–	–
Vegetable oil	–	–	2.0	136
Compressed yeast	2	60	2.25	102
Water	50	1500	48.0	2180
Oregon hazelnuts (sliced thin)	–	–	25	1135
Total	160.0	4800	183.25	8173

Specifications

Mixer: Hobart A-200 with a dough arm and 20-quart bowl

Directions for basic bagel formula:

- Add all ingredients to the mixing bowl and mix at first speed for 2 to 3 min or until the dough comes together
- Mix at second spend for 8 to 10 min or until the gluten in the dough is developed
- Scale dough into 2.35 oz. (70 g) pieces and roll into cylinders 6 in. long
- Slightly moisten and join the cylinder ends to form a circle
- Roll the dough to seal the ends together
- Place the formed dough onto a sheet pan dusted with corn meal or lined with silicone paper
- Retard the dough by storing for approximately 18 h at 4°C
- Proof for 20 min at 30°C
- Place each piece of dough into water heated to 93°C and float the bagel on the water surface for 1 min, turn the bagel over and cook for another minute
- Remove bagels from the water with a wire sieve and place on a screen to dry for about 5 min
- Bake bagels on oiled sheet pans or aluminum sheet pans lined with silicone treated paper
- Scaling weight: 2.35 oz. (70 g) batter
- Yield: 5 dozen bagels
- Bake at 232°C for 17 min

Directions for Oregon Hazelnut Bagel formula:

- Maintain temperature of ingredients during preparation and proofing between 25°C and 27°C
- Add all ingredients to the mixing bowl and mix at first speed for 2 to 3 min or until the dough comes together
- Mix at second speed for 8 to 10 min or until the gluten in the dough is developed
- Proof for 10 min
- Scale at 2 oz. (60 g) with an automated bagel forming machine and place on silicone lined sheet pans
- Proof for 30 min
- Bake in a low-pressure steam oven; turn the bagels after the first 5 min of baking to produce a rounded surface on both sides of the bagel
- Scaling weight: 2 oz. (60 g) batter
- Yield: 12 dozen bagels
- Bake at 198°C for 17 min

Long known as a Jewish ethnic food available only in large metropolitan centers, bagels have been available since the 1970s in bakeries (including franchise bagel bakeries), restaurants, and grocery stores across the United States and Canada. Retail bakers can purchase bagels in several forms – ready to eat, baked and frozen, frozen dough that has been shaped, proofed and boiled in water, or frozen dough (Petrofsky 1986). The bagel is a traditional breakfast bread served with cream cheese; however, bagel bakeries also serve bagel sandwiches. Bagels come in a variety of sizes, shapes, and flavors with added ingredients such as cheese, fruit, seeds, nut meats, and chocolate chips. In 2004, the number of bagels sold in U.S. grocery stores totaled 223,000,000, representing $507,000,000 in sales (Anon. 2004).

New York style bagels use traditional formulas and preparation methods brought from Eastern Europe. The formula consists of five ingredients: high protein wheat flour, fresh yeast, malt extract, water, and salt. Strips of dough are formed into bagels, allowed to proof, dropped into boiling water and placed on wooden slabs, and put into the oven for drying. The bagels are then turned onto the hearth of a stone oven to finish baking. The product is a bagel with a shiny, hard outer crust, deep amber in color, with a dense, chewy texture inside. Many commercial bakeries modify the formula with the addition of sugar and oil for a softer crumb and longer shelf-life. Egg-bagel formulas made with whole eggs (4–12%, on a flour weight basis) or yolks (1.5–3.0%) provide variety in crumb color and flavor.

Bagel production in large commercial bakeries is often completely automated and does not require human labor. After mixing, the dough is put into the hopper of a dough divider, which scales dough into uniform portions that are delivered to a molder for shaping. Conveyors move shaped bagels into a proofing chamber and then into an automatic cooker, dryer, and tunnel oven. Automatic slicers and packaging systems complete the process (Petrofsky 1986).

15.2.2 Preparation

15.2.2.1 Selection and Scaling of Ingredients.

Flour. Flour represents 56–63% of the total weight of the bagel formula (Table 15.7). High-protein (13.5–14%) flour made from hard wheat is preferred (Petrofsky 1986). An alternative to using high-gluten/high-protein flour is to combine bread flour (11.2% protein) with vital wheat gluten (70% protein) to increase the protein content up to 14%. Bagels require high-gluten flour for a product with the desirable high volume, toughness, and round bottom crust. The gluten proteins, gliadin and glutenin, provide structural support in yeast-leavened bakery products. The high percentage of flour in the formula also contributes to the bagel's flavor.

Sweeteners. The level of sweeteners in bagel formulas is low (0–4%, on a flour weight basis) (Petrofsky 1986). Granulated sugar, malt syrup, honey, molasses, dextrose, corn syrup, or high-fructose corn syrup can be used in bagel formulas. Sweeteners are a source of carbohydrate for yeast fermentation and contribute to crust browning. Formulas with 3% or more sweeteners promote excessive yeast fermentation and overexpansion of dough, which may collapse after boiling, resulting in a bagel with low volume and an overly dark crust. Bagels made with less than 2% sweetener have pale crusts. New York style bagels lack sweeteners and depend on malt extract for crust browning.

Sodium Chloride. Salt levels in bagel formulas range between 1.5 and 2.2%. The functions of salt are to toughen the gluten during mixing and proofing, and to control yeast fermentation after the bagels have been boiled. Bagels lack flavor when salt is omitted from the formula because of the lack of both salt and sugar, as all of the sugar is used for yeast fermentation in the absence of salt. In addition, bagels made without salt have a tendency to over proof and then collapse after removal from the boiling water. Excessive salt results in bagels with a salty taste and a small compact form (due to the retarding effect of salt on fermentation) (Meloan and Doerry 1988).

Fat. Vegetable oil or shortening lubricates the bagel dough and contributes to crumb tenderness. The amount of fat in bagel formulas ranges from 0 to 5%. Bagels made from formulas with 3% fat have a higher volume and are more tender than formulas without fat. Increasing the fat content to 4% results in bagels with surface blisters (Meloan and Doerry 1988).

Yeast. The functions of yeast are dough fermentation and expansion during proofing, boiling, and baking. Compressed yeast is used at a level between 0.5 and 2%. Active or instant dry yeast can be substituted for compressed yeast but requires hydration prior to being added to the formula, as bagel dough has low water absorption. Bagels with 3% yeast over proof and collapse after boiling, resulting in a flat bagel (Meloan and Doerry 1988).

Liquid. The source of liquid in bagels is water at 50–53% on a flour weight basis. Water is necessary for moistening dry ingredients and gluten development. Stiff dough is desirable for holding shape during proofing, boiling, and baking. Formulas with more than 50% water form a soft dough and yield a bagel with low volume and surface blisters.

Additional Ingredients. Bagel variety is achieved by adding additional ingredients during processing. The most common added ingredients are fresh or dried fruit, nutmeats, minced garlic or onions, sesame seeds, poppy seeds, cornmeal, grated cheese, chocolate pieces, and spices. Spices are mixed with the dry ingredients before water is added, and seeds, cornmeal, and other toppings are sprinkled over the bagels just before baking.

15.2.2.2 Processing

Stage 1 — Mixing. The purpose of mixing is to moisten and disperse dry ingredients and develop gluten. Bagel dough is very stiff because of low water absorption, and mixing can overload mixing equipment. Dough quantity should be limited to 60% of mixer capacity to avoid overstressing the mixer (Petrofsky 1986). The mixer is set at the first (lowest) speed to disperse ingredients (approximately 2–3 min); then the mixer is set at the second (higher) speed for 8–10 min for gluten development. An alternative is to mix at a low speed for about 16 min for the total process (Petrofsky 1986). Undermixing stiff bagel dough is more likely to be a problem than overmixing. Undermixing the dough results in poor quality bagels – small and asymmetrical in shape with a blotched crust and a very dense crumb that gives a gummy mouthfeel when eaten (Meloan and Doerry 1988).

Maintaining the dough temperature at 24–27°C during mixing will produce a bagel of high quality. Bagels made at low dough temperatures (<19°C) have a dense crumb and

poor texture, and cracks appear in the crust of bagels made at high dough temperatures (>33°C) (Meloan and Doerry 1988). Some mixers have cooling devices to regulate dough temperature, because heat is generated during mixing. Iced water is also used to regulate dough temperature.

Stage 2 — Scaling and Makeup. Bagels range in size from small cocktail bagels to the very large "super bagel", or "bull bagel". However, most bagels are made from about 2.5–3 ounces (70–90 g) of dough. Bagels can be shaped either manually or with fully automatic bagel-forming machines at a rate of up to 18,000 bagels per hour. Shaped bagels are placed on sheet pans either dusted with cornmeal or lined with silicone-treated paper sheets to prevent the dough from sticking to the pan.

Shaped bagels are typically refrigerated for 12–18 h at 2–6°C to retard yeast fermentation and to allow dough fermentation by lactic acid bacteria. Retardation can be as long as 2 days or can be shortened by increasing the amount of yeast or adding dough conditioners (Petrofsky 1986). A longer fermentation period allows for development of a desirable flavor and aroma but can result in crust blisters that may be undesirable for some consumers (Meloan and Doerry 1988).

Stage 3 — Proofing. Shaped bagels that have been refrigerated to retard fermentation are proofed to allow warming and expansion of the dough before boiling in water. When bagel dough is retarded, yeast fermentation is limited to the relatively short period during proofing, boiling, and transferring to the oven for baking. Bagels are proofed under controlled conditions at 30–33°C and 65–75% relative humidity for 20–30 min to prevent crust formation during proofing (Meloan and Doerry 1988).

Stage 4 — Boiling. Boiling or "kettling" the shaped dough after proofing is unique to bagel production. Boiling sets the protein structure to form a hard crust and gelatinizes the starch to produce a glossy crust. The addition of 2.5% sugar or malt to the boiling water promotes a shiny crust. Omitting the boiling step in bagel production will cause the dough to expand excessively during baking, resulting in a collapsed or flat bagel.

Some large industrial bakeries omit the boiling step, and instead the bagels are baked in an atmosphere of wet steam (Meloan and Doerry 1988). In small-scale production, raw bagels are dropped into a kettle of water at a temperature just below boiling until floating bagels cover the water surface. The bagels will first sink to the bottom of the kettle for about 30 s and then float to the surface. The bagels should be cooked for about 30 s on one side, and then turned and cooked on the other side for another 30 s. The bagels are then removed from the water and placed on a pan. A sieve or screen is an efficient tool for turning and transferring bagels (Petrofsky 1986).

Stage 5 — Baking. Traditionally, bagels were baked on redwood boards placed on oven shelves; the bagels were turned over after 5 min of baking to produce a bagel with a round bottom. Transite or metal plates can be used instead of wood for baking bagels directly on the oven shelf. Bagels can also be baked on oiled or glazed sheet pans or sheet pans lined with parchment paper. Bagels baked on solid pans will have slightly flatter bottoms than bagels baked directly on oven shelves (Petrofsky 1986). However, bagels baked directly on perforated screen pans will have a more symmetrical rounded bottom. A relatively high temperature is needed for baking bagels to develop a good crust color, because

ingredients that promote browning are in low amounts or completely lacking in bagel formulas for example, sugar or other sweeteners, milk, eggs, whey, or soy protein (Meloan and Doerry 1988). Toppings such as caraway seed, poppy seed, sesame seed, minced onion or garlic, cornmeal, or grated cheese are applied to the bagel tops immediately before baking. Bagels are baked at an oven temperature of 204°C for 20–25 min or at 232°C for 17 min, or until golden brown.

Stage 6 — Packaging. Bagels are allowed to cool at room temperature before packaging. Bagels are packed in paper bags if purchased while still warm to allow cooling without condensation. Completely cooled bagels are packed tightly in plastic bags for sale. Bagels have a short shelf-life because of the low fat and sugar content and should be frozen if anticipated storage time is longer than 24 h.

TABLE 15.8 Scorecard for Bagels.

Evaluator:
Product:
Date:

Score

External Qualities

1a. Volume
Specific Volume: $\pi(r^2) \times$ height $\div$ weight in grams (cm) 1 = low volume, shriveled appearance; 5 = light with moderate cells; 9 = large with collapsed top

1b. Contour of the surface
1 = absolutely flat bottom; 5 = pleasingly rounded top and bottom; 9 = somewhat rounded bottom;

1c. Crust surface
1 = irregular, mottled surface; 3 = dull surface; 5 = shiny, smooth surface; 7 = surfac blisters; 9 = surface cracks and/or tears

1d. Crust color
1 = much too pale; 3 = somewhat pale; 5 = pleasingly golden brown; 7 = somewhat too brown; 9 = much too brown, burned appearance

Internal Qualities

1e. Interior color
1 = much too white; 5 = pleasingly creamy; 9 = much too dark

1f. Texture
1 = extremely dense, compact cells; 5 = even cells throughout; 9 = very large cells

1g. Flavor
1 = strong yeast flavor; 3 = bland flavor; 5 = pleasingly sweet; 9 = overly salty flavor

1h. Aftertaste
1 = extremely distinct; 3 = somewhat distinct; 5 = none

1i. Aroma
1 = lack of aroma; 5 = sweet and fresh aroma; 9 = sharp, bitter or foreign aroma

1j. Mouthfeel
1 = gummy, cohesive interior; 3 = somewhat gummy interior; 5 = tender, moist and easy to chew; 7 = somewhat dry and tough; 9 = tough and hard to chew

Overall Acceptability

1 = very unacceptable; 3 = somewhat acceptable; 5 = very acceptable

TABLE 15.9 Bagel Troubleshooting.

Problem	Possible Cause	Solution
Dull crust	Boiling water too cool	Increase water temperature to 93–100°C
	Oven too cool	Increase oven temperature to 204°C
Bagel is small and hard	Insufficient water in the dough	Adjust water level
	Yeast level too low	Adjust yeast level
	Retardation time not long enough before boiling	Adjust holding time
Bagel is very large and soft	Too much yeast	Adjust yeast level
	Bagels are overproofed	Adjust proof time before boiling
Bagels collapse or shrink during baking	Undermixing of dough	Mix to ensure gluten development
	Bagels are overproofed	Adjust proof time before boiling
Bagels have surface; tears	Temperature during mixing or retardation too high	Adjust temperature during mixing to 24–27°C and during retardation to 30–33°C
Bagel surface; has blisters	Bagels are retarded too long	Adjust proof time
	Too low humidity during proofing	Adjust humidity to 65–75%
Bagel has a flat bottom	Dough is too soft	Mix dough sufficiently to develop gluten
	Flour too weak	Use high-gluten flour or adjust protein to 14% by adding Vital Wheat Gluten

15.2.3 Bagel Evaluation

A desirable bagel has a round top and bottom with a definite hole in the center; a crust that is hard, shiny, and amber in color; and a tender crumb that is easy to chew. Factors that can contribute to a bagel of poor quality include the quality of ingredients, the formula, and the entire bagel process from mixing, retardation, boiling, and proofing to baking. Refer to Table 15.8, Scorecard for Bagels, and Table 15.9, Bagel Troubleshooting, for use in evaluating bagels.

GLOSSARY

Allergen: A substance that causes an abnormal immune response in individuals with an allergy to that substance. The most common food allergens are peanuts, milk, eggs, wheat, soy, tree nuts, fish, and shellfish.

AMS/USDA: Agricultural Marketing Service/U.S. Department of Agriculture.

Anthoxanthin: A naturally occurring color pigment in plants and wheat flour. The pigment turns yellow in the presence of an alkaline medium; for example, the crumb is yellow when excessive amounts of baking soda have been added to the muffin batter.

Antioxidant: Naturally occurring compounds, found in plant foods, that provide possible health benefits by quenching free radicals and thus preventing cancer, cardiovascular disease, and other chronic diseases. Color pigments in fruits and vegetables are important sources of antioxidants, for example, proanthocyanidin in blueberries, lycopene in tomatoes, and lutein in spinach.

Baker's percent: Term used by the baking industry to describe the amount of each ingredient by weight for a "recipe" or formula compared with the weight of flour at 100%. Also described as flour weight basis.

Caramelization: Chemical changes in sucrose (dehydration and polymerization) in response to heat during baking; caramelization provides the characteristic color and flavor in baked products.

Carbon dioxide: Gas produced by chemical leavening agents that expands muffin batter during baking.

Cell structure: An internal characteristic of baked products. A desirable cell structure is uniform with moderately sized cells. Factors that influence cell structure are the formula, mixing process, and baking temperature.

Chemical leavening agent: Agents made of a mixture of alkaline bicarbonates and a leavening acid phosphate that is activated by water and baking temperatures to generate carbon dioxide, which expands the muffin batter during baking.

Coagulation: Changes in the structure of protein in flour, milk, and eggs during baking that binds the ingredients; denaturation of protein breaks weak chemical bonds and allows formation of stronger bonds among strands of protein, causing "clumping" and setting the structure of baked products.

Crumb: An internal characteristic of baked products that describes the texture. It is related to tenderness or ease in breaking into pieces, from very crumbly to tough with little tendency to crumble.

Deck oven: A type of oven used in industrial bakeries, small bakeries, or restaurants. A deck oven may consist of a single oven or multiple ovens stacked horizontally; each oven has individual temperature controls.

DHHS/FDA: Department of Health and Human Services, Food and Drug Administration.

Emulsifying agent: An ingredient having both polar and nonpolar groups, allowing for attraction of both polar (water) and nonpolar (oils) ingredients. Emulsifying agents improve keeping qualities of muffins by dispersing water throughout the batter.

FAO/WHO: Food and Agricultural Organization of the World Health Organization.

Fat replacer: Ingredients used to replace fat in baked products to meet consumer demand for "healthier" foods lower in calories and saturated fat. Fat replacers replicate the mouthfeel and keeping qualities of fat by attracting water.

FDA: U.S. Food and Drug Administration.

FDA/CFSAN: Food and Drug Administration/Center for Food Safety and Applied Nutrition.

FDA/ORA: Food and Drug Administration/Office of Regulatory Affairs.

Formula: Term used instead of "recipe" by the baking industry; the weight of each ingredient is determined based on the weight of flour at 100%.

FSA: Food Standard Agency of the United Kingdom.

FSANZ: Food Standards Australia and New Zealand.

Functional foods: Food marketed to have specific health benefits; for example, a health benefit of including oats in the diet is lowering blood cholesterol.

Gelatinization: Changes in the starch granules of flour (breaking of hydrogen bonds and swelling) in the presence of water and heat; starch gelatinization gives structure to quick breads.

GMO (genetically modified organism): Refers to new plant varieties developed using genetic engineering or biotechnology, and ingredients made from GMO plants, for example, cornmeal made from genetically modified corn.

Hard wheat: A type of wheat used for making flour with high or intermediate amounts of protein (11–14%) and gluten strength suitable for the production of bagels, sourdough breads, and other yeast breads.

Hydration: The addition of liquids to dry ingredients in the preparation of quick breads; hydration promotes starch gelatinization, which gives structure to the final baked product.

Hygroscopic: A quality of attracting water molecules; sugar in muffin batter attracts water and contributes to the moistness and keeping qualities of baked products.

Lactose: The disaccharide made of glucose and galactose and found in milk. Both lactose and protein in milk contribute to Maillard browning in baked products.

Maillard browning: A change in color that occurs during the baking process as a result of the reaction between an aldehyde or ketone group from sugar and the amino acids from protein sources in the batter such as milk, soy, and eggs.

Malt extract: An ingredient used in water bagels to promote crust browning. The liquid extract is obtained from malt by mashing at progressively higher temperatures until all starch has been converted to maltose and dextrin. The extract is concentrated to form a thick syrup with a color ranging from light amber to deep brown.

Mouthfeel: Refers to the textural qualities of food perceived in the mouth. Characteristics can be described as gritty, hard, tough, tender, light, or moist.

NLEA: Nutrition Labeling and Education Act.

Nutraceuticals: Naturally derived compounds from food, botanicals, and dietary supplements marketed to prevent disease or to treat specific medical conditions. For example, plant sterol esters are added to vegetable oil spreads; the health benefit of these spreads is lowering of serum cholesterol.

Neutralizing value: The parts of sodium bicarbonate that will be neutralized by 100 parts of a leavening acid such as monocalcium phosphate.

NV: Neutralizing value.

Organic: Term used on food labels to identify agricultural products produced under specific guidelines as defined by regulatory agencies, such as the U.S. Department of Agriculture National Organic Program and the Joint FAO/WHO Food Standards Programme Codex Alimentarius Commission on Organically Produced Foods. Vegetables

are grown without using conventional pesticides, petroleum-based fertilizers, or sewage sludge-based fertilizers. Animal products identified as organic come from animals that are grown without the use of antibiotics or growth hormones, are given organic feed, and have access to the outdoors.

Rate of reaction: The percent of carbon dioxide released during the reaction between sodium bicarbonate and a leavening acid phosphate under standard conditions of temperature and pressure.

Reel oven: Ovens with a Ferris-wheel-type mechanism to move four to eight shelves in a circle, allowing baking pans to be moved to the front of the oven for removal.

Scaling: A term used by the baking industry to describe the weighing of ingredients, dough, or batter.

Shelf-life: The "keeping" qualities of baked products such as moistness and tenderness; sugar and fat extend the shelf-life of breads.

Sodium aluminum sulfate: A slow-acting acid, used in combination with a fast-acting acid such as monocalcium phosphate in double-acting baking powder, which acts as a leavening agent in quick breads.

Sodium bicarbonate: Commonly called baking soda, a leavening agent used in combination with acid ingredients such as sour cream, yogurt, buttermilk, or fruit juice in muffin batter. Baking powder includes both an acid salt (monocalcium phosphate) and an alkaline salt (sodium bicarbonate).

Sodium chloride: Commonly called salt, and added to baked products to enhance other flavors.

Sugar replacers: Calorie-free or reduced-calorie ingredients used in baked products to give sweetness with fewer calories than sugar; sugar replacers are used to meet the demands of consumers for "healthier" foods.

Trans fat: The form of fat in partially hydrogenated vegetable oil or "shortening", used in commercial bakery products. Diets high in trans fat raise LDL-cholesterol and increase the risk for cardiovascular disease.

Transite: A high-density, fiber-reinforced, cement sheet that can withstand very high temperatures up to 315°C. Used as a baking surface in ovens for baking bagels.

True formula percent (*true percent*): Term used by the baking industry to describe the amount of each ingredient by weight for a "recipe" or formula compared with the total weight of all ingredients.

Vital wheat gluten: The insoluble gluten protein of wheat flour that has been concentrated by removing starch and other soluble components and drying to produce a free-flowing powder that contains 75–80% protein and has a water absorption of 150–200%. Used as an ingredient in bakery products to strengthen and control expansion of dough to ensure a product of uniform shape.

Water activity: The ratio of vapor pressure in food compared with the vapor pressure of water. Meats and fresh fruits and vegetables have high water activity; the addition of salt or sugar to foods lowers water activity because both salt and sugar attract and hold water.

WHO: World Health Organization.

16.1 INTRODUCTION

The art of baking cakes dates back to the time of the earliest settled communities. Traces of small cakes, rather like modern cookies, have been found in Neolithic villages inhabited more than 10,000 years ago. The first cakes were probably baked around the time people discovered how to grind grain, thereby producing flour (Anon. 2003). Cakes gained in popularity once cooks had access to sugar. Cane sugar, which historians believe was first manufactured in India, traveled from India to Arab countries, where it was artfully combined with spices and flavorings imported from the Far East. By the seventeenth century, many cooks were using beaten egg whites to replace yeast in leavening cakes. The era of the light-as-air sponge cake had arrived. These European cakes form the basis of our cake heritage (Anon. 2003).

The two basic categories of cakes – foam and shortened – are distinctly different in their preparation and problems. The butter or shortened style of cake (pound cake, yellow cake, chocolate cake, and so on) is made with fat. Foam style cakes are made without fat and include angel and sponge cakes. Chiffon cakes are made with oil, but resemble sponge cakes.

The quality of a cake is dependent on variations of certain factors. However, there is much more to making an acceptable product. The main principle involved in a cake formula is to provide the proper proportions of the various ingredients so that the tenderizing agents – sugar, shortening, egg yolks, leavening agents, and chocolate – counteract the toughening or binding ingredients – flour, egg whites, and milk solids. The final step is adherence to optimal mixing and baking procedures. This chapter will deal with the different aspects of cake production, such as function of ingredients, mixing methods, and baking requirements, focusing on their effects on cake quality.

16.2 INGREDIENTS

Cakes have a higher proportion of sugar, milk, and fat to flour than do breads, and the flour used is usually cake flour. Both flour and eggs contain the proteins that contribute strength and structure to cakes (Corriher 2001).

16.2.1 Flour

Flour provides structure, texture, and flavor to baked products. Starch is one of the components in flour that strengthens the baked item through gelatinization (changes that starch undergoes when subjected to moist heat), and is one of the factors that contributes to crumb.

Crumb is partially created during baking by the number and size of air cells produced, the degree of starch gelatinization, and the amount of protein coagulation (Jacobson 1997).

For cakes the flour of choice is cake flour. It is pure white and has a fine, silky soft texture. Its protein content may vary from 7.5 to 8.8% for high-sugar cakes, and 8.5 to 9.5% for heavier cakes (Pyler 1988). Cake flour has a small particle size compared to all-purpose flour, resulting in less gluten formation, which gives the cake a fine grain, a delicate structure, and a velvety texture. In most cakes the protein should produce a soft gluten that does not toughen significantly during the mixing process, but is still strong enough to support the foam structure of the cake. Although gluten formation is important, the ability of the intact starch granules to gelatinize is more essential for cake structure. Because gelatinization is dependent on the presence of the necessary amount of water, the liquid-carrying capacity of cake flour should be as high as possible. The capacity is dependent on not only the protein content of the flour, but also on its maturing treatment and granulation (Freeland-Graves and Peckham 1996).

The maturing treatment of flour consists of two steps. The first step is chlorination, which decreases the pH of the flour from 5.8–6.1 to 4.6–5.1, bleaches the plant pigments, and improves baking quality (Fustier and Gelinas 1998). Chlorination increases the water absorbency of the starch, which contributes to a firmer, smaller crumb and a stable product. This is especially important with the high amount of sugar in the cake formula and, because sugar is a good competitor for water, chlorination aids the starch in this capacity (Conforti and Johnson 1992). Chlorination is also believed to increase the surface porosity of starch granules (Varriano-Marston 1985). The porosity of the starch permits increased uptake of liquid which improves starch geletinization. The second step in maturing is treatment with benzoyl peroxide. This treatment eliminates any traces of color left from chlorination and produces a pure white color.

All-purpose flour can be used to make cakes, but the cakes may have a slightly coarser texture and lower volume (Yamazaki and Donelson 1972). The protein content of all-purpose flour averages about 11%, but bread flours, which need strong gluten development, have between 12 and 14% protein. Blending hard and soft wheat flours yields flour that can be used for all purposes – breads, cakes, or pastry. Despite what appears to be a uniform product, the actual protein content of all-purpose flour may differ from region to region and brand to brand. Regional differences have influenced manufacturers to place more protein in flour sold in the northern United States where yeast breads are more popular, compared to the South, where biscuits requiring a softer flour are more routinely consumed. All-purpose flour may or may not be bleached.

Self-rising flour is usually all-purpose flour, but cake flour could also be self-rising. The leavening agent and salt are added to the flour. The leavening agent is a baking powder (baking soda combined with a salt, monocalcium phosphate). One cup of self-rising flour contains about $1\frac{1}{2}$ teaspoons baking powder and $\frac{1}{2}$ teaspoon salt.

16.2.2 Liquid

Whether water, milk, or buttermilk is used in the recipe, their function will be the same. Liquid hydrates the starch in the flour and, when heated, causes gelatinization of starch. Liquid dissolves the ingredients, especially sugar, during mixing and baking of the cake batter. It is also essential for the release of carbon dioxide from either the baking powder or baking soda. Liquid also produces steam along with carbon dioxide, which aids in leavening. Milk is a popular liquid to be used in cake batter. In addition to contributing water, milk adds flavor and nutrients (complete protein, B-vitamins, and calcium), and contains certain

compounds that help produce a velvety texture, a creamy white crumb, and a browner crust. The lactose in the milk participates in the Maillard reaction (see the section on Sugar), resulting in a brown crust. Non-fat dry milk (NFDM) is often added for the enhancement of a golden crust color because of the Maillard browning reaction of the lactose and proteins. This NFDM changes the structural characteristics of the cake because it decreases the swelling of the starch granules, but has no effect on cake volume (Pearce and others 1984).

The liquid portion in a cake recipe must be worked out with care; too little liquid could cause (1) a peaked center and/or a cracked top because the batter is too thick; (2) a dip in the center due to insufficient starch gelatinization; and (3) a dry cake that stales very quickly. Too much liquid can produce a cake with (1) low volume due to poor retention of air in the batter and (2) a very moist (soggy) heavy texture.

16.2.3 Sugar

Aside from contributing sweetness, sugar also influences the volume, moistness, tenderness, color, appearance, and calorie (kcal) content of baked products. One important function is that it increases the volume of cakes by the incorporation of air into the fat during creaming. During baking, sugar raises the temperature at which gelatinization and coagulation occur, which gives the gluten more time to stretch, thereby further increasing the volume of the baked product and contributing to a finer, more even texture (Bean and Yamazaki 1978). The hydroscopic or water-retaining nature of the sugar increases moistness of the baked cake. This is evident when brown sugar is used in the formula. Brown sugar is used in some low-fat products because of its hydroscopic nature, which, therefore, increases moistness in the cake. Sugar competes with starch for available water necessary for the hydration of proteins and starch and eventually gluten development. Finally, sugar helps to brown the crust through caramelization and Maillard browning. Caramelization is a process in which sucrose alone is involved in a series of chemical reactions caused by the baking temperatures (Camire and others 1990). Maillard browning involves two components: protein and carbohydrate. Flour contains protein and carbohydrate. Sugar, also a carbohydrate, participates in the reaction, which produces a brown crust (Whistler and BeMiller 1997).

Syrups of various kinds are used in cake batters, but these, too, produce a difference in the appearance and palatability of the baked product. For example, honey in a cake formula produces a product that remains moist for a longer period of time owing to its fructose content (fructose is a sugar that is highly hydroscopic). However, honey cakes are heavier and more compact than cakes made with crystalline sugar.

For special diets and products, alternative sweeteners are used in cakes. Only four alternative sweeteners are currently approved by the FDA for use in the United States: saccharin, aspartame, acesulfame-K, and sucralose. Two new sweeteners that have been approved by the FDA are alitame and neotame. In addition, cyclamates, which were approved but later banned in the United States as a potential carcinogen, are attempting a comeback.

One drawback of alternative sweeteners is that they do not provide the important functional characters of sugar: bulking, binding, texturing, and fermenting. However, certain compounds can be added to foods to compensate for bulking. These compounds include cellulose, maltodextrin (also used as a binding property), the sugar alcohols, and polydextrose. Polydextrose provides a texture similar to sugar, but the amount may have an adverse effect on texture in high-ratio cakes (cakes with a higher ratio of sugar and liquid to flour) (Pateras and Rosenthal 1992).

16.2.4 Shortening

Shortening is the primary tenderizing agent in the cake. Shortening also imparts moistness. A layer cake made with oil as the shortening gives the impression of a moister crumb than does a cake from the same formula made with an emulsified plastic shortening (Stauffer 1998). Keeping quality and, depending upon the type of shortening, flavor, round out the attributes. Pound cakes prepared with butter impart a flavor that cannot be equaled compared with when prepared with a plain shortening.

The hydrogenation process creates a plastic fat that is important to the creation of a cake batter that traps air bubbles to produce a fine-grained and high-volume cake. Cakes typically contain 15–25% fat on a batter weight basis. Therefore, high-ratio shortenings (containing mono- and diglycerides) are recommended. This type of shortening significantly enhances the structure of the cake batter, thus permitting the sugar-to-flour ratio to be increased and, consequently, improving cake quality (Wainwright 1999). Use of an emulsified shortening distributes the fat more evenly and finely in the batter (Moncrieff 1970). During mixing, fat and sugar are combined and mixed (creamed). During this step, the air is dispersed in the solid phase. In the presence of an emulsifier such as monoglyceride, these bubbles are divided into numerous small air cells by the action of the beater. The shortening must be solid so that the bubbles do not escape but also plastic so that it can fold around each air pocket (β' crystal structure of fatty acids in the fat).

When a one-stage process (all ingredients are added at once) is used in the mixing the air is entrapped in the water phase rather than in the shortening. To form the air-in-water foam, an α-tending emulsifier in the shortening is required. The most common emulsifiers that are used, at 7–10%, in the plastic fat are propylene glycol monoesters (PGME) and acetylated monoglyceride (AcMG) (Stauffer 1998).

Cakes made with oil as the shortening are more tender than those made with a plastic shortening. The cake gives an impression of moistness when eaten, even after storage for a week or more (Stauffer 1998). In commercial cake production, unfortunately, oil cakes are often too tender to withstand the necessary handling along the production line. However, tenderness is highly desirable from the consumer's standpoint, and so packaged cake mixes for home use are usually made with oil for the shortening. Again α-emulsifiers are used to stabilize the foam created by proteins contributed by eggs and flour. Propylene glycerol monostearate (PGMS) and stearic acid (80 : 20) help to form a strong film (Stauffer 1998).

Fat can be reduced in cakes, but the properties of the final product will be altered. Decreasing the amount of fat in a cake will create a lower volume and denser crumb with tunnels. Because the "ideal" fat substitute does not exist, a systems approach to reduced-fat or low-fat food formulations has been proposed. Simply put, a systems approach uses a combination of different ingredients that may or may not belong to either of the classes of fat replacers and requires a basic knowledge of ingredient technology to formulate desired products. The system may contain emulsifiers, fat substitutes or mimetics, fibers, water control ingredients, flavor, and bulking agents. Water or moisture control poses one of the greatest challenges in formulating reduced-fat snacks or baked goods. In these systems water is used to replace fat, to increase bulk, or for functionality (Akoh 2002).

16.2.5 Leavening Agents

Leavening agents are characterized as air, steam, and CO_2 (carbon dioxide). Chemical sources of CO_2 in a cake batter are baking powder and baking soda. These ingredients are essential for a risen product and will be described below.

The initial leavening agent incorporated into the cake batter is air. Simple manipulation of the ingredients and batter incorporates air. Air is incorporated by the simple action of sifting together the flour and other dry ingredients (salt, baking powder, and/or baking soda). In many angel-food-cake recipes the sifting of flour and sugar is recommended at least four times to ensure proper air incorporation. Another method that incorporates air is "creaming" of fat and sugar. The characteristic of the fat (plastic fat) helps in the incorporation and trapping of air and distribution of air cells into small units in the batter. During heating, air is released and the product rises. Beating egg whites, especially important for foam-style cakes, is another example of incorporating air into the batter. Egg whites warmed to room temperature are able to hold onto the air that is beaten into them. Whole eggs are beaten into a foam for some cakes (genoise, for example). Usually the eggs are warmed over a water bath and beaten at the same time in order to trap air during beating. Whether it is a whole egg or egg white, the foam must be baked immediately because if it stands for any length of time air is lost and so is the volume of the cake. Careful folding of the ingredients is a manipulation technique that must be carefully observed. Over-manipulation of the foam causes loss of air and a heavy, low-volume cake.

Steam is formed by the liquid in the recipe. Whether the liquid is water or milk, when heated steam is produced, the cake rises. Liquid has other functions in the recipe (see section on Liquid). Egg whites are made up of water ($\sim$88%). A foam-style cake, particularly angel food cake, relies on the steam produced by the egg whites. Therefore, a true foam-style cake is leavened predominately by air and steam.

In shortened cakes, the major part of leavening is done by a commercial baking powder or baking soda. When either of these compounds comes in contact with a liquid and heat, a chemical reaction occurs that produces CO_2, and the product rises. When a cake rises to the proper height, the texture is porous and light.

Baking soda (sodium bicarbonate) chemically yields CO_2 when it reacts with an acid in the recipe. Examples of an acid would be buttermilk, sour milk, cocoa, yogurt, sour cream, applesauce, honey, brown sugar (contains organic acids), and fruit juice. Up to $\frac{1}{4}$ teaspoon baking soda per cup of flour is recommended.

The two types of baking powder are fast, single-acting powder and slow, double-acting baking powder. The different types of baking powder all give off the same amount of carbon dioxide, but they have different effects on cake quality because of the distinctive tastes of their salts, different rates of evolution of carbon dioxide, and effects on stability of emulsions in the batter. A flour mixture made with fast or single-acting baking powder should be handled quickly and efficiently and placed in the oven as soon as possible, because it starts to produce carbon dioxide as soon as water is added. Any delay allows the carbon dioxide to escape and decreases the ability of the mixture to rise. Almost 75% of the carbon dioxide is evolved in the mixing of the batter when a single-acting baking powder is used, compared with less than 50% with a double-acting baking powder. The greater loss of carbon dioxide before baking when using single-acting baking powder can decrease the volume of the baked cake. Approximately $1\frac{1}{2}$ to 2 teaspoons of single-acting baking powder are required for every cup of flour.

Many commercial bakers use double-acting baking powder (sodium aluminum sulfate[SAS]-phosphate powder), which reacts twice: once in the mixing bowl and then in the oven (heating). Approximately 1 to $1\frac{1}{2}$ teaspoons of double-acting baking powder is required for every cup of flour.

16.2.6 Eggs

Eggs are added to help strengthen the structure, as well as to increase leavening, to act as emulsifiers, and to add color and flavor (Brown 2004). It is important to increase the amount of liquid as the amount of egg increases; otherwise the overall volume will decrease. Because eggs have a toughening effect, the addition of eggs is normally balanced by an increase of tenderizing agents – fat and sugar. Too much egg produces a tough product; too little may cause an irregular or coarse crumb.

Eggs are available in shell form, frozen, and dried as a powder. Unless treated, shell eggs will only keep a limited time, as the shell is porous and the membrane lining is semipermeable. Bacteria are able to penetrate to the interior of the egg, and as the egg is broken down by the bacteria, strong-smelling gases are given off (Whiteley 1971a).

Egg yolks are particularly rich and would enhance the flavor and appearance of most cakes. The yolk is rich in lecithin, which is valuable for its emulsifying properties in batters. Yolks are available both frozen or dried. Frozen yolks are either treated with sugar or salt to prevent any break down of the yolk after it is defrosted.

Egg whites are available because of their ability to form a foam. It is easier to whip frozen egg whites to a foam compared with fresh egg whites that have been pasteurized (either frozen or dried), and dried whole eggs that have been reconstituted do not whip to a foam as easily as their fresh counterparts. The foaming ability is reduced by the heat of pasteurization of the egg whites and by the partial disruption of the emulsion of fat in the yolk for the whole eggs. The foaming ability of dried whole eggs can be improved by whipping them at 140°F (60°C) (Freeland-Graves and Peckham 1996).

Sugar is added to the egg-white foam to form a meringue. The addition of sugar stabilizes the foam. When beating egg whites, the whites go through four stages: foamy, soft peak, stiff peak, and dry. At the dry stage the egg whites become dry and brittle and at the same time the cells become overstretched. When this occurs it is difficult to fold in the ingredients, and the cake will not rise. Usually the cells are overstretched and will collapse. Some cakes, such as angel food, call for the addition of sugar to the egg-white foam. When sugar is added, a meringue is formed (this is known as the meringue method). Cream of tartar is added to the egg whites during the foamy stage when the whites, are being whisked. Cream of tartar is an acid, and lowers the pH of the whites, thus stabilizing the whites. Sugar is added during the soft peak stage (peaks fall over when beaters are removed). Sugar is added gradually and then beating continues until the peaks are stiff and shiny. Sugar stabilizes the meringue, and there is no danger of overbeating the whites.

Demand for low-fat and low-cholesterol products has motivated the food industry to find substitutes for eggs in cakes. As eggs are used for the emulsification properties of lecithin, soybean lecithin can be substituted. Its advantage is that it contains no cholesterol, as soybean originates from a plant. A better approach is to use concentrated blends of the phospholipids present in eggs, such as phosphatidyl choline and ethanolamine. These blends of phospholipids create very soft and tender cakes (Silva 1990). The level of fat may be reduced 40–60%, because the phospholipid blends have the ability to complex with sugar and fat.

16.3 CAKE BATTERS: CHARACTERISTICS AND MIXING

Accurate measurement of the ingredients will help to guarantee a quality product. In the home, the use of correct measuring utensils and techniques will ensure an acceptable

product. On a larger scale, weighing of the ingredient is a more accurate way to prevent any mishaps in the cake formula.

16.3.1 Shortened-Style Cakes

Shortened-style cakes are the most commonly prepared cakes, especially for birthday and wedding celebrations. The modern shortened-style cake recipes have a higher sugar content for use with shortenings that contain mono- and diglycerides. Rules for these recipes have been generalized: (1) the weight of the sugar should exceed that of the flour; (2) the weight of the eggs should exceed that of the fat; and (3) the weight of the liquid in the eggs and milk should equal or slightly exceed the weight of the sugar.

The weight of sugar varies, as was established earlier. In yellow and white cakes, the sugar to flour ratio generally does not exceed 3 : 2 or fall below 1 : 1. Batters that have appreciable amounts of chocolate or cocoa may have a sugar to flour ratio higher than 3 : 2. Too much flour is undesirable as it can produce a heavy, dry cake with tunnels in the crumb. Tunnels can also form in excessive baking temperatures as well as from overmanipulation.

Because eggs have a toughening effect on batter structure, an equal or almost equal weight of fat must be used to provide a tenderizing effect. The term liquid refers to the total weight of the liquid ingredient and eggs. In a high-sugar-ratio cake made with emulsified shortening or fluid cake shortening, the amount of milk or liquid may be higher than in other recipes, and the combined weight of the liquid ingredients may exceed the equal-weight rule, rising as high as 165% of the flour weight.

The structure of the plain shortened cake is that of an air-in-fat foam distributed in a flour-in-liquid mixture. Starch is suspended as lumps in the batter; air, which is incorporated during the initial mixing, appears near the fat/starch pools. The presence and dispersion of the air bubbles is essential and can be regarded as the nucleus for the expansion of the cake. The complete dispersion of the ingredients is also a fundamental requirement for a good cake. Therefore, the purpose of batter mixing is (1) to disperse all the ingredients as efficiently as possible, and (2) to incorporate air into the mix. The incorporation of air takes place during (1) a period of rapid incorporation in the form of large bubbles, and (2) a stabilizing period when the bubbles are reduced in size (Bennion and Bamford 1973).

Fat melts and releases the air bubbles into the aqueous phase of the batter, the air and carbon dioxide expand throughout the batter, water is changed to vapor, and the fluid batter is lightened until the starch gelatinizes. The solid porous structure of the crumb is set by heat gelatinizing the starch and denaturing the proteins of the eggs and flour.

16.3.2 Methods for Mixing Shortened Cakes

16.3.2.1 Creaming Method (Conventional Method). The creaming method initially combines the shortening with the granulated sugar at slow to medium mixing speed until the components are thoroughly blended and the mixture has become aerated. This stage is followed by the incorporation of the eggs, and the creaming action is continued. Mixing is completed with the addition of milk and flour in alternate small portions (Pyler 1988).

Among the major advantages of the creaming method are the incorporation of large volumes of air in the form of minuscule cells in the fat phase of the batter: the

coating by the fat on the flour and sugar, which delays their respective hydration and solubility; and the near absence of flour gluten development. In the case of the current flours in the market, the last benefit no longer possesses the significance it formerly had, because these flours are bleached and have a low protein content.

Mixing time is important. Overmixing will cause a loss of air and a heavy cake. Total mixing time for the creaming method will range from 15 to 20 minutes: the initial creaming stage takes 8–10 minutes; the second stage with the incorporation of the egg, 5–6 minutes; and the final stage of milk and flour addition, 5–6 minutes. If the milk is added too quickly it will cause curdling of the batter and cause the emulsion to be inverted to a water-in-oil emulsion. If the egg whites have been separated from the yolks, they are beaten until stiff and folded into the batter at the very end. This is a time-consuming method for mixing a cake, yet it is a popular household method because it produces a fine-grained cake with a velvet crumb.

16.3.2.2 Conventional Meringue Method. This is a modification of the conventional method. It differs from the aforementioned method in that the separated egg whites and part of the sugar may be made into a meringue and folded into the batter at the very end.

16.3.2.3 Conventional Sponge Method. In this method the eggs are separated and about half the sugar is added to them. The sugar–egg mixture is beaten until foamy and stiff and then added to the other ingredients at the end of mixing. The advantage of the conventional meringue method and the conventional sponge method is that less fat is creamed with the sugar and more air is added at the end of mixing.

Quick Mixing Methods. Cakes made by the quick mixing methods are formulated to be made with emulsified shortenings. These are the high-sugar-ratio cakes. All the dry ingredients are sifted together in a bowl and then the fat, milk, and flavoring are added. After the mixture has been beaten vigorously for 2 minutes by an electric mixer, the eggs are added and the mixture is beaten for another 2 minutes.

SINGLE-STAGE (DUMP METHOD). This method is closely related to the quick method. This method consists of placing all the ingredients into a bowl and mixing them until they are combined.

PASTRY BLEND METHOD. In the pastry blend method the fat and flour are creamed together to produce a foam. Into this a mixture of the sugar, salt, baking powder, and one-half of the milk is blended; finally, the egg and the remainder of the milk are mixed in.

16.3.3 Baking

The batter should be baked as quickly as possible after being mixed. Cake batters that are not to be baked immediately should be covered tightly with plastic wrap and refrigerated until the batter is to be placed in the oven. Once the baking powder has entered the solution, some carbon dioxide is evolved. If the mixture is left standing for prolonged periods, some of the carbon dioxide will escape and the baked product will have a characteristically coarse cell structure.

During baking there is considerable movement of the batter by convection currents. Development of these currents is dependent on the temperature, batter type, and pan shape. Batters of high viscosity, such as pound cake, exhibit much less movement compared to batters of a low viscosity, such as high-ratio cakes. As the batter is heated, its viscosity decreases, as would be expected. However, the higher temperature also triggers the leavening system and produces gas. As the bubbles increase in size, the batter becomes a foam. The foam results in a higher apparent viscosity of the system. As the temperature of the system increases, the starch gelatinizes, and much of the free water becomes bound. This sets the cake into a rigid system that does not collapse as it cools. The top center of the cake is the last to bake. If the cake has too little or too much water, a dip forms at the center. With the correct amount of water, a smooth contoured crown is produced (Trimbo and Miller 1966, 1973).

16.3.4 Cake Pans

Cake pans are available in a variety of shapes and forms, ranging from flat sheet pans to cupcake molds to form-pans of various configurations. Pans for larger product sizes are generally fabricated as individual units, whereas pans for snake cake items are normally strapped into sets or consist of frames containing rows of individual cups or molds.

The weight, or gauge, of the pan's metal also affects quality – the heavier the pan the better. Crumb formation is partially dependent on the degree of heating that occurs when the cake batter is first placed in the oven, and rapid heat absorption plays a role in this. Cake pans have shiny sides with dull, rough bottoms. The shiny sides will reflect radiant energy, so that the batter will rise before the cake sets, and the dull rough bottoms will absorb radiant energy to form the bottom crust.

The pans are prepared prior to mixing the batter. For a shortened-style cake the bottom is greased, but the sides generally are not. The ungreased sides provide traction allowing the rising mixture to reach full volume. When greasing the bottom of the pan waxed or parchment paper may also be placed in the bottom before greasing to allow for easier cake removal.

To avoid cake hanging over the side, the pan should be filled only half full with batter before the cake is baked. If an odd-shaped pan is to be used the capacity can be measured with water, then only half as much batter is spread in the pan.

Cakes are done if the top springs back when lightly touched with a finger or when a cake tester inserted into the center of the cake comes out clean. The cake should not be tested until the minimum baking period is over. If the oven door is opened during the early stage of the baking time, complete gelatinization of the starch has not occurred, and the cake will collapse.

Cakes should be allowed to stand for 5–10 minutes or until the interior reaches 140°F (60°C) before they are removed from the pan. The cooling-off period permits the interior of the cake to become firm.

16.3.5 High-Altitude Adjustments

Cake ingredients must be modified at altitudes higher than 3000 ft. The lower atmospheric pressure at higher elevations reduces the need for baking powder, or baking soda. This affects the leavening agent because the volume of gas obtained from steam, air, baking powder, or soda expands with increases in altitude. If there is no mobilization, the reduced pressure of the atmosphere at higher altitudes presents less resistance to

expanding gases, and the cell structure of the cake becomes overstretched. This overstretching results in a coarse texture with large cells, which may cause the cake to fall. Also, at higher altitudes, water evaporates more quickly and the concentration of sugar increases. Structural strength can be improved by

1. Adding 1 to 2 tablespoons of cake flour;
2. Increasing the amount of liquid; or
3. Reducing baking powder and/or baking soda and sugar quantities.

Increasing the baking temperature 15–25°F (8–14°C) will help the protein structure denature before the expanding gases overstretch the gas cell walls.

16.3.6 Foam-Style Cakes (Unshortened Cakes)

Foam-style cakes include angel food and sponge cakes. Foam-style cakes depend on eggs for their structure and volume. This is dependent on the egg's ability to occlude air and to form stable foams. Typically, as the egg white is beaten or whipped, air is incorporated, and the air cells become increasingly smaller as beating continues. Also, as beating continues, the foam loses its sheen and reaches its maximum volume and stiffness.

16.3.6.1 Angel Food Cake. Angel food cake should be very light–almost fluffy. The cake is leavened only by air and steam, with no chemical leavening. The air and steam are primarily derived from the egg whites. Egg whites constitute the main ingredient along with sugar. Sugar is the tenderizing agent for the cake because the cake does not contain shortening. The major proportion of egg whites to sugar is 42 : 42 and flour is 15%. Cake flour plays a secondary role.

The lightness and volume of an angel food cake depend to a large extent on the method of combining ingredients. The goal in mixing is to completely blend the ingredients with the beaten egg whites without losing the air held by the egg foam.

In commercial practice, the general procedure in preparing angel food cake is to first whip the egg whites to which have been added salt and cream of tartar. Cream of tartar is considered an acid and a whipping aid for the egg-white foam. In addition, cream of tartar helps to whiten the cake batter by its effect on the flavonoid pigments of the egg whites, produces a fine-grained cake by stabilizing the proteins in the batter, stabilizing the foam sufficiently so it will not collapse in the oven before the temperature of coagulation is reached and prevents the drastic shrinkage of the foam during the last stage of baking and during subsequent cooling (Bennion and Scheule 2004).

Once the egg-white foam starts to form soft peaks, 50–60% of the sugar (of fine crystallinity to promote rapid solution) is added in a slow stream, while whipping is continued until the meringue retains a stiff peak. The flavor materials are then added, followed by the remainder of the sugar and the cake flour, which have been sifted together. Careful addition of the flour/sugar mixture is imperative. This mixture is added using the lowest speed on the mixer, or "folded in" by hand, in which a rubber spatula is used to cut down vertically through the two mixtures, across the bottom of the bowl and up the nearest side. The bowl is rotated a quarter turn with each series of strokes. The down-across-up-and-over motion gently turns the mixtures over on top of each other, combining them in the process.

The browning of the crust is not as dark as with other cakes. The Maillard browning reaction is not as intense due to the acidic pH of the batter caused by the cream of tartar. The color of the crust is characterized as "macaroon" in color, which is crisp and more sugary than that of a shortened cake.

Angel food cakes are usually baked at a high temperature (375–400°F; 191–204°C). Also, the majority of angel food cakes are baked in ungreased tube-style cake pans, which provide a more efficient heat distribution within the batter, as well as an additional internal temperature that promotes cake volume expansion.

16.3.6.2 Yellow Sponge Cake. The yellow sponge cake does not differ much from angel food cake except that the yolks as well as the whites are used. In some sponge cakes, a small amount of water may also be used. In making a sponge cake the goal is to reduce the toughening effect of the whole eggs by including a sufficient amount of sugar.

The making of sponge-cake batters may be carried out in a variety of ways. In some instances, bakers prefer to separate the white and yolks of eggs and beat them separately with the portion of the sugar to the desired specific gravity before recombining them. The aim of the approach is to attain maximum batter volume. Another procedure, however, is to beat the whole eggs, which have been tempered to a temperature of about 80°F (27°C) with a wire whip or blade beater at medium speed. Remember that the size of the bowl is important; for example, if three whole eggs are used, then use a 1 qt. bowl for beating so that the eggs are confined to a smaller area and will incorporate more air. Sugar is added at the onset of mixing or in a slow stream during beating. After the egg foam has achieved the proper volume, flour and liquid are folded in as lightly as possible to avoid breakdown of the foam. If shortening or butter is to be added, first it is melted and folded in at the end to minimize loss in volume. This procedure is desirable when preparing a small recipe.

In the egg separated method, the egg yolks are beaten. The sugar, salt, flavoring, and water are added, and the whole mass is beaten until very stiff. The flour is folded lightly into the mixture, after which the stiffly beaten egg whites (stiff, but shiny and not dry looking) are folded in (Briant and William 1956).

16.3.6.3 Chiffon Cake. Chiffon cake has some of the characteristics of cakes made without fat, yet oil is one of the ingredients used. The large quantity of eggs used in the basic recipe imparts to the cake the lightness characteristic of sponge cakes. The method of combination includes that the dry ingredients are sifted together in a bowl and a well is made in the center. To this mixture, the oil, egg yolks, liquid, and flavoring are added and the whole is combined until the mixture is blended. The egg whites and cream of tartar are beaten together until the whites are stiff and then folded into the flour mixture. Chiffon cakes are baked in an ungreased tube pan and are tested done when they spring back when touched with the finger. It is cooled upside down just like angel food and sponge cakes.

16.3.6.4 Genoise Cake. This rich light cake is made with cake flour, sugar, eggs, butter, and flavoring. It is similar in texture to a moist sponge cake. Because the genoise cake contains clarified butter, it can be considered a relative to the chiffon cake. Clarified butter is known as drawn butter. This butter has been slowly melted, thereby evaporating most of the water and separating most of the milk solids (which sink to the bottom of the

pan) from the golden liquid on the surface. After any foam is skimmed off the top, the clear (clarified) butter is poured or skimmed off the milky residue and used in cooking.

Preparation of the genoise batter is similar to the whole-egg sponge method. Traditionally, the eggs are placed in a bowl and tempered over simmering water until a temperature of 80°F (27°C) is reached. The eggs are then whisked or beaten with a mixer until light and fluffy (tripled in size). Sugar is beaten in gradually along with the flavoring. Cake flour is sifted prior to addition to the batter and then folded gradually into the mixture. Approximately, $\frac{1}{2}$ cup of the batter is added to the clarified butter and mixed lightly, but thoroughly mixed. This mixture is then folded into the batter. In an alternative method, the clarified butter alone is folded into the batter. Either way this step must be done swiftly but gently, because the fat could deflate the batter, air will be lost, resulting in a heavy product.

16.4 INDUSTRIAL MANUFACTURING OF CAKES

16.4.1 Mixers

Less energy is needed in the efficient mixing of cake batters. The type of mixer that is used requires the enfolding of air into the batter and subdividing the air into small bubbles.

Generally, the same type of mixer can be used for the shortened-style and foam-style cakes. The only factor that would be different would be the agitation that would be needed for the incorporation of the ingredients and this is accomplished by using specialized agitators and different speeds. Both batch and continuous mixers can be used for nearly all types of cake batters.

16.4.1.1 Vertical Dough Mixers. Vertical dough mixers, a class identified by the perpendicular orientation of the mixer shaft, are used widely in the food industry. A feature common to most vertical mixers is the use of removable bowls. Their other characteristics may be quite diverse; for example, there may be one or more beater shafts. The beater shafts may move in a planetary action or remain stationary, and the design of the agitators may be varied over a wide range. The types of vertical mixers of chief interest are the planetary mixers, which are capable of preparing most batters and some doughs and often are used for adjuncts such as icings, and the spindle mixers, commonly found in cookie and cracker factories (Matz 1992).

Planetary mixing for bakery products has been the world standard for many years. This method has now been perfected in the complex planetary mixing system design. The addition of a second tool inside the bowl permits product mixing with far superior results, greater versatility, and reduced mix time. The continuous bowl scraper that is used is a most important feature because it constantly scrapes the bowl's sides and bottom. This greatly reduces the mix time. It is no longer necessary to stop the mixer to scrape the bowl, because all the batter or dough is being constantly remixed, therefore yielding the best and most consistent product.

The bowl sizes for the mixer may be obtained as 20, 40, 80, 120, 140, 160, and 340 quarts. Even smaller sizes are available for home kitchens, bakeries, laboratories, and so on. Using the usual two-stage addition for layer cake batters, a 340-qt mixer can complete four 400- to 550-lb batches in an hour. The amount per batch depends largely on the specific volume reached. Whipped-type cakes prepared with wire whips (sponge, chiffon, angel food), require smaller batches (Matz 1992).

In large modern mixing installations a computer is utilized in the operation of the mixer. In fact, the mixing bowl can be automatically loaded while the cycle is under constant computer control. The computer permits memory storage of many of the recipes, which can be recalled and re-run by recipe number without expert baker supervision. Ingredients may be added at any stage of the mix cycle because the computer controls the entire cycle.

Pressure-bowl mixing is a method of maintaining a constant amount of air in the batter. Traditional mixing systems have only ambient pressure (room air) available for whipping or mixing. With a pressure bowl, the bowl is sealed at the top. Whenever a light batter is desired, instead of whipping for a longer time, or at a higher speed, an increase of gauge pressure to around 10 psi is made in the bowl. This results in small bubbles being generated by the wire whip and dispersed throughout the batter. At the end of the cycle, the air pressure in the bowl is released, which causes the bubbles to expand to about twice the previous size. A small amount of additional mixing will break up these bubbles into a uniform size while evenly dispersing them throughout the batter. With a controlled amount of air this will yield the same specific gravity for the batter.

16.4.1.2 Continuous Mixers. Semicontinuous mixing of cake batters was introduced in the United States in the mid-1940s. One of the first commercial continuous cake-mixing systems was designed around a votator scraped surface mixer whose design is based on an ice-cream freezer machine. Another early system used a modified Oakes marshmallow mixer. In both plants, the mixer operated continuously but was fed with a premix prepared batchwise in a standard batter mixer. About 1950, a truly continuous cake-mixing plant based on the Oakes mixer was designed and installed. Since then, other manufacturers have introduced similar mixers.

Continuous batter mixers can be incorporated into completely continuous systems if production schedules warrant, as in plants making only a few varieties, and those in long unbroken runs. In such plants, liquid ingredients and plasticized shortening are premixed in vertical tanks equipped with high-speed propeller agitators. The resultant emulsion is metered into an open vortex-type premixer to which flour is fed by a gavimetric feeder. The premixer forms a slurry that is metered into the continuous mixer along with a stream of air.

Cake batter is much easier than bread dough to transfer through pumps, pipes, valves, and meters, so the engineering for continuous production is easier for a cake plant than for a bread bakery. The economics of cake manufacture is such that expenditure of a large amount of money for continuous-mixing equipment may not be warranted, however, particularly for small- to medium-sized plants handling a large number of different formulas (Matz 1992). There are basically two types of continuous mixers: the barrel type, which is suitable for mixing doughs, and the rotor and stator head type, which is suitable for fluid mixings such as batters and marshmallows.

The Oakes continuous automatic mixer of the rotor and stator head type is suited for the production of marshmallow and batters, such as cake and sponge. The mixing head consists of three parts, rear stator, rotor, and front stator. The stators are bolted together, with the rotor mounted on a revolving shaft between the two stators. The mixing head is small, measuring up to 14 in. diameter and 2 in. depth. The head is surrounded by a water jacket to facilitate temperature control. The internal faces of the stators and both faces of the rotors are provided with concentric rows of blades, which intermesh, with ample clearance, when the rotor is in motion. Provision is made for the prepared syrup, or batter,

together with a supply of air under pressure, to enter the mixing head through the center of the rear stator and flow between the blades of the rear stator and rotor to the outer circumference of the stator cavity. The mixture then flows between the blades of the front stator and rotor to the discharge point in the center of the front stator. The mixing action is very precise, and can be readily controlled by rotor speed, syrup or batter flow speed, and air pressure, to produce the required specific gravity of the mixing. The aerated mix is very stable and has a smooth and uniform texture. As the mixing head is small (the largest has a capacity of less than 3 qt.), the specific gravity can be rapidly adjusted, and when changing color and/or flavor of a similar mixing, very little waste between mixings will occur. The stainless steel head can be stripped down for inspection and/or cleaning in a very short time. The Baker Perkins Homogenizer or continuous batter mixer, consists of a two-section mixing head, with a rotor and triple impellers in the inlet section, and the main section contains three more impellers, situated between pierced static plates, through which the batter is forced (Whitely 1971b). The Oakes continuous mixer takes advantage of a state-of-the-art, automatic specific-gravity control system.

The AMF mixer is similar in external appearance to the Oakes, but the mixer head is considerably different. Instead of splitting axially for dismantling, the stator separates radially. The rotor has several rows of teeth on its periphery. These teeth mesh with rows of teeth on the inside of the stator wall. Rotor speed is continuously variable. The mixers are equipped with a batter metering pump, air meter, and speed controls (Matz 1992).

The Goodway mixer/foamer has a slightly conical mixing chamber, pyramidal teeth, thermal jackets, and a working pressure of 150 psi. The Fedco mixer has a cylindrical chamber several inches long with hundreds of square-tipped teeth. It encloses a cylindrical rotor having many teeth on its periphery. Flow of product is straight through the annular space. The intense shear applied to the batter in mixing heads of this design is sufficient to emulsify air and shortening in a complete formula blend. Conventional batch mixers often require that the water be kept back until the shortening has been creamed with some of the dry ingredients. Their principal advantage, however, lies in the continuous mixer's unique ability to produce highly aerated batters such as angel cake batter from a rough premix. Air or inert gas is metered into the mixer head at a calculated rate (Matz 1992).

16.4.2 Baking Cakes

16.4.2.1 Depositing the Batter. Cakes and other products made out of fluid batters assume the contours of the containers in which they are baked, so the forming or shaping machinery may be regarded as the pans themselves, along with the pipes, pumps, and metering devices that deliver batter to the pans. Finishing equipment that enrobes, deposits, injects, spreads, or otherwise adds fillings, toppings, and so on, has very important effects on the appearance, cost, and nutrition of the final products.

Batter depositors may be either manifold-type or volumetric hopper-type. Accuracy is a prime consideration. Ability to handle batters containing pieces such as raisins, nuts, and chocolate chips without reducing their size is important. The depositor should not markedly change the specific gravity established at the mixer. Sometimes the viscosity of the batter is adjusted to allow flow into all parts of the pan. Vibrating the pan strongly during and after depositing the batter is of considerable help, but it may bring all the gas bubbles to the surface, with unfortunate effects on the appearance of the cake.

Whether deposited on the oven band or in open pans, the top surface of these cakes will be flat or slightly domed.

16.4.2.2 Heat Transfer in the Oven. Whether a gas or electric oven is used in baking a cake, heat is produced. This heat energy is transferred to the food through conduction, convection, and radiation when using a conventional oven.

Conduction can take place in solids, liquids, and gases, but cannot take place in a vacuum where there is no matter present to transfer the energy. It is the only way heat can be transferred in solids. Transference of heat by conduction can be illustrated by using a poker. If the end of a poker is placed in a fire, the other end soon becomes hot; the heat has been transmitted by conduction from one end of the poker to the other. Good conductors are used for hot plates, saucepans, shelves and sides of oven, and for baking trays and tins, so that heat is easily transferred to the bread or confectionery being baked (Dean and Russell 1980).

Convection has been defined as "the movement of a body carrying heat with it". Convection currents play a very important part in the heating of ovens. The heated air and flue gases circulate all around the ovens by convection currents, and in order that they should give up as much of their heat as possible before going out into the atmosphere, baffle plates are fitted to help the gases to circulate. These are metal plates with holes in them (Dean and Russell 1980).

The third manner of heat transfer is radiation. Radiation is defined as "the transference of heat from one body to another, without the intervening space being affected". A dull black surface is preferable for the inner walls of an oven, as they are required to radiate as much heat as possible. New baking trays are often put in the oven for some time before use, in order that their shininess should wear off; they will then absorb radiated heat better (Dean and Russell 1980).

The conventional oven relies on hot air for heating food, primarily by convection, but conduction and radiation can also occur. Baked goods rely on freely moving currents for the transfer of heat, so it is important to ensure that baking pans are placed on racks in such a way as to allow for the efficient flow of air currents. The position of the rack in the conventional oven is important to promote an even cooking and browning of the cake. For layer cake pans the rack should be in the middle or the lower third of the oven, and for a tube pan the rack should be in the lowest position, so the top of the pan is centered in the middle of the oven for even browning.

In the convection oven, hot air is circulated by a fan. Therefore, baking is accomplished more quickly. Usually, the position of the rack is not an issue because there is an even distribution of heat during baking and no hot or cold spot should exist depending on the quality and make of the oven. As the convection oven is a more efficient way to cook food, the temperature is lower by 25°F (−4°C) than the recipe suggests. Also, cooking time is less (as much as 25% less) than it would be in a conventional oven, even with the 25°F reduction (Middleton 2000).

16.4.2.3 Ovens. There are many types of ovens in use, and it is difficult to state which types are the best, but for confectionery work there has been, for years, an increasing tendency to use either gas or electricity as fuel, because they are clean and involve the lowest labor cost in their operation. Ovens may be classified in various ways, according to their construction, method of use, and method of heating.

Reel Oven. Reel ovens are really hot boxes, heated for the most part by gas, within which a set of 6–8 swing tray carriers revolve slowly about a central axis. The carriers are

stabilized and the baking sheets are loaded and unloaded at the same point. One advantages of this arrangement is considerable saving in space compared with peel ovens, which of necessity require a large peeling area for loading and unloading, which is an uneconomic use of floor space. An indicator on the front of the oven identifies the shelf that is passing the door at any given time, so that the operator can stop rotation and add pans to, or remove them from, specific shelves. They are very suitable for the baking of morning and other small goods and also for slab cakes.

Rotary Rack. The oven is a hot vertical box into which whole racks of goods are loaded. They have one- or two-rack capacity. The ovens are either electro-heated, oil- or gas-fired. The oil or gas burner is a high-pressure type suited to the oven and fitted with automatic temperature control and flame failure devices. The transmission of heat is by forced-air convection. The whole volume of air in the oven is recirculated many times per minute, passing through a compact heat exchanger unit and then horizontally across the chamber through the rack or racks on which the baked goods are set on standard baking sheets. During baking the racks are rotating continuously, thus ensuring even heating across the trays. The racks take up to 18 or 20 trays each according to the finished height of the goods being baked, and can accommodate mixed batches providing the articles require similar temperatures and baking times.

Band Ovens. The characteristic feature of a band oven is the continuous steel belt that forms the baking surface and which turns around two large metal drums, one at each end of the oven. There are many advantages to this. The baking chamber can be made very long (300 ft is a fairly common length), leading to fast transit times and high production rates. The band could be extended beyond the oven entrance sufficiently to accommodate certain forming operations or it could be extended past the exit to allow a modest amount of cooling and some additional drying so that the product does not have to be removed from the belt until it is set, thus providing support for the piece during the whole period of its maximum fragility. There is no need for elaborate transfer mechanisms. The baking chamber itself can be restricted in volume to almost the minimum theoretical space required to hold the product and the hearth so that the heat control is simplified and heat loss reduced.

Baking cakes as a continuous ribbon on an oven band has become common in large installations. Individual cakes are formed by cutting pieces from the baked strip and combining them in several ways. In manufacturing cakes, batter is prepared in a continuous mixer and pumped to a manifold, or batter distributor, positioned above the band oven. The manifold spreads the batter to a uniform depth, although more than one strip may be placed on the band if baked edges are preferred to cut edges, as they may be when preparing Swiss rolls (Freihofer 1985).

In addition to restricting the shape of the finished products, baking cakes on a band also establishes limits on formulation. It is important that the batter does not spread significantly during baking. Sponge-cake batters of high specific gravity are preferred. The finished cakes are often lower in moisture than is considered satisfactory for conventional cakes.

Travelling. Most confectionery traveling ovens are of the horizontal tunnel type. The oven chamber, divided into a number of zones, is a long tunnel up to 200 ft in length. Transmission of the goods through the oven is carried out in a number of ways, each of which is best suited for different types of products:

1. A continuous linked chain on which baking sheets are placed, which is suitable for a very extensive range of small goods;
2. A continuous band consisting of fairly heavy metal plates, which is suitable for the transmission of heavier products, such as slab cake; and
3. A flexible band on which a continuous stream of the mix is spread. This is the type universally used for baking swiss roll. It is also suitable for drop mixings, deposited direct onto the band.

Tunnel ovens are the most commonly used oven type in the cake-baking industry because they meet the baker's major concerns, such as minimization of energy consumption and an increase in mass production (Baik and others 2000). Compared to the batch oven, a predominant characteristic of tunnel-type ovens is that the whole baking chamber is divided into several zones along the oven length. In each zone, the temperature of the upper and lower baking chamber can be independently controlled, so the application of a temperature sequence is possible. This gives the baker more flexibility in adjusting conditions to the optimum values for a given product. However, baking phenomena in tunnel ovens are more difficult to predict than in batch-type ovens, usually operating at a constant temperature. The baking chamber of tunnel-type multizone ovens exhibits wavy temperature profiles along its length (Baik and others 2000).

17.1 INTRODUCTION

Foods derived from cereals, especially wheat, have always played a significant role in the diet of the peoples of the Mediterranean area (Ferro-Luzzi and Branca 1995), thanks to the optimal environment for the cultivation of grains. The reason for the success and widespread diffusion of the so-called "Mediterranean diet" lies not only in its renowned nutritional characteristics, with its foods rich in complex carbohydrates such as starch (Willett and others 1995; Riccardi and others 2003; Biesalski 2004; Trichopoulou and others 2005), but also in the broad "technological versatility" distinctive to wheat.

After being ground and mixed with water, this raw material is transformed into a cohesive dough that can be molded into different shapes (Serventi and Sabban 2000) to produce foods with highly diversified textures. This is possible, thanks to the exceptional viscoelastic properties of gluten (Hoseney 1989).

From wheat we can therefore obtain foods such as pasta. Pasta is a processed food that has an unusual long shelf-life before being cooked, thanks to its low moisture content and high compact texture. Its macromolecules have exceptional hydrating capacity, which enables it to increase its weight two-fold and acquire a palatable structure when cooked in boiling water. The pasta can then be combined with many different kinds of sauces to suit every taste (Antognelli 1980). Although pasta is doubtless the Italian food "par excellence", it would seem that the Greeks and the Romans were not familiar with this product in its present form (Serventi and Sabban 2000). We cannot find any explicit reference to pasta in any cooking texts until the end of the Middle Ages. Other sources from the twelfth century testify to the diffusion of this product from Italy and throughout the Mediterranean basin.

Wheat flour can also be transformed into other foods that have different physical properties from pasta, such as bread and all so-called baked products. These are characterized by a particular physical structure with a highly fragrant crust that encloses the internal alveolar-textured crumb that is often soft and light. Tasting and chewing a food with these properties produces a strong sense of pleasure and fully satisfies all our sensorial "requirements", from sight to touch, and from smell to taste. For these reasons, the social and religious importance given to bread by peoples of the Mediterranean throughout history is fully justified. Inscriptions of the ancient Rome era include bread in the list of indispensable foods for the people of Rome, administered by the Annona, the administrative organization that provided the city with victuals (Rebora 2000).

Because of Italy's specific configuration, it forms a narrow peninsula approximately 1200 km long, with 75% of the area being covered by hills and mountains. The cultivation of common wheat is mainly limited to the plains of central-northern regions, where it is in

competition with corn, a cereal that assures a higher productivity. The pedo-climatic characteristics of the Alpine and Apennine regions, where intensive farming is not possible, have given rise to the development of other crops (cereals and noncereals), able to assure fairly good productivity and therefore being economically profitable. This explains the significant diversification of raw materials used for bread-making and other cereal products in Italy, a tradition that has found renewed interest with both consumers and the scientific community in recent years.

In particular, the resistance of rye to the harsh winter temperatures of the Alps and its greater availability in this area justify the large number of types of rye-based breads produced over the centuries throughout the entire Alpine area and which are still produced and consumed there (INSOR 2000). Sourdough leavening is also preferred, given the low bread-making quality of rye, in accordance with the traditions of the central and north European countries where this cereal is widely used for bread-making (Katina 2003; Stolz 2003). On the other hand, breads containing emmer wheat (*Triticum spelta*), barley, potato, and chestnut flours are still common in central Italy (Bordo and Surrasca 2002), an area with a milder climate but with a soil that is not suitable to intensive farming. Agronomic conditions in southern Italy (Puglia in particular) and in the two main islands Sicily and Sardinia, where durum wheat (*Triticum durum* Desf.) has been cultivated for thousands of years with excellent results in both quantity and quality, are completely different. The most frequent types of breads produced, consumed, and appreciated in these areas contain only re-milled semolina of durum wheat (semolina with a fine particle size). They are made using the sourdough process, a technology that achieves better results with this particular raw material (INSOR 2000; Consorzio Gian Pietro Ballatore 2001; Bordo and Surrasca 2002).

In this chapter, we will discuss the production processes and characteristics of the most well-known starch-based foods of Italian tradition, with special emphasis on the evolution of the artisanal processes, which in many cases have led to an optimization and transformation of their production into a truly industrial cycle.

Another important aspect closely connected to the reason for the widespread popularity of both dry and fresh pasta and baked products throughout Italy involves machines. A large number of manufacturers have made available to the artisans and industrial sectors high-quality equipment to make pasta and bread. This segment holds a strategic position in Italian manufacturing. The trade directory for the sector (Leone 2004) states that the production of machinery for the bread- and pasta-making industry represents more than 50% of the total production of installations for the food industry. The expertise of Italian manufacturers in this field is also demonstrated by the significant sales turnover for cereal transformation machinery, totaling about 53% in 2002.

17.2 PASTA

17.2.1 A Brief History

There are very few documents attesting to the true origins of pasta and this has given rise to numerous legends. Some attribute the origins of pasta to Italy, and others to more distant lands, perhaps even China (Serventi and Sabban 2000). A product similar to the current *lasagna* was known to both the ancient Romans and to the Etruscans (Agnesi 1996). However, it is not until the twelfth century that can we find references to and documents about this food. In the early twelfth century, the Arab geographer Al-Idris reported the existence of the production of a dried pasta in Sicily, which was distributed throughout the Mediterranean basis, thanks to its long-term preservation properties. Its production was strictly a

"family" business, and it was not until the mid-1300s that we have documented evidence of the first artisan pasta shops. Despite its Sicilian origins, the pasta-making industry expanded and flourished in Naples (Portesi 1957; Serventi and Sabban 2000).

Together with the production of dried pasta, an activity that was mainly concentrated in southern Italy and the Ligurian coasts, thanks to a microclimate that facilitates the drying of the product, we also have documented evidence of small pasta-making businesses that supplied fresh pasta to local demand. These artisans were active in central-northern Italy, where durum wheat semolina was more difficult to find. This explains why the majority of fresh pasta is still today produced with common wheat flour, often with the addition of eggs, an important ingredient both from the point of view of nutrition and technology. The *vermicellai* (pasta-makers) gave way to factories in the early 1900s, when the first electric motors appeared. Surely the introduction of the continuous press for the kneading process around the 1930s represented a decisive innovation for the development of this product. The production process, which had been discontinuous until this time, became continuous, giving rise to greater productivity and greater cost-savings (Portesi 1957; Serventi and Sabban 2000).

17.2.2 Dried Pasta

The reasons for the success and diffusion of pasta worldwide in the last few decades include the possibility of using other kinds of cereals in its production, not just durum wheat (UNIPI 2006). According to the producing country and its culinary traditions, other cheaper and more easily available cereals can be used. In any case, the ingredients and technological processes required for pasta production are extremely simple (Pagani 1986; Lucisano and Pagani 1997). Today, pasta is a product that well represents "globalization", because it comprises the traditional and typically Italian dried pasta made of semolina, with or without eggs, as well as the oriental pasta made of rice or leguminous flour (Pavan 1998).

As shown in Figure 17.1, and in accordance with the provisions of Italian Legislation (1967 and amendments), pasta-making involves the kneading of the semolina with water. The mass is then worked into various shapes using two technological methods, extrusion under pressure and/or lamination, and is finally dried and packaged. These operations ensure a three-year preservation of the dried pasta and, given the absence of any additives or preservatives, it is a truly natural product.

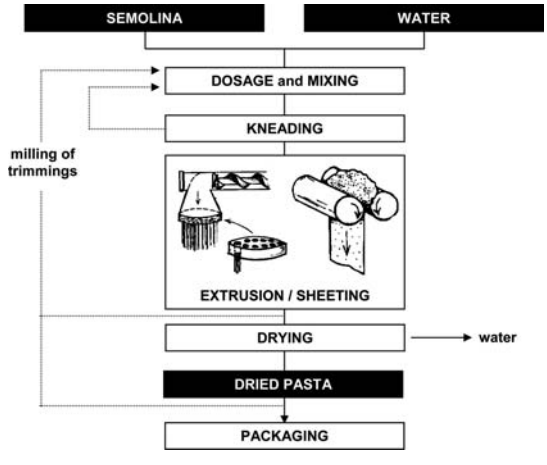

Figure 17.1 *The pasta-making process.*

TABLE 17.1 Italian Production of Pasta[a].

		Italian Consumption		
	Total Production (t)	Total (t)	Percapita/Year (kg)	Total Export (t)
Dried Pasta	3,023,598	1,493,540	26	1,530,058
Semolina pasta	2,735,800	1,386,400	–	1,349,400
Egg pasta	179,175	98,830	–	80,345
Stuffed pasta	108,613	8,310	–	100,313
Fresh Pasta	98,000	98,000	2	

[a]Data refer to 2004.

Other factors have increased interest in pasta during the last few years, especially overseas. Together with the traditional product, prepared exclusively with cereal flours, there are other similar products that are the same in shape but have a higher nutritional value because of the addition of different kinds of proteins (egg pasta, pasta enriched with whey proteins, and so on), vitamins, and mineral salts. These products can be dried as well as ready-to-use, that is, already cooked and with the sauce added (convenience foods). Finally, the rediscovery of the nutritional benefits of the so-called Mediterranean diet has finally rid this food of the stigma of being a "fattening food" (Ferro-Luzzi and Branca 1995).

17.2.2.1 Definition of the Product and Quality Characteristics. Dried pasta is without doubt the favorite kind of pasta in Italy. It represents approximately 90% of the purchasing volume of the sector (Table 17.1). Pasta therefore plays a significant part in the Italian diet, as demonstrated by the high yearly consumption, approximately 26 kg per capita/year and still slowly increasing (UNIPI 2006). Fresh pasta is also becoming more and more popular. According to Italian law (1967), the appellation "fresh pasta" refers to the moisture content of the food. This product will be discussed in detail in Section 17.2.3. Although this classification criterion based on "final moisture" is the one most commonly used (Fig. 17.2), there are other useful parameters for identifying the different kinds of pasta, such as ingredients (egg, vegetables, and so on), process, and consequently the type of format (long/short pasta, laminated/extruded pasta). The most suitable raw material used for the production of dried pasta, and the only one allowed by Italian law (as also in France and Greece), is

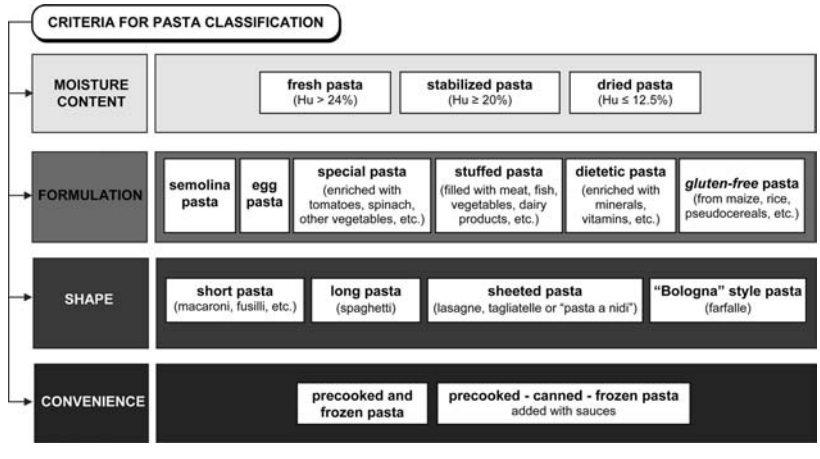

Figure 17.2 *Pasta classification.*

durum wheat semolina (Italian Legislation 1967). This raw material differs in many ways from common wheat flour, both from the point of view of the chemical parameters (as required by law, Table 17.2) and its rheological characteristics, useful for predicting the behavior of the raw material during processing (D'Egidio and others 1990; UNI 2001).

TABLE 17.2 Semolina and Wheat Flour Properties According to Italian Law and to Italian Voluntary Classification.

	Semolina Properties – Italian Law (L 580/1967 and Amendments)			
	Moisture (%)	Ash (%db)		Protein (%db)
From Durum Wheat	Max	Min	Max	Min
Semolina	14.50	–	0.90	10.50
Coarse semolina	14.50	0.90	1.35	11.50
Wholemeal semolina	14.50	1.40	1.80	11.50
Re-milled semolina	14.50	1.36	1.70	11.50

	Italian Voluntary Classification (UNI 10940, 2001)				
From Durum Wheat	Protein (%db)	Dried Gluten (%db)	Gluten Index	W ($\times 10^{-4}$ J)	P/L

Pasta Characteristics – Consumer Requirements	
Appearance	Cooking Quality
Typical yellow color	Optimum consistence
Black specks: absent	Lack of stickiness
White spots: absent	Lack of bulkiness
Fractures, fissures: absent	

In particular, the functional properties of proteins in the durum and the high pigment content contribute to a high-quality product.

However, the characteristics that pasta must have, to be judged to be of good quality by the consumer, often do not coincide with those required by law, and may be highly different according to consumer eating habits (Table 17.3). In other words, the evaluation scale is highly subjective, because it is based on personal preference (Cole 1991; D'Egidio and Nardi 1996). It is important to remember that the judgment of pasta does not consider the nutritional value of the product, a characteristic that can be greatly influenced by the technological process, as will be discussed later.

The consumer's final judgment will surely consider the appearance of the product in its dry state and its behavior when cooked. To this end, it is useful to note briefly the role and behavior of the two main components of semolina and pasta, that is, starch and protein. In dried pasta, the starch is still in the form of whole native granules, as in semolina. The proteins, arranged more or less uniformly and regularly between each granule, are mostly interactive and form the gluten complex (Dexter and Matsuo 1977; Resmini and Pagani 1983).

During cooking, the starch granules and proteins behave in a completely different manner. The starch granules swell up rapidly and tend to disperse and in part become soluble. The proteins, on the contrary, become completely insoluble and coagulate, creating a netlike structure (Fig. 17.3). Because these phenomena occur at approximately the same temperatures, the more rapidly the proteins form a compact netlike structure during cooking, the more limited will be the swelling of the starch. The starch components will remain trapped inside the protein network, ensuring a firm consistency and absence of stickiness (Resmini and Pagani 1983). However, if the netlike structure lacks elasticity or its formation is delayed, the starch granules are not confined and will swell up easily. Part of the gelatinized and soluble material will pass into the cooking water. The product will be judged sticky and of poor consistency. It is therefore easy to understand how good cooking quality depends on a high content of protein in the semolina and the proteins'

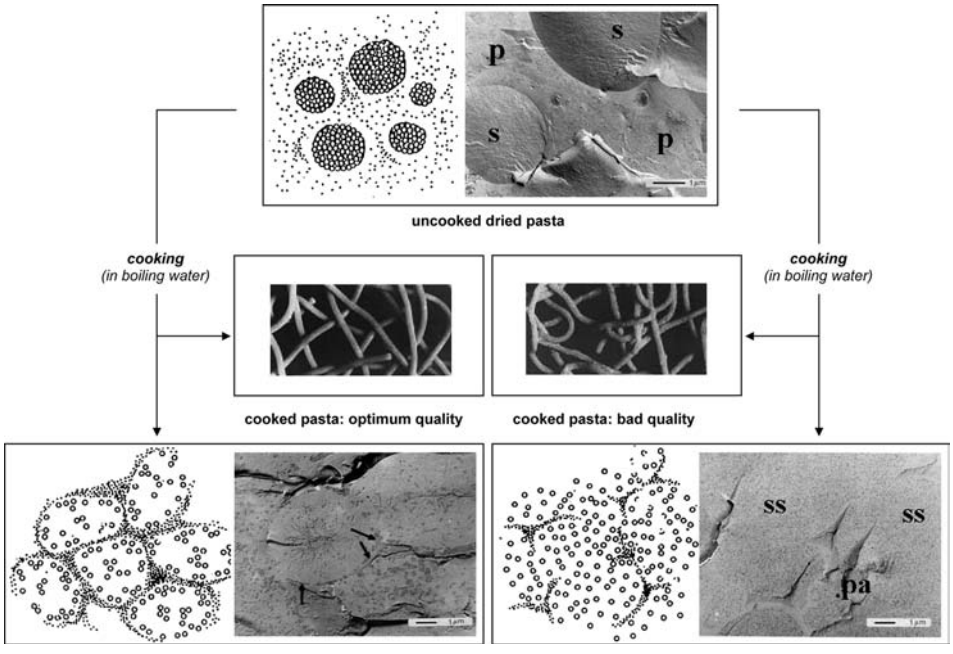

Figure 17.3 *Starch and protein organization in uncooked and cooked pasta (p = protein; s = starch; ss = swollen starch; pa = protein aggregates; arrows = protein network).*

readiness to reticulate and form gluten. A number of studies have been made to select new varieties that better satisfy the requirements of pasta producers.

17.2.2.2 Production Technology. As well as being influenced by the properties of the raw material, pasta quality is also influenced by the conditions during the pasta-making process. The effects on the components can be highly different, affecting the outcome of the competition between starch and proteins during cooking (Resmini and Pagani 1983). Although pasta is a food that has been known for centuries, its production process is still today undergoing technological innovation, more often than not dictated by production needs. For a detailed description of the process, the individual operations thereof and the characteristics of the finished product, see Kruger and others (1996) and Kill and Turnbull (2001).

The pasta-making process today is performed completely via automation (Fig. 17.4). The semolina is taken to the first section of the continuous press via a pneumatic system. Here it is kneaded with water to obtain a dough of approximately 30% moisture. During this phase, which lasts about 15–20 min in traditional machines, it is important to ensure a uniform moisture content of the semolina particles to prevent white spots in the finished product.

The moistened mass has the appearance of irregularly shaped lumps and is extruded in the second part of the press, which comprises a horizontal cylinder with a worm screw that ensures the movement of the dough and facilitates the interaction of the hydrated proteins and the formation of gluten. This operation is mainly carried out in vacuum to prevent loss of shine and attenuation of color caused by the intrusion of tiny air bubbles and the oxidation of the semolina natural pigments (Feillet and Dexter 1996). The compression screw then pushes the dough towards the die, a bronze plate (a material capable of resisting the pressures inside the machine), with different holes according to the shapes desired, and usually lined with Teflon to obtain a smooth surface of the product.

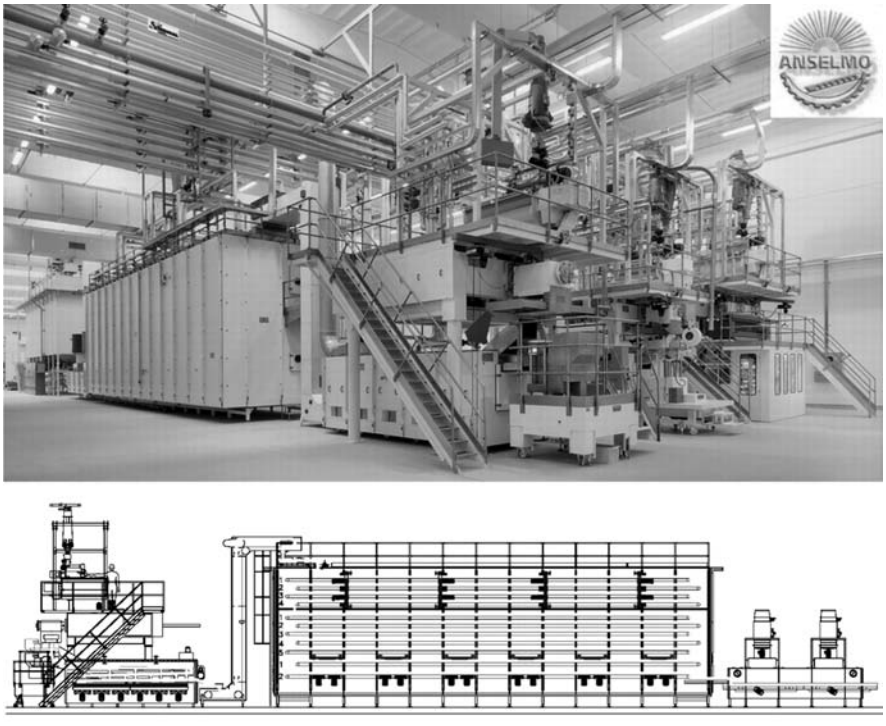

Figure 17.4 *Automated pasta-making set-up. (Courtesy of ANSELMO, Italy).*

If a bronze die is used, this gives a rough surface, which, according to some consumers, is preferable as it enables the pasta to hold the sauce better. Significant pressure develops inside the machine during this phase of the process, called extrusion under pressure, which can even exceed 10 MPa (~100 atm) (Pagani and others 1989; Dawe and others 2001). The low fluidity of the mass also produces high friction with increases in temperature. This is an undesirable effect, which can be controlled in part via the cylinder water jacket, which assures a temperature of 40–45°C. Higher temperatures would stimulate the swelling of the starch granules and coagulation of the proteins into irregular masses. Both these phenomena would have negative effects on the pasta behavior during cooking. The present equipment control systems prevent damage to the product. The pasta that is expelled from the die reflects the quality characteristics of the type of semolina/flour used (Pagani and others 1989; Dalbon and others 1996).

The innovations, even the most recent, regarding this first phase of the pasta-making process that have evolved over the years have focused on optimization of machine performance from an engineering point of view, but have not substantially changed the way the dough is shaped. All the main producers for pasta-making equipment have dedicated special attention to the elimination of one of the most frequent defects of dried pasta, the "white spots" formed due to the presence of unmoistened particles during the prekneading phases, which are clearly noticeable in the finished product. Not only does this defect have a significant effect on the hesthetic appearance of the product, but when observed through a microscope, it shows an incomplete and nonhomogenous structure of the protein network structure, which results in a high fragility of the pasta both in its dry state and during cooking. The appearance of white spots can be reduced by using fine-grain semolina

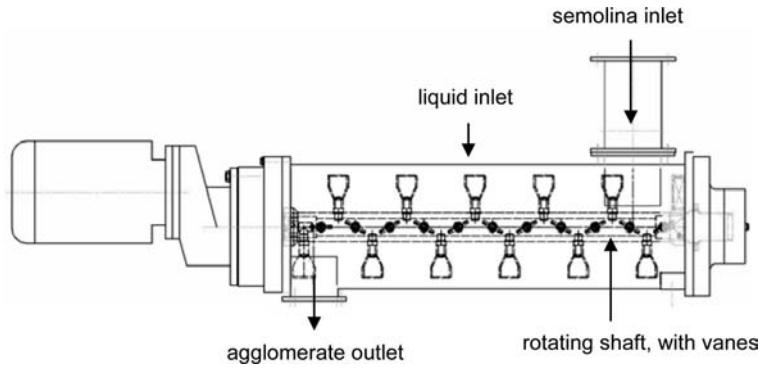

Figure 17.5 *The "centrifuge" – a high speed horizontal premixer. (Courtesy of PREFOR, Italy).*

(with a particle diameter of less than 300–350 μm) (Dalbon and others 1996). However, some pasta producers consider this type of semolina to be of poorer quality due to the mechanical stress induced on the starch and proteins during milling (Pagani and others 1996).

The most frequently adopted technological configuration is the so-called "centrifuge", a high-speed horizontal premixer (Fig. 17.5). The function of this machine is to distribute water between the semolina particles in the most homogenous way possible. More recently, a number of equipment manufacturers have contributed to the optimization of the mixing phases and of the subsequent kneading with interesting and highly diverse technological configurations. The extrusion press, with co-rotating screws, developed by Bühler a few years ago (Dawe and others 2001), improves both the productivity and hygiene aspects of the process (Fig. 17.6). Another alternative is the "dough stabilization belt" proposed by an Italian company for pasta equipment (Fig. 17.7), a conveyor belt that collects the dough and conveys it to the vacuum mixer, and then to the press. This configuration assures considerable ease of cleaning in this part of the process and a progressive moistening of the semolina without mechanical stress. Furthermore, the formation of a layer of ~15–20 cm of dough limits the quantity of oxygen that comes into contact with the mass, preventing the oxidation of most of the carotenoid pigments and avoiding discoloration.

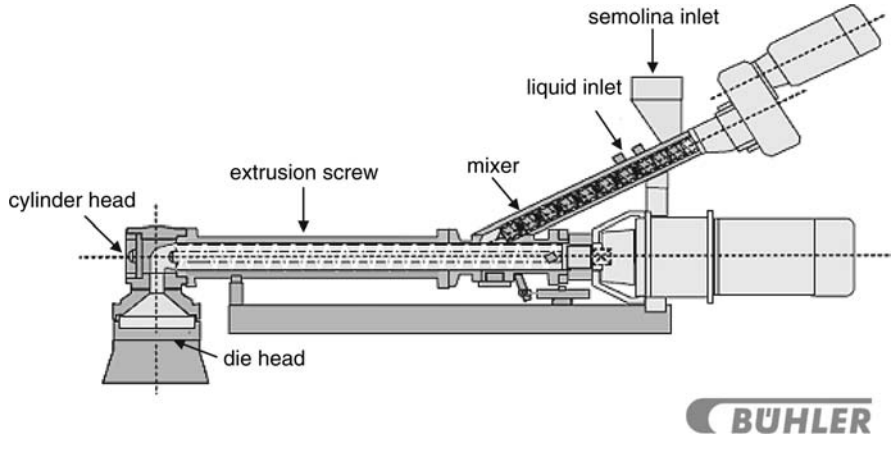

Figure 17.6 *The extrusion press with co-rotating screws – "Polymatic®". (Courtesy of Bühler, Switzerland).*

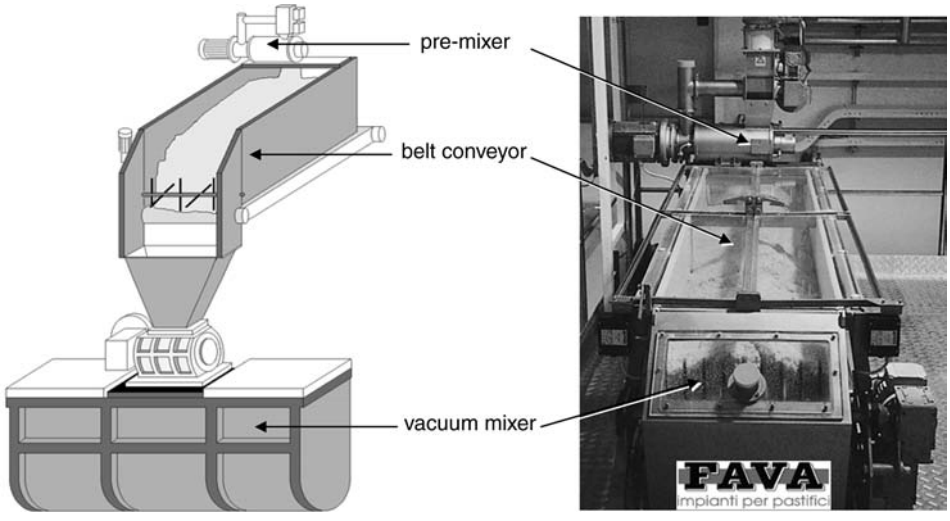

Figure 17.7 *"The dough stabilization belt". (Courtesy of FAVA, Italy).*

Another system for obtaining liquid–solid agglomerates with maximum uniformity is provided by a special appliance called the Vortex® or "vertical imbibition device". The machine works on aerodynamic principles and is essentially divided into three parts (Fig. 17.8): a vertical cylindrical chamber, a rotating shaft with a series of blades, and

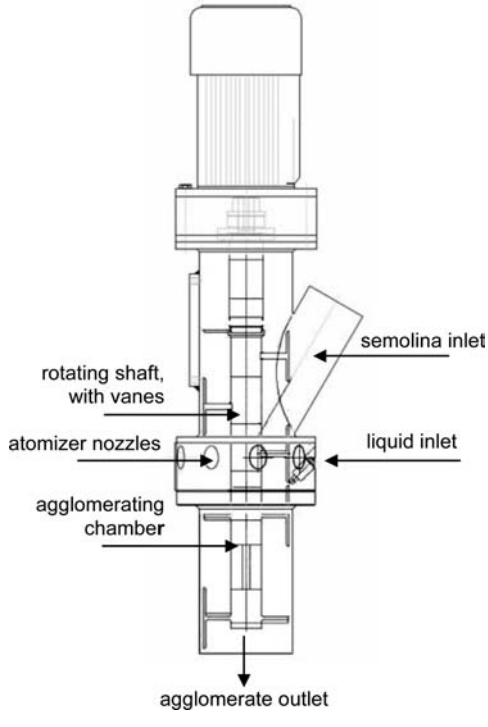

Figure 17.8 *The Vortex® device. (Courtesy of PREFOR, Italy).*

spray nozzles for the distribution of water. An electric motor drives the shaft, which is situated vertically inside the imbibition chamber. Thanks to their rotation speed and insertion angle in the shaft, the two blades produce a vortex. Each single semolina particle "floats" in the imbibition chamber and then falls into the mixer machine only after having been duly moistened, which is possible only after having reached a "threshold" specific weight.

Upon extrusion, the fresh pasta has a moisture content of about 30%, with the resulting low preservation characteristics at room temperature. Drying has the objective of lowering the moisture content down to 12.5%, the maximum value set by our laws and which ensures a water activity (a_w) of less than 0.6 (room temperature), enough to prevent the undesired proliferation of microorganisms and to reduce the numerous enzymatic activities. At the same time, the product acquires its characteristic flavor, aroma, and consistency. The drying process has always been, and still is today, the most crucial phase of the entire pasta-making process. A clear indication of this is the surface area required for the drying chamber, the time required for the operation (which varies according to the shape of the pasta; even the shortest cycle requires several hours) and the innovations dedicated to this phase presented by pasta equipment companies.

Drying the pasta does not only mean evaporating the water. This operation must be performed according to the chemical-physical structure of the product. Above all, stress that could occur in the different areas and between the pasta components due to the nonhomogenous distribution of water between the surface and internal areas and due to the different affinities of proteins and starch with water must be avoided. The moisture and volume of the pasta must be reduced uniformly and homogenously (Antognelli 1980; Paraventi 1984).

Until the last century, successful drying depended solely on the ability of the pasta-maker and the existence of specific environmental–climatic conditions such as those of the areas overlooking the gulf of Naples and the gulf of Genoa (Portesi 1957; Serventi and Sabban 2000). The drying cycle of long pasta could last as long as several days and required a considerable number of workers (Lirici 1983).

The technological progress that took place at the beginning of the twentieth century finally freed the drying phase from being dependant on climatic conditions. From the 1940s onwards, this phase was carried out in a tunnel with an artificial climate with air at controlled temperature and moisture, thus controlling the kinetics of the drying process.

The pasta drying cycle can, for the sake of simplicity, be divided into phases. The first stage is called the pre-drying phase (in Italian, *incartamento*, from the word *carta*, paper, due to the fine surface crust that is formed). During this phase, the pasta can lose water very quickly, up to a third of that added during kneading.

Upon completion of the pre-drying phase, the moisture present in the pasta, ($\sim$18–20%) varies in distribution between the surface (up to 15% moisture) and the internal part, where the water content is comparable to the state of the pasta upon extrusion. To prevent cracking (*bottature*) of the pasta caused by physical stress between the areas of different water content, it is vital that the drying cycle has so-called "resting" periods in high-humidity environments, in order to enable a homogeneous distribution of moisture inside the product (Paraventi 1984). Until the end of the 1980s, the drying cycle included periods of drying or "ventilation", alternated with periods of rest, determined by selecting the appropriate hygrometric conditions inside the dryers. Today's machines are designed with only one water evaporation phase, followed by a long stabilization phase for obtaining a uniform distribution of the moisture. At the end of the drying cycle, the pasta is cooled at ambient temperature before being packaged.

Until the 1970s, the maximum temperatures used for the drying cycle were 50–55°C (today defined as "low temperatures", or LT). Under these conditions, over 24 h were necessary to dry the long-shaped pasta. Fermentation could thus occur, and some kinds of fermentation could also be desirable as they gave the product characteristic tastes and aromas. However, no significant changes to the functional properties of the semolina components were noted (Resmini and Pagani 1983).

Quality during cooking was strictly linked to the quality of the raw material used. Making pasta with excellent-quality semolina was, in those days, the only guarantee for obtaining a product with good cooking properties.

The technological innovations in this scenario were obviously based on the search for greater cost saving, together with greater hygiene and constant quality of the product. One of the most logical and technologically easiest solutions was to raise the temperature up to 70–90°C and over ("high-temperature" diagrams, or HT) (Manser 1979). These conditions provided a drastic reduction in the processing time, up to 10-fold (4–8 h according to the pasta shapes), with consequently significant advantages from the points of view of cost, hygiene, and appearance (the dried pasta had a deeper color). The improvements in the quality level of the product observed during cooking were unexpected and even surprising at times when considering the characteristics of the raw material. These changes can be attributed to the changes induced by the HT treatment on the starch and above all on the proteins (Dexter and others 1981). In suitable temperature and moisture conditions (from 70°C with a sample moisture of less than 16–18%), proteins in the raw product coagulate and create a structure very similar to the one formed during cooking. This kind of network is effective in preventing an excessive swelling of the starch granules, thus assuring low stickiness and high firmness (in Italian, *nervo*) in the cooked pasta (Resmini and Pagani 1983).

The changes attributable to the HT drying diagrams are not, however, all positive. These conditions have a considerable influence on a number of sensory properties, resulting in a dullness of taste, excessive browning, and, above all, high thermal damage in the dried pasta (as discussed in Section 17.2.4).

17.2.3 Fresh Pasta

Although fresh pasta is used throughout Italy on special occasions, it is particularly popular in the northern-central regions, where dried semolina pasta was historically less known and consumed (Serventi and Sabban 2000).

In Italy, the market for fresh pasta is much smaller compared with dried pasta, but demand for both industrial and artisanal products is continually growing (Fig. 17.9). One of the reasons for the success of this segment is the consumer's subconscious belief in the close relationship between "freshness" and artisanal production, together with the opinion that artisanal production is the best expression of "mild technology". It should be stressed, however, that industrially produced fresh pasta is often obtained using highly sophisticated technological processes (a detailed description is given in Sections 17.2.3.4 and 17.2.3.5) in order to guarantee product freshness and authenticity, and at the same time ensuring the prolonged storage time and "convenience properties" demanded by the consumer.

In contrast with the marked commercial expansion of this sector, the scientific world gives little attention to the field of fresh pasta. If we consider the period between 1990 and 2005, over 230 works were published on dried pasta worldwide (as cited by *Food*

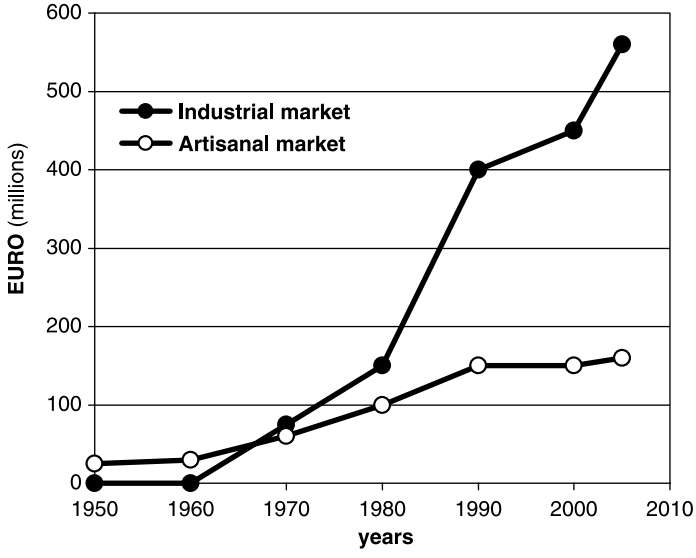

Figure 17.9 *Markets for industrial and artisanal pasta between 1950 and 2005.*

Science & Technology Abstracts). These studies were made to define the optimal characteristics of semolina, changes introduced to the process, in particular to the drying phase, and their influence on cooking behavior and nutritional properties. Only 84 works were published on fresh pasta during that same period, and most referred to the safety and hygiene problems involved and the new modified atmosphere packaging (MAP) technologies. Little attention was given to the influence of the raw materials and the process conditions on the properties of the finished product.

This chapter does not discuss pre-cooked pasta, as it has little economic relevance in Italy.

17.2.3.1 Classification Criteria. The classification criteria applied instinctively by the consumer to distinguish between "fresh pasta" and "dried pasta" correspond only in part to those applied by Italian law (1967; DPR 2001). As illustrated in Table 17.4, the

TABLE 17.4 Characteristics of Fresh Pasta According to Italian Law.

	Fresh Pasta Characteristics (Different Types, Having the Same Properties of Those Reported in Table 17.3, Except for:)					
Fresh Pasta	Moisture (%) Min	Acidity[a] Max	a_w Range	Heat Treatment (yes/no)	T Conservation (°C) Max (Tolerance)	Shelf-Life (days) Max[c]
Loose fresh pasta	24	7	—	No	4([b])	5
Packaged fresh pasta	24	7	0.92–0.97	Yes (pasteurization)	4 (±2)	60
Stabilized pasta	20	7	<0.92	Yes	Room temperature	30–120

[a]The amount of KOH in (mL) necessary to neutralize 100 g of dried pasta; [b]±3 during transport; ±2 in the other cases; [c]recommended.

law identifies the two categories on the basis of humidity, the value of which should not exceed 12.5% in dried products and should not be less than 24%, with a_w between 0.92 and 0.97, in fresh pasta. A third category, "stabilized pasta" is also described. This product must present a moisture content higher than 20% with a_w lower than 0.92. These properties are obtained by using specific thermal treatments and process conditions suitable to guarantee product transport and storage without refrigeration.

There are many different types of fresh pasta on the market (Fig. 17.2), but the ingredients in the basic formulation are simply flour and/or semolina and water. This basic recipe is often enriched with the addition of eggs. By law, there should be a minimum of four eggs per kilogram of flour. The richest and most complex formulations are those for the so-called "filled" or "stuffed pasta", where the pasta forms a shell that contains the filling or *farcia*. The filling is a soft mixture of animal and/or vegetable origin (meat, charcuterie, fish, cheese, vegetables, mushrooms, and so on), according to regional recipes and customs and availability. These ingredients are usually mixed with eggs and grated bread and comply with the health and authenticity requirements of the law (Italian Legislation, 1985).

Taking the shaping process as a classification criterion, we have the following:

1. "Long-cut pasta" or laminated pasta, made with a sheet of pasta about 1 mm thick, which is then cut into "ribbons" of different widths (for *lasagne*, *tagliatelle*, or *fettuccine*);
2. Short pasta with particular shapes (*orecchiette*, *trofie*, and so on); and
3. Products obtained by die-shaping (*fusilli*, *macaroni*, and so on).

In the cases of both long pasta and filled pasta, the formats vary in size and geometrical shape (Fig. 17.10) according to its consumption: "*pasta asciutta*" (pasta with sauce) or "*pasta in brodo*" (pasta in soup). Especially appreciated and renowned internationally are *tortellini* and *ravioli*, typical dishes of the cuisine of the Emilia region.

In the past, and even today, in artisanal products, the dough sheet represents a significant percentage of the product global gross weight, making it ideal as a single dish. The changes in eating habits and the need for faster cooking times has led to a preference for filled pasta where the pasta sheet is 0.5-mm-thick paper-thin (*sfoglia-velo*). This does not cover the flavor of the filling and requires just a few minutes' cooking. In this type of fresh filled pasta, the ratio of filling to dough is at least 50:100 (Table 17.5).

One of the most common criteria for classifying fresh pasta (apart from filled and unfilled) is its shelf-life (Fig. 17.2). The typical artisanal product is sold unpackaged and can be stored for a maximum of just five days, due to the absence of stabilizers. The commercial products have a longer shelf-life, from 30–40 days up to 120 days (Italian Legislation, DPR 2001). Given the high a_w values of the fresh product, this result can be achieved by applying pasteurizing heat treatments. The fresh pasta is then isolated from the environment in sealed packages where oxygen is removed using nitrogen and/or carbon dioxide atmospheres (MAP) and stored at low temperatures (+4°C).

These conditions (described in detail in Section 17.2.3.5) guarantee the hygiene of the product, a highly critical aspect, especially if the formulation contains eggs (usually included due to the positive effects at the technological level), and other animal and/or vegetable products used in special and filled pasta. These raw materials can often carry pathogenic microorganisms such as *Salmonella* and *Staphylococci*.

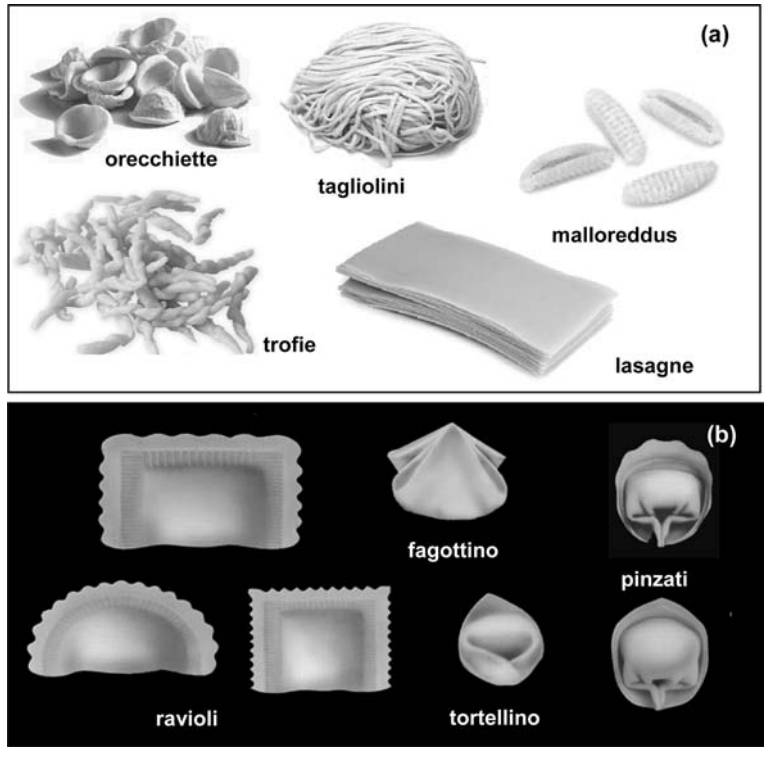

Figure 17.10 *Forms of pasta: (a) long and short pasta and (b) filled pasta.*

17.2.3.2 Quality Indices. Regardless of the technological process used, the fresh pasta produced in Italy must comply with the limits of microbial count set by Italian Legislation (1985) as illustrated in Table 17.6. These properties must therefore be considered as prerequisites for quality.

With regard to the characteristics considered by consumers, some may refer to the raw product, others to the behavior during cooking, as illustrated in Table 17.7 Anon. 2003). Before cooking, the laminated pasta must not contain any bubbles or fissures or tears, which are defects resulting from the kneading or rolling out and shaping of the dough. The color should be yellow, and the pasta must maintain its color even after cooking. Color can be improved by adding eggs and using flour and/or semolina with low enzymatic activities (lipoxygenase and oxidases). And lastly, as for dry pasta, good fresh

TABLE 17.5 Different Properties of Different Types of Artisanal and Industrial Stuffed Fresh Pasta.

Fresh Stuffed Pasta	Total Moisture (%)	Pasta Moisture (%)	Stuff Moisture (%)	% Stuff Weight (g/100 g mb)
Industrial *tortellini*	37.4	27.8 ± 0.8	47.6 ± 1.6	50 ± 0.10

Increase in weight	High and rapid absorption of water
Color	Maintenance of color
Rheological properties	Absence of stickness

common wheat flour for the preparation of fresh pasta (Italian Legislation 1967). This is justified if we take into account the regions of origin of fresh pasta (with unsuitable environmental conditions for the cultivation of durum wheat, as previously mentioned), and the technological lamination process, which is not suitable for excessively strong dough. However, as there are no legal provisions regarding the percentage ratio of common wheat and durum wheat flours used, there is a high heterogeneity between the ratios used, as discussed by Pagani and others (1999) and Alamprese and others (2005a). The picture is further complicated by the lack of knowledge regarding the optimal characteristics of flours and/or semolina for this transformation. Last, but not least, the role and technological behavior of the flours may be concealed by the fact that most products, both artisanal and industrial, contain eggs, which not only give pasta its color but also its binding and structural properties. Each producer therefore uses formulations based on his own experience, and not on any specific basic knowledge. Consequently, even if we just consider fresh egg pasta, the composition of the products available on the market can vary widely within each parameter provided for in the law (Fig. 17.11).

With regard to the influence of eggs, a recent work by Italian authors (Alamprese and others 2005b) shows that the use of fresh or pasteurized eggs does not cause any significant change to the rheological properties of the pasta and its cooking behavior.

17.2.3.4 Pasta-Making Process. If we consider the production process as a whole, we can see marked differences with respect to dried pasta (Fig. 17.12). The final drying process is obviously left out, and the kneading and shaping operations of the dough are obtained using different methods (Pavan 1990). In particular, the ingredients are often mixed with a kneading machine called *gramola* (Fig. 17.13), which is exactly the same machine as those used historically in the discontinuous pasta-making process (Portesi 1957). The kneading machine mixes the ingredients slowly, without causing friction or heating the dough. In more automated industrial processes, the kneading is made inside vats with a single rotating shaft for 15–20 min (Fig. 17.14). At the end of the kneading process, the dough is sent to the dough sheeter, where it is pressed into a compact sheet by a couple of smooth rolls. The next stage is the calibration stage, which comprises a sequence of steps using smooth calibrators adjusted to give the thickness desired and a smooth and velvety finish.

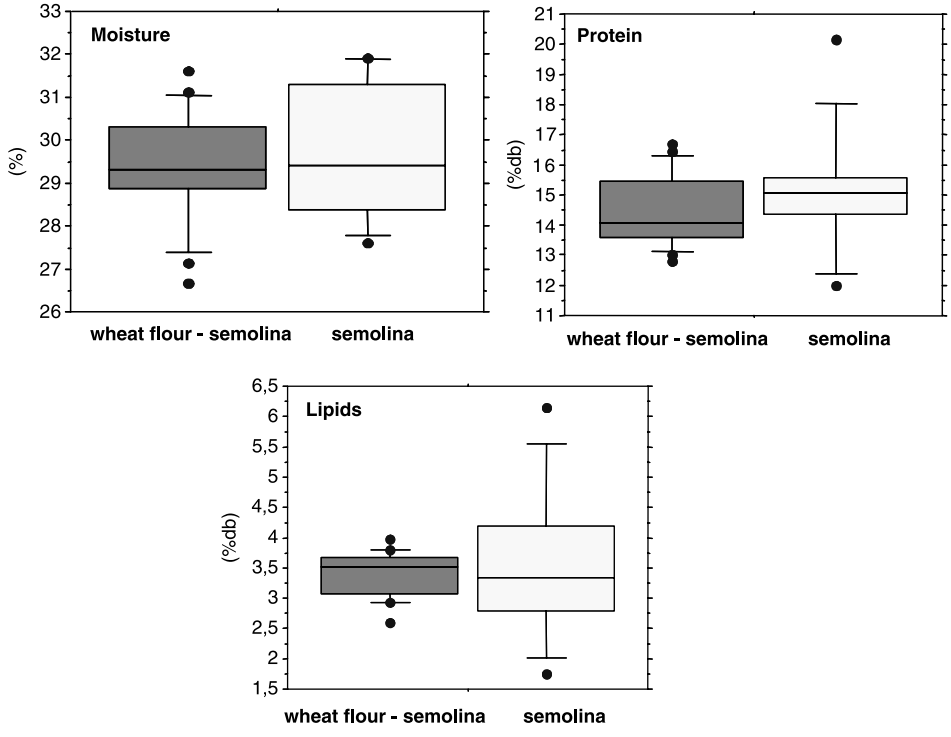

Figure 17.11 *Composition of pasta products with regard to moisture, protein, and lipids.*

The most recent innovations in the dough-kneading and sheeting phase relate to ease of cleaning and the possibility of reducing physical stress during dough lamination. A solution is given in Figure 17.15. This new machine, which is fully constructed in stainless steel, has three kneading rolls with a new self-cleaning design that eliminates dough accumulation and guarantees limited heating of the mass. A patented device allows dough mixing and kneading under vacuum, enhancing the yellow color and texture of the final product.

Industrial pasta sheets are usually given a final thickness of 0.5–1.5 mm. Some producers prefer to shape the first sheet (5–15 mm thickness) with an extruder. Although the extrusion head is such as to extrude the pasta at low speed, friction is formed, producing a rough surface on the product, a characteristic that is not eliminated in the successive calibration phases.

In the case of filled pasta, the filling is dosed by a machine that distributes it between the two sheets, producing *ravioli*, or on a single sheet that is and then folded and sealed to produce *tortellini*, *fagottini*, and so on.

Lamination with cylinders is a technology with a much lower productivity than extrusion under pressure, and, in general, makes it possible to obtain a better protein network of the gluten. The images obtained by the SEM in Figure 17.16 clearly show how the die-shaping process can cause heavy physical stress in the pasta, with a resulting breakage of the protein network when the raw material does not contain strong proteins, as in the case of common wheat. This three-dimensional organization justifies the modest performance in cooking, with the formation of large masses of gelatinized starchy material, which

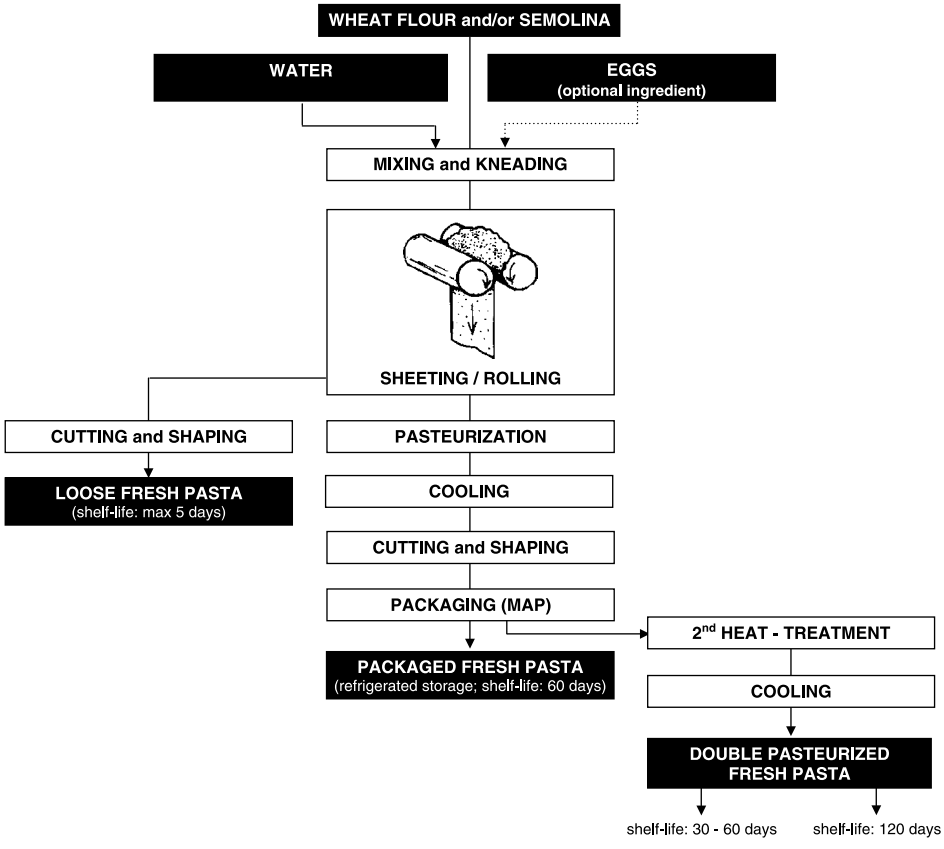

Figure 17.12 *Production process for fresh pasta.*

Figure 17.13 *Artisanal fresh pasta-making process: mixing (a); dough kneading with gramola (b); dough cutting (c); intermediate dough sheeting (d); final sheeting (e); pasta after the first pasteurization (f). (Courtesy of Fontaneto, Italy).*

is responsible for the starchiness of the water and lack of firmness of the pasta. However, from the same flour and with a sheeting process, it is possible to obtain fresh raw pasta with a well-developed and continuous protein network. In cooking, the fusion of the starch granules is limited by the presence of the protein network that surrounds each starch granules (Pagani and others 1989).

Whatever the production process used, fresh pasta is difficult to store and must be used within several days. A pasteurizing heat treatment must be applied to the product if we

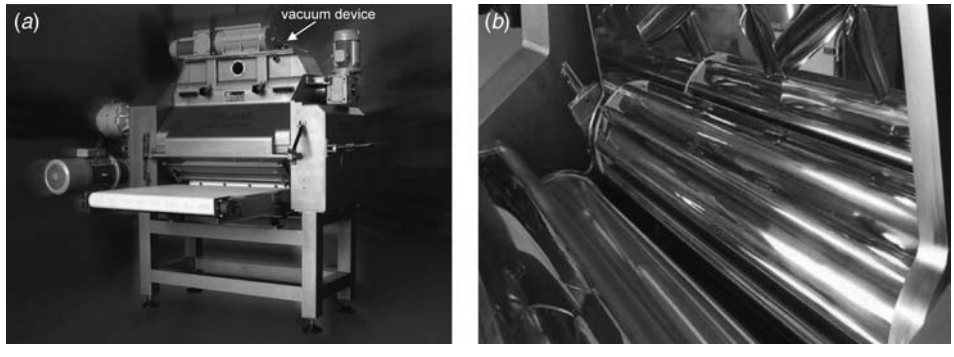

Figure 17.15 *Innovative dough-kneading machine (a) with self cleaning design (b). (Courtesy of STORCI, Italy).*

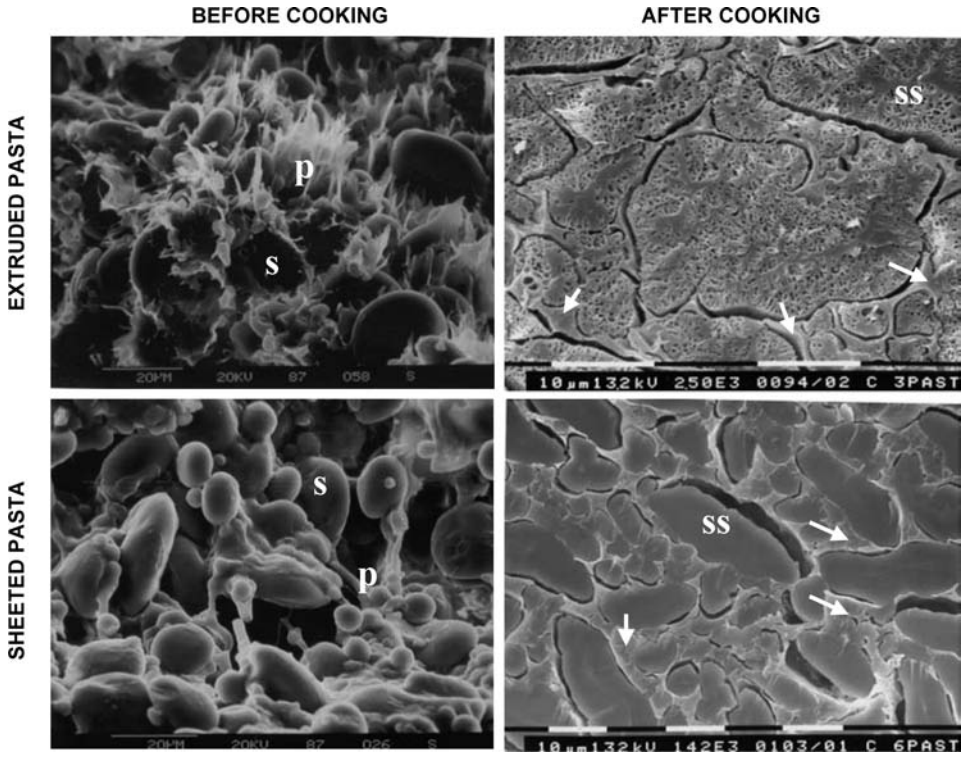

Figure 17.16 *SEM images of pasta after extrusion and sheeting processes (p = protein; s = starch; ss = swollen starch; arrows = protein network).*

want to prolong the shelf-life. However, this process must not compromise the nutritional and sensory characteristics, as stated by Mondelli (2003a,b). The conditions adopted are highly variable, due mainly to the number of stabilization heat treatments applied. Today, production processes with a single pasteurizing treatment are preferred. The conditions also vary according to the thickness of the pasta sheet and the filling (whose ingredients contribute to the potential presence of microorganisms), and the proportion of the amount of filling to the amount of pasta sheet.

The fresh product is loaded onto a conveyor belt that enters the pasteurization tunnel where steam is injected from the opposite end (Fig. 17.17). Treatment with saturated steam, however, produces condensation on the surface of the pasta. This layer of water could induce starch gelatinization, causing pieces to stick together and giving the pasta a shiny surface (Mondelli 2003a). These defects can be avoided by using superheated steam, although this technology is more costly.

The most frequently used conditions for pasteurization require temperatures of 75–90°C at the core of the product for several minutes, achieved by using an air temperature of 98–108°C, according to the shape. These conditions are nevertheless not enough for destroying the most heat-resistant microorganisms (i.e., spore-forming bacteria), unless the treatment is prolonged for a period of time that would be incompatible with the maintenance of the sensory characteristics typical of a "fresh" product. It is therefore important to apply preventive measures in order to keep the bacteria in the raw materials and the dough under control (Mondelli 2003a).

Figure 17.17 *Pasteurization tunnel. (Courtesy of STORCI, Italy).*

Pasteurization is followed by a surface-drying stage, an important step for reducing pasta humidity and a_w levels as required by law. The formation of a fine dehydrated layer on the surface of the product also avoids adhesion between the pieces.

The subsequent cooling phase is a very delicate one because the air must be filtered to prevent contamination of the product. Rapid cooling is highly preferable (Mondelli 2003b), as it limits the time that the product is exposed to temperatures favorable to microbial development. If the process does not provide for further heat treatments, the product temperature is then set to 4°C before packaging (this operation is discussed in Section 17.2.3.5).

The packaged product can be subjected to a second heat treatment, which can be omitted when there is no recontamination of the product after the first pasteurization and before packaging in a protected atmosphere. As well as giving priority to the hygiene characteristics of the raw materials and the working environment during the initial process operations, some industrial producers have elected to perform the final cooling and packaging in a clean room. The fresh pasta thus obtained has a flavor that is similar to products that have not been subjected to heat treatment, but it has a shelf-life of up to 60 days. Pasta obtained from modern technology can therefore guarantee a greater quality and safety than artisan products.

A second pasteurization treatment is often performed on sealed packages in an environment of 95–98°C for 40–50 min, in order to ensure a treatment at the core of the product of 80°C for about 10 min (Batisti and others 1995). The process can be discontinuous or continuous (with hot air or steam), and completed with a cooling phase. A more recent method with a lower impact on the pasta sensory and nutritional characteristics involves the use of microwaves in a tunnel where trays are transported on a conveyor belt at a set speed and exposed to temperatures over 75°C for several minutes.

The heat treatments, which are indispensable for ensuring health safety characteristics, give rise to important modifications to the protein and starch macromolecules, with interesting consequences on the rheological properties and behavior in cooking (Pagani and others 1999; Alamprese and others 2005a). As illustrated in Figure 17.18, after pasteurization, the pasta sheet appears less extensible and clearly stiffer due to the denaturation phenomena of gluten and egg proteins. This result reduces the significant heterogeneity of the texture (assessable via tensile test until the breakage of the product) that characterizes untreated fresh pasta. Cooking (Figs 17.18 and 17.19) restores flexibility to the texture of the product following a high absorption of water. In pasteurized products, where the protein network cannot be deformed as it is denatured and more efficient at

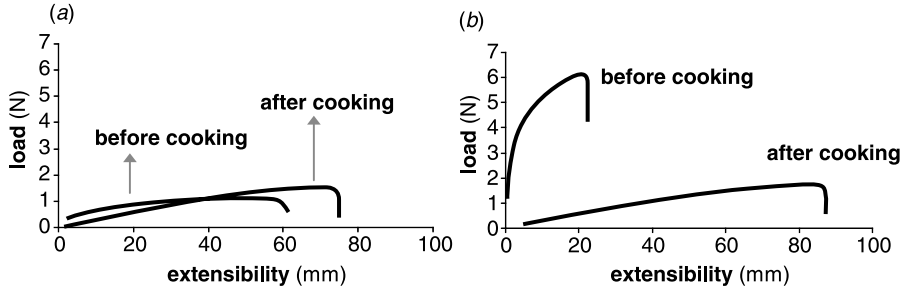

Figure 17.18 *Mechanical properties of pasta before pasteurization (a) and after pasteurization (b).*

preventing the swelling and solubilization of the starch material, the cooking loss is less than in the nontreated product (Fig. 17.20).

17.2.3.5 Packaging. In recent years, packaging has undergone highly interesting developments and innovations, which have favorably influenced product characteristics. Health characteristics have been improved too, lengthening shelf-life considerably, with a resulting increase in consumption.

The aerobic and microaerophilic microorganisms (*Lactobacillus*, *Staphylococcus*, *Bacillus*, yeasts, and moulds) find the best conditions for their development on the surface and inside the product, even at refrigeration temperatures. The removal of oxygen from the environment that surrounds fresh pasta can therefore control and significantly delay the development of these microorganisms without having to resort to drastic pasteurization or sterilization treatments that would damage the flavor and compromise the image of the fresh product.

Towards the end of the 1980s, several technological solutions were put forward based on vacuum packaging (Castelvetri 1991a), but were soon abandoned mainly because of the negative changes caused to the appearance of the product. The modified atmosphere packaging (MAP) technology involves the substitution of air in the fresh pasta packaging with a gas mixture in different proportions, mainly nitrogen and

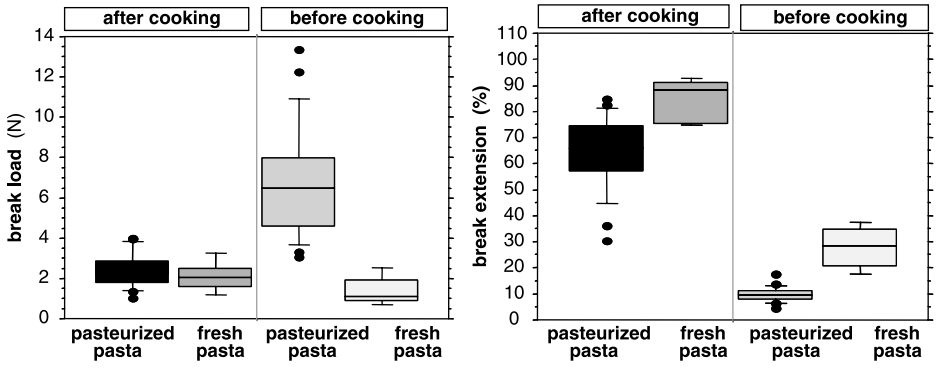

Figure 17.19 *Mechanical properties of pasta before and after cooking.*

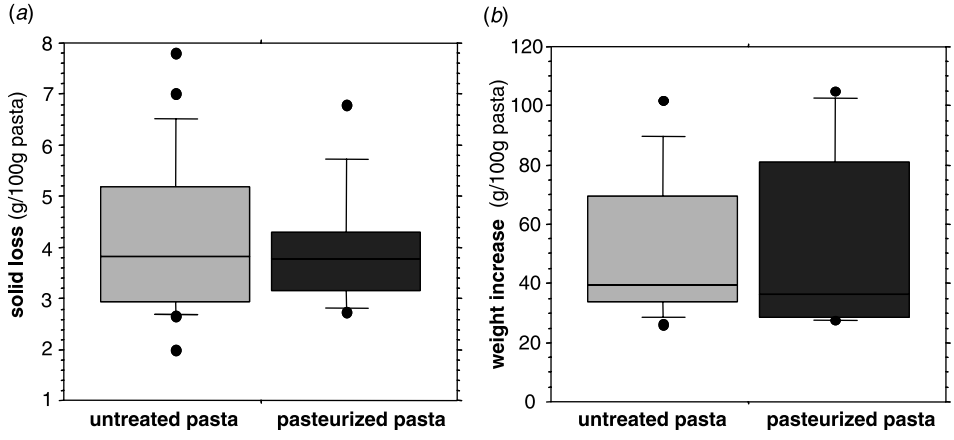

Figure 17.20 *Effect of pasteurization on cooking quality of pasta.*

carbon dioxide, and potentially, argon, helium, and nitrogen protoxide. These gases are called "packaging gases" by the Italian Legislation for Additives (Ministerial Decree 1996). This Decree allows this packaging technique to be used for all food products, without any restrictions.

The EC Directive 94/54 (1994) for food product labeling has introduced the term "protective atmosphere". The use of this practice (but not the gases used) must be written on the label. The use of MAP must not be seen as a remedy or means of improvement of a poor-quality food, but rather as a support technique that can have positive results only if combined with other technologies such as refrigeration (Squarzoni and others 2001).

The primary objective of MAP is to maintain a concentration of oxygen not higher than 1% inside the food packaging (Zardetto 2004). As well as preventing the risk of microbial development, the absence of oxygen in the packaging guarantees the maintenance of the sensory characteristics of the filling ingredients (eggs, meat, spinach, or cheese), which are highly sensitive to oxidation. Although this result can be achieved by substituting environmental air with nitrogen, it is useful to use a certain proportion of carbon dioxide that has a specific toxic effect on all aerobic microorganisms (Castelvetri 1991b; Farber and others 1993).

The percentage of CO_2 varies according to the process used (if pasteurization is made after packaging the CO_2 amount can be lower), and the characteristics of the product, that is, its tendency to release this gas. Generally, a proportion of CO_2 to N_2 equal to 30 : 70 is used, even though a better stabilizing effect is obtained with 50% CO_2 (Castelvetri 1991a).

However, these quantities are often associated with the formation of bubbles on the surface of the product at the time of cooking (Table 17.7). This defect can be traced back to the dilation of the gas, which has no way of being released during cooking (Sensidoni and others 1994). Although this phenomenon does not have any negative effects on the hygiene of the product, it is not appreciated by the consumer and so considered as a valid reason for rejection.

The selection of the packaging material is very important and must be made bearing in mind

1. The strict standards of barriers required;
2. The need to maintain the sensory characteristics typical to product; and
3. The heat-resistance level of the packaging in case it has to be subjected to a further heat-treatment (second pasteurization).

Plastic materials are used (envelopes or flexible or semirigid trays), with the exception of very short shelf-life fresh pasta, which is packaged using nonbarrier plastic materials. An efficacious barrier against O_2 and CO_2 is required when MAP is used. These properties are guaranteed by using co-extruded plastic materials, generally polypropylene (PP), polyamide (PA), polyethylene-terephtalate (PET), and ethylene-vinylalcohol (EVOH) (Stollman and others 1994).

Among the most interesting innovations in the field of fresh pasta packaging, have been made by Giavedoni and others (1994) on the possibility of further extending the shelf-life of fresh pasta with MAP packaging by the introduction of ethanol vapors.

17.2.4 Heat Damage to Pasta

Food quality is directly influenced by the intrinsic chemical and physical characteristics of the raw materials and also by the conditions of the processes used in each phase of the technological cycle. The heat treatments that food products are subjected to often give rise to undesirable changes in the color, flavor, and chemical macromolecules of the goods, and can also affect the availability of some nutrients. All these different changes have been covered by a single term, "heat damage". In a system that contains both proteins and reducing sugars, as in the case of cereal products, heat damage is mainly attributed to the Maillard reaction, or nonenzymatic browning (Nursten 2005; International Maillard Reaction Society 2006). The Maillard reaction is a complex reaction with two distinct stages, the early stage and the advanced stage (Friedman 1996). In the first stage of the reaction, part of the lysine molecule in the food product is chemically blocked and is not available from a nutritional point of view (Finot and Mauron 1972). At this point, this phenomenon is not yet accompanied by the formation of the molecules responsible for the flavor and color that distinguish the advanced phase and give the name to the reaction as a whole.

Evaluation of the heat damage is held to be highly significant nowadays as it makes it possible to complete the description of the foods' properties and distinguish and classify similar products in different quality classes. This criterion has already been applied with success to the dairy industry (Resmini and others 1993a).

In the previous sections, we have shown how the production of pasta, both fresh and dry, includes heat treatments at different temperatures and times. The extension of heat damage therefore contributes to a wide range of a variabilities) (Fig. 17.21). Quantification of this phenomenon is possible through establishing the dosage of particular molecules, the most widely known of which is furosine (Resmini and others 1990), a marker in the initial phase of the Maillard reaction. The intensity of the secondary phase in the pasta system is well illustrated in other neoformed products, both soluble (Resmini and others 1993b) and insoluble (Resmini and Pellegrino 1994).

As well as producing a negative effect on a number of the sensory characteristics of pasta, these changes also cause a decrease in the amount of bioavailable lysine (up to

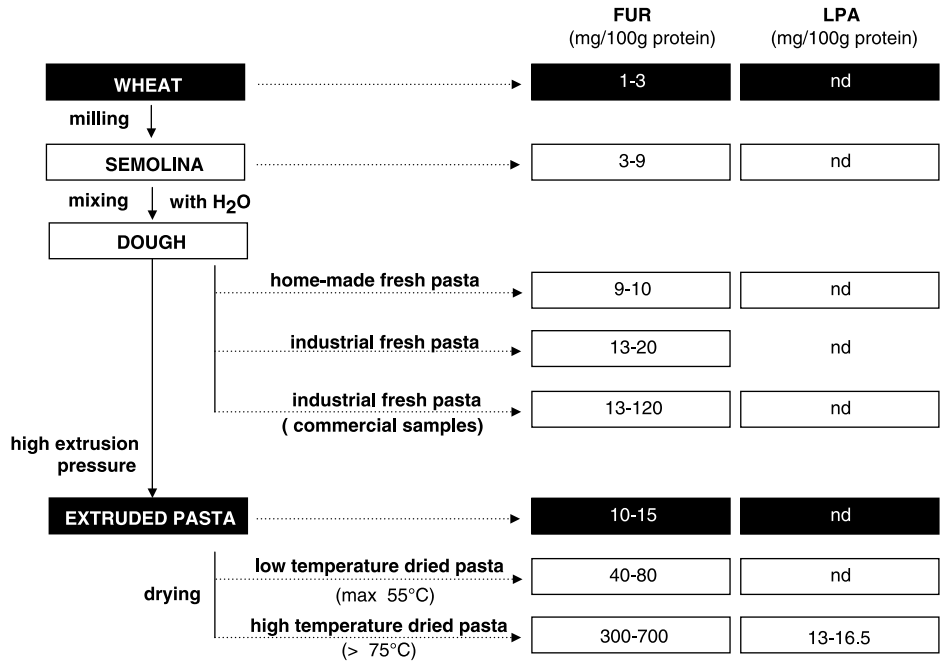

Figure 17.21 *Quantification of heat damage in different pasta products (FUR = furosine; LPA = lysylpyrrolaldehyde; nd = not detectable).*

40% of the original amount present in semolina; Resmini and others 1990), and the appearance of neoformed compounds that are typical of the crust of baked products (Resmini and Pellegrino 1994). Without doubt, the phase in pasta-making that is the greatest culprit when it comes to heat damage is the drying process. The intensity of the reaction is controlled by the drying diagram parameters (temperature, time, and pasta moisture) (Pagani and others 1992). In particular, the HT cycles widely used nowadays, thanks to the numerous benefits obtained with regard to behavior in cooking as mentioned above, can produce considerable heat damage, especially if the high temperatures are applied in conditions of low moisture (less than 15–17%) (HT-LM cycles). These conditions correspond to optimal a_w levels for the Maillard reaction.

These authors (Pagani and others 1996) demonstrated that each phase of the pasta-making process before the drying phase is associated with changes that directly or indirectly control the concentration of the molecules involved in the Maillard reaction. Special significance should be given to the glucidic fraction, which is the most highly affected with regard to quantitative variations. The critical parameters are those that influence the concentration of soluble sugars in extruded pasta, such as amylase activities and the mechanical damage to the starch granules during milling.

Even with fresh pasta, the Maillard reaction can vary over a wide range (Fig. 17.21); some industrial products are subjected to a double heat pasteurization treatment that is almost a "precooking" treatment (Mondelli 2003b), showing furosine levels that are 3–4 times higher than in fresh artisanal products.

It is difficult for the consumer to quantify heat damage directly, but this information could be included in the nutritional label given on the packaging. Although nutritional loss of lysine can be recovered through seasonings, sauces, and dressings, it is important

to state that the addition of animal proteins is considerably more costly than keeping the original proteins of the product. Future innovations in this sector will have to take these factors into account.

17.3 BREAD AND OTHER SAVORY PRODUCTS

It is difficult to establish who developed the first bread-making process. On the other hand, it is clear that both bread-making formulations and conditions have been handed down for millennia, continuously improving through to the present time. Bread production continues to be a complex and sophisticated process to this day, requiring much time, attention, and experience to guarantee good results.

The generic term "bread" embraces hundreds of different types of this product, each reflecting the traditions and cultures of the different countries of origin (Pomeranz 1987). Italian consumers prefer their bread with a crispy, highly fragrant crust and a soft crumb, with innumerable alveoli of different shapes and forms. The enormous difference in the humidity of the crust and that of the crumb (between 3–6% and 38–45%, respectively) and the preference for formulations with negligible percentage of sugars and fats (ingredients with the strong task of slowing down the staling process; Gray and Bemiller 2003) result in an extremely short shelf-life, a few days at most. This fact partly justifies the widespread presence of artisan bakeries throughout Italy (Pagani and others 2006).

For Anglo-Saxon populations on the other hand, the presence of a crust is considered a defect and the crumb must have fine, regular "bubbles" (Cauvain and others 1999). These characteristics can be clearly seen in pan bread, whose formulation includes antistaling ingredients and additives that slow down ageing and prolong shelf-life (longer than 2 weeks).

Some phases of the production process have a decisive influence on the product characteristics. In particular, the leavening of the dough due to yeast activity is fundamental not only to the formation of a soft, porous texture (which will be completed and stabilized during baking), but also to the production of metabolites that determine the taste and fragrance of the product. We can safely say, therefore, that bread production is one of the oldest, if not the first example, of food biotechnology.

Although critical to the bread structure, the leavening is not the only phase responsible for the creation of alveoli. The technological process of bread making, as for all baked-product processes, comprises a sequence of operations: mixing and kneading, leavening, and final baking in the oven. All these operations are indispensable for creating, maintaining, and "setting" the millions of gas bubbles in the dough and giving a product with a soft texture that is pleasant to chew (Dobraszczyk and others 2001). The wide variability of conditions in which each one of these phases can be carried out is responsible for the huge number of bread types available in Italy (Pagani and others 2006). In this chapter, we will highlight the main distinctive features common to Italian breads that can be found at the formulation and technological process level.

17.3.1 The Raw Materials

17.3.1.1 Wheat Flours and Flours from Other Cereals. The basic ingredients required for making dough for bread making are wheat flour, water, and yeast. Both soft wheat flour and durum wheat semolina are used in Italy. The widespread consumption of semolina bread in the regions of southern Italy is directly linked to the availability of

this product in that area (ISMEA 2002). Common wheat flour is, however, held to be the optimal raw material for bread making, because it gives the best leavening results (Hoseney 1989). This result does not depend on the quantity of the gluten proteins, which on average are higher in semolina than in remilled semolina (Table 17.2), but on the viscoelastic properties of the gluten network (Goesaert and others 2005). The flours with the best bread-making performance must contain insoluble proteins able to produce a dough with a strong yet extensible texture that is able to withstand the physical stresses of kneading and leavening. In other words, the most suitable flours for bread making must have an appropriate balance between dough viscosity and elasticity/strength (Belton 1999; Goesaert and others 2005).

The many works on this subject all agree that the key factors are the gliadin/glutenin ratio and the structure, composition, and molecular weight of the different subunits in the protein fractions (MacRitchie 1992). In particular, the high-molecular-weight (HMW) glutenin subunits have a key role in defining the strength characteristics of the dough, as discussed in a recent work by Shewry (2003).

The study of the properties of the macromolecules and the biochemical mechanisms involved in the formation of the dough is therefore indispensable in the search for new varieties of wheat of optimal bread-making quality. Nonetheless, the identification of these new types of wheat by operators in the sector is usually based simply on observation of the behavior of the flour during rheological tests defined as descriptive or imitative because they simulate the strain exerted during the bread-making process (Dobraszczyk 2003). The information obtained from the so-called fundamental rheological tests are more difficult to correlate to the behavior of the material during a real production process (Dobraszczyk 2003).

The most frequently used voluntary policy in Italy (Aldovrandi and Vitali 1995; Table 17.2) for defining the classification of commercial wheat flours provides for five classes, as a function of the total protein content and the main rheological indices, such as the alveographic indices (W and P/L) and farinographic stability. Information obtained from the rheofermentograph (Mariotti and others 2006b) is also being increasingly used. This test completes the description of the behavior of a flour in bread making by supplying data regarding the development of the mass due to CO_2 and the quantity of gas actually retained in the dough.

The durum wheat doughs are distinguished by a high resistance to deformation and consequently limited extensibility, characteristics typical to the proteins of this raw material (Boyaciogly and D'Appolonia 1994; Pogna and others 1996), which allow only a modest development in mass volume during leavening. To be judged suitable for bread making, the semolina must have a high protein content ($>12\%$), a good farinographic stability, and alveographic P/L index values below 1 (Boggini and others 1995, 1997).

It should also be noted that the bread-making process preferred in the case of durum wheat requires the use of sourdough. A case in point is the *pane di Altamura*, Altamura Bread, whose process is described in detail in Section 17.3.3. The proteolitic activities of semolina and/or of the lactobacilli may produce considerable changes in the rheological properties of the gluten network, reducing the natural excessive elasticity of dough made from durum wheat (Martinez-Anaya 1996; Brandt and others 2003; Clarke and others 2004).

The availability of cereal flours other than wheat flour in the mountainous and hilly areas of Italy, in particular rye, barley, oats, and corn, justifies the extraordinary variety of bread formulations existing in this country. A survey of the many existing bread formulations was recently made by Bordo and Surrasca (2002) and INSOR (2000). Today, the

use of flours other than common wheat for bread making is being seriously reconsidered, because their use would improve the nutritional properties of the food (Pagani and others 2002; Shfali and Sudesh 2002). However, this practice produces dough systems with special rheological properties and technological performance (Dendy 2001; Mariotti and others 2006b). Raw materials such as rye or barley, whose proteins have a lower capacity for assembling into a viscoelastic network than wheat gluten, provide mixtures with a low expansion capacity for developing during leavening (Panigone 2004). The low bread-making quality of these cereals can be improved with the addition of wheat flour having superior gluten performance. This solution makes it possible to obtain a sufficiently developed product (Fig. 17.22). The presence of high percentages of fiber in these cereals also ensures a prolonged shelf-life (Katina 2003).

The bread-making performance of wheat mixtures enriched with gluten-free flours such as corn or oats flours is also critical. The "dilution" of gluten has a negative influence on the formation of a regular network and consequently on the development of the volume of the product (Zhang and others 1998; Dendy 2001). A number of studies by Mariotti (2004) and Pagani and others (2002) have shown that mixtures of top quality bread-making wheat flour enriched with 40% buckwheat flour or toasted oats give satisfactory results with regard to volume development proportional to the bubble's area during leavening and baking (Fig. 17.23). It is possible to optimize the formulation by adding 5% puffed buckwheat flour (PBF) with consequent improvement in the shelf-life of the bread, which maintains its fresh-bread softness for longer (Mariotti 2004) (Fig. 17.24).

17.3.1.2 Yeast. The term baker's yeast is used to refer to *Saccharomyces cerevisiae* strains selected for their fermenting powers in bread making. At the end of the kneading phase and after an initial rest phase (a brief period of only several minutes, during which the oxygen in the microbubbles dispersed in the dough is consumed), the microorganisms start fermenting, first using the free sugars in the flour (glucose, fructose, maltose, and so

FORMULATION	Bread characteristics(*) height (mm)	diameter (mm)	volume (mL)
100% wheat flour (WF)	52	99	280

on) and then those freed by the endogen amylase activities or by the consequent addition of enzymes.

From the industrial production process of bread-making yeast, we obtain a cell suspension in water of 18–20% yeast solids, called yeasts cream. This biomass is cooled to 2°C to block all metabolic activity and filtered using a rotating drum vacuum filter to produce compressed yeast (approximately 26–28% yeast solids), which is usually shaped into cakes. The product is left to stand in a cold-storage room for several days awaiting laboratory analyses, including the evaluation of the reserve carbohydrates trealose and glycogen, which are good quality markers. The color of the compressed yeast depends on the substrate used for its production and the pretreatments applied to molasses to reduce

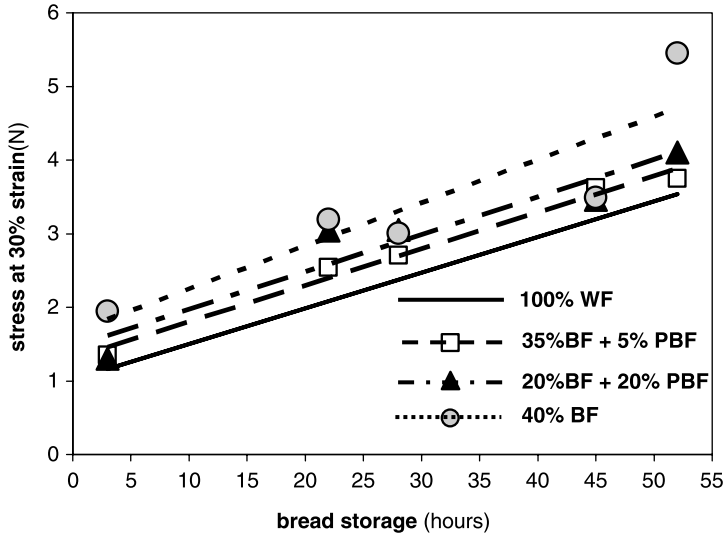

Figure 17.24 *Measures of shelf life of bread for different flour mixtures (WF = wheat flour; BF = buckwheat flour; PBF = puffed buckwheat flour).*

the tannin and fiber content. Compressed yeast can be subjected to an extrusion process and subsequent drying. In this way, we obtain a dried form that is easier to preserve and has a longer shelf-life. However, the product requires a rehydration phase (e.g., at 30–40°C for 10–15 min) before being used for bread making.

Dried "instant" yeasts with morphological and structural characteristics that preclude the rehydration phase and so can be mixed directly with the dry ingredients have been on the market since the 1960s. These are small, yet highly porous granules, with a high specific surface (Pointrenaud 1994). In addition, the genetic selection of the microorganisms has made it possible to obtain strains that can be dried, but maintain their good fermenting capacities. Recently, yeast in the yeast cream form has also been used.

The different types of yeasts differ in temperature and storage time, which varies between 3 and 4 weeks for the compressed yeast and up to 12 months for the dried yeast. According to the law (Italian legislation, Presidential Decree 1998), yeast sold for bread making must contain a maximum part of vital cells with an adequate fermenting power, and humidity and ash not exceeding 75% and 8%, respectively (on a dried basis), for the compressed yeast, and 80% and 8% for yeast cream.

17.3.1.3 The Other Ingredients. The large number of types of bread produced in Italy vary greatly, depending on the kind of flour and the quantity of water used. The amount of water used varies widely, between 40 and 70 parts per 100 parts of flour (Pagani and others 2006). This parameter has a significant effect on the rheological properties of the dough and consequently on the bread crumb grain. A low-humidity dough (about 35–40% water) is firm and stiff and the gluten presents a low extensibility: during the leavening phases, the expansion is considerably limited, giving the bread a compact crumb texture, like in *pane di pasta dura* and *pane Ferrarese*. On the other hand, a high-humidity dough (65–70% water), characterized by a relevant extensibility, cannot be molded into regular shapes and the CO_2 developed during leavening tends to collect into large bubbles typical of the irregular, flat loaves called *Ciabatta*, which have an uneven grain (Pagani and others 2006).

The action of water is indispensable for the formation of gluten. It also acts as a solvent for the other ingredients such as salt and sugars, and promotes the enzymatic activities of the flour, both those that are endogenous and those that are added enzyme to improve the behavior of the dough, especially during leavening. Water also contributes to the swelling of the starch grains during baking, and their gelatinization, a key phase for the development of both the physical properties of the bread and its nutritional value (Eliasson 2003).

In the artisanal preparation of bread, other additives are added such as malt extract, malted cereal flour, and ascorbic acid (Italian Legislation 1998). The use of malt and/or malted cereal flours enriches the dough with enzymes, especially amylase, which hydrolyzes the starch into fermentiscible sugars, a substrate for yeasts during the fermentation phase. There is a rapid start to the leavening, with an increase in the product final volume and consequent improvement in the alveoli structure (Goesaert and others 2005). Ascorbic acid is added (the Italian Legislation quoted does not specify the "maximum quantity" but says "enough": it is a question of parts per million), thanks to its ability to promote the formation of sulfur bridges between the gluten proteins that increase the strength of the dough (Goesaert and others 2005).

Other optional ingredients are shortenings, such as butter, lard, or olive oil. In order to be able to include these ingredients in the name of the bread (e.g., *pane all'olio*, oil bread),

they must constitute at least 3% of the dry material in the finished product. The main technological role of shortening, when present in small percentages, is as a lubricant. Shortening facilitates the flow among the gluten macromolecules, which will have a greater extensibility (greater volume of the final product) (Desgrets 1994). In addition, a number of the lipid fractions stabilize the air bubbles created during kneading, ensuring a more regular alveoli of the crumb. Lastly, during storage, the lipids prevent interaction between the starch granules, slowing down starch retrogradation and blocking water migration between starch and proteins, consequently slowing down the staling process (Gray and Bemiller 2003).

17.3.2 Bread-Making Process

17.3.2.1 Bread-Making Processes with Baker's Yeast. Bread production is mostly made up of unit operations as shown in Table 17.8, which also summarizes the specific objectives and modifications of each technological step. A fundamental difference, which distinguishes almost all breads produced in Italy from breads produced in Anglo-Saxon countries, is the absence of a pan used in the leavening and baking phases. Not using a pan gives the possibility of shaping the bread into endless numbers

TABLE 17.8 Main Phases of the Bread-Making Process and Related Modifications.

Phase	Aim	Modifications
Mixing	• Distribute ingredients homogeneously	• Hydration and solubilization of the water soluble compounds
	• Form a uniform and "coherent" structure	• Formation of gluten
	• Include air bubbles	• Inclusion of microbubbles
Leavening	• Increase volume of dough	• Formation of gas (CO_2)
	• Develop typical "flavor" characteristics	• Production of fermentation metabolites important for developing flavor and changing macromolecule solubility
Shaping	• Subdivide gas bubbles and include new air	• Division of dough into final pieces
	• Give shape to dough	
Baking	• Decrease water content	• Increase in volume due to evaporation of gases: 20–30% of the volume is obtained during baking (oven-spring)
	• Fix the leavened and shaped dough	• Formation of crust and crumb
	• Make product appetizing and digestible	• Denaturization of proteins
	• Give the product its typical coloring	• Gelatinization of the starch
		• Development of flavor
		• Evaporation of water and ethanol
Cooling	• Product packaging	• Change of sugar solubility
		• Hardening of fats

of shapes and sizes, with the most sophisticated and refined reserved for special occasions (Bordo and Surrasca 2002).

The production of bread in Italy is traditionally a discontinuous process, because each phase of kneading, leavening, and baking is conducted on a moderate quantity of material and there is a separate machine for each. The process is typically artisanal in every region. The number of bread-making laboratories, often family-run, totals about 30,000 (Pagani and others 2006).

The discontinuous bread-making processes are performed using the straight-dough (in Italian *metodo diretto*) or the sponge and dough (*metodo indiretto*) processes; sourdough-bread-making can be considered as a particular sponge and dough method (Fig. 17.25).

With the straight-dough method, all the ingredients are mixed together at the same time to form a dough, which is then left to rise. The yeast is composed of selected cultures of *Saccharomyces cerevisiae*. Fermentation must occur in at least two phases. The first fermentation, called *puntata*, is generally effected on large masses of dough, at variable periods of time from about 30 minutes to three hours, according to the process. The objective of this operation is not to obtain an increase in volume, but to induce important changes in the rheological properties of the dough (Chargelegue and others 1994). In particular, the solubilization of part of the CO_2 produced lightly acidifies the system and causes the gluten to become stronger. This phenomenon improves the kneading of the dough and its ability to maintain the shape given during the second fermentation or *appretto*. In this phase, the dough is given its final shape and left for an hour under controlled temperature and humidity until it has reached its maximum volume. The advantage

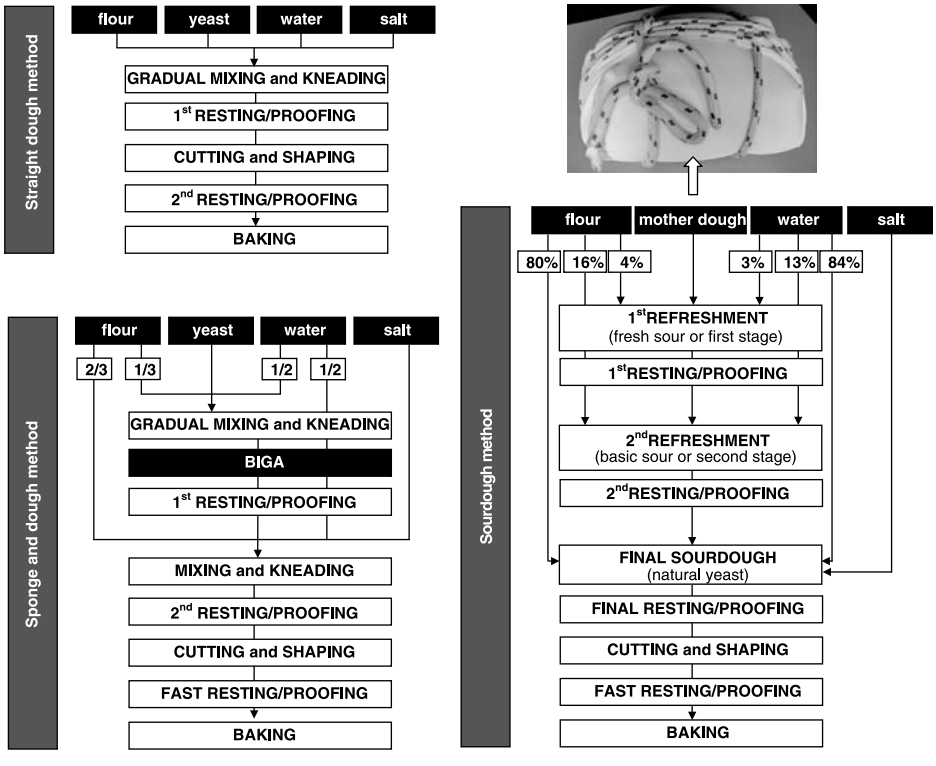

Figure 17.25 *Different methods of bread-making.*

of using the straight-dough method, thanks to its speed and use of compressed yeast, is the possibility of using lower-strength flours, because a shorter leavening time is required.

In the sponge and dough processes, the ingredients are added at different times (Fig. 17.25). These processes are still widely used in Italy, both at the artisanal and industrial level (Pagani and others 2006). The processes include the formation of a preparatory sponge, called *biga*, which involves mixing part of the compressed yeast (selected *Saccharomyces cerevisiae* strains), part of the flour, and part of the water required for the entire formulation. After a holding period (which can vary from 3–4 to 20 hours according to the type of bread desired), the remaining flour and water are added, and then the remaining ingredients. During the long rest phase, the yeast adapts itself to the dough-system, and reaches optimal fermentation capacity when all the ingredients have been added. After 30–60 min of leavening, the dough is cut, shaped, and left to rise again for about an hour, and is then baked.

The long leavening times required for the sponge process provide, in the final product, a crumb grain texture with a high number of bubbles (Brown 1993), often with an irregular size distribution. This alveolar structure provides greater initial softness, as indicated by the lower consistency, and longer storage times with respect to the product obtained with the same raw material using the straight-dough process. After 24 hours, the crumb hardness of a straight-dough loaf is 50% higher than that of a sponge-and-dough loaf (Pagani and others 2006).

17.3.2.2 Bread-Making Processes with Sourdough. Sourdough bread-making processes are still widely used in Italy. Without doubt, they can be considered one of the most delicate and complex transformations found in food technology.

As recently summarized by De Vuyst and Neysens (2005), referring to the classification of Böcker and others (1995), sourdough is conventionally subdivided into three types on the basis of the preparation method.

Type I Sourdough or Traditional Sourdough. At present, this is the most widely used type of sourdough used in the production of traditional breads. The process is characterized by continuous steps at environmental temperature (22–28°C) and ~pH 4, with the objective of keeping the microbial population vital and constant, both from the point of view of the number of microorganisms and also the number of species. Sourdough contains both yeasts and lactobacilli. In particular, type Ia sourdough is composed of a well-adapted microflora and maintains a constant composition. Type Ib sourdough requires regular fermentation or refreshment phases (fresh sour, basic sour, and full sour, Fig. 17.25) in order to maintain the dough microbial association unchanged over time (even decades). The mother dough or starter represents the starting point (inoculum) of every bread-making process. Type Ic sourdough refers to products at higher temperatures; a case in point is the sorghum dough, typical of a number of African countries.

Type II Sourdough or Accelerated Sourdough. This is a semifluid dough developed to satisfy the requirements of industrial processes that demand fast and controllable techniques on a large scale. They are obtained at temperatures over 30°C and generally have a shelf-life of several days (approximately one week in a cold environment). During the preparation of these sourdoughs, the microorganisms are in a stationary phase and have limited metabolic activity. This procedure requires the addition of

Saccharomyces cervisiae, of commercial origin, which is responsible for the increase in volume during leavening, an operation performed in a single stage.

Type III Sourdough or Dried Sourdough. This dough is obtained by using commercially dehydrated starters aimed at giving acidity and fragrance to the product. The type III dough also requires the addition of *Saccharomyces cerevisae* to guarantee leavening.

As already mentioned, regardless of the process adopted (artisanal or industrial) and of the formulation (savory as in the case of bread or sweet as in the case of festivity cakes), most Italian sourdough products are obtained using type Ib sourdough (De Vuyst and Neysens 2005; Pagani and others 2006). These products require inoculum (mother), that is, the addition of a piece of dough from the previous day. This primary dough, which represents 5–20% (w/w) of the final dough, goes through several refreshment or backslopping phases under controlled conditions to obtain the full sourdough after a single or multistage process (Spicher 1983; Ottogalli and others 1996; Vogel and others 1996). Each refreshment stage causes a significant increase in the leavening mass and its fermentation capacities (Pagani and others 2006).

The type Ib sourdough contains several lactic acid bacteria (LAB): works on this subject refer to over 50 LAB species of *Lactobacillus*, *Pediococcus*, and *Leuconostoc* in concentrations of about 10^8–10^9 cfu/g (Gobbetti and others 1994; Ottogalli and others 1996; Stolz 2003; De Vuyst and Neysens 2005). The microbial groups are linked in a noncompetitive and often mutualistic equilibrium, forming an ecosystem that is quite stable to external perturbation (Martinez-Anaya and others 1990; Foschino and others 1995; Gobbetti 1998; Stolz 2003; De Vuyst and Neysens 2005). Generally, sourdough contains yeasts of the *Saccharomyces* and *Candida* species, which are responsible for alcoholic fermentation and consequently for the development of the volume of the dough. The yeasts are in association with the LAB in a ratio of 1:100 (Ottogalli and others 1996; Stolz 2003). The LAB perform an intense acidifying activity, producing lactic acid and acetic acid in quantities related to the species present in the sourdough (obligate homofermentative, facultative heterofermentative, and obligate heterofermentative). They are capable in any case to determine both the significant increase of the total acidity and the decrease of pH (Foschino and Galli 1997; Stolz 2003; Gobbetti and others 2005). Characterization of the acid dough can be completed by calculating the so-called fermentation quotient (FQ), that is, lactate/acetate molar ratio.

These changes not only influence the sensorial properties of the dough and the finished product (Spicher 1983; Schieberle 1996), but also their consistency (Crowley and others 2002), thus providing an extended shelf-life (physical and microbiological) of the bread obtained using this process (Röcken 1996; Corsetti and others 1998; Raffo and others 2002, 2003). Equally important for assuring fragrance and prolonging shelf-life are the metabolites produced by the amylase activities (sugars and low-molecular-weight maltooligosaccharides with a degree of polymerization from 3 to 9) and the protease activities (peptides, amino acids) performed by the LAB, as illustrated in the review by Martinez-Anaya (1996) and in the work of Gobbetti and others (1996). The production of exopolysaccharides from cereal-associated LAB is also being studied with increasing attention thanks to the positive effects on the dough rheological properties and bread quality (Tieking and Gänzle 2005). Moreover, the changes in the hydration state of the gluten proteins promoted by the souring could also be involved in maintaining crumb freshness for a longer time (Crowley and others 2002). Nevertheless, the delay in bread

staling promoted by biological acidification may differ according to the lactic acid bacteria strains and the level of acidity obtained (Corsetti and others 1998, 2000). The extended shelf-life of sourdough bread is not only due to the slowing down of the development of mold and bacteria in an acid environment but also to the production of bacteriocins by a large number of LAB (Gobbetti and others 2005). The greater softness of the crumb with respect to bread obtained using the straight-dough method is partly due to the greater and more uneven alveoli (Brown 1993). This is associated with the slower and more gradual production of CO_2 and the merger of small bubbles into larger alveoli.

Bread obtained from sourdough has a characteristic flavor and fragrance due to the formation of volatile organic substances (fermentation byproducts) and fragrant substances formed during baking following the Maillard reaction between the glucose and amino acids produced during the long fermentation process (Schieberle 1996). It must be remembered that sourdough bread is more easily digestible due to the macromolecule-extended enzymatic hydrolysis action by the LAB that facilitates hydrolysis (Katina and others 2005).

As already mentioned, the development and maintenance of the microbial species typical to sourdough are achieved using traditional discontinuous processes that require subsequent refreshments of the primary dough in order to obtain the full sourdough. Although all producers apply a constant microorganism propagation process in their bread making, the sourdoughs differ both from the point of view of formulation and of storage conditions (Hammes and others 1996). These factors are conducive to specific symbioses between microorganisms with interesting repercussions on the sensorial properties of the finished product. All researchers engaged on this subject agree that *Lb. sanfranciscensis* can be considered the key bacterium in the sourdough process (Gobbetti and others 1996; Gobbetti and Corsetti 1997). In fact, together with *Lb. pontis*, it constitutes the major part of the microbial flora and establishes interesting trophic relationships with the sourdough yeasts (*S. cerevisiae*, *S. exiguus*, or *Candida milleri*) due to its effective maltose metabolism (Stolz and others 1993). The overall metabolic activities of these dominating bacteria assure a rapid acidification, a balanced production of lactic and acetic acid (as expressed by the FQ), and gas production.

17.3.2.3 Optimization and Innovation of the Sourdough Process. As we have seen, the sourdough processes require a long working time and considerable experience. In spite of the significant complexity of the process, this ancient technology is still in practice today, even at the industrial level. This is because it is able to produce bread and other sweet and savory products that combine high sensorial characteristics such as softness and lightness of crumb, and the typical fragrance and taste, with longer and easier storage.

For some time, proposals have been put forward for improving the process with methods that maintain the numerous advantages associated with acid dough and simplify the management of the technological cycle. The type II and type III sourdoughs may be considered effective examples in this sense.

As already seen, the type II sourdough is a semifluid silo preparation for use in continuous processes and guarantees a correct acidification level of the dough (Böcker and others 1995; De Vuyst and Neysens 2005; Decock and Cappelle 2005). The type II sourdoughs are obtained with a long process (2–5 days) at a temperature $>30^{\circ}$C aimed at bringing the microorganisms to the stationary phase, characterized by a limited metabolic activity. Under these conditions, *Lb. sanfranciscensis* is not sufficiently competitive to dominate the fermentation. The ecosystem is characterized by LAB of other genera and species, both homofermentative and heterofermentative. Yeasts are not found in significant

amounts; therefore, the addition of baker's yeast is necessary (Martinez-Anaya 2003) and the fermentation occurs using a long-term single step. As stated by Stolz and Böcker (1996), this approach has transformed traditional sourdough technology "from work-consuming multiple-stage processes (the type I sourdough) to work-saving one-stage processes", capable of guaranteeing greater flexibility and stability in the final characteristics of the product. Another important advantage of the type II sourdough is its low consistency, which makes the inoculum pumpable, resulting in a higher dough yield.

The evolution of this technology is represented by equipment that provides for continuous sourdough fermentation (Stolz and Böcker 1996; DeVuyst and Neysens 2005). This process has been adopted in Italy by a small number of producers of festivity cakes and breads at the industrial level. In this case, and similar to what has occurred in the dairy and meat sectors, the starter, often called preferment, is represented by LAB selected cultures (rarely in combination with yeasts), which are prepared by specialized companies and sold in the form of lyophilized granules. The production of these starters is shown in Figure 17.26. Starting with selected strains, an intermediate culture is obtained. The following fermentations are carried on in reactors. The biomass is then separated, washed with isotonic solutions, has added cryoprotectants, and is lyophilized. The industrial process continues with grinding of the lyophilized biomass, standardization of the viable cell count, and packaging of the finished product.

The concentration of vital microorganisms is extremely high (the LAB are greater than 10^9 cfu/g) (ANIDRAL Srl, personal communication). After a thorough and extended revitalization phase of the microorganisms in fermenters at 27–32°C, generally in the presence of flour, the liquid preferment is mixed with the remaining part of the ingredients, applying the all-in-one process (Stolz and Böcker 1996). The comparison between the traditional process and the preferment process not only highlights a saving of time, but also emphasizes the greater facility and standardization of the operations (Fig. 17.27).

Although the starters have significantly simplified the production of sourdough, this approach is still considered too expensive (because of the need for fermenters and the time required, from 16 to 24 hours to obtain the full sourdough) for small artisanal producers. These disadvantages may be overcome in part by type III sourdoughs or dried sourdoughs (*madri essiccate* in Italian). Products of this type are widely used in rye bread making because the high acidity level that distinguishes them inhibits the amylase activity typical of this cereal. Type III sourdoughs are commercial products that are obtained from mature sourdough and stabilized via spray-drying or drum-drying (Stolz and Böcker 1996). Another technological solution based on methods used in the past to preserve acid yeast is known as the "granulation process". First, the moisture content of the acid mass is lowered with the addition of an appropriate amount of flour, then brought to values lower than 15% via drying (BakeMark Italia, personal communication). Following the dehydration/drying phase, the microorganisms are no longer vital, but the products contain the metabolites of the microbial populations from which they were obtained. With the use of these starters, the fragrance and acidity properties that with a conventional process would be seen only after many hours of leavening can already be observed at the end of the kneading phase.

Similarly to what we have seen for the type II sourdough, the addition of baker's yeast is nevertheless indispensable for ensuring leavening capacity. Other advantages of dried sourdoughs include ease of use and high standardization, a longer shelf-life, and easy storage of the finished products. The most popular microorganisms for this process are

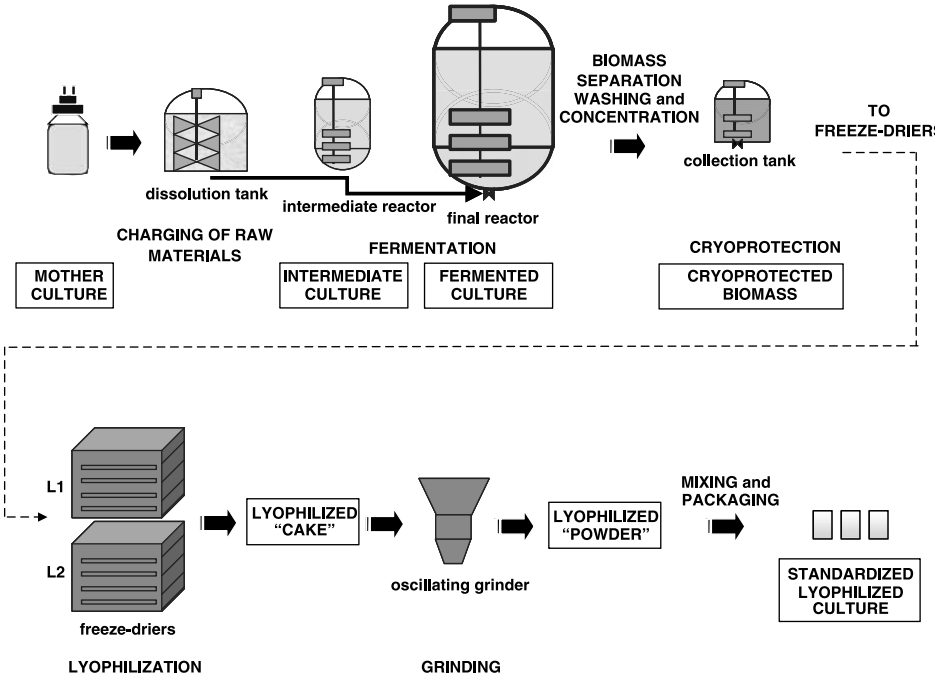

Figure 17.26 *Production of starters: fermentation reactors (a), lyophilizers (b). (Courtesy of ANIDRAL, Italy).*

Lactobacillus plantarum, *brevis*, *casei*, *diacetylactis*, *fermentum* and *Pediococcus acidilactici*, and *pentosaceus* species, because they have a greater resistance to drying (Martinez-Anaya 2003).

These commercial preparations can be classified on the basis of color, fragrance, and acid content. The acid content is extremely important, because it determines both the technological characteristics of the product and the fragrance. Dried sourdoughs can be found on the market with an acid value (expressed as mL NaOH 0.1 N used to neutralize 10 g of suspended sourdough in 100 mL water) that can vary between 15 and 60 and more according to the production process of the sourdough and the initial raw material (wheat flour or

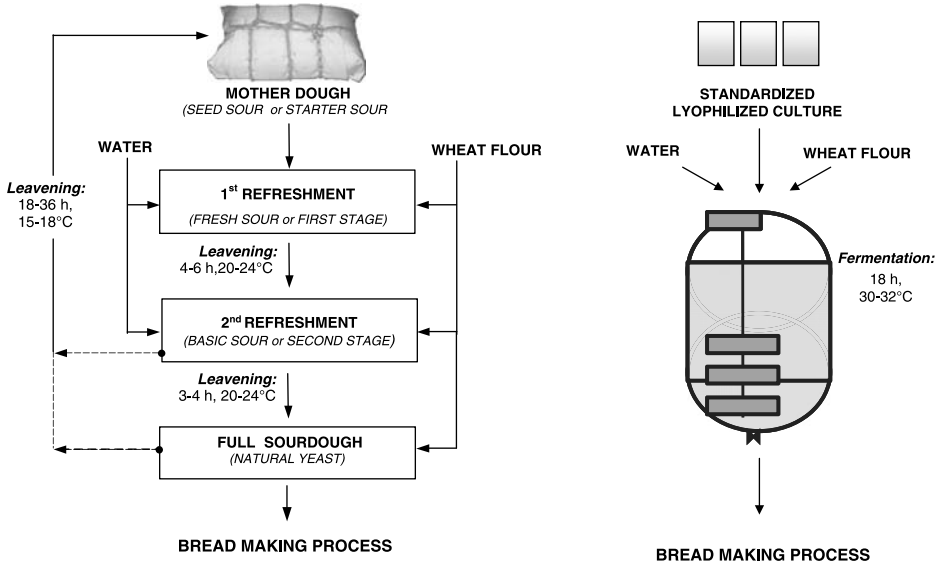

Figure 17.27 *Comparison between the traditional sourdough process and the preferment process.*

rye). As acidity is increased, a strong sour fragrance is developed and the color of the bread becomes more intense due to the catalyzation of the Maillard reaction in an acid environment. The use of dried sourdough with an acid value of 15–30 gives a more elastic and stable bread that is less sour, has a more delicate fragrance, and a more friable crust (Bake-Mark Italia, personal communication).

17.3.3 Process Card of Typical Italian Savory Products

Over the centuries, the experience and skills of Italian breadmakers have given rise to a very large number of types of bread. The Bordo and Surrasca (2002) and INSOR (2000) guides mention at least 200 types of bread still produced in Italy today. Each differs from the others from the point of view of formulation (presence of cereal flours other than bread wheat flour), size or shape, and process conditions, due in particular to the leavening and baking phases. Rightly therefore, the artisanal activity has been given the name "white art", as it has been successful in developing original methods for employing the raw materials found in such a heterogeneous territory as Italy to the greatest possible advantage.

A number of these methods have been used in industry, especially in the sweet baked products sector (Pagani and others 2006). In fact, the most well-known traditional Christmas products, *Panettone* and *Pandoro*, are today available on an industrial scale. Thus, it is possible satisfy the demands of a much larger number of consumers far from the region of origin of the product, guaranteeing low costs combined with high quality. The regulations applied by the Italian Legislation (2005) have set the minimum parameters for content as well as a number of process variables.

As an example of the complexity of the Italian baked products sector, we present here the "product and process cards" for a number of savory foods of this category. The first card refers to the *pane di Altamura*, Altamura bread, a typical durum wheat semolina

bread of ancient origin. There are extremely strict conditions to be complied with in order for *pane di Altamura* to be called such, and, consequently, it cannot be produced on an industrial scale.

The other cards refer to two products that belong to the "bread substitute" category, *grissini* (breadsticks) and *taralli*. Although their geographical origins are distant from one another (*grissini* are from northern Italy, *taralli* from southern Italy), they are similar with regard to consumption. Together with artisanal products, industrial products are also sold using the same names but with completely different distribution channels and shelf-life so as to satisfy the requirements of different kinds of consumers.

17.3.3.1 An Example of the Sourdough Process: Pane di Altamura. Historical sources date the beginnings of bread-making activity in Altamura to 1420, but Horace (37 A.D.) referred to bread in the murgiane area as the "best in the world".

The bread of Altamura (a small town not far from Bari) is a typical bread from the Puglia region and was the first bread in Europe to be recognized with the label of Protected Designation of Origin (PDO) (EEC 2003). The PDO denomination (DOP in Italian, *Denominazione di Origine Protetta*) is assigned to products that have a strong link with their region of origin. Two conditions must be satisfied to receive the PDO designation: production of the raw materials and their processing through to the finished product must be made within the region and meeting precise conditions. Furthermore, evidence must be provided that the special quality characteristics of the product are exclusively or essentially dependent on the geographical environment (climate, quality of the soil, human factors, and so on) of the place of origin.

The bread is obtained from re-milled semolina of four durum wheat varieties, Appulo, Arcangelo, Duilio, and Simeto, grown in the area of Altamura (Pasqualone and others 2002). These raw materials can be used on their own or in combination, making up at least 80% of the total semolina. The production specifications (see also www.panedialtamura.info) specify all the bread-making steps, which are described in every detail (Fig. 17.28 shows the flow-sheet and some operations of the process). The official recipe consists of 20 parts full sourdough to 100 parts durum wheat re-milled semolina, 2 parts salt, and 60 parts water. The full sourdough is prepared with three refreshment steps (type Ib sourdough). The final kneading takes 20 min and the mass is then covered with a thick cloth to maintain a constant temperature and left to rest for 90 min, generally on wooden slabs. The final shape is obtained via three distinct molding phases, each with rest phases (intermediate proof) of established times. This operation is still performed manually. The baking operation must also be performed under controlled conditions in ovens heated with oak wood in order to obtain bread loaves with the characteristic crust at least 3 mm thick, and the typical flavor, due both to the presence of durum wheat semolina and to the sourdough process.

Each loaf is placed into the oven, one at a time, with a 4 m-long baker shovel starting from the innermost part of the oven. Great skill and experience is necessary for placing the loaves into the oven quickly and systematically in order to use up the space in the most effective way, and ensuring that the loaves do not touch each other. A bread brand was used to mark the bread of each family. In the past, the baking of *pane di Altamura* was made exclusively in public ovens due to the fact that bread-making in the home was prohibited; violation of the regulation meant a huge fine. The families therefore, made the dough in the home and took it to the baker for baking. In order to distinguish between the loaves the families used wooden or metal brands bearing the family's initials or other symbols.

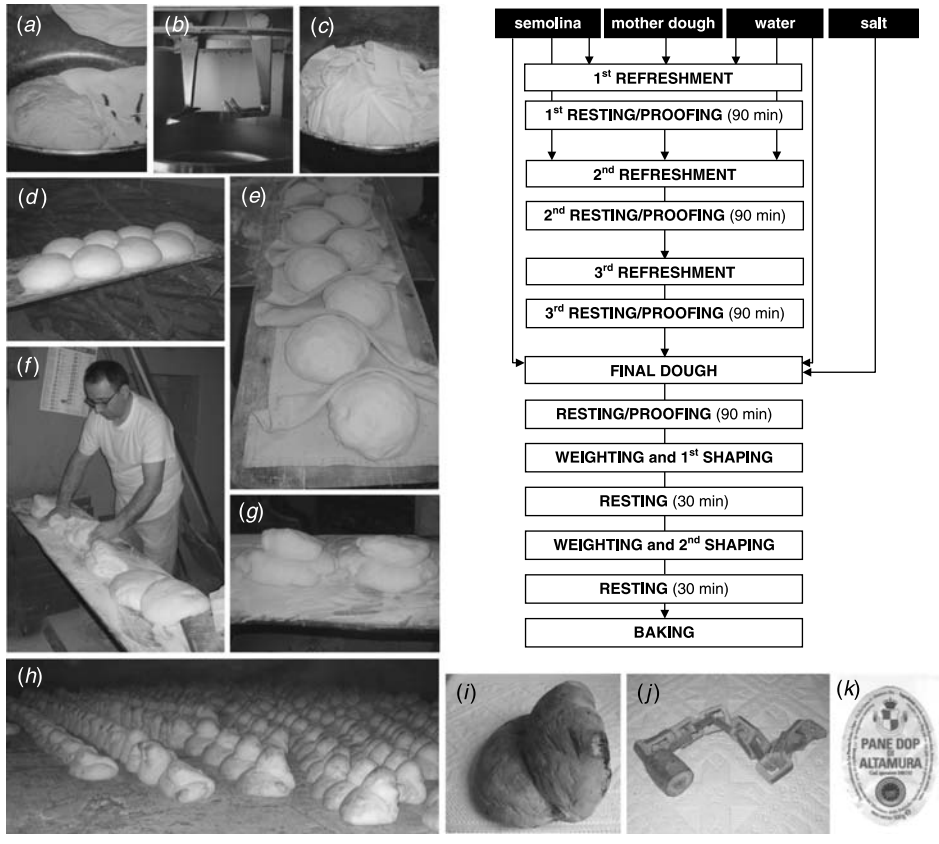

Figure 17.28 *Flow sheet and operations of the pane di Altamura bread-making process: mother dough refreshments (a, b, c); first shaping and resting (d, e); manual shaping of the dough (f); an example of Pane di Altamura dough shape (g); the baking phase (h); bread after baking (i); the ancient instrument used to mark the bread (j); the current "logo" of the Pane di Altamura DOP (k). (Courtesy of Panificio Di Gesù, Italy).*

The traditional shape of *pane di Altamura* resembles a hat with a wide brim (Fig. 17.28*i*). It is also produced in the form of a large loaf, which can weigh up to 2 kg. Its main characteristic, as well as the typical yellow color of the crumb due to the semolina pigments, is its long shelf-life of at least one week (Raffo and others 2002, 2003), equal to the time the farmers and shepherds spent with their herds before returning home.

17.3.3.2 Examples of the Straight and Dough Process: Grissini and Taralli. Both *grissini* (breadsticks) and *taralli* are dry oven-baked products characterized by a high friability and long shelf-life if suitably packaged to prevent absorption of water from the environment. The formulations of both products include added ingredients (fats, generally olive oil) which improve palatability and friability.

The differences lie in the raw material, common wheat flour used in *grissini* and re-milled semolina in *taralli* according to the region of origin and consequently the availability of one type of flour or another. *Grissini* or breadsticks first appeared in a region of northern Italy (Piedmont). This particular bread probably dates back to the middle of the

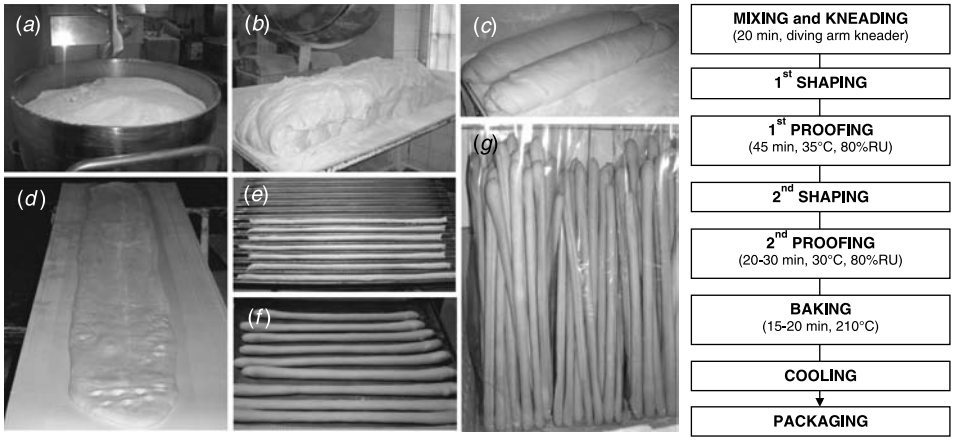

Figure 17.29 *The manufacture of grissini stirati: mixing (a); dough appearance after kneading (b); first shaping and proofing (c); sheeting (d); dough cutting, manual shaping and resting (e); leavening phase (f); packaged product (g). (Courtesy of Panificio Collia, Italy).*

fourteenth century and it was already in wide use in the 1600s (Bordo and Surrasca 2002). The origin of the word is Piedmontese, and derives from *grizia*, a general term for loaf that in time became *gherssin* (small loaf), and hence the modern word *grissino*. A particular category is the *grissini stirati* (stretched *grissini*), which owes its name to the manual shaping technique, which involves stretching and rolling the dough strips by hand after the first leavening phase.

Recognition of the IGP denomination (*Indicazione Geografica Protetta*) for the *Grissino Stirato Torinese* has been initiated to confirm a bond between the product and the Piedmont region. The traditional recipe requires wheat flour, water, yeast, olive oil, and salt. The various phases of the industrial process (Fig. 17.29) include a first shaping of the dough in batches of 5 kg and then a second when the dough is shaped into "tongues" 3 cm thick, 20 cm wide, and 2 m long, and coated with oil. After the first leavening phase at 35°C for 45 min when the dough may be covered with cotton clothes, the "tongues" are cut crosswise into strips 2 cm wide and about 20 cm long. The final shaping of the *grissini* is done manually by holding the rolled strips in the hands and stretching and vibrating the arms until the desired length is obtained. Before baking at 210°C, the dough strips are placed in pans and left to rise again to reach a sufficient alveolar network, which is vital for achieving a highly friable texture.

Other product technologies require the *grissini* to be shaped and cooked in molds. This technique is used for a greater productivity and standardization of the finished industrial product.

Taralli are a typical product of the Puglia region that require the dough to be placed in boiling water before baking (Bordo and Surrasca 2002). It seems that this phase is necessary for impeding the leavening of the product before baking, which in the past took place in a public town bakery. This procedure made it possible to delay baking, unlike bread dough, which must be baked as soon as the leavened dough is ready.

The main ingredients of *taralli* are re-milled semolina, olive oil, water, and salt, to which may be added fennel seeds, compressed yeast, and natural yeast (Table 17.9). The production technology for *taralli* used to be exclusively artisanal. Nowadays, the same procedures are applied while using equipment that ensures greater productivity (Fig. 17.30). Special machinery is used in the industry (*tarallatrici*), which, from a sheet of laminated dough, shapes long rolled strips of dough that are placed inside

TABLE 17.9 ***Taralli*** **Formulation.**

Ingredient	Amount
Main	
Durum wheat re-milled semolina	10 kg
Olive oil	1.5 kg
Water	10% more than farinograph adsorption
Salt	400
Optional	
Fennel seeds	50 g
Compressed yeast	50 g
Natural yeast	0.5–1 kg

(Courtesy of Panificio Di Gesù, Italy).*

mobile tubes which make a rotating movement. A piece of dough is thus formed into a partially twisted ring (Fig. 17.30*f*) and placed on metal grid trays that are rapidly dipped into boiling water. The trays are then removed, stacked on mobile trolleys, and left at room temperature for 30 min to allow the water absorbed on the surface of the *taralli* to evaporate before baking in a rotating oven.

17.4 CONVENTIONAL AND TYPICAL ITALIAN PRODUCTS FROM CORN

Together with rice and wheat, corn is one of the most widely cultivated cereals in the world. Its production of about 700 million tons is similar in volume to that of wheat, but because of its higher yield it requires a smaller surface area of 60%, thanks mainly to the cultivation of high-production hybrids (Lucisano and Pagani 1997).

Almost 40% of the corn produced in the world is grown in the United States, although European production (EU-25) totals about 53 million tons (Corn Refiners Association 2005). Italy produces approximately 11 million tons of corn, 10% of which is for human consumption, 80% for livestock feed, and 10% for industrial use (D'Egidio 2004).

Compared with other cereal grains, corn is distinctive for its dimensions and the development of the cereal germ that represents approximately 10% of the entire kernel.

Consequently, this cereal, which is rich in lipids, has an important use in the production of a much appreciated seed oil, rich in oleic and linoleic acids.

Corn is often harvested when the grain has high levels of humidity, between 18 and 35%, which prevents long-term preservation. The cereal is therefore subject to drying treatments to reduce the maximum moisture content to about 15%. This is a critical operation, because if it is not performed under suitable conditions the physical properties of the grain could deteriorate, and these properties are important for defining the commercial value of the lot. Too high a temperature, usually greater than 70–80°C, can easily cause stress cracking, with resulting higher fragility of the kernel due to deep fissures.

There are two main processes used for the industrial processing of the kernel (Cantarelli and Lucisano 1983):

1. Wet milling to separate the corn into its chemical parts (starch, proteins, fiber, and oil) by soaking the grains in water (Fig. 17.31);
2. Dry milling to separate the grain into its anatomical parts (endosperm, bran, germ), which are then milled. Flours of different particle sizes are obtained, which are usually reprocessed or, to a lesser extent, used in the production of *polenta* or for ingredients for baked products (Fig. 17.32).

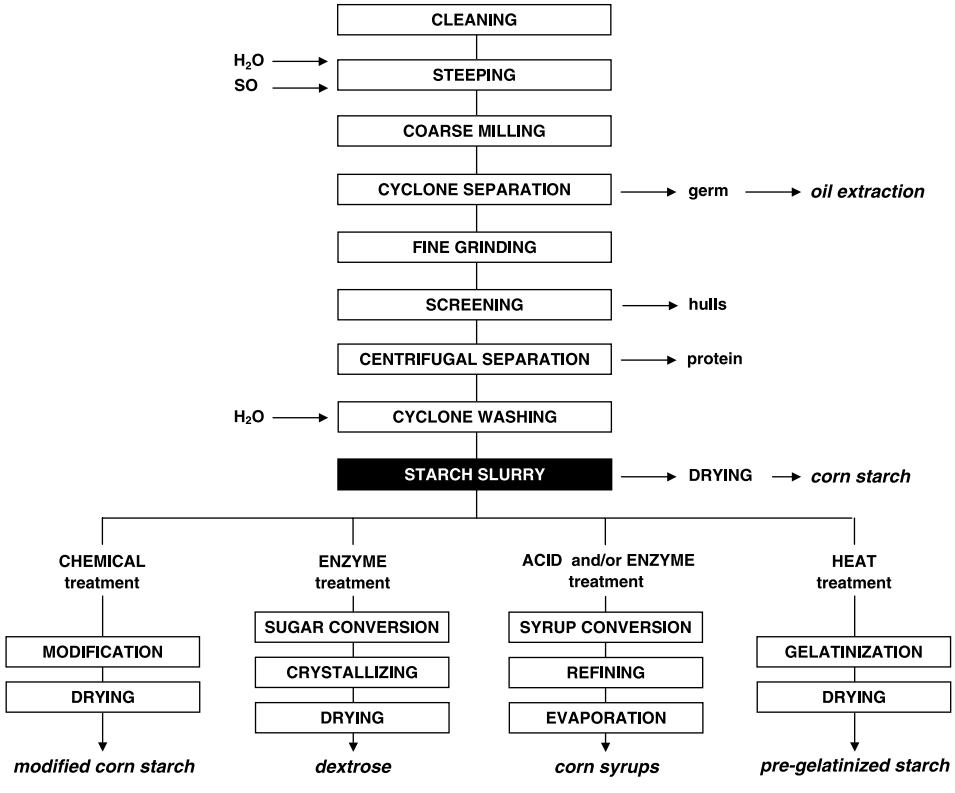

Figure 17.31 *Wet milling of corn.*

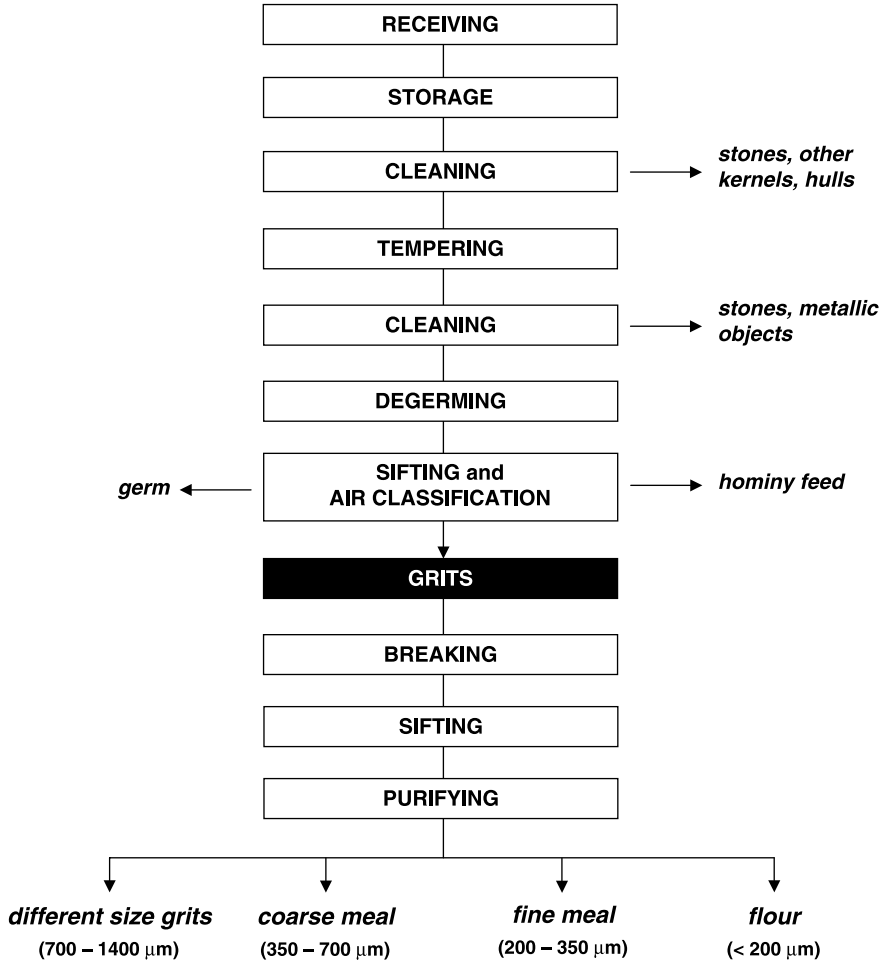

Figure 17.32 *Dry milling of corn.*

17.4.1 Wet Milling

A large part of the world production of corn is destined for use in the starch industry. The starch is extracted from the corn and converted into a large number of byproducts such as modified starches, dextrins, and glucose syrups (Fig. 17.31).

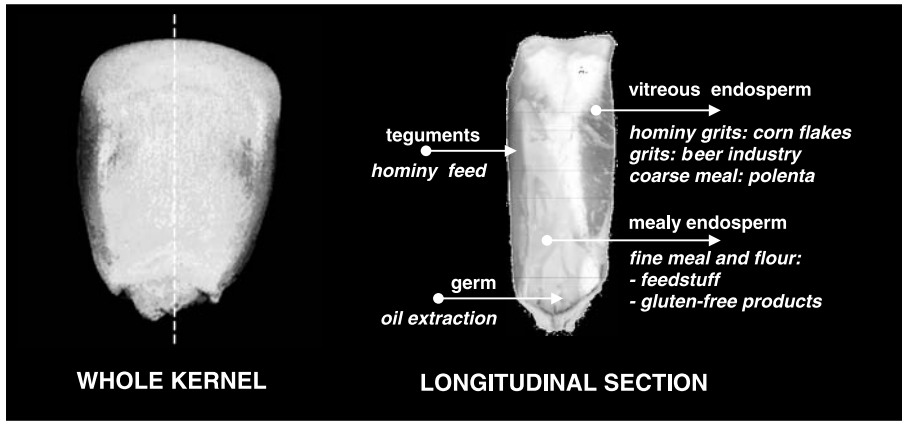
The first operation of the wet-milling process (which gives the name to the entire process) involves wetting the grains by soaking in water that contains small quantities of SO_2 at approximately 50°C for 30–50 h. This compound has antiseptic properties and promotes reduction of protein S–S bridges, facilitating the successive operation of starch separation. The final humidity value of the kernels reaches 45–50%. The endosperm structure is therefore highly softened, facilitating the removal of the cereal germ (the germ is sent on for the extraction of the oil) and the separation of the fibrous and protein materials from the starch during the milling, sifting, and sedimentation phases. The byproducts from this process are widely used in the production of livestock feed (Brockway 2001). The extracted starch is purified and further transformed into an extremely wide range of byproducts, that are widely used as additives in the food

industry: pregelatinized starches, chemically or enzymatically modified starches (thickening and coating agents, and so on), and byproducts of lower molecular weight such as corn syrups. In the latter products, amylose and amylopectin are hydrolyzed into smaller molecules until they become soluble sugars (glucose, maltose, maltotriose, and so on). This process is controlled by choosing the appropriate type of enzyme and appropriate hydrolysis conditions (acidity and time of the treatments). It is therefore possible to produce both high-viscosity syrups with a low sugar concentration and therefore low fermentation levels, as well as syrups with a high sweetening capacity, easily fermentable and with distinct osmotic properties, where the depolymerization of the starch is almost total (Cantarelli and Lucisano 1983).

Further modifications of an enzymatic nature cause the isomerization of the glucose into fructose. The use of this sugar is becoming more and more popular thanks to its sweetening power, which is considerably higher than sucrose.

17.4.2 Dry Milling

The starchy endosperm of corn grain has a peculiar structure: it has translucent vitrous areas, and other opaque and "floury" areas (Fig. 17.33). This difference is due to the different compactness with which the reserve materials, starch, and proteins are stocked during the ripening stage. The percentage distribution between these two areas varies



Corn milling fractions composition

Milling fractions	**moisture** (%)	**starch** (%db)	**protein** (%db)	**lipids** (%db)
Whole kernel	11–15	67–74	8.0–11.5	3.9–6.0
Hominy grits	12.0–14.0	73–75	8.3–8.6	0.7–1.4
Coarse and regular grits	11.5–13.0	81–83	7.4–8.0	0.8–1.8
Coarse meal	11.5–14.0	75–81	6.5–7.5	1.0–2.1
Fine meal	11.5–13.5	77–80	6.5–7.5	2.0–2.5
Flour	11.5–13.5	76–79	6.0–7.0	2.0–3.0
Hominy feed	11–13	67–72	11–13	6.3–7.0
Germ	14–16	50–55	14–15	17–19

%db: percentage dry basis.

Figure 17.33 *View of a whole corn kernel and a section through it. Also, a breakdown of the fractions resulting from milling the corn.*

considerably between each variety. In the most widely grown hybrid in Italy, the dent corn (*Zea mays indentata*), so-called because of the characteristic shape of the kernel, the floury area is in the central part and surrounded by vitrous areas. The kernel of the flint corn (*Zea mays indurata*) is mostly vitreous.

This different structure conditions the destination of the kernel when it is milled with the dry milling process. The vitreous and flint hybrids tend to make up only a small percentage of "flour" (material with particles no greater than a few hundred microns) and are mainly coarsely ground (divided into hominy, coarser grind; and grits, intermediate grind). This material is suitable for transformation into flakes and is highly valued by the beer industry and *polenta* flour producers.

There are two methods that are used for the dry-milling process: milling without removal of the cereal germ, the oldest method, and milling with removal of the cereal germ, the method most used today to ensure a better preservation of the flours (Pomeranz 1987).

The method without removal of the cereal germ grinds the corn grain with a reduced separation of the germ. Flour is obtained by grinding the entire seed with millstones and is aimed at small market niches where its rich and oily flavor is appreciated. Often, the flour is sifted to eliminate the coarser particles of the teguments and the cereal germ. The flour obtained has a lower preservation time with respect to the flours obtained after removal of the germ. This is because the oil, 32–35% of which is contained in the germ, deposits on the surface of the flour particles, increasing the area exposed to oxygen and facilitating the enzymatic attack of the lipases. The different methods available for dry milling with removal of the cereal germ differ greatly in the amount of water added to the grains before the removal of the cereal germ phase (Molino Favero, personal communication). In wet removal of the cereal germ, the corn is brought to a humidity level of 24–25% before milling (this procedure is used for the production of hominy grits for corn flakes). Semiwet processing (corn humidity of about 20%) is used for the production of grits for beer making and in dry milling the humidity level reaches about 15% during the conditioning phase.

Most of the mills in Italy use the dry-milling process (Fig. 17.32), because the main product is coarse flour (*farina bramata*) for the production of the typical Italian product, *polenta*.

After an initial cleaning process using a magnetic separator, a stone separator and an air classification system, the grain undergoes a tempering phase until it reaches a humidity level of 14–15%, which renders the teguments less brittle, swells up the seed germs and facilitates their separation in the degerminator. After a rest phase (of variable duration from 2 to 8 h), the corn is sent through a second cleaning process to completely eliminate any stones or pieces of metal. The grains are then broken up in the degerminator, usually an impact mill. The bran is removed by a classifier aspirator, and the germ and the grits are separated by a gravity separator.

The next phase, the grinding down of the grits, is made using corrugated rolls, sifters, and purifiers, similar to those used in the milling of wheat, but the diagram is less complex with fewer stages at the lower end of the process (Fig. 17.34). During these operations, different amounts of products are produced, according to the endosperm vitreosity of the endosperm: grits of different sizes (700–1400 μm) and flours with particles of different sizes including coarse meal flour (350–700 μm), fine meal flour (200–350 μm), and oil-rich flour (~2.5–3.5% oil), with a particle size <200 μm.

17.4.2.1 Polenta. The coarse meal (called *farina bramata*), a sharp-edge product from the vitreous area of the kernel, is used for the preparation of *polenta*, a typical dish of the regions of northern Italy. *Polenta* was a basic food of the northern Italian regions (Piedmont, Lombardy,

Figure 17.34 *Corn milling equipment. (Courtesy of Molino Favero, Italy).*

Veneto) long before Columbus brought corn to Europe. In those days, the poor rural populations made a porridge with emmer wheat, millet, spelt, or chickpeas, which was cooked on a hot stone. In Roman times, *pulmentum* was the staple of Roman legionnaires, who ate it either in a porridge or in a hard cake form. Later, with the introduction of buckwheat into Italy by the Saracens, *polenta* was prepared with this pseudo-cereal and become more appealing to the taste. Buckwheat *polenta* would eventually fall out of favour when corn from the New World arrived in Italy. The new crop was grown primarily in the northern regions where rainfall was abundant and where other cereals had smaller yields (Rebora 2000). It thus became the most economically viable product grown in the area – the food of the poor peasants. Corn *polenta* was to solve the food problems of the poor until the mid-eighteenth century, with the outbreak of the disease pellagra, caused by a lack of integration of other foods into the diet. Pellagra is caused by a deficiency of the vitamin B group, and especially niacin. The addition of simple supplements such as cheese or other traditional foods such as sausages, fish, or meat make this a versatile and nutritionally complete dish.

Most *polenta* in Italy is nowadays made from corn, and ranges in color from golden yellow to white, according to the variety used. In some areas of the Italian peninsula buckwheat flour mixed with cornmeal is still used for preparing typical local dishes such as *polenta taragna*.

Traditionally *polenta* is cooked in a round-bottom copper pot known as *paiolo*, where water is heated and cornmeal sprinkled into it (Fig. 17.35). The mash is vigorously stirred

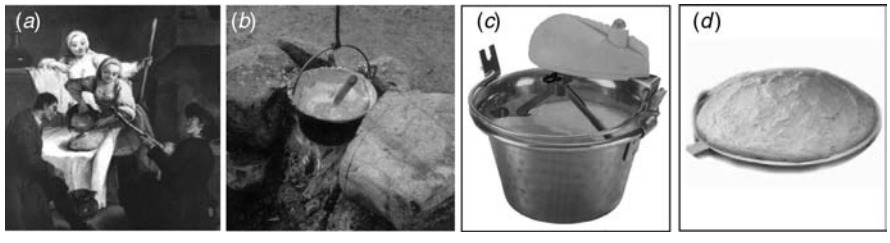


Figure 17.35 *"LA POLENTA" painting by Pietro Longhi (1702–1785) (a); traditional methods of cooking polenta (b, c); presentation of polenta on a wooden board (d).*

for up to 50 minutes with a long wooden spoon and is then poured onto a wooden board and traditionally cut with a piece of string. The long cooking time in water causes the complete gelatinization of the starch and the formation of a more or less compact texture according to the water–flour ratio used.

The long preparation times of this dish can be reduced to just a few minutes if the material is gelatinized in advance at the milling factory. For this purpose, coarse grits are humidified at 18–20% water content and cooked for 35–45 min at 110–125°C under pressure (0.2–0.35 MPa). The material is then rolled out to obtain flakes of thickness 400–500 μm and then dried to a humidity level of 12–13%. There follows the milling and classification phases from which are obtained the precooked *bramata* flour and a small portion of precooked, fine flour.

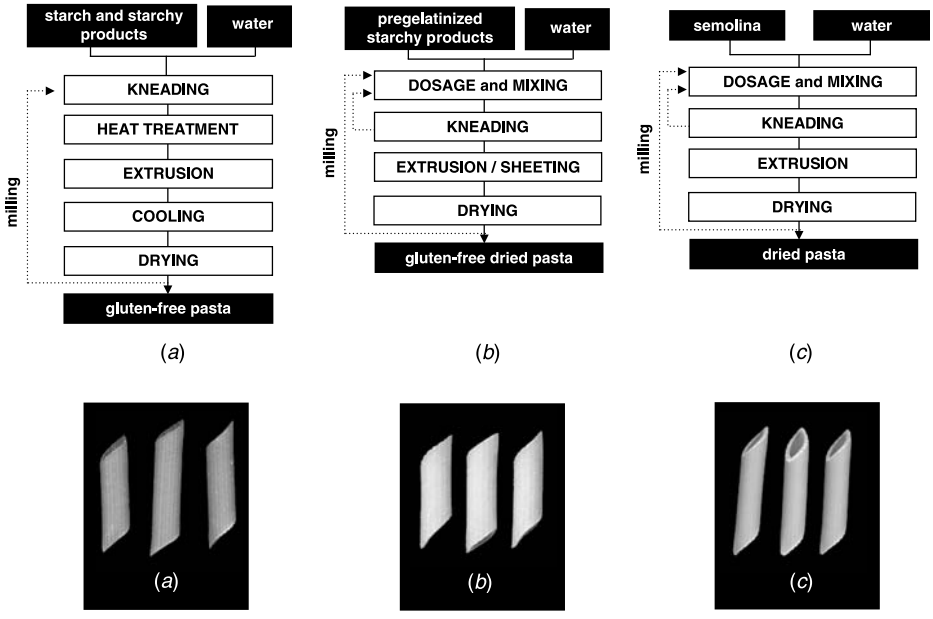
Another type of *polenta* is a ready-to-eat product obtained by cooking the coarse corn flour with water in the presence of an acid solution (citric or tartaric acid) in order to reduce the pH to 3.0–3.5. This consequently increases the product shelf-life, then cooling and packaging, usually in a plastic film. This product can be warmed inside the package or cut and grilled.

17.4.2.2 Corn Flour as Raw Material for Gluten-Free Pasta. During the dry-milling stage of the corn, a small amount (a yield of about 10%) of fine meal or dusted meal is also obtained (Molino Favero srl, personal communication). This product has a starch content that is similar to the one in the coarser grains, a slightly lower protein content, and a higher lipid content of 0.5% (Fig. 17.33). This small amount of byproduct is usually destined to become livestock feed, but is being considered as an interesting raw material for the production of gluten-free products such as bread and pasta, especially if derived from the milling of white corn. These varieties are not only characterized by their neutral color, but also by a more delicate flavor, thus being more suitable for the preparation of products that are traditionally prepared with wheat flour. Precooked meal after size reduction can also be used in the industrial production of gluten-free pasta.

In these types of pasta where the three-dimensional network of proteins is missing, an optimal texture both before and after cooking is assured by the retrograded starch induced by a particular technological process (Fig. 17.36*a*). In fact, a flour that contains starch in its natural form is not capable of forming a compact structure via hydration, mixing, and compacting in the extrusion screw (Resmini and Pagani 1983). A heat-kneading phase that encourages gelatinization of the starch is therefore indispensable. In this way, an easily shapeable mass is formed whose structure is consolidated in the cooling of the product that induces retrogradation of the starch. This procedure, which has been adopted for centuries in the production of oriental pasta (Serventi and Sabban 2000), creates a three-dimensional network where most of the heat-soluble components are restrained in the cooked pasta (Pagani and others 1981). On the contrary, the use of pregelatinized starches or flours makes it possible to use similar technology to that used in the preparation of traditional semolina pasta, thanks to the changes to the starch caused by the previous heat treatment (Fig. 17.36*b*,*c*). In this case the pasta absorbs less water but is subjected to greater cooking loss in the boiling water.

17.5 TYPICAL AND NEW ITALIAN PRODUCTS FROM BUCKWHEAT

Buckwheat is an annual dicotyledon plant that can reach a height of 1 m. A characteristic peculiar to buckwheat is its extremely brief life cycle (60–90 days), which makes it suitable for cultivation at high altitudes as a second crop after the winter crop, and makes it



Cooked pasta quality indices	(a)	(b)	(c)
Weight increase (g/100g pasta)	78.02	57.39	97.43
Solid loss (g/100g pasta)	3.24	7.27	3.76

Figure 17.36 *Pasta production from untreated corn flour (a), pregelatinized corn flour (b), wheat semolina (c), and cooking characteristics.*

highly competitive compared with other kinds of vegetation. The main product of buckwheat is the grain, botanically named achene.

For many centuries buckwheat represented an important source of food for the populations of the Italian Alps and to a lesser extent to the populations of the Apennines (Borghi 1997). Buckwheat is thought to have originated from Manchuria and Siberia and there is evidence that it has been grown in China since 1000 B.C. It is an important crop in Japan, and reached Europe via Turkey and Russia during the fourteenth and fifteenth centuries (Mazza 2000). Today, buckwheat is still used in a number of typical dishes of eastern Europe and Asia such bagels, soba, and noodles (Fig. 17.37).

There are several species of buckwheat, but only the *Fagopyrum esculentum* Moench (common buckwheat) is cultivated worldwide. The production of buckwheat reached its peak at the beginning of the nineteenth century and has been gradually decreasing until today.

The major producer of buckwheat today is Russia, followed by China (Si-Quan-Li and Zhang 2001). With regard to Italy, until just a few decades ago, buckwheat was the most important crop in the mountainous areas of the Alps, in particular the Valtellina area, a valley in the north of Lombardy bordering with Switzerland. However, the period following the Second World War saw a drastic decrease in the cultivation of buckwheat and it has not been grown in these areas for several decades, not even at the smallholder level. Most of the buckwheat consumed in Italy is imported from China as grains. The flour ground in the mills in the mountainous areas of northern Italy is used for the production of

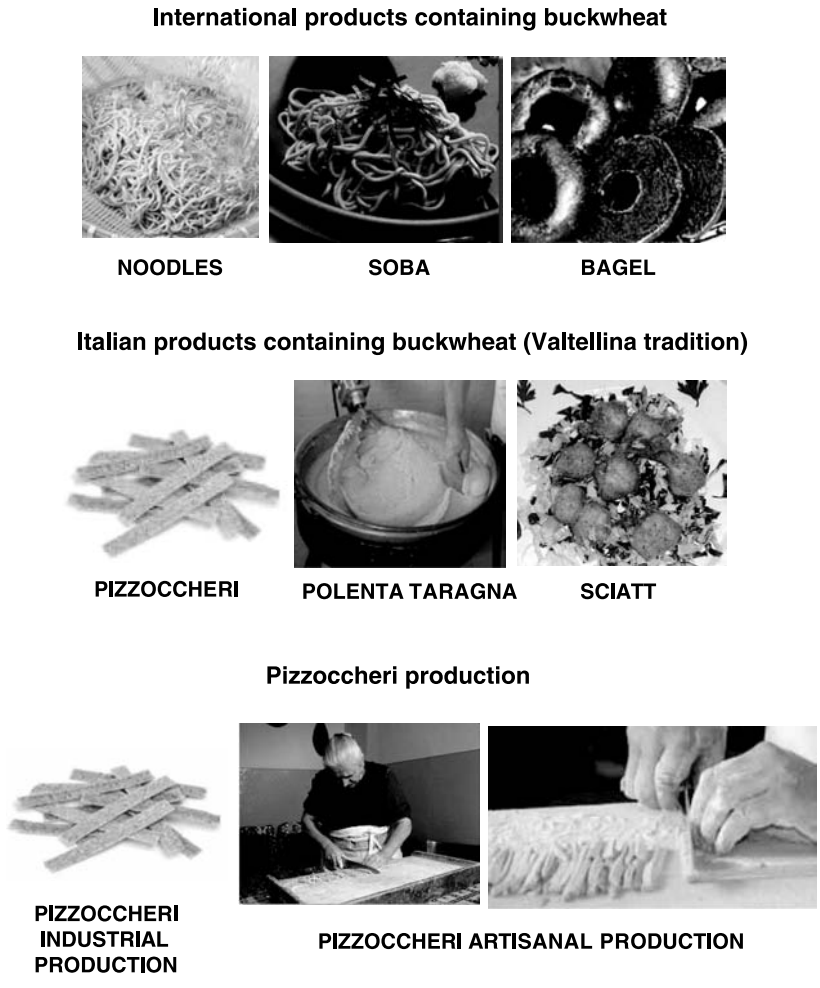


Figure 17.37 *Buckwheat products.*

pizzoccheri or other types of pasta obtained from a mixture of durum wheat semolina and buckwheat flour, and also for the preparation of a dark *polenta* (*polenta taragna*), cheese fritters (*sciatt*) and typical cakes of the area (Fig. 17.37).

The structure of buckwheat is characterized by a very compact hull and by the presence of an embryo with a characteristic sinusoidal shape, which extends throughout the whole cross-section of the grain (Fig. 17.38). The dominant component is starch and its concentration varies from 59 to 70% db (Zhang and Wel 1995). The starch granules of buckwheat are very small (1–7 μm in diameter), clearly grouped in regular clusters delineated by the presence of an air space between them, and their surface is highly irregular in form (Mariotti and others 2006a).

The protein level in the grains can vary between 7 and 21% according to the variety and environmental factors (Biacs and others 2002). Buckwheat proteins present a high biological value, because they are particularly rich in lysine. The proteins, however, are not easily digestible because of the high fiber content, which does not allow proteolytic enzymes easy access to them. The buckwheat achenes contain between 1.5 and 2.7% lipids, but because they are mostly concentrated in the germ the flour contains a much less significant

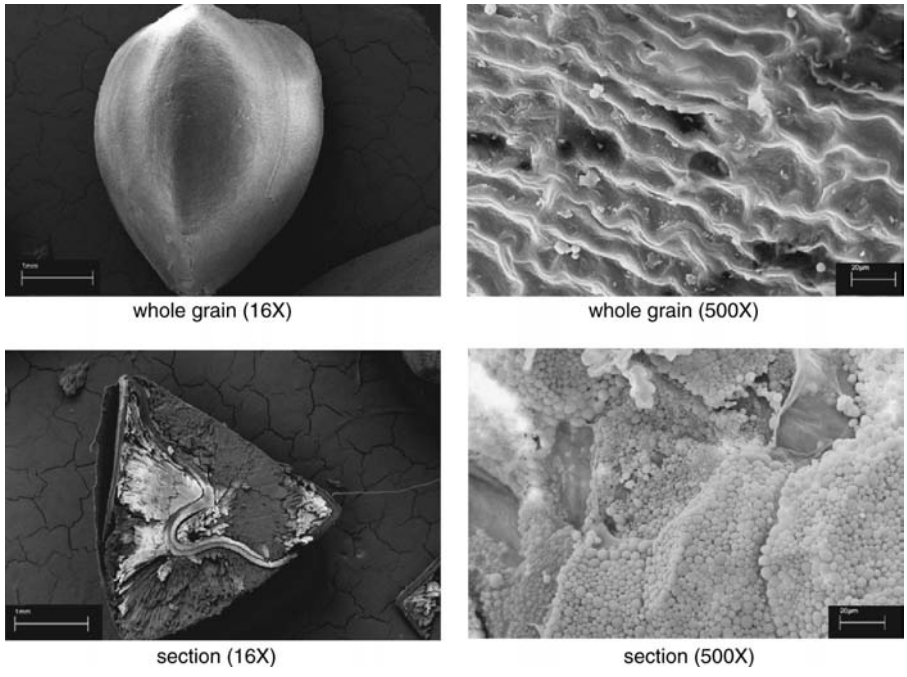

Figure 17.38 *SEM images of buckwheat grain.*

amount. The fatty acids are mainly represented by palmitic acid, oleic acid, linoleic acid, stearic acid, and linoleic acid (Fornal and others 1987).

With regard to the phenolic compounds, the classes mainly represented are the flavonoids, phenolic acids, and condensed tannins. Among the flavonols, rutin is the most important. Rutin is a compound known for its peculiar ability to contrast capillary fragility associated with hemorrhage- or hypertension-related diseases (Kitabayashi and others 1995). Rutin is also effective in reducing cholesterol levels in the blood (Edwardson 1996). Last but not least important is the high content of vitamins, especially B_1, B_2, and E. Buckwheat is also rich in minerals and microelements. The potassium content is similar to that in wheat and there is also a moderate amount of calcium and magnesium. With regard to the microelements, buckwheat contains large quantities of copper and iron.

Buckwheat flour is obtained by grinding the achenes. This is usually performed in one single operation with rolls or millstones. The grain is conditioned to reach a low humidity level, ground until the desired particle size is reached and then sifted. The extraction rates vary between 73 and 78%. Different fractions featuring different content levels of proteins, starch, and ash are obtained (Table 17.10).

TABLE 17.10 Composition of Buckwheat Seed and Milling Fractions.

Component	Seed	De-hulled Seed	Semi-dark Flour	Light Flour	Hulls	Bran
Humidity (%)	12.46	12.55	11.70	12.00	9.75	12.00
Protein (%db)	12.01	13.48	13.81	7.14	3.19	25.19
Starch (%db)	57.17	75.69	71.36	86.49	0.00	52.87
Ash (%db)	2.26	1.80	2.21	0.85	2.31	3.99
Rutin (mg/100 g)	21.70	9.90	22.10	5.00	50.60	15.80

%db: percentage dry basis.

Despite the fact that buckwheat has not been cultivated in Italy for decades, it is still deeply rooted in the culinary traditions of the Alpine valleys, where buckwheat is widely used in the preparation of a large number of local dishes. There is a sector of small commercial enterprises that includes millers, pasta-makers, and factories that use buckwheat grains or flours for the production of pasta, cakes, and other foods. A sector that has not yet been fully developed but which has considerable potential is the health-food segment.

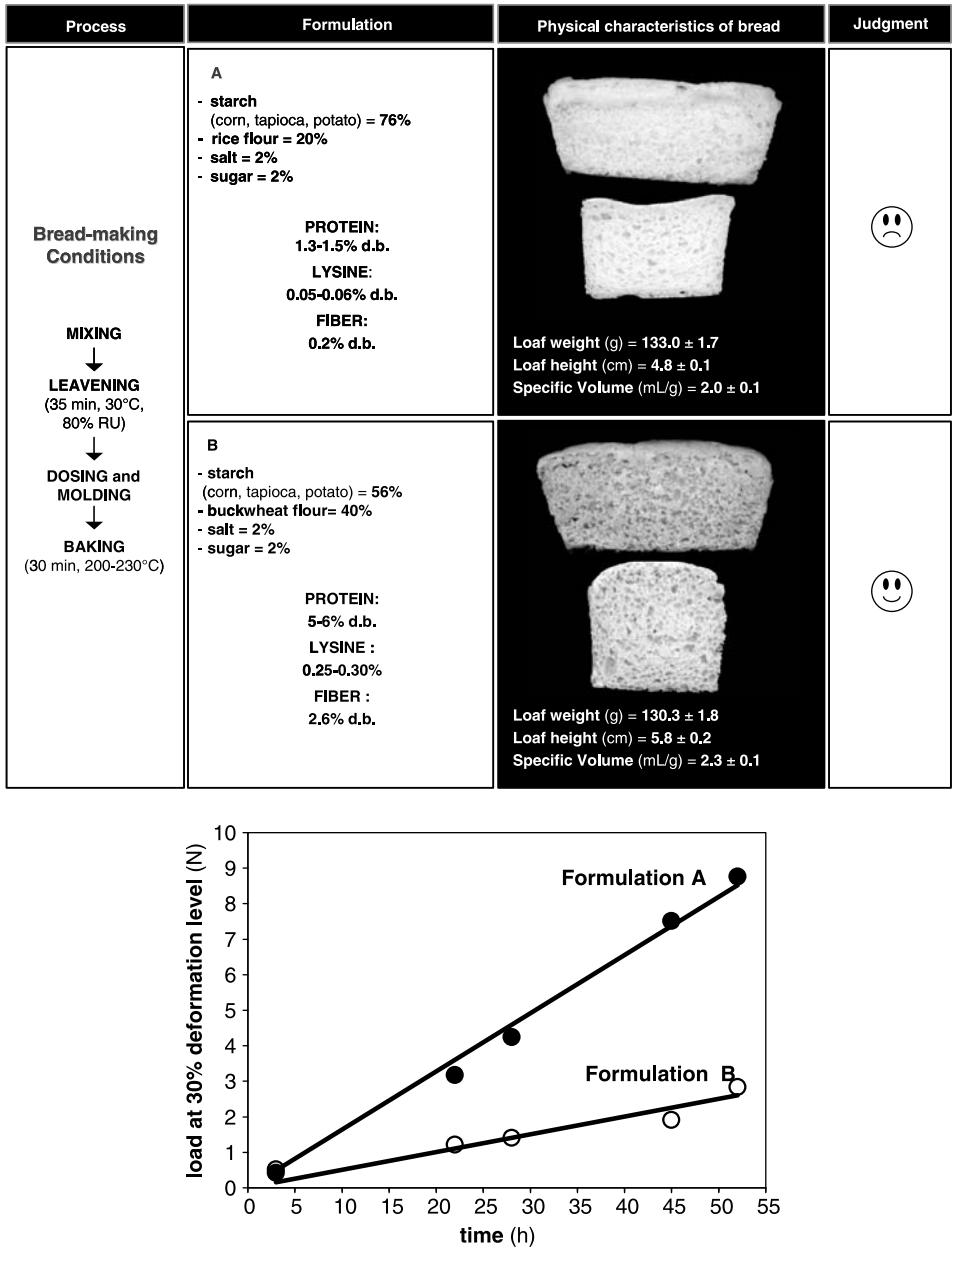

Figure 17.39 *Formulation and physical characteristics of buckwheat-flour bread.*

Buckwheat contains a type of starch that is slower to digest, and so is especially suitable for diabetics (Edwardson 1996). It has recently been observed that buckwheat is fully tolerated by sufferers of celiac disease, and so flour made from buckwheat can be used to produce pasta and baked products.

To this end, the addition of buckwheat flour in a commercial product for the production of gluten-free bread that contains rice flour and starches from various sources has proved interesting. The total substitution of commercial rice flour and starch, each with a concentration of 20% (for a total buckwheat content of 40%), has increased the specific volume of the bread from 2.0 to 2.3 mL/g. This has significantly improved the nutritional value of the formulation, thanks to the protein, lysine, and fiber content (Fig. 17.39). It is important to stress that for this line of products the specific volume does not reach the high values of breads made exclusively of wheat due to the lack of the structural effect of gluten and the lower retention of gas during leavening. A further positive result is the ability of buckwheat flour to maintain the original crumb softness of bread. If, on the one hand, the presence of fiber enables the bread to retain greater quantities of water and therefore improve the softness of the product, on the other it has a dilution effect on the starch present in the original formulation. This results in a lower incidence of starch retrogradation and consequently slower staling kinetics (Fig. 17.39).

18.1 INTRODUCTION

A major problem associated with many flavor systems during heating and baking is loss of desired flavor, and the flavors already present may need to be supplemented. There are several alternative ways to overcome flavor loss due to heating or baking. The most direct and effective is to add excessive amounts of flavor compounds into food matrices. Retention of a flavor compound in a food product cannot be predicted accurately based only on the physical and chemical properties of individual flavor components. There are several important parameters affecting retention of flavor compounds during heating:

1. Temperature,
2. Moisture content of the food,
3. Porosity of the food solid matrix,
4. Molecular weight and volatility of flavor compounds, and
5. Interactions between the food solid matrix and flavor compounds.

To quantify the amount of flavor to add to a product, it is essential to understand the interaction of flavor components with food systems and the parameters that affect flavor migration during heating or baking. Lack of information on migration or breakdown of desirable flavors in food products during heating or baking is also a major concern to the food industry as it formulates products with maximum consumer acceptance for flavor. There is comparatively little available literature on flavor migration in food systems during heating and baking (Thijssen and Rulkens 1968; Solms 1986; Van Osnabrugge 1988, 1989; Karel 1990; Bruin 1992; Eijk 1994; Etzel 1994; Roos and Graf 1995; Hills and Harrison 1995; Voilley 1995; Harrison and Hill 1997; Harrison 1998; Harrison and others 1997, 1998; Hao and others 1999; Springett and others 1999; Hahon and others 2000).

However, in order to obtain useful and meaningful information on the contributions of rates of flavor migration and kinetics of degradation under various conditions, there are several important steps that have to be followed. A unique apparatus for on-line flavor concentration measurement should be developed. For the purpose of measuring flavor migration kinetics in porous solid food systems, an isothermal temperature control for kinetic study had to be constructed that could provide a uniform temperature distribution in a dough sample. Because loss of desired flavor during heating or baking can also be attributed to thermal degradation of flavor compounds, a thermally stable compound is needed. If a compound is not thermally stable then total flavor loss will be contributed to by both thermal degradation and migration. So, a thermally stable flavor compound is needed to demonstrate the usefulness of this apparatus for studying flavor migration kinetics.

This chapter is organized according to a research project on moisture migration and flavor migration in solid food matrices (Fu 1996). The following sections will attempt to provide an understanding of the heat and mass transfer processes of flavor compounds based on experimental data and mathematical models, as available. Details of the on-line and off-line flavor concentration measurement techniques are also discussed. A final comment is that there is no single effect which explains the rate of migration of flavor. This approach can be adopted as a tool to increase our understanding of parameters that affect flavor migration rate in porous solid food systems.

18.2 SYSTEM DEVELOPMENT

This section will discuss how to design and build a closed vessel for holding the flavor-dough sample, which provides a minimal system response time for on-line measurement of flavor concentration. This section will also explain how to formulate a model flavor-dough system and to fulfil isothermal heating condition in the sample at desired temperatures by applying microwave energy to achieve isothermal conditions.

18.2.1 Apparatus for On-Line Measurement of Flavor Concentration

A plastic vessel (Fig. 18.1) with an appropriate geometry and venturi angle-taper was designed for holding samples. Two cone-shaped plastic bases with an angle of 14° were used to minimize air turbulence around the sample and also to reduce inside vessel volume to minimize system response time. Carrier gas is forced through a fitted plastic disk to achieve an even distribution. Either solid food or liquid materials, such as flavor or oil, may be placed in the vessel. The vessel was made from acetal resins, which are resistant to a wide variety of chemicals and have a maximum recommended continuous use temperature in air of 105°C (Sinker 1986). The mean residence time of carrier gas at flow rates of 243, 348, and 595 mL/min are 7, 6.25, and 5.5 s, respectively. A carrier gas flow rate of

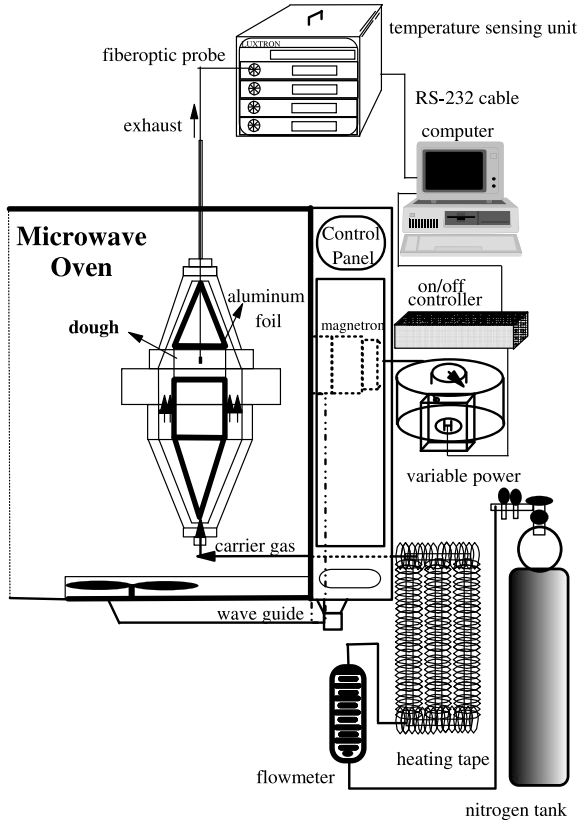

Figure 18.1 *Schematic diagram of the flavor on-line experiment. (Fu and others 2001).*

595 mL/min was selected, because it offers the smallest mean residence time that is insignificant compared to the 1- to 5-h heating times used in the experiments (Fu and others 2003a).

18.2.2 A Model Flavor-Dough System

Dough matrices and flavor compounds have been separated, ideally, into two kinds based on hydrophobicity (Lund 1993). Hydrophobic and Hydrophilic model food matrices were selected, as were hydrophobic and hydrophilic flavor compounds having similar volatility and molecular weight. A hydrophilic flavor (ethyl acetoacetate) and three hydrophobic flavors (limonene, *tert*-butylbenzene, and 2,5-dimethylpyrazine) were chosen. Ethyl acetoacetate, limonene, and *tert*-butylbenzene were chosen because they have similar boiling points (181, 176, and 169°C, respectively) and similar molecular weights (130, 136, and 134, respectively), allowing us to minimize the effects of these parameters in the interpretation of the data. 2,5-Dimethylpyrazine (boiling point 108°C, molecular weight 155) is a thermally induced product of the Maillard reaction and is an important flavor compound for roasted and toasted foods. The flavor compound must be thermally stable during heating and baking. Gelatinized flour-based and gluten-based systems were chosen to serve as hydrophilic and hydrophobic systems, respectively. Regarding porosity distribution, the flour-based hydrophilic dough had a very even texture and uniform porosity distribution. However, the gluten-based hydrophobic dough had a wide porosity distribution, with large air pockets and areas of high dough density. Based on the above analysis and observations, the best model dough system was a flour-based dough system with moisture content between 40 and 50% and porosity between 0.5 and 0.6 (Fu and others 2003a).

18.2.3 Thermal Stability of Flavor Compounds

Flavor compounds selected for study must exhibit thermal stability under three conditions:

1. Thermal stability in the absence of dough;
2. Thermal stability in the presence of uncooked dough; and
3. Thermal stability in the presence of dough that is being heated.

Recovery efficiency and accuracy of the isolation procedure need to be determined before proceeding to reaction experiments. The results show that the four abovementioned flavors are thermally stable in the absence of dough when exposed to steam and when heated with dough in which the starch has been gelatinized (cooked) (Fu and others 2003a). Thermal stability of flavor compounds in flour-based matrices was assessed in a flavor material balance experiment. The experiment was conducted by adding known amounts of flavors into the flavor-dough sample, mixing well, and heating the flavor-mixed raw dough with steam for varying amounts of time. The results show that the three flavor compounds 2,5-dimethylpyrazine, *tert*-butylbenzene, and limonene were thermally stable when mixed with all flour ingredients and steam-heated. However, the more severe the heat treatment, the less ethyl acetoacetate was extracted from the matrices. Compounds indicating chemical degradation were not detected by gas chromatography (GC) analysis. A possible explanation is that ethyl acetoacetate chemically reacted with starch during the heat processing, resulting in poor extraction. Consequently, ethyl acetoacetate is either not stable or it irreversibly binds with ingredients when steam heated (Fu and others 2003a).

From this experiment, in order to totally extract the flavor from the matrices, the particle size of the flavor-formulated dough must be very small and the extraction time needs to be very long. The flavor-dough matrices must therefore be ground or pressed to reduce particle size before applying further extraction processes.

18.2.4 Isothermal Heating System

The microwave system consisted of a modified microwave oven, a fiber-optic temperature sensing system, an on/off temperature controller, and a computer (Fig. 18.1). A microwave oven rated at 700 W was modified so that the field intensity in the cavity could be changed continuously. A detailed description of this system can be found in Tong and others (1993). The optical-fiber temperature probe was centered in the sample. When a program was started, upper and lower set-point temperatures, $\pm 0.1^{\circ}C$ of the desired set-point isothermal temperature, were input by a computer program for data acquisition and control. Eight fiber-optic temperature probes were inserted to map the sample temperatures. With accurately controlled microwave energy input and preheated carrier gas, the sample was maintained at the desired temperature without significant temperature profiles. For the constant-temperature experiments, the average temperature and temperature variation of flour-dough samples with porosity 0.42 and initial moisture content of 0.48 wet basis (w.b.) were $38 \pm 0.8^{\circ}C$, $57 \pm 1.4^{\circ}C$, $76 \pm 1.7^{\circ}C$, $85.5 \pm 1.9^{\circ}C$, and $90 \pm 2.2^{\circ}C$ through the heating and accompanying drying processes (Fu and others 2003a). Temperature variance was not dependent on the location of the control probe. Temperature gradient deviation can be further reduced if the sample size is reduced or porosity is increased.

18.3 METHODOLOGY FOR ON-LINE FLAVOR CONCENTRATION MEASUREMENT

The methodology for measuring on-line flavor concentration in effluent gas from a closed vessel is discussed in this section. A photoionization detection method (PID) and two cold-trap on-line methods based on an isolation technique will be discussed.

18.3.1 Photoionization Detection (PID) Method

Photoionization has been used as a means of detection for about 25 years. The photoionization detector is designed to detect the concentration of gases present in the effluent from a gas chromatograph, utilizing the principle of photoionization. Photoionization occurs when a molecule absorbs a photon of sufficient energy to cause an electron to leave its orbit and create a positive ion. If the ionization potential of the compound is less than the lamp energy, then the PID will respond to that molecule (Driscoll 1977). Compared to the flame ionization detector, the PID has an enhanced response for aromatic compounds. This improved selectivity allows the instrument to operate as either a continuous or chromatographic analyzer, because the PID does not respond to light hydrocarbons such as methane (Driscoll and others 1982). Further, as a result of its versatility and performance, PID is one of the most widely used selective detectors for GC (Driscoll 1985). By utilizing UV lamps with different photon energies, the detector can be modified easily for either almost-universal or quite-selective detection of compounds.

A schematic diagram of the system for on-line measurement of flavor concentration using PID is presented in Figure 18.2. By adjusting the metering valves and vacuum

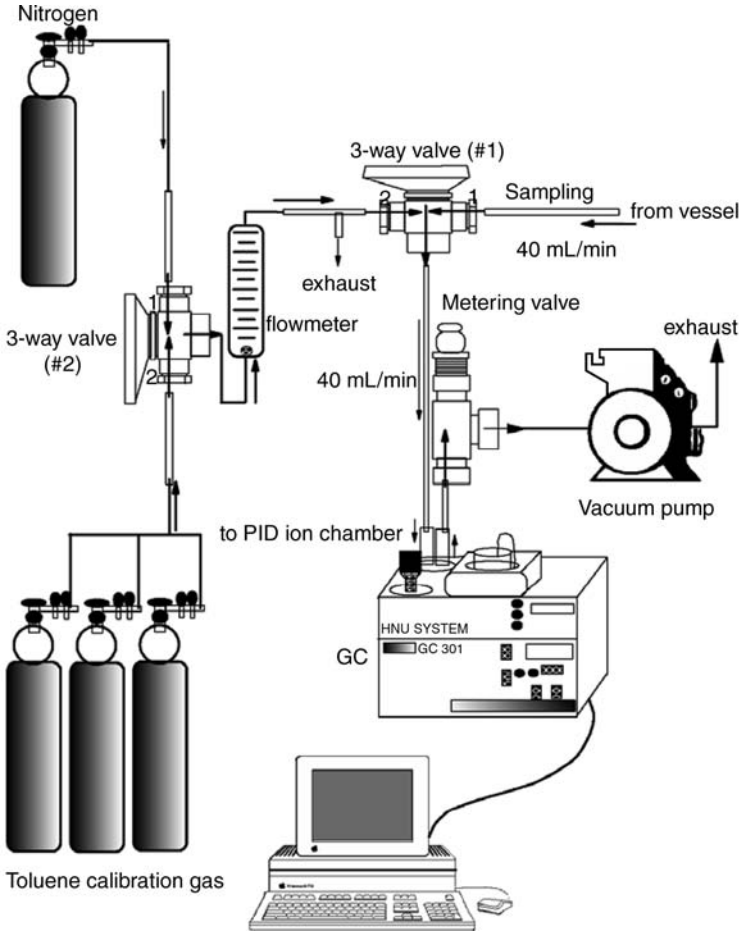

Figure 18.2 *Schematic diagram of the system for on-line measurement of flavor concentration by using PID method. (Fu and others 2001).*

pump, a gas stream (40 mL/min) carrying the flavor may be separated from the main flow, entering directly through the inlet into the ion chamber. No GC column is required for this method. Four tanks of individual gas mixtures (2, 12.7, 22, and 127 ppm toluene in nitrogen) were purchased to calibrate the photoionization detector. One nitrogen tank was used for checking the baseline of the PID detector before and after the experiment. A pair of three-way valves were used to control the gas flow. By changing the first three-way valve to position 1, the system measured flavor on-line. After removing the sample from the vessel, the first valve was immediately changed to position 2, and the second to position 1 (nitrogen flow) to check the baseline. After this, the second valve was changed to position 2 to run the toluene calibration curve using different concentrations of toluene mixtures. Serial dilutions of toluene/2,5-dimethylpyrazine, toluene/ethyl acetoacetate, toluene/limonene, and toluene/*tert*-butylbenzene solutions were prepared in methylene chloride to cover the dynamic range of the instrument. Aliquots of each solution were injected in triplicate, and the average result was used for all future calculations. The full concentration range was studied with the carrier gas flow constant at 40 mL/min. Solution concentrations were converted to micrograms of material injected,

based on an injection volume of 1 μL. Then, values for *peak area* (*response values*)/*weight* were calculated for each compound. In addition, relative responses for limonene and ethyl acetoacetate to toluene were calculated for each solution. The relative response factor, K_f, normalized to toluene on a weight basis, was calculated using the following equation:

$$K_f = \frac{peak\ area_i}{weight_i} \Bigg/ \frac{peak\ area_{toluene}}{weight_{toluene}} \tag{18.1}$$

where K_f is the relative response factor, $weight_i$ is the injected weight of compound i, and $peak\ area_i$ is the area of the GC peak for compound i. Daily calibration was performed using a toluene-gas standard (mixed with nitrogen) passed through the GC detector. Four toluene calibration points (2, 12.7, 22, and 127 ppm) were used to calibrate PID voltage responses at attenuations of 1, 10, and 100. The toluene-gas flow rate through the PID was exactly that used for collection of the gases passing through the vessel. The PID voltage response to the toluene-gas standard, and the PID gas-flow rates through the vessel were recorded, with the measurement protocol very tightly controlled. Toluene-gas concentration is given in volume percent, and can be converted to mass concentration as follows:

$$\frac{Volume_{toluene}}{Volume_{nitrogen}} = \frac{\left(\frac{Weight_{toluene}}{92.14}\right)}{\left(\frac{Weight_{nitrogen}}{28.012}\right)}, \qquad (PV = nRT), \tag{18.2}$$

$$[C]_{toluene}\ (\text{ppm, by weight}) = \frac{g_{toluene}}{g_{nitrogen}} = \frac{l_{toluene}}{l_{nitrogen}}\ (\text{ppm, by volume}) \times 3.2893. \tag{18.3}$$

Concentrations of limonene, ethyl acetoacetate, *tert*-butylbenzene, and 2,5-dimethylpyrazine in the effluent gas from the vessel can be calculated directly from the PID output voltage as follows:

$$\frac{[C]_i}{peak\ area_i} = \frac{[C]_{toluene}}{peak\ area_{toluene}} \Bigg| K_f, \tag{18.4}$$

where $[C]_i$ is the flavor concentration in the effluent gas from the vessel, $(g_{flavor}/g_{nitrogen})$, and

$$[C]_{toluene} = \text{toluene standard gas}, \qquad \frac{g_{toluene}}{g_{nitrogen}}.$$

The daily toluene-calibration curve, $voltage_{toluene}$ *vs.* $[C]_{toluene}$, can be converted to a daily flavor-calibration curve using Equation (18.4). As the GC detector was only used for measuring the concentration of a single flavor compound in effluent gas from the vessel, the sampling gas, at a flow rate of 40 mL/min, should have the same flavor concentration as the main gas stream. The amount of flavor emitted from the sample can be calculated as follows:

$$g\ \text{of flavor} = \left(\int \cdot\, dt\right)(gas\ flow\ rate) \cdot (gas\ density), \tag{18.5}$$

where $(\int \cdot\, dt)$ is the integral area under the *concentration* (ppm) *vs. time* curve.

The following is an example of calculations for on-line measurement of limonene concentration using PID. Daily calibration was carried out by passing a toluene-gas standard (mixed with nitrogen) through the PID detector. Based on the relative response value for limonene, the toluene calibration curve can be transformed to the limonene analog using Equations (18.3) and (18.4). Figure 18.3 presents the results of an on-line experiment to transfer voltage output *vs*. time for the limonene analog using a limonene calibration curve. Using Equation (18.5), we can further transfer the limonene concentration *vs*. time to the cumulative analog (Fig. 18.3). Then the weight loss, as measured by a balance, is compared to the amount of PID-detected flavor. Performance of the on-line apparatus and efficacy of the associated protocol were verified by conducting a series of recovery and retention experiments using four flavor compounds, with excellent observed recoveries ($101.7 \pm 1.5\%$, $n = 13$) (Fu and others 2001). Photoionization detection provides rapid and accurate on-line measurement, with its enhanced and selective response features most suitable for on-line measurement of flavor at lower concentrations.

Several important points need to be emphasized. Using nitrogen as a carrier gas, a negative PID-response peak has been reported for injection of various gases (Driscoll 1977; Senum 1981). Other gases with comparable electron capture, such as nitrous oxide (N_2O) and, to a lesser extent, carbon dioxide (CO_2), exhibit a similar, negative PID response. It is more likely that the greater predominance of the removal mechanism, which results in a reduction in PID background current, was due to quenching via electron capture rather than the quenching mechanism (Senum 1981). The negative PID signal response observed by Fu and others (2001) is possibly due to quenching via electron capture from water and oxygen. Although a reduced quenching effect has been reported for carbon dioxide compared to oxygen, similar investigations have never been undertaken for water. Fu and others (2001) hypothesize that water has a more significant quenching effect than either oxygen or carbon dioxide. In future studies of flavor-concentration measurement from a real, isothermally heated, solid food matrix, water and oxygen should be trapped using a molecular sieve, gas purifier, line filter, and so on, to prevent effects associated with PID quenching via electron capture.

18.3.2 Cold-Trap, On-Line Sampling Method

In the selection of an appropriate isolation technique for on-line measurement of flavor concentration from heated, flavor-formulated dough, requirements to obtain accurate quantification include:

1. Single batch processing;
2. On-line sampling in very small quantities, taking as many samples as possible (for example, 20 samples for one measurement);
3. Measurement of flavor migration at low temperatures (for example, 40°C), requiring sampling in time periods in excess of 5 h;
4. Total desorption, and
5. Accurate quantitative analysis of the compounds of interest.

Two different cold-trap methods, which meet the above requirements, were developed to measure single or multiple flavor compounds in effluent gas from the closed vessel with or without water present (Fu and others 2003a). The principles of these set-ups are the

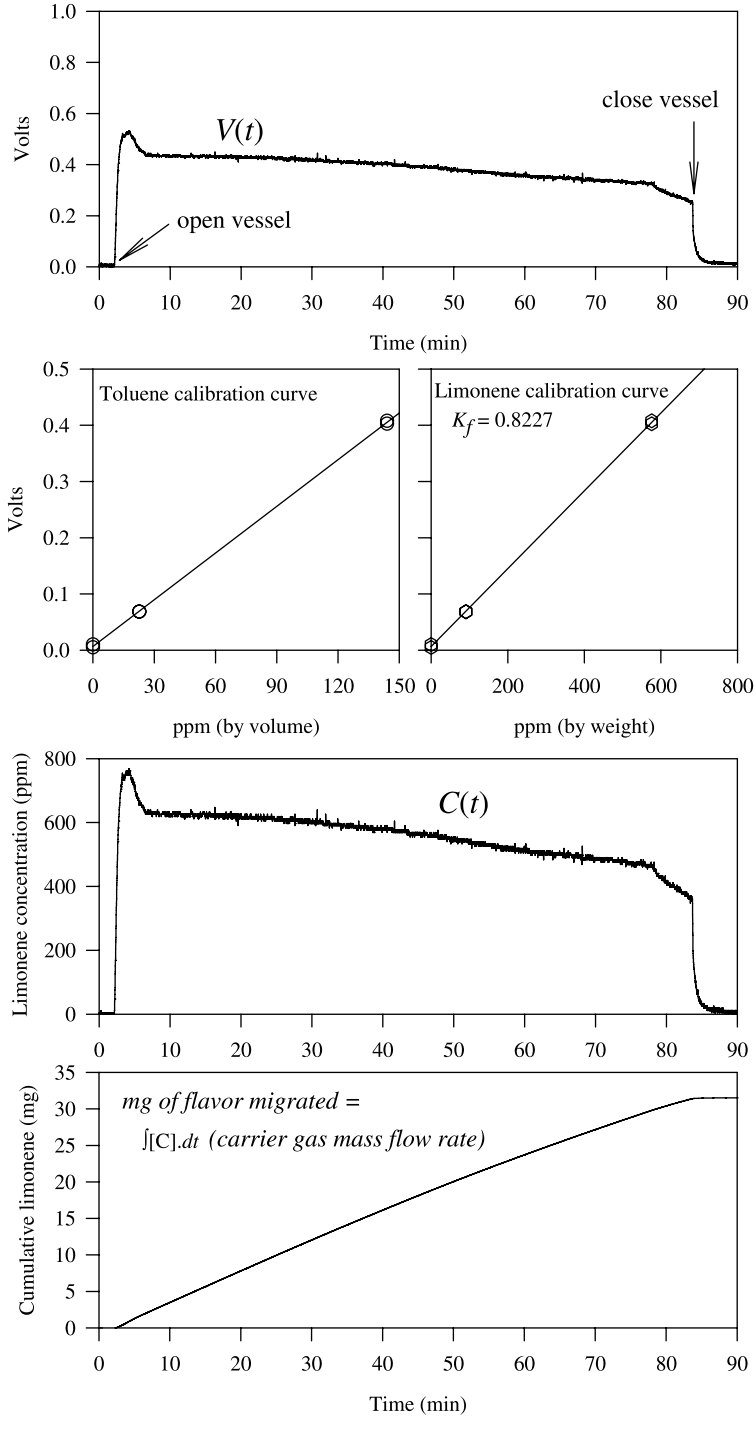

Figure 18.3 *Illustration of transforming voltage output vs. time to cumulative flavor migration vs. time. (Fu and others 2001).*

removal and subsequent liquid absorption of the volatile flavor compounds in the effluent gas from the vessel at very low temperatures. The gas samples are allowed to flow through a solvent in which the volatile compounds are dissolved and cold-trapped at −24 to −36°C.

In the first method (Fig. 18.4), the carrier gas passing around the small container carries the flavor in the headspace out of the vessel into a cold-trap unit. The cold-trap unit consists of a 68-mL glass tube with screw cap (25 × 200 mm) containing 50 mL methylene chloride placed inside a cold bath at −36°C (40% antifreeze and 60% water). A piece of plastic tubing (0.3175 cm, i.d.) is passed through the cap, terminating at the bottom of the tube in a mobile phase filter, which is so designed that a flow of finely dispersed purge gas (nitrogen and volatiles) is dispersed through the solvent, methylene chloride. The carrier-gas flow rate is either 375 mL/min or 645 mL/min. After capturing flavor compound for 2–5 h, the tube was removed and the trapping liquid analyzed for flavor concentration by GC. An aliquot of the trapping solvent was removed from the long tube at different times using a syringe with a 15-cm-long needle and stored in a 0.3-mL-capacity microvial. The amount of sample in the microvial was weighed and equilibrated to 27°C for subsequent GC analysis. Routinely, 10–15 samples of 0.15 g each were obtained for on-line measurement. This procedure worked well for effluent gas containing no water (Fu and others 2003a). For gas effluent containing water vapor, it was necessary to design a system that avoided plugging the inlet tube with ice. The system presented in Figure 18.5 was developed for this purpose (Fu and others 2003a). The glass test tube was replaced by a 100-mL three-necked round-bottomed flask containing 70–90 mL methylene chloride. The diameter

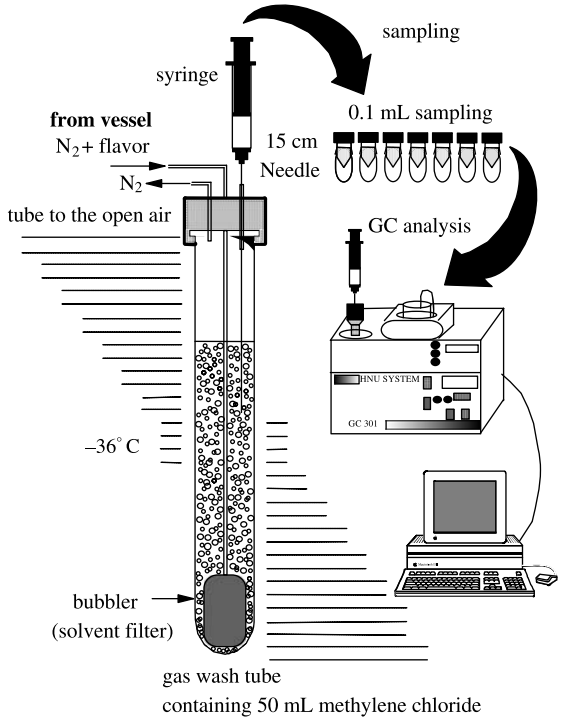

Figure 18.4 *Schematic diagram of the system for on-line measurement of flavor concentration by using cold-trap method with a long tube. (Fu and others 2003a).*

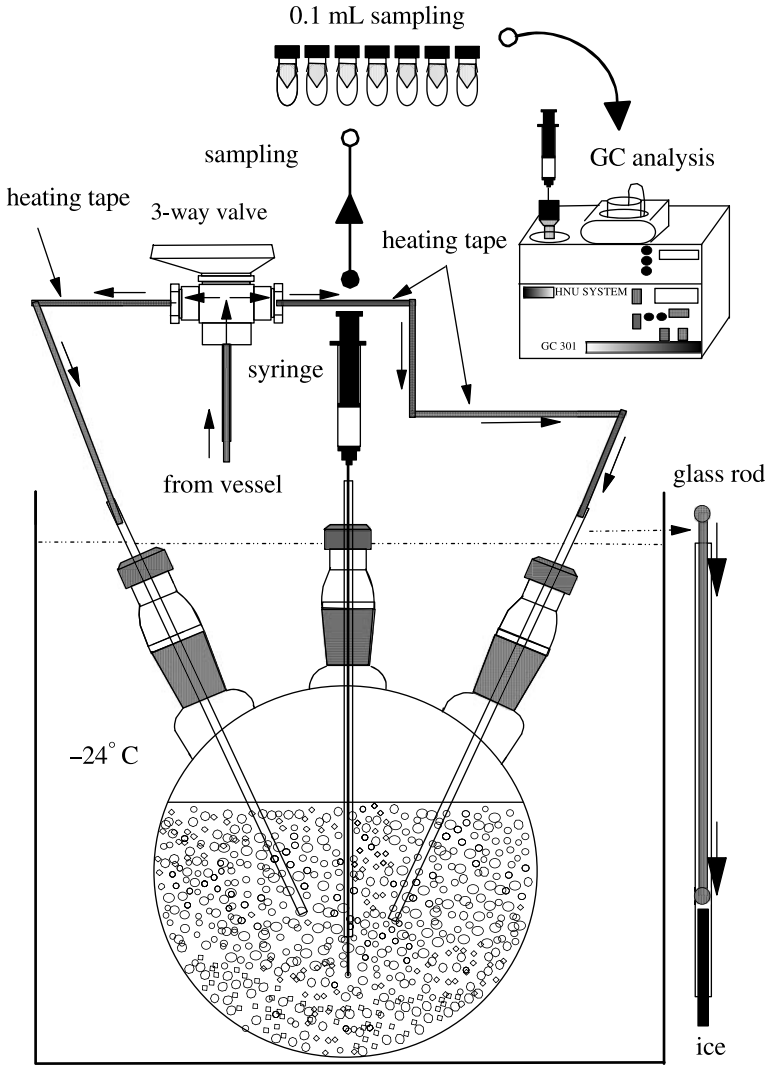

Figure 18.5 *Schematic diagram of the system for on-line measurement of flavor concentration by using the cold-trap method with a three-necked flask. (Fu and others 2003a).*

of plastic tubing was increased from 0.3175 to 0.635 cm. To overcome blockage due to frozen water, a three-way valve was used to switch from one gas effluent supply line to another. A round glass rod (3 × 125 mm) was used to push the frozen ice into the flask and clear the gas passage of the plastic tubing that was not in use. By switching the three-way valve, the system was efficiently controlled without ice blockage. The ice in the solvent was easily separated from the solvent. Heating tapes insulated with fiberglass cloth were installed on all inlet gas lines to the cold-trap unit to prevent condensation. The performance of the cold-trap on-line sampling method was verified by conducting a series of recovery and retention experiments:

1. Recovery of pure flavor compounds, which simulated removal of aroma from food and demonstrated recovering the compound;

2. Retention of pure flavor compounds, which demonstrated the efficacy of capturing flavor compounds of interest; and
3. On-line sampling measurement of pure flavor compounds, which affirmed the procedures for calculating on-line flavor concentration and reconfirmed the suitability of using the cold-trap method for on-line sampling flavor concentration measurement.

This quantitative study for demonstrating a material balance on the flavor compound has been described by Fu and others (2003a). Good quantitative recovery data were obtained. This method can therefore be used for measuring flavor concentration on-line.

18.4 QUANTIFYING FLAVOR MIGRATION FROM DOUGH

A new approach using cold-trap, on-line sampling and off-line methods was applied to investigate the migration rates of limonene, *tert*-butylbenzene, and pyrazine in a flour-dough matrix. The term "off-line flavor concentration measurement" is used to describe the method by which the residual concentration of the flavor material in the sample is measured after the sample is removed from the apparatus and subsequently subjected to solvent extraction to measure its flavor concentration. Instead of measuring residual flavor concentration (off-line method) in the matrix using solvent extraction of the matrix, the term "on-line sampling flavor concentration measurement" is used to describe the method by which the flavor compound that migrates out of the sample into the gas stream is captured and the solvent is subsequently analyzed for flavor concentration.

In the following sections, cold-trap on-line sampling and off-line methods are used to investigate the dependence of the migration of flavor compounds in a real solid food matrix (flour dough) on concentration under different isothermal temperatures. Temperature dependence was appropriately modeled by the Arrhenius relationship. The activation energies for migration of limonene, pyrazine, and water were calculated.

18.4.1 Concentration Dependence of Flavor Migration in Formulated Dough

A majority of reactions occurring in foods obey well-established kinetics. Thermal destruction of microorganisms, most nutrients, quality factors (texture, color, and flavor) and enzymes generally obey first-order reaction kinetics (Lund 1975). The reaction rate constant defines the reaction rate. The reaction rate constant defines the reaction rate. There are several ways in which the rate of a chemical reaction can be reported. To determine reaction kinetics, it is essential to know the extent of the reaction at any time. The extent of reaction at any time or the fractional conversion f at a constant temperature can be described as

$$f = \textit{fraction accomplished} = \frac{\textit{amount of flavor removed}}{\textit{maximum amount that can be removed}}. \tag{18.6}$$

When the flavor concentration as a function of time is known, f can be defined as

$$f = \frac{C_0 - C_t}{C_0 - C_\infty}, \tag{18.7}$$

where C_0 is the initial flavor concentration (g/g dry solid) at time 0, C_t is the flavor concentration (g/g dry solid) at time t, and C_∞ is the equilibrium flavor concentration (g/g dry solid) at ∞. For moisture, the values of the equilibrium moisture content C_∞ are relatively small compared to C_t or C_0, and can be assumed to be zero. However, for flavors, the values of the equilibrium flavor content C_∞ generally may not be assumed zero and can also be temperature-dependent.

The data were analyzed using a first-order reaction kinetic model (first-order rate constant k) with temperature dependence described by the Arrhenius equation (activation energy E_a) and the decimal reduction time model (D-value):

$$-\frac{dC}{dt} = k(C - C_\infty), \qquad \ln\frac{C_t - C_\infty}{C_0 - C_\infty} = \ln(1-f) = -kt; \tag{18.8}$$

$$-\frac{dC}{dt} = \frac{\ln(10)}{D}(C - C_\infty), \qquad \log\frac{C_t - C_\infty}{C_0 - C_\infty} = \log(1-f) = -\frac{t}{D}; \tag{18.9}$$

$$\frac{1}{D} = \frac{k}{\ln(10)}, \qquad D = \frac{\ln(10)}{k}; \tag{18.10}$$

$$\ln k = \ln A_0 - \frac{E_a}{RT}; \tag{18.11}$$

where A_0 is the pre-exponential constant, E_a is the activation energy (J/mol), R is the universal gas constant (8.314 J/mol), and T is the temperature in kelvin (K). The activation energy expressed in terms of k is given by

$$\frac{k_2}{k_1} = \exp\left[-\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)\right]. \tag{18.12}$$

Regardless of isothermal temperature, the flavor-formulated dough samples were heated sufficiently long for the moisture content to approach the equilibrium moisture content (close to zero). As shown in Figure 18.6, moisture content decreased exponentially ($r^2 \geq 0.99$) with time at each temperature for each flavor-formulated sample (Fu and others 2003d). Pyrazine's behavior appeared very similar to that of water. Because pyrazine is more water soluble than either limonene or *tert*-butylbenzene, it is expected that pyrazine would be vapor-stripped from the dough in some direct proportion to water vapor. An important observation of the behavior of the flavor concentration is that the flavor concentration of limonene, *tert*-butylbenzene, and pyrazine dropped precipitously when moisture content approached 0.1 g water/g solid and subsequently remained unchanged (Fu and others 2003b). An explanation for the abrupt change in flavor concentration at a moisture content around 0.1 g water/g solid is flavor encapsulation (Karel 1990; Reneccius 1990). Thus, due to changes of the matrix structure during drying, flavor compounds may be physically entrapped, presenting a difficulty for extraction by methylene chloride. Consequently, data from the off-line method may not represent the true flavor concentration.

Figure 18.7 presents limonene concentration in formulated dough as a function of time at 85.5°C for varying initial limonene concentrations (Fu and others 2003b). The largest concentration (0.08 g/g solid) from on-line experiments is about twice that from off-line experiments (0.035 g/g solid). Flavor concentration decreased with time and leveled off after about 50 min heating. Figure 18.7 also presents data on limonene concentration as a function of moisture content for both on-line sampling and off-line

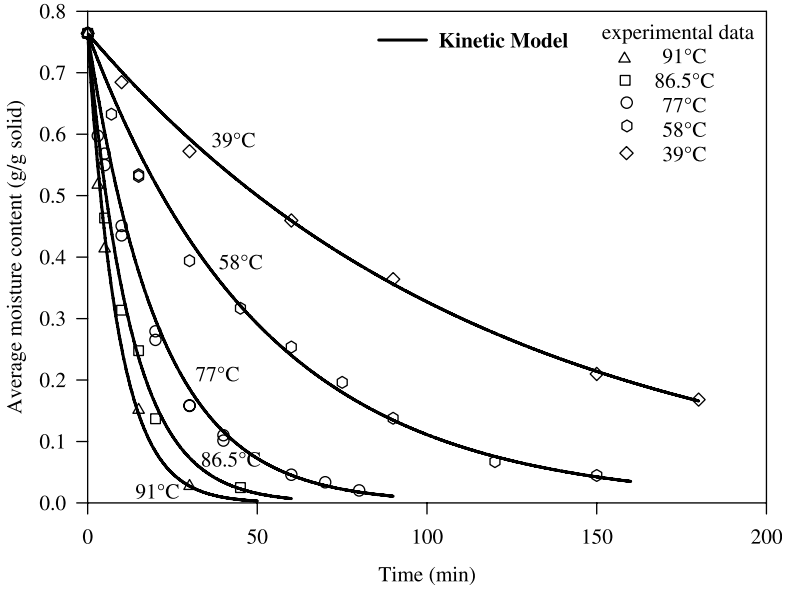

Figure 18.6 *Moisture content-time curves for dough during isothermal heating at various temperatures (porosity = 0.55, initial moisture content = 0.764 g/g solid). (Fu and others 2003d).*

measurements during isothermal heating at 85.5°C. It can be clearly seen that the data from off-line measurement did not present the true concentration of limonene left in the dough matrix at moisture contents less than about 0.1 g water/g solid. If moisture content is greater than 0.1 g water/g solid, the flavor concentration measured from off-line experiments was about the same as that measured by on-line sampling. At higher moisture content, the solvent extraction method efficiently extracts the limonene from the matrix. However, methylene chloride is not capable of extracting all limonene from the matrix when moisture content is less than around 0.1 g water/g solid. As described earlier, this is due to physical entrapment of flavor at lower moisture contents.

Several important points need to be emphasized. In preliminary studies (Fu and others 2003a), it was determined that an extraction time of 48–72 h at room temperature was necessary to completely extract limonene, *tert*-butylbenzene, pyrazine, 2,5-dimethylpyrazine, and ethyl acetoacetate from the dough matrix. It was reasoned that diffusion limited extraction of the flavor compounds by the nonpolar solvent from the hydrophilic matrix. However, at moisture content lower than 0.1 g water/g solid, an even greater effort was necessary to extract limonene from the samples. In fact, the flavor was never completely extracted from the matrix by methylene chloride. Several experiments were also conducted in which the rehydrated, ground-dried samples were heated in a sealed ampule by steam at 100°C for an additional two hours followed by extraction by methylene chloride. An additional 10% was recovered from the matrix. Although it may be possible to find a solvent that can infiltrate the encapsulated structure and extract the limonene, that was not the purpose of this study.

Under this isothermal heating condition, the equilibrium concentration of limonene is predictable. Equation (18.13) relates the equilibrium concentration C_∞ to initial

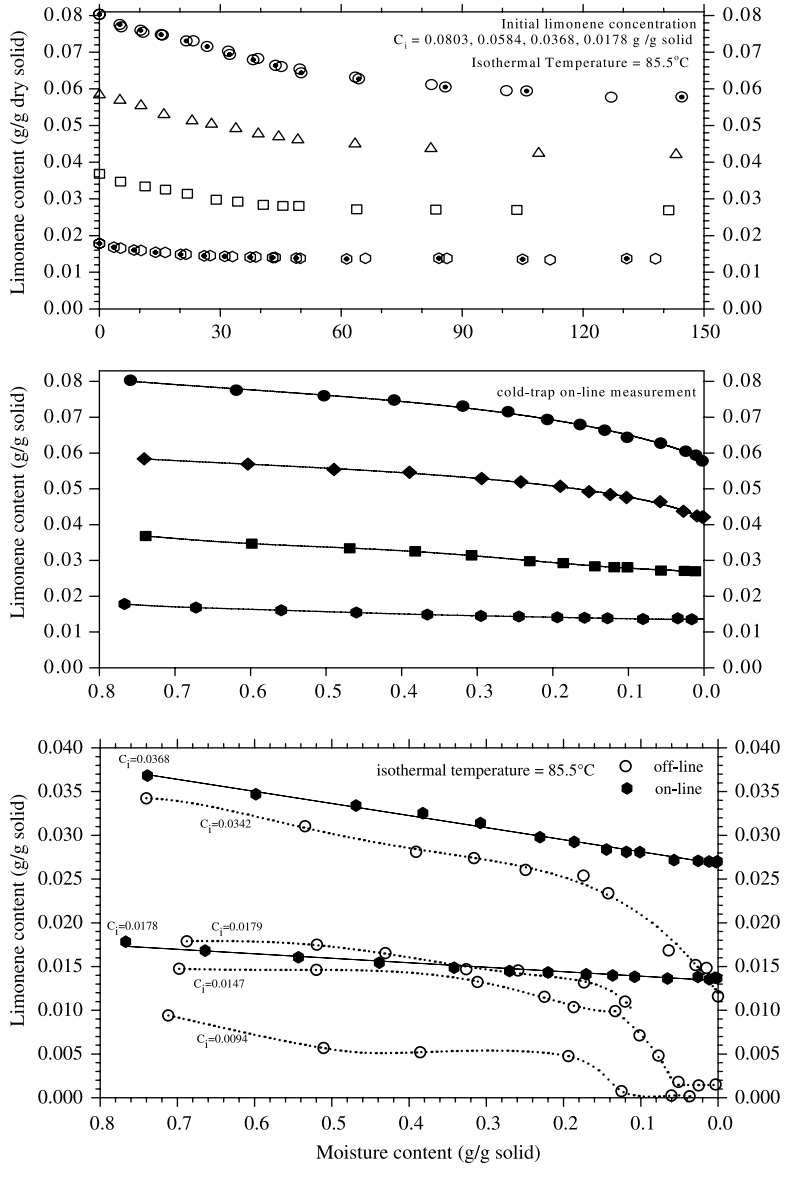

Figure 18.7 *Limonene concentration in formulated dough (porosity = 0.43 − 0.51) as a function of moisture content at 85.5°C as determined by off-line and on-line measurement. (Fu and others 2003b).*

concentration C_0:

$$C_\infty = 0.6563 \cdot C_0.002334 \text{ (g/g dry solid)}. \tag{18.13}$$

Note that when $C_0 = 0.0068$ (g/g dry solid), $C_\infty = C_0$. If the initial limonene concentration is greater than 0.0068 g/g solid, this predicts that 35% of the limonene can migrate out of the matrix (Fu and others 2003b). If the initial limonene concentration is less than or equal to 0.0068 g/g solid, no limonene should migrate at all. This amount

of limonene may be treated as bound limonene. It may interact with hydrophobic protein sites in the flour dough by a hydrophobic interaction.

Experimental data, which shows first-order behavior, can be mathematically modeled by either the rate constant or *D*-value (time required to reduce the concentration by 90%). Because the equilibrium concentration of limonene is a strong function of its initial concentration, comparing the rate of migration of limonene is more properly presented as a function of concentration driving potential, $C_0 - C_\infty$. As the *D*-value model ($r^2 = 0.965$) describes the data better than the rate constant model ($r^2 = 0.897$), further modeling will be done using *D*-values. Equation (18.11) relates the *D*-value to concentration driving potential, $C_0 - C_\infty$. Based on Equation (18.9) limonene concentration C_t can be calculated by Equations (18.10), (18.13), and (18.14), which results in Equations (18.15) and (18.16) after appropriate substitution:

$$D = 4712.7 \cdot (C_0 - C_\infty) + 12.98 \ (r^2 = 0.965), \tag{18.14}$$

$$C_t = 10^{-\frac{t}{D}} \cdot (C_0 - C_\infty) + C_\infty, \tag{18.15}$$

$$C_t = 10^{-\frac{t}{1619.76 \cdot C_0 + 1.98}} \cdot (0.3437 \cdot C_0 - 0.002334) + (0.6563 \cdot C_0 + 0.002334). \tag{18.16}$$

Predicted limonene concentration as a function of time at 85.5°C isothermal heating was calculated using Equation (18.16), and there is excellent agreement between experimental and calculated values (Fu and others 2003b).

The moisture concentration related to that *D*-value is also given and the *D*-value increases with a decrease in initial limonene concentration. The *D*-value in this paper is not diffusivity, but is the time for the concentration to change by 90%. Consequently, a decrease in *D*-value (less time) implies an increase in diffusivity that matches expectation. The *D*-values can be simply modeled by a second-order curve based on its trend. When the curve is extrapolated to zero *D*-value (*y*-axis), the initial limonene concentration is equal to 0.0064 g/g solid. This means that no flavor migration will occur when the initial limonene concentration is less than or equal to 0.0064 g/g solid (Fu and others 2003b). It is interesting to note that this value of 0.0064 g/g solid determined by extrapolating the curve to *D* equal to zero is very close to the previously determined value of 0.0068 g/g solid (determined by Equation (18.13)) at which limonene migration does not occur even with abundant water. Consequently, if the moisture content of the solid matrix remains greater than 0.1 g water/g solid, we would expect that all of the limonene would migrate out of the matrix. The set of experiments that illustrate this hypothesis is shown in Figure 18.8. Equation (18.17) also shows the results of a mathematical model based on the above assumption:

$$C_t = 10^{-\frac{t}{452}} \cdot (C_0 - 0.0068) + 0.0068 \ (D = 452\,\text{min}, C_\infty = 0.0068\,\text{g/g dry solid}). \tag{18.17}$$

There is excellent agreement between the model and experimental data from all four sets of experiments with moisture content greater than 0.10 g/g solid (Fu and others 2003b).

To validate the hypothesis that limonene is irreversibly bound in the dough matrix when moisture content is lower than 0.1 g water/g solid, an experiment was conducted

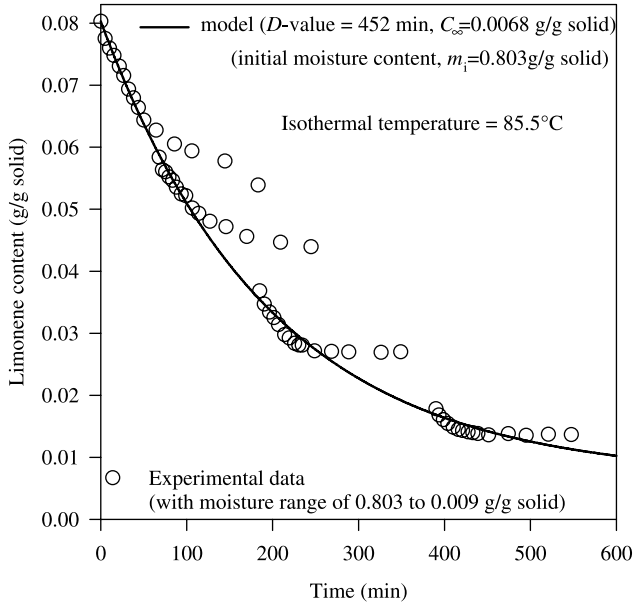

Figure 18.8 *Experimental and predicted limonene content as a function of time and D-value for formulated dough during isothermal heating at 85.5° C. (Fu and others 2003b).*

in which an unflavored dough was dried to 0.1 g water/g solid, and 0.0491 g limonene/g solid was added. The limonene was initially diluted with methylene chloride and then added to the dried matrix. The matrix was held at room temperature to evaporate the methylene chloride. The final weight difference was assumed to be the amount of added limonene. After the on-line experiments, the limonene was extracted from the matrix and its initial concentration was reconfirmed. The matrix temperature was brought to 85.5°C for about 90 min. The experiment shows that limonene can be irreversibly bound or physically entrapped in the dried matrix (Fu and others 2003b). Furthermore, the hydrophobic limonene is removed even more rapidly when water content is low. One further experiment was conducted to verify the hypothesis. The limonene-formulated dough was dehydrated to exactly 0.1 g/g solid and then rehydrated to 0.8 g water/g solid. The rehydrated sample was held for 4 h and then isothermally heated at 85.5°C for about 55 min. The result shows that flavor migration is precisely the same with or without added water (Fu and others 2003b). Thus, once the limonene has been entrapped, rehydration does not return the structure to its original configuration. This has been shown repeatedly for dehydrated solid-form foods (Van Arsdel and others 1973).

18.4.2 Temperature Dependence of Flavor Migration in Formulated Dough

There are two principal methods of describing the dependence of reaction rate constant or *D*-value on temperature:

1. The Arrhenius equation and
2. *z*-Value (°C temperature change to change the rate by a factor of 10) (Lund 1975).

Temperature dependence of limonene migration was determined for the highest concentration (0.0803 g/g solid) samples only. To fit these data to a linear model, equilibrium concentration was a function of temperature. Although there is no theoretical basis for this relationship, it is interesting to observe that C_∞ for limonene decreased linearly with decreased isothermal heating temperature. The lower the isothermal temperature, the smaller the equilibrium content and the greater the concentration driving potential, $C_0 - C_\infty$. The following equation relates C_∞ to isothermal heating temperatures:

$$C_\infty = 0.0005665\left(\frac{\text{g/g solid}}{^\circ\text{C}}\right) \cdot \text{temperature } (^\circ\text{C}) + 0.0006149 \text{ g/g solid.} \qquad (18.18)$$

An excellent agreement exists between predicted limonene and pyrazine concentration and experimental data (Fu and others 2003c).

For temperature dependence, the activation energies of limonene (58.2 kJ/mol) and pyrazine (51.5 kJ/mol) are greater than that of water (46.4 kJ/mol) at 85.5°C. For the *D*-value, the *z*-values of limonene and pyrazine are 39.5°C and 44.4°C, respectively. Given the same final moisture content of dried sample, more flavor would migrate from the matrix with lower isothermal heating temperature and longer heating time. This may be due to differences in structural changes caused by combinations of isothermal heating temperature and heating time. However, structural differences among samples dried under different isothermal heating temperatures were not apparent to the naked eye.

The area of aroma retention during drying processes, in particular for spray-drying and freeze-drying of food liquids, has been studied extensively by Karel, Thijssen, King, and others over several decades (Bruin 1992). Selective diffusion (Thijssen and Rulkens 1968; Thijssen 1970, 1971) and microregions (Flink and Karel 1970a,b) are two basic mechanisms that have been proposed to explain retention of homogeneously dissolved volatile aroma components during drying of liquid food materials. Most research has focused on liquid solutions and food gels such as extracts, juices, and milk. However, the retention of aroma in structured foods has received little attention. Neither of these two mechanisms explained the results of our experiments. Structural changes in dried samples in our case is likely different than those in spray-drying and freeze-drying. Another possible phenomenon that could influence flavor release or retention is a phase transition for the water–polymer matrix. The glass transition temperature (T_g) characterizes a transition from a solid "glassy" state to a liquid-like "rubbery" state when heated to temperatures greater than T_g. State diagrams show relationships between product composition and its physical state. At a temperature above T_g, the main consequence is an exponential increase in molecular mobility and free volume, and a decrease in viscosity in the rubbery state that affects various physico-chemical properties (Roos and Karel 1991a,b,c; Slade and Levine 1991). Increased molecular mobility also improves diffusion. When the temperature of a polymeric melt drops suddenly to a point below its T_g, the polymer backbones are immobilized. Molecules of amorphous food components are "entrapped" in the high-viscosity solid glass (Slade and Levine 1991; Roos 1995). Many state diagrams for starch and protein are available. For example, a state diagram of pregelatinized wheat starch has been constructed by Zeleznak and Hoseney (1987). As isothermal heating temperature is decreased, it is predicted that the moisture content for that transition state would be greater than for higher isothermal heating temperature. From the state diagram, the lower the isothermal heating temperature, the greater the moisture content corresponding to the glassy state. Thus, if the transformation from rubbery to glassy

states is related to flavor encapsulation, then C_∞ would increase as temperature of isothermal heating is decreased. However, in our case, lower isothermal temperatures result in lower C_∞ and thus a higher concentration driving potential, $C_0 - C_\infty$. Further experiments were not conducted to explain these observations.

The flour dough matrix (50% flour and 9% starch) is more hydrophilic than limonene. Based on formulation, water content ($\sim$0.72 g/g solid) is about 10 to 40 times higher than that of limonene (0.018–0.08 g/g solid) and 30 to 36 times higher than that of pyrazine (0.024– 0.0199 g/g solid). Based on mixing procedures, the flavor compound was the last ingredient added into the mixing bowl before mixing. After starch gelatinization, the water hydrates the hydrophilic sites of the nonaqueous constituents (flour matrix) by water–dipole associations. Similarly, limonene interacts with hydrophobic sites (protein) in the flour-dough matrix by a hydrophobic interaction. As discussed in a previous paper, 0.0068 g limonene/g solid was determined to be bound limonene (Fu and others 2003b). On the other hand, pyrazine is a hydrophilic compound and interacts with water and polar sites. Figure 18.9 (upper graph) shows the comparison of the *D*-values of limonene, pyrazine, and water as a function of initial concentration C_0, and concentration driving potential $C_0 - C_\infty$. When *D*-value is presented as a function of initial

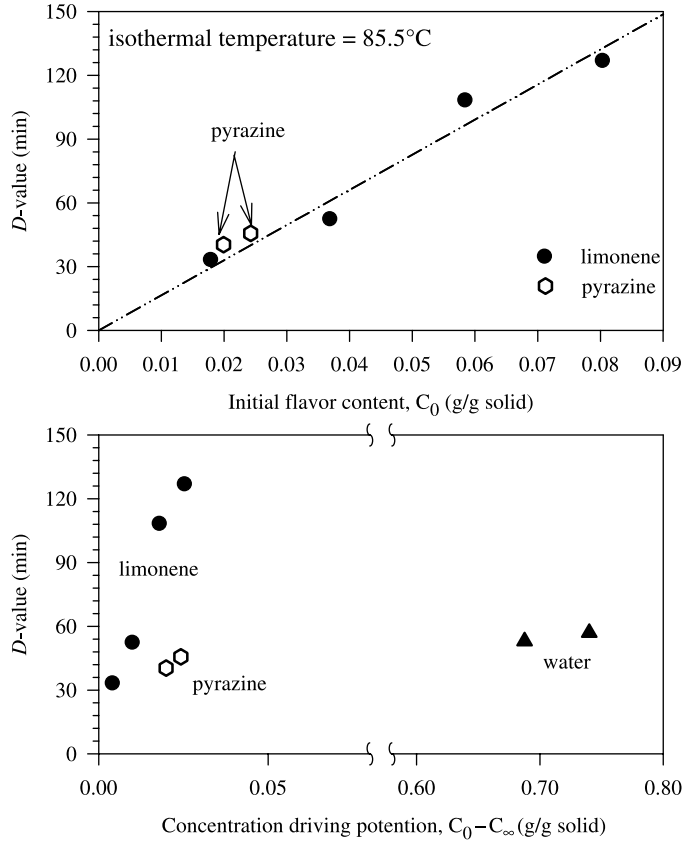

Figure 18.9 *D-value of water, pyrazine and limonene as a function of initial flavor content and concentration driving potential at 85.5°C isothermal temperature. (Fu and others 2003c).*

concentration, it appears that the migration rate of pyrazine is similar to that of limonene because the equilibrium concentration of limonene is a very strong function of its initial concentration. Consequently, to compare the rate of migration among these three components, it may more properly be presented as a function of concentration driving potential, $C_0 - C_\infty$. From the lower graph in Figure 18.9 it can be seen that the migration rates of pyrazine, limonene, and water are very different. The fourth point for the three components is the origin (i.e., the *D*-value is equal to zero when there is no concentration driving potential, $C_0 - C_\infty = 0$). The hypothesized bound limonene, 0.0068 g/g solid, was not an appropriate choice as the equilibrium concentration for all initial concentrations because the experiments that resulted in this value produced a matrix that was dried, and consequently the structure had changed. In these experiments, the migration rate decreased and leveled off at a much higher value. When the moisture content of the matrix was reduced to 0.1 g/g solid, the limonene was already entrapped. As shown in a previous paper (Fu and others 2003b), grinding did not bring about the release of entrapped materials. However, loss of volatiles does occur when the samples (with or without grinding) are heated or exposed to moisture (rehydration). The observation that the rate of flavor loss is much smaller than that before structural change indicates that the ability to release encapsulated volatile is dependent on the integrity of the dried structure. A dried limonene–dough matrix, when rehydrated, is unable to regain its original configuration, and, consequently, additional flavor will not be released even during reheating. For porous bodies, the Knudsen diffusion model can be used when the size of the pores is the order of the mean free path of the diffusing molecule. A relationship that describes Knudsen diffusion and its diffusion coefficient has been developed (Welty and others 1984), and the relation between diffusion coefficient and molecular weight is given by

$$D_{k,\text{eff}} \propto \sqrt{\frac{1}{M}}. \tag{18.19}$$

Therefore, based on molecular weight, the greater the molecular weight of a compound, the lower its diffusivity and the lower its migration. Thus, for molecular diffusion, the migration rates of limonene (MW = 136) and *tert*-butylbenzene (MW = 134) are smaller than that of water (MW = 18). In trying to obtain an accurate picture of the behavior of flavor chemicals in a food system, the volatility of these substances must also be considered. Water is the most important solvent in food products. The volatility of insoluble components is purely a function of the vapor pressure (or the boiling point as an approximation). The boiling point of limonene (bp = 176°C) is higher than that of water (bp = 100°C), so the migration rate of limonene should be smaller than that of water, based not only on the effect of molecular weight but also on the effect of volatility. For soluble components, such as pyrazine, volatility is a function of the partial vapor pressure and hence the concentration of the component in the solvent. The boiling points of limonene (bp = 176°C) and *tert*-butylbenzene (bp = 169°C) are very close and both are greater than that of pyrazine (bp = 115°C). However, volatility of pyrazine and limonene based on their boiling point cannot be compared because pyrazine is soluble and the solubility of limonene is negligible compared to that of pyrazine. The evaporation of soluble components, such as pyrazine, represents an ordinary distillation process, where volatility is a function of the partial vapor pressure and hence the concentration of the component in the solvent. Consequently, there is no single effect that explains the rate of migration of water, pyrazine, and limonene.

18.5 MICROWAVE HEATING OF FLAVOR-FORMULATED DOUGH

With conventional cooking methods, we have high-temperature ambient air (e.g., 180°C) at a rather low relative humidity. Heat permeates the surface and there is a temperature gradient and a corresponding water vapor pressure gradient directed towards the center. Because water vapor density is highest near the surface, this results in a pressure gradient that creates a driving force from the surface toward the center (Wei and others 1985a,b), thus helping to retain volatiles within the product. Due to the high ambient temperature, surface dehydration, protein denaturation, starch gelatinization, caramelization, and so on take place, and result in the formation of a crust (Van Eijk 1992). When collapse of the surface occurs, a sealing surface layer surrounds the food product and prevents or delays further evaporation of the water vapor and the associated flavoring substances into the ambient air. The very subtle but mouth-watering flavor nuances found in oven-baked products are largely due to flavors generated from the Maillard reaction. The Maillard reaction, which encompasses a complex series of reactions that starts with the condensation of amino acids and reducing sugars, has long been used as a tool for reproducing, enhancing, and improving mother nature's handiwork in a whole variety of food products. For the nonenzymatic browning or Maillard reaction to occur, the moisture content of the food product's surface must be greatly reduced (water activity levels between 0.6 and 0.8), and the surrounding air cannot be saturated with moisture (Risch 1989). There is no distinct temperature that must be attained for browning to occur; however, the higher the temperature, the greater the extent of browning.

18.5.1 Lack of Crispness (Texture) and Browning (Color, Flavor) of Microwave Foods

It is indisputable that microwave heating has many advantages over conventional heating, but the process itself is extremely complicated (Fu 2004). The well-recognized shortcomings of a microwaveable product compared to a conventionally prepared product are lack of surface browning and crisping, flavor loss, and flavor distortion. Microwave toughening is most probably related to moisture migration and loss in these reheated baked products, which can also lead to other undesirable protein–protein interactions. The lack of conventionally styled browning and crisping in microwave ovens is due to the microwave frequency used. At 2450 MHz, the wavelength, 12.2 cm, is too long to create the intense surface heat that occurs at the higher infrared frequencies, limiting the food item to a temperature of approximately 100°C. This is ideal for wet foods like vegetables and stews, but unacceptable for pastry, breaded or batter-coated items, and roast meat. In contrast to convectively heated food, we have relatively low-temperature ambient air (60–75°C) with a rather high relative humidity in most cases during microwave heating. The level of maximum temperature and consequently of maximum water vapor pressure generally lies further below the surface. The main driving force, therefore, is directed towards the surface instead of towards the center (Wei and others 1985a,b). Water vapor generated inside the food continuously migrates to the surface, drawing flavoring substances with it on the way out. The evaporation rate of water is not high enough to dry out the surface, and the evaporated water is continuously replaced by migration of water from the inside (Van Eijk 1992). For foods that require a long heating time, such as meat joints, the effect can be significant, and the resulting moisture loss from the surface of the product can be appreciable. An electromagnetic phenomenon creating "hot" and

"cold" spots is inherent in all microwave ovens and is responsible for much of the uneven cooking associated with them. Liquid products quickly dissipate the microwave energy and result in a more uniform product. Solid food products, multiphase systems, or frozen products develop hot and cold spots during heating, which further complicates flavor delivery in these systems (Steinke and others 1989).

During microwave heating the low surface temperature, its much higher water activity (approximately 1.0), and the lack of prolonged baking time have the following consequences:

1. No crust is formed because the necessary physical changes (protein denaturation, starch gelatinization, and so on) are inhibited, and
2. The formation of many flavor compounds and/or pigments (Maillard browning reactions) does not occur to the required extent.

Thus, some flavors that typically develop in a conventionally cooked product will not necessarily work in a microwaved product. Van Eijk (1992) states that the differences in flavor generation and the performance of flavoring substances in microwave foods can be explained satisfactorily by the differences in heating pattern, the corresponding differences in water vapor migration, and the resulting physical changes, particularly at the surface of the food. No athermal effects have been observed. To date, some very sophisticated packaging along with advanced susceptor technology has been the predominant solution to the lack of conventionally styled browning and crisping. Susceptors rapidly heat to temperatures where browning readily occurs and thus help produce flavor in the product. However, susceptors solve the flavor-related problems only on the surface.

Linking the formation of roast or baked flavor notes only to Maillard reactions is an oversimplification. The reactions of fats with other food constituents, for example, in meat, are also of great importance for the ultimate flavor profile. Because reactions of this type are also lacking in microwave cooking, an incomplete flavor profile may result. The ability to simulate a specific flavor in a food is significantly influenced by the flavor-binding capacity of the protein used. Denaturing of the protein can enhance flavor absorption. This probably reflects the greater exposure of hydrophobic segments of the protein because hydrophobic interaction is the principal force in the random coil-folding of proteins and accounts for binding of nonpolar flavor compounds. The extent that different proteins bind flavors cannot always be predicted in complicated food systems, because the presence of other factors (salts, lipids) will influence flavor behavior. Indeed, the moisture content of the system can influence the extent of aroma released.

18.5.2 Evaporative Cooling and Steam Distillation

During the heating process of foods containing water, the resulting evaporation at the surface causes a depression of the temperature, known as evaporative cooling. The surface of food is seen to be cooler than the region just below the surface and warmer than the surrounding air. This phenomenon is readily seen during the cooking of a meat roast (Nykvist and Decareau 1976; Nykvist 1977). At the same time, this surface evaporation can cause steam distillation of certain flavor components. Flavor release in microwave cooking is increased by steam distillation. In microwave heating, water vapor (steam) is one of the most important transport mechanisms contributing to the movement of flavor compounds within a food matrix (Fu and others 2003a,b,c). Individual compounds that make up a flavor that are particularly low in molecular weight and

water-soluble may be driven off or steam-distilled out of the product during microwave heating. Fruit and other "sweet" flavorings are more of a problem. They evaporate easily in foods with high initial water content because they contain a great number of short-chain, volatile flavoring substance. Moreover, they are often of a more hydrophilic character, and therefore a great part of the flavoring substance migrates to the aqueous phase of the food, which selectively absorbs the greater part of the microwave energy (Van Eijk 1992). The percentage loss may range from less than 10% for high-boiling compounds to 95% for very volatile compounds (Risch 1989). The latter are the ones that create a strong aroma, which is necessary when the flavor is designed to impart a balanced aroma profile in the room during microwave heating (Steinke and others 1989). In this case the flavor was added solely for aroma generation and contributed very little to the flavor profile of the microwave product itself. However, this phenomenon, flash-off, often leads to imbalance of flavor concentrations in a finished product with a different character from the flavor that was added before cooking. Formulations that compensate for flash-off may require a highly imbalanced flavor character prior to microwaving. The specific loss is dependent on the types of flavor components used and the food system in which it is incorporated. Moreover, the amount of flash-off can be highly variable within a product because temperature at any given moment can be quite local. As the outward migration of water vapor is the most important factor influencing flavor retention in the food product, the flavorings used for microwave application should have low water-vapor volatility unless the flavorings are intended to create the "oven aroma" of conventional cooking methods, or to cover undesirable off-notes released during microwave cooking.

18.5.3 A Case Study: Migration of Limonene in Formulated Dough Undergoing Microwave Reheating

Microwave reheating of ready-made cakes or desserts is one of the main domestic applications of microwave heating. The advantage is the ability of microwaves to penetrate a product and produce heat from within, thus generating heating profiles unattainable through conventional methods (Gerling 1986). The preparation time for microwave reheating is generally shorter than that of conventional heating. Loss of desired flavor may be associated with many flavor systems during microwave reheating. Fu and others (2003c) initiated an experiment by considering the migration of limonene during microwave reheating. Consequently, a series of experiments were performed to determine temperature and flavor-compound profiles in dough samples exposed to microwave energy. These experiments were limited in scope because

1. Reheating time was short (30 s to 2 min) and
2. Moisture content could not be less than 0.2 g water/g solid because the solvent extraction method did not totally remove the flavor compounds from the sample.

Three different reheating times and power combinations (335 s/600 W, 470 s/400 W, and 200 s/150 W) were used to create significantly different temperature profiles. Samples could then be created by cutting three shells with local moisture content greater than 0.2 g/g solid. Temperature profiles of three microwave reheating samples are shown in Figure 18.10. Due to microwave energy focusing on the central axis, the geometric

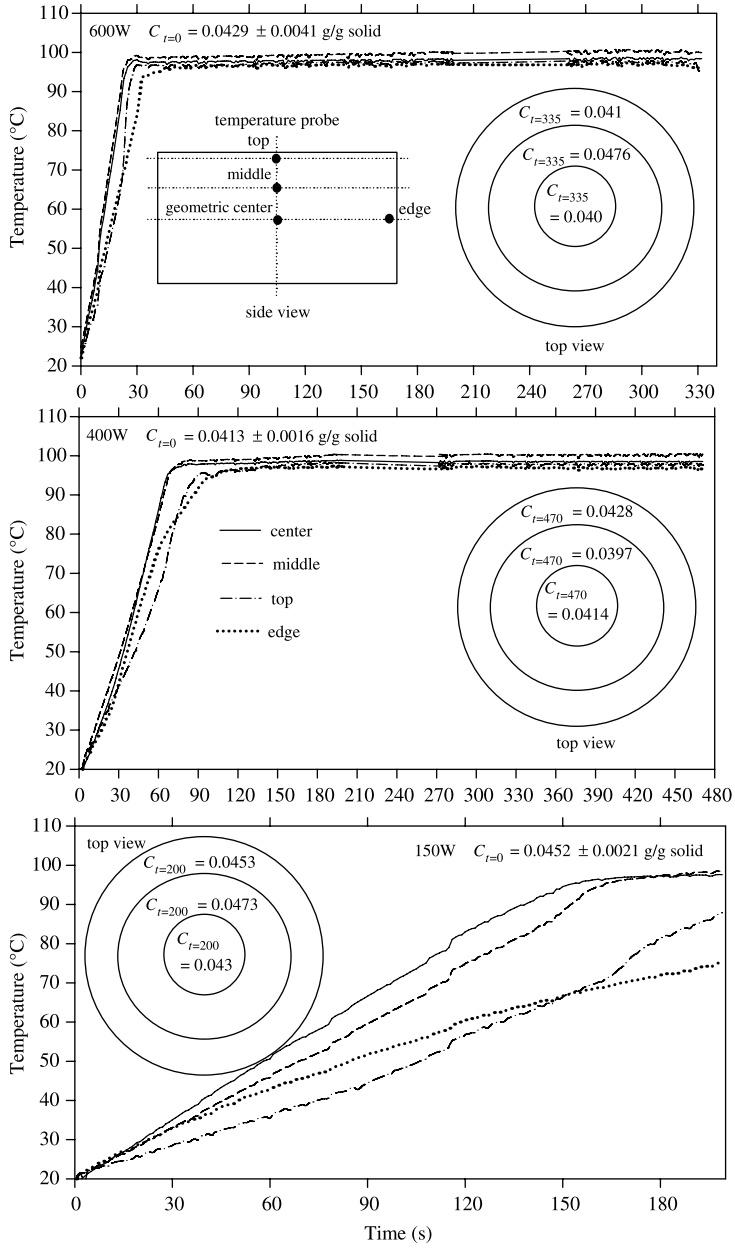

Figure 18.10 *Temperature profile of microwave heated limonene dough at 600, 400, 150 W. (Fu and others 2003c).*

center heated faster than the top of the center axis and edge. The temperature of the middle shell was between that of the center and outer shells. With higher power, 400–600 W, a 10–20°C difference between the highest and lowest temperatures was generated but lasted less than 20 s. As expected, eventually, the sample temperatures at all locations attained 95–100°C. With very low power (200 s/150 W), a 25°C temperature difference was

created for less than 70 s and the sample was at 95–98°C for less than 30 s. As expected, this sample exhibited greater temperature-difference profiles than those exposed to higher power levels. Regardless of different heating times and power combinations, the results show no significant limonene concentration difference between these three shells and also less than 1% overall change in total limonene content as a result of microwave reheating. Consequently, from a practical standpoint, there is essentially no loss of limonene from microwave-reheated dough-matrix samples.

ACKNOWLEDGMENT

Much of the work presented here was supported by state funds through the New Jersey Agricultural Experiment Station and this report is a research contribution of the Department of Food Science, Rutgers, The State University of New Jersey.

19.1 BACKGROUND INFORMATION

19.1.1 History of Soft Drinks

The first carbonated beverage, of sorts, was provided by nature, and dates back to antiquity, when the first carbonated natural mineral waters were discovered. However, they were not usually used for drinking. Instead, they were used for bathing by the ancient Greeks and Romans, owing to their purported therapeutic properties. It was not until thousands of years later, in 1767, that the British chemist, Joseph Priestley, was credited with noticing that the carbon dioxide he introduced into water gave a "pleasant and acidulated taste to the water in which it was dissolved" (Jacobs 1951). The history of carbonated soft drinks (CSDs) is somewhat sparse during its early evolution, but most agree that development of CSDs is due, in large part, to pharmacists.

Today, carbonated beverages are primarily recognized for their refreshing and thirst-quenching properties. In the early to middle 1800s, however, it was these pharmacists that experimented with adding "gas carbonium", or carbon dioxide, to water, and supplementing its palatability with everything from birch bark to dandelions in the hopes of enhancing the curative properties of these carbonated beverages (NSDA 2003). The term "Soft drinks", a more colloquial yet very common name for carbonated beverages, distinguishes them from "hard drinks", as they do not contain alcohol in their ingredient listing (NSDA 1999). This is in clear contrast to other beverages, such as distilled spirits, beer, or wine. These nonalcoholic, carbonated beverages are also called "pop" in some areas of the world, due to the characteristic noise made when the gaseous pressure within the bottle is released upon opening of the package (Riley 1972). Figure 19.1 provides a brief illustration of the major milestones in the history of American soft drinks. CSDs, pop, soda . . . whatever the moniker given to these beverages, one thing is clear: they have been an important part of our popular culture for decades, and will continue to be for many years to come.

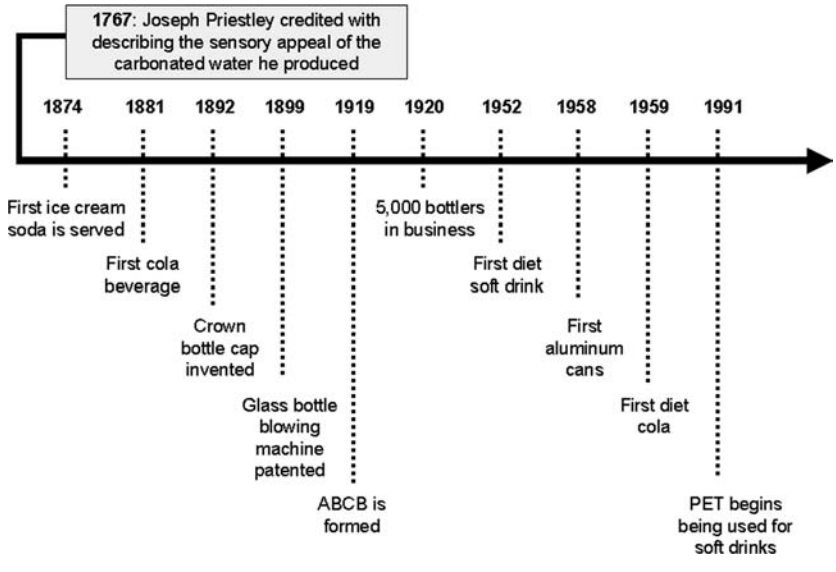

Figure 19.1 *Key milestones in the U.S. beverage industry.*

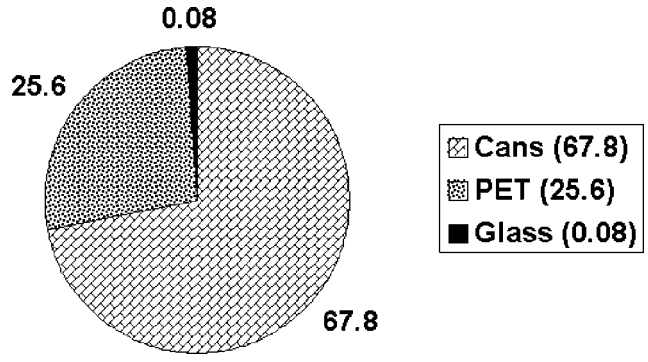

Figure 19.2 *Distribution of cans, PET, and glass CSD packages.*

19.1.2 Soft Drink Facts and Figures

Few people consciously consider how something as ostensibly simple as "soda pop" can markedly affect the economy on several fronts. The National Soft Drink Association (NSDA), founded in 1919 as the American Bottlers of Carbonated Beverages (ABCB), today represents hundreds of beverage manufacturers, distributors, franchise companies, and support industries in the United States. According to NSDA, Americans consumed nearly 53 gallons of carbonated soft drinks per person in 2002, and this translated into retail sales in excess of $61 billion. Nearly 500 bottlers operate across the United States, and provide more than 450 different soft drink varieties, at a production speed of up to 2000 cans per minute on each operating line! Figure 19.2 summarizes the apportionment of total soft drink production in the year 2000.

Finally, as an industry, soft drink companies employ more than 183,000 people nationwide, pay more than $18 billion in state and local taxes annually, and contribute more than $230 million to charities each year. Few could argue that the soft drink industry has not earned its place in the history of the American (and global) economy!

19.1.3 Carbonation Science

Before discussing the process of manufacturing carbonated soft drinks, it is important to establish some fundamental chemical/physical concepts with regard to the carbonation process itself. Simply put, in the beverage industry, "carbonation" is the introduction of carbon dioxide gas into water, as depicted in Figure 19.3.

The favorable results of this simple combination are many:

1. The carbonation provides the characteristic "refreshing" quality for which carbonated beverages are most popular;
2. The dissolved carbon dioxide acts as both a bacteristat and a bactericide, and

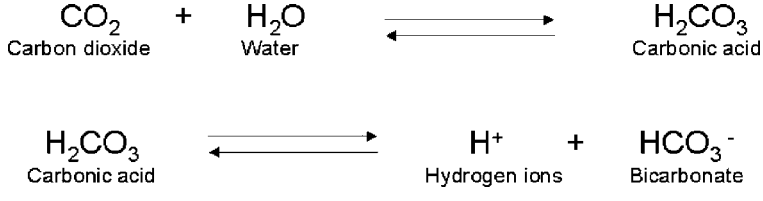

Figure 19.3 *Carbonation reactions.*

3. The carbon dioxide dissociates in aqueous media to form carbonic acid, which depresses the pH of the solution, thereby making the product even more protected from microbial harm (Granata 1946).

All in all, from a microbiologic perspective, carbonated soft drinks are innately very safe beverages. Once the carbon dioxide is introduced into the water, which will ultimately join with flavors and sweeteners to form the complete beverage, the beverage technologist must understand how to measure and express the level of carbonation. The accepted convention in the beverage industry is *not* to measure carbon dioxide as a true concentration, expressed in parts per million, or milligrams per liter. Instead, carbonation is expressed in units called "volumes". The concept is ultimately based on the physical gas laws of Henry, Boyle, and Charles, wherein pressure, temperature, and volume are closely interdependent. The colder the liquid, the more gas can be dissolved within it. Even within the industry, however, there is some confusion over what the exact definition of a "volume" is (Medina 1993), usually arising from the temperature included in the definition. For our purposes, we will define one "volume" based on the Bunsen coefficient, described by Loomis as, "the volume of gas (reduced to 0°C and 760 mm) which, at the temperature of the experiment, is dissolved in one volume of the solvent when the partial pressure of the gas is 760 mm" (Loomis 1928). More informally, and to put this concept in perspective, consider a 10-oz bottle of carbonated beverage, representing roughly 300 mL of liquid. If this carbonated beverage is prepared at one "gas volume", the package would contain approximately 300 cc of carbon dioxide. We would consider this very low carbonation from a sensory perspective, and would have a barely noticeable "fizz" upon removal of the closure. Imagine, however, for the same 300 mL of liquid, we carbonate to four gas volumes (a level typical of many products on the market today). This means that roughly 1200 cc of carbon dioxide has been introduced into the same 300 mL volume of liquid. More gas, into the same amount of liquid, and the same vessel size – imagine the increase in pressure contained within the bottle. This example explains why the characteristic "pop" of soda pop is heard when a bottle is uncapped, or a can is opened!

For the purposes of this text, the discussion of carbonation has been somewhat oversimplified, in order to make the concept more easily understood. As with any industry, the more one investigates any given topic, the more complicated and scientifically intense the subject usually becomes. Carbonation, for example, can be affected by a variety of factors, including other solids present in the liquid being carbonated, temperatures of the gas and the liquid, atmospheric pressure/altitude, and how far carbon dioxide varies from ideal gas behavior (Gidden 2001). These are cited merely for consideration, but are outside the scope of this manuscript.

19.1.4 Process Overview

The process of manufacturing carbonated beverages has remained fundamentally the same for the last several decades. Certainly, new equipment has allowed faster filling speeds, more accurate and consistent fill heights, more efficient gas transfer during carbonation, and other improvements, but the process remains one of cooling water, carbonating it, adding flavor and sweeteners, and packaging it in a sealed container. Figure 19.4 illustrates the overall process in somewhat more detail, as we continue to build upon the basic foundation we will be discussing throughout this chapter. As we proceed, the figures depicted will become more complete, as each critical process to carbonated beverage manufacture is explained.

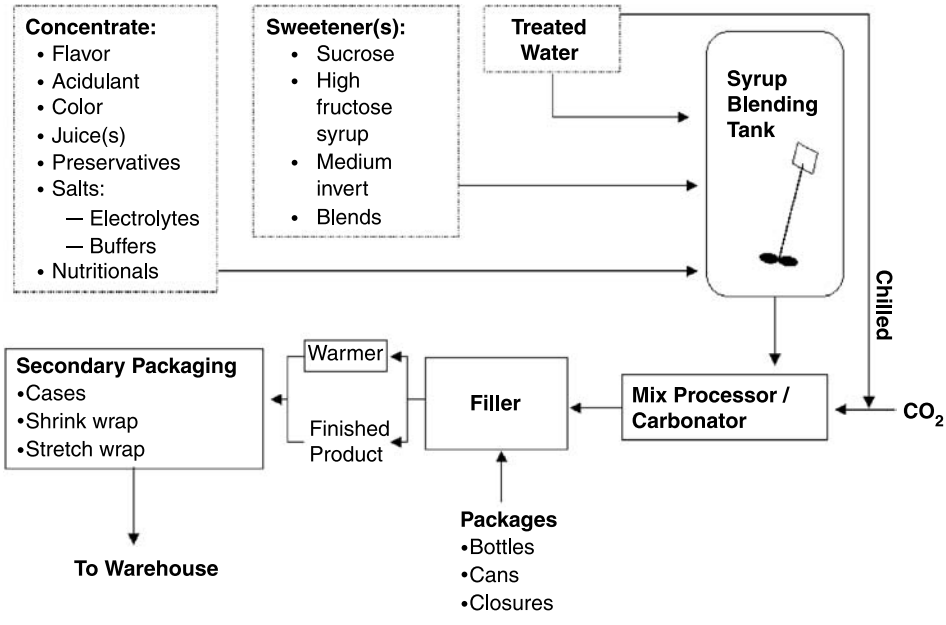

Figure 19.4 *Process overview of carbonated beverage manufacture.*

Carbonated beverage production begins with careful measurement of the formula quantities of each component into the syrup blending tank. Critical components include the *concentrate*, which contains the bulk of the flavor system, the *sweetener*, which typically includes the nutritive sweeteners high-fructose syrup or sucrose (in the case of diet beverages, these are replaced with one of the high-potency sweeteners available), and *water*, which generally begins as municipal drinking water, and is further purified within the beverage plant. These are then blended to assure homogeneity of the batch according to carefully prescribed standard operating procedures. Once blending in the syrup tank is complete, the "finished syrup" is tested for correct assembly, then pumped to the mix processor, where the syrup is diluted to finished beverage level with chilled, carbonated, treated water (often a 1 : 6 dilution of syrup:treated water, although this varies by product). After this, the now carbonated beverage-level solution proceeds to the filler, where it is fed (usually volumetrically, by gravity) into bottles or cans, then sealed (capped in the case of bottles, seamed in the case of cans). The finished product is then either passed through a warmer, in order to prevent excessive condensation from forming (depending on the type of secondary packaging used), or sent directly to secondary packaging. This can include plastic or cardboard cases, shrink wrap, stretch wrap, or even more innovative devices. After packaging, the product is palletized, and stored in the warehouse until it is ready for distribution.

19.2 RAW MATERIALS PREPARATION

19.2.1 Concentrate

In the carbonated soft drink industry, "concentrate" is the name given to a mixture of many different categories of ingredients, as illustrated in Figure 19.5. The most notable of these,

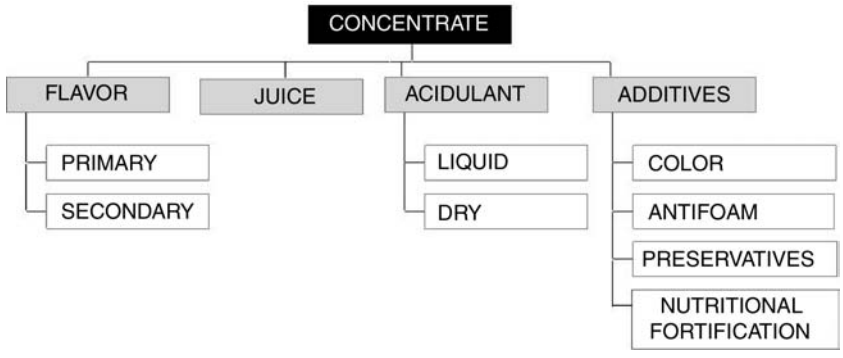

Figure 19.5 *Concentrate components.*

and, indeed, the topic of many urban legends surrounding its utter secrecy, is the flavor component. This is where the proprietary formulations of essential oils are found, which combine to form the characteristic flavor of the trademark beverage. Flavor components can include a single, "primary" component, or be distributed in various ways among multiple components, for example, a high-potency sweetener supplied as a dry salt as part of a secondary flavor component. In general, the majority of flavor systems include primary flavor components, and these fall into three broad categories:

1. Simple mixtures,
2. Extracts, or
3. Emulsions.

19.2.1.1 Simple Mixtures. These are perhaps the simplest of the flavor categories to understand, but they also represent the minority of those in existence. Here, a combination of miscible liquids, or easily soluble solids, are blended together to form a homogeneous aqueous mixture. Because so many essential flavor oils are not readily water soluble, the beverage technologist must abandon the idea of the simple mixture for one of the other, more flexible categories of flavors.

19.2.1.2 Extracts. As the name implies, this category of flavors involves extracting the desired flavor constituents from essential oils. Simply put, the extraction solvent – usually ethanol (although sometimes propylene glycol is used) – is used to partition those flavor constituents that are soluble in the solvent, but not freely soluble in the water directly. In this way, these flavor compounds become fully dissolved in the ethanol first. Then, this ethanolic "extract" (which is, in effect, an ethanolic solution of the flavor compounds) is added to water. Because ethanol is freely miscible with water, it acts as a carrier vehicle to help dissolve or disperse the otherwise water-insoluble flavor constituents (Woodruff 1974). Today, equipment for both batch and continuous liquid extraction of flavor oils is available, and more novel approaches have also been developed (for example, gas extraction, supercritical fluid extraction, and other patented processes).

19.2.1.3 Emulsions. This third category is likely the largest, encompassing the bulk of the flavor systems available today. In the carbonated beverage industry, oil-in-water (or o/w) emulsions are the standard. This model involves an oil (lipophilic) internal phase, and an aqueous (hydrophilic) external phase, being made "compatible" by the use of a surfactant, or emulsifier. Surfactants are compounds that are amphiphilic; that is, there are

both hydrophilic and lipophilic portions on the same molecule! This facilitates a decrease in the surface tension when oil and water are mixed together, and also allows the lipophilic portion to align with the oil, and the hydrophilic portion to align with the water (Banker 1996). In so doing, the emulsifier forms a bridge, of sorts, between the two phases, and allows them to be dispersed, without gross separation, for the desired length of time (generally at least as long as the technical shelf-life of the beverage).

As carbonated beverages are of low pH, owing in part to the carbonic acid from the dissolved carbon dioxide, but also from the acid components of the formulas, acid hydrolysis is one of the major concerns to the beverage flavor developer. By positioning itself between the oil and water phases, the emulsifier protects the sensitive flavor oils from chemical degradation in this acidic environment. In addition, the emulsifier protects the flavor oils from oxidation from the naturally dissolved oxygen in the water that constitutes the aqueous phase. So, a well-designed and prepared emulsion can dramatically extend the sensory shelf-life of the flavor system, and the overall physical stability of the beverage.

In addition to the flavors, Figure 19.5 also depicts a variety of other components that may be part of the concentrate. These include juices, which must be handled and stored carefully in order to preserve their quality, acidulants (both liquid and dry), and a host of other additives, depending on their desired function (for example, antifoam, preservative, nutrients, and so on).

19.2.2 Water

Water is the major component in carbonated beverages, and represents anywhere from 85 to near 100% of the finished product. Interestingly, it is unlike any other ingredient, because we rarely have the number of options for water supply that we have with other raw materials! Obviously, then, particular diligence must be employed when selecting a water supply. Beverage plants use water from ground supplies, surface supplies, or both. Ground supplies include springs, deep and shallow wells, and artesian aquifers. Surface supplies include rivers, lakes, streams, and reservoirs. Within these sources, there is wide variation in type and content of inorganic (for example, metals, minerals, sulfate, chloride, nitrate), organic (for example, volatile organics, natural organic matter), microbiologic (bacteria, viruses, protozoa), and radiologics (radionuclides, alpha- and beta-activity) material. Table 19.1 provides a relative comparison of some characteristics of ground and surface supplies (Bena 2003).

One critical point of which to be aware is that municipal treatment plants should not normally be depended upon to consistently supply water suitable for the needs of most carbonated beverage manufacturers. Although the municipality treats the water so that it is safe to drink, and is esthetically pleasing to the consumer (potable and palatable), they cannot afford to consider the needs of all industrial end users, so they may not consistently supply a water of the high quality needed for producing our finished product and assuring the beverage a long shelf-life. There is also the possibility of contamination of the city water as it passes through the distribution system from the municipal treating plant to the beverage plant. This is particularly true with respect to organic matter and metal content, such as iron. The quality of the water used for carbonated soft drinks must be considered from several perspectives:

1. *Regulatory Compliance*. The water used must be in compliance with all presiding local and national laws and guidelines. The jurisdiction is generally clear in the United States, between the Environmental Protection Agency and the Food and Drug Administration. However, as you consider the international beverage locations, the regulatory picture sometimes becomes more cloudy.

TABLE 19.1 Comparison of Ground and Surface Water Supplies.

Parameter	Ground Water	Surface Water
Total dissolved solids	Higher	Lower
Suspended solids	Lower	Higher
Turbidity and color	Lower	Higher
Alkalinity	Higher	Lower
Total organic carbon	Lower	Higher
Microbiology		
Protection from bacteria and viruses	Highly protected	Highly susceptible
Protection from protozoa	Almost completely protected	Highly susceptible
Presence of iron and/or manganese bacteria	Common	Rare
Hydrogen sulfide gas	Common	Uncommon
Aeration/dissolved oxygen	Lower	Higher
Temperature	More consistent	More variable
Flow rate	Very slow (1 m/day)	Very fast (1 m/s)
Flow pattern	Laminar	Turbulent
Susceptibility to pollution through surface run-off	Low	High
Time for a contaminant plume to resolve	Very long, often decades, potentially centuries!	Usually short, days/months, sometimes years

Source: Bena (2003).

2. *Beverage Stability*. Intuitively, as the major ingredient in carbonated soft drinks, the constituents in water can have a profound impact on the overall quality and shelf-life of the beverage products. For example, if alkalinity is not controlled, the acidic profile of the beverage formulas will be compromised, making the beverage more susceptible to microbial growth and spoilage.
3. *Sensory*. Many contaminants, even at levels within drinking-water standards, may adversely affect the finished beverage. For example, some algae produce compounds (geosmin and methyl isoborneol) that are sensory active at levels as low as nanograms per liter (Suffet 1995). These can result in a "dirty, musty" flavor and aroma in finished products.
4. *Plant Operations*. Water for nonproduct (auxiliary) uses must also meet the performance standards of the carbonated soft drink producer. These standards and guidelines are usually enacted to prevent corrosion (for example, from high chloride content in heat exchangers) and scaling (for example, from hardness salts in boilers), which may result in premature equipment failure and/or loss of operational efficiency.

Whether the beverage plant has its own well, or the water supply comes from a modern municipal treatment plant, each individual water supply presents its own particular problems. In most, if not all cases, the incoming raw water that supplies a beverage plant already meets the applicable standards for potability of drinking water. The beverage producer then further purifies the water to meet the quality necessary for their products. This treatment can take many forms, but the three largest categories of in-plant beverage water treatments are

1. Conventional lime treatment systems (CLTS);
2. Membrane systems (including reverse osmosis, nanofiltration, and ultrafiltration); and
3. Ion-exchange.

Volumes have been written about each treatment modality, and a detailed discussion is beyond the focus of this chapter. However, a brief summary of each treatment category is provided in the following (Bena 2003).

19.2.2.1 Conventional Lime Treatment Systems (CLTS). This treatment chain represents the majority of most beverage treatment armadas worldwide, although the balance is quickly shifting in favor of membrane technologies. CLTS involves the addition of a coagulant (as an iron or aluminum salt), hydrated lime (for pH control), and chlorine (for oxidation and disinfection) to a reaction tank. The agitation is gently controlled over the course of a two-hour retention period, during which time a floc begins to form, grow, and settle, bringing contaminants with it to the bottom of the tank, where they await discharge. Figure 19.6 illustrates what happens in this reaction vessel.

Historically, and as little as 25 years ago, conventional lime treatment was regarded as the "ideal" treatment for raw water of virtually any quality. Indeed, this system, coupled with the required support technology – fine sand filtration, granular activated carbon, polishing filtration, and ultraviolet irradiation – does address a broad range of water contaminants. The advantages and disadvantages of conventional lime treatment are summarized in Table 19.2.

19.2.2.2 Membrane Technology. Clearly, this has seen the most growth in recent years with the advent of more resistant membrane materials of construction and more flexible rejection characteristics. Included in this category is the prototype of the cross-flow, polymeric membrane filtration systems – reverse osmosis, along with nanofiltration and ultrafiltration (both polymeric and ceramic). By carefully controlling the membrane pore size during manufacture, and applied pressure during operation, reverse osmosis

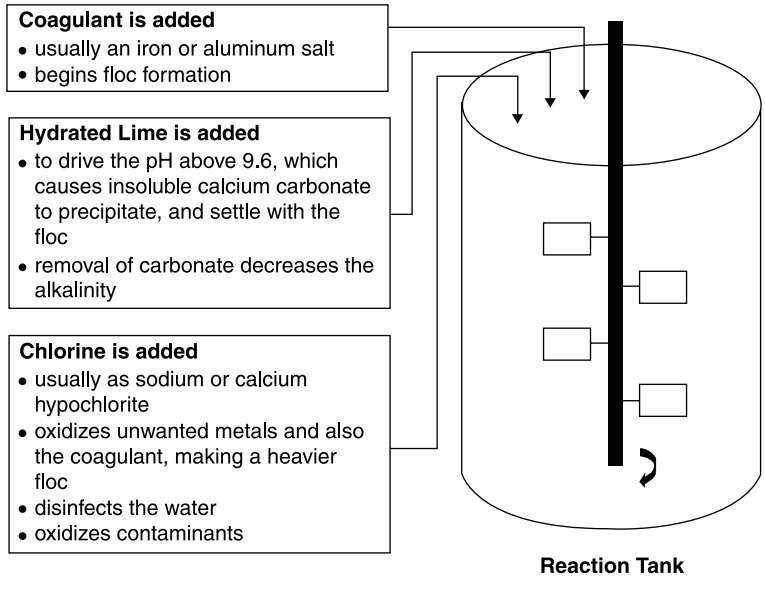

Figure 19.6 *Reaction tank in a conventional lime treatment system.*

TABLE 19.2 Advantages and Disadvantages of CLTS.

Advantages	Disadvantages
Removes alkalinity and hardness	Does not effectively reduce nitrate, sulfate, or chloride concentration
Removes organic debris, particulates, and natural organic matter (NOM)	Sludge formation and disposal requirements need to be addressed
Reduces metal concentrations (iron, manganese, arsenic, others) and some radionuclides	May promote the formation of disinfection byproducts (trihalomethanes) under certain conditions
Reduces some color compounds (tannins), off-tastes, and off-odors	Often difficult to operate consistently in waters with very low dissolved solids
Reduces bacteria, virus, and protozoan populations	These are relatively large space requirements on the plant floor ("footprint")

Source: Bena (2003).

membranes can effectively remove in excess of 99% of many dissolved species – down to the ionic level (for example, dissolved calcium or sulfate). Table 19.3 illustrates the relative capabilities of the three major membrane processes with regard to a variety of possible constituents in the incoming water (Brittan 1997).

Because reverse osmosis is often the cited "membrane standard" against which the performance of others are judged, the advantages and disadvantages of reverse osmosis are listed in Table 19.4. It is also worth mentioning, although not discussed here, that among this group are the "hybrid" technologies, which include novel membrane and ion-exchange utilization. Examples are electrodialysis technology for removal of ionic species in water, and continuous electrodeionization.

19.2.2.3 Ion-Exchange. This technology is routinely utilized for partial or complete demineralization of the water supply, softening, dealkalization, or it can be customized for selective removal of a specific contaminant (for example, denitratization). In simplest

TABLE 19.3 Relative Comparison of Reverse Osmosis, Nanofiltration, and Ultrafiltration.

Component	Reverse Osmosis[a]	Nanofiltration[a]	Ultrafiltration[a]
Alkalinity	95–98%	50–70%	None
TDS	95–98%	50–70%	None
Particulates	Nearly 100%	Nearly 100%	Nearly 100%
Organic matter	Most >100 MW	Most >200 MW	Some >2000 MW
THM precursors	90+%	90+%	30–60%
Sodium	90–99%	35–75%	None
Chloride	90–99%	35–60%	None
Hardness	90–99%	50–95+%	None
Sulfate	90–99%	70–95+%	None
Nitrate	90–95%	20–35%	None
Protozoa	Nearly 100%	Nearly 100%	Nearly 100%
Bacteria	Nearly 100%	Nearly 100%	Nearly 100%
Viruses	Nearly 100%	Nearly 100%	Nearly 100%
Operating pressure	200–450 psi	100–200 psi	80–150 psi

Source: Adapted from Brittan (1997).
[a]Approximate removal percentages; actual performance is system-specific.

TABLE 19.4 Advantages and Disadvantages of Reverse Osmosis.

Advantages	Disadvantages
Removes nearly all suspended material, and greater than 99% of dissolved salts in full-flow operation	Pretreatment must be carefully considered, and typically involves operating costs for chemicals (acid, antiscalant, chlorine removal)
Significantly reduces microbial load (viruses, bacteria, and protozoans)	Does not produce a commercially sterile water
Removes nearly all natural organic matter (NOM)	Membranes still represent a substantial portion of the capital cost, and may typically last 3–5 years
May be designed as a fully automated system with little maintenance	Low solids water may be aggressive toward piping and equipment, so this must be considered for downstream operations
It has relatively small space requirements on the plant floor ("footprint")	High-pressure inlet pump is required

Source: Bena (2003).

terms, ion-exchange involves using a selective resin to exchange a less desirable ion with a more desirable ion. Of course, a great deal of chemical research goes into the development of these selective resin materials, but the functional outcome remains straightforward. For example, softening resins are often employed to remove hardness (calcium and magnesium) from the water entering boilers and heat exchangers. In this application, the hardness ions are not wanted. The softening resin (for example, a sodium zeolite clay) is charged with active and replaceable sodium ions. When the "hard" water passes across the softening bed, the resin has a selectivity for calcium and magnesium, so it replaces them for sodium. The result is that the water exiting the softener is virtually free of calcium and magnesium (because they were replaced by sodium), and is safe to use in boilers and other equipment, as it will no longer have the tendency to form scale.

To supplement the major treatment systems mentioned above, the carbonated beverage producer often utilizes a host of other "support technologies", including activated carbon filtration (to remove organic contaminants and chlorine), sand filtration (to remove particulates), and primary and secondary disinfection (using chlorine, ozone, ultraviolet, heat, or a combination). By the time the treated water is finished, it is microbially and chemically safe, clear, colorless, and ready to be used for syrup and beverage production.

19.2.3 Sweeteners

The two major categories of sweetener are nutritive (that is, they provide some caloric value) and "high-potency" (that is, the type used in diet beverages, because they are many times sweeter than sucrose, and generally noncaloric). There are several high-potency sweeteners available to the worldwide beverage developer (aspartame, acesulfame potassium, and others), which are almost exclusively, if not always, included as part of the "concentrate" flavor system as a dry substance package. As such, their quality can be more easily controlled by the vendor, as with any of the other concentrate ingredients, and minimal intervention is needed at the carbonated soft drink manufacturing facility. These high-potency sweeteners, therefore, will not be addressed in this chapter. A concise treatise on the topic, however, is provided by the International Society of Beverage Technologists (Koch 2000).

Next to water, however, the nutritive sweeteners represent the second most prevalent ingredient in the finished beverage. The most common nutritive sweeteners used in the

carbonated soft drink industry are sucrose and high-fructose syrups, with sucrose (from cane or beet) being the most common internationally. Within the United States, nearly all of the nutritive sweetener used in carbonated beverages is high-fructose corn syrup (HFCS, either 42 or 55%). In 1996, the U.S. corn-refining industry produced over 21 billion pounds of high-fructose corn syrups, representing about 12% of the total corn crop (Hobbs 1997).

Although high-fructose syrups may be obtained from other starting materials, like wheat, or tapioca starch, corn remains the most prevalent starting material. A starch slurry is first digested by the addition of the α-amylase enzyme, which results in gelatinization and ultimate dextrinization of the starting starch. Then, glucoamylase enzyme is added, resulting in an enriched glucose syrup (95% glucose). After this the glucose syrup is purified via particle filtration, activated carbon adsorption, and both cation and anion exchange. Then, evaporation brings the solids content within range for effective passage through the isomerization column containing the glucose isomerase enzyme. This enzyme converts much of the 95% glucose syrup to fructose, which is again purified as before, and evaporated. The result is HFCS-55 of high quality. In some formulas and/or markets, HFCS-42 is used, which is simply a blend of the HFCS-55 with a 95% glucose stream to result in a product that is 42% fructose. The generic process by which corn starch is transformed to high-fructose corn syrup is illustrated in Figure 19.7 (Boyce 1986).

In general, HFCS-55 (55% fructose) is a highly pure ingredient, due, in large part, to the activated carbon, cation, and anion exchange steps required of the process. However, the most recent research highlights the occurrence of potent sensory-active compounds that could form via chemical or microbial pathways in HFCS, including isovaleraldehyde, 2-amino acetophenone, and maltol (Finnerty 2002). When properly produced and stored, no additional treatment is necessary at the beverage plant.

Sucrose, although the clear exception in the North American beverage industry, continues to be the mainstay for international beverage markets. It may be obtained from

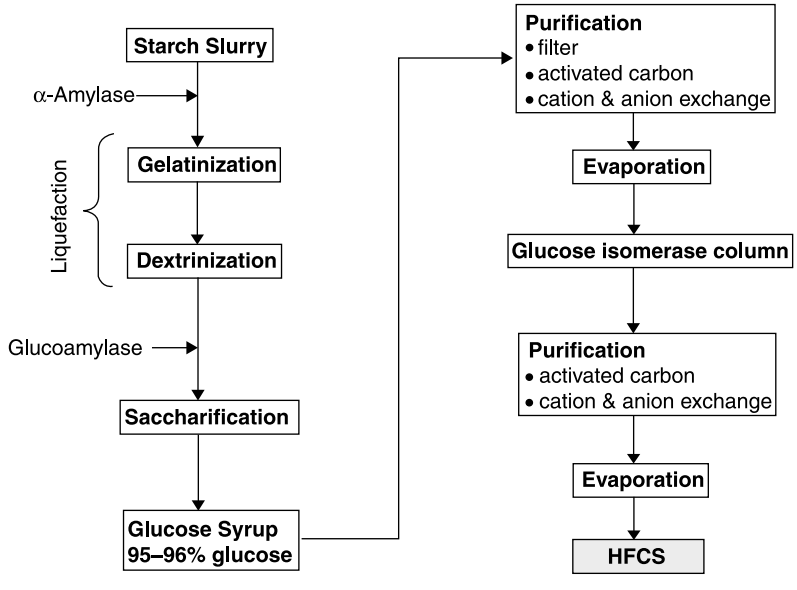

Figure 19.7 *High-fructose corn syrup manufacture.*

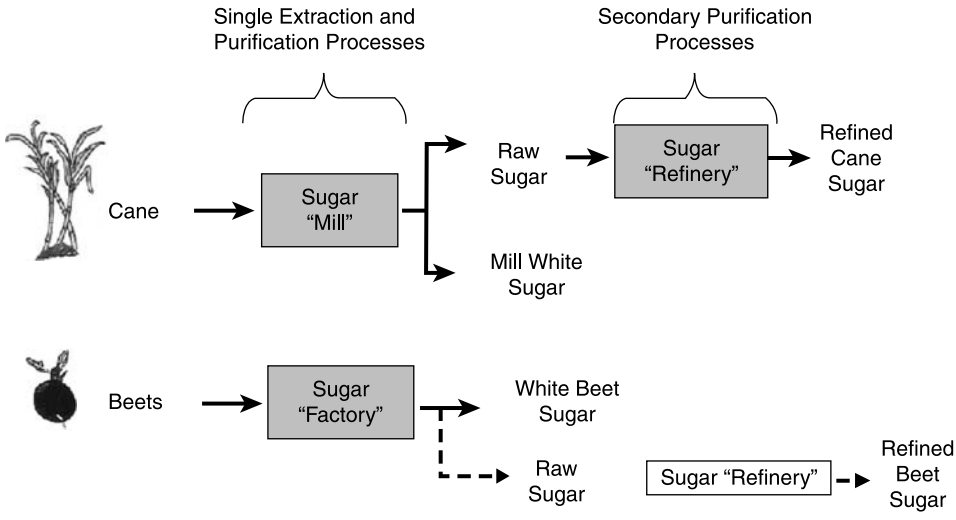

Figure 19.8 *Cane* vs. *beet sugar process flow.*

sugar cane or sugar beet, following two distinct separation and purification schemes, as depicted in Figure 19.8 (Galluzzo 2000). The three indicators of sucrose quality generally recognized by the sugar industry are color, ash, and turbidity. Internationally, depending on the quality of the available sucrose, it is not uncommon to subject the incoming granular or liquid sucrose to additional treatment at the beverage plant. Ash, or residual inorganic minerals, remains difficult to adequately treat at the carbonated soft drink plant, so great effort is made to source sucrose with an acceptable ash content (as defined by the individual company specifications). Turbidity is easily remedied at the beverage plant via an in-line filtration step, often incorporating diatomaceous earth as a filter aid. Color, considered by some as the primary indicator of sucrose quality, is also able to be treated at the beverage plant, but typically requires hot treatment through activated carbon. This removes color and many sensory-active compounds, and also serves to render the sucrose free of most viable microorganisms. Figure 19.9 (McLeod 2001) briefly summarizes the handling and treatment of sucrose at the carbonated soft drink facility.

Liquid sucrose, usually commercially available at 67 Brix concentration (67 Brix is equivalent to 67% sucrose, by weight), is sometimes used for the production of carbonated soft drinks. These are two distinct disadvantages of using liquid sucrose instead of granulated sucrose:

1. The end user ultimately pays for shipping 33% water, because the ingredient is only 67% sucrose solids, as compared to granulated sucrose, which is 100% sucrose solids, and
2. This water also means that the liquid has a higher water activity than granulated sucrose, making it much more susceptible to microbial spoilage. With liquid sucrose operations, absolutely diligent transport and handling procedures are imperative.

The last, less common type of nutritive sweetener used in this industry is medium invert sugar. Chemically, this product has similarities to both sucrose and high-fructose corn

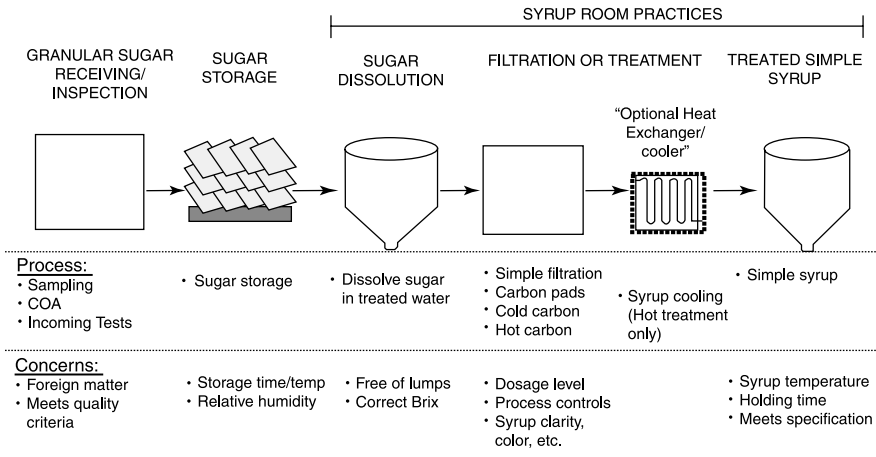

Figure 19.9 *Sucrose handling and treatment at the beverage plant.*

syrup. With medium invert sugar, or MIS, the starting material is liquid sucrose, which is then treated by one of three processes:

1. Heat and acid;
2. Ion-exchange; or
3. Invertase enzyme.

The end result of any of these processes is that roughly 50% of the starting sucrose is transformed into "invert sugar", an equimolar mixture of glucose and fructose. At this point, the inversion process is stopped, and the final commercial product contains 50% sucrose, 25% glucose, and 25% fructose. This gained favor over liquid sucrose in the beverage industry for two main reasons:

1. The finished material is 76 Brix, *vs.* 67 Brix for liquid sucrose, so less water is shipped; and
2. MIS has a much lower water activity, and is, therefore, much more microbiologically stable.

In summary, the producers of carbonated soft drinks have several options at their disposal for providing the sweetness to the consumer that is so characteristic of these products. Internationally, sucrose is the major sweetener used, but in the United States, high-fructose corn syrup is preferred. Irrespective of the type of sweetener, the beverage industry has treatment methods at its disposal to ensure that this ingredient consistently meets the high standards of chemical and microbial quality necessary to be used in the production of syrup and beverage.

19.2.4 Carbon Dioxide

At normal temperatures and pressures, carbon dioxide is a colorless gas, with a slightly pungent odor at high concentrations. When compressed and cooled to the proper temperature, the gas turns into a liquid. The liquid in turn can be converted into solid dry ice. The dry ice, on absorbing heat, returns to its natural gaseous state.

We learned a little of the history of carbonation earlier in this chapter, because the concept is so critical to the production of carbonated soft drinks. Just as critical is the quality of the carbon dioxide used in this application. For many years, the quality of carbon dioxide was minimized, largely because there were no uniformly available methods with which to test the gas, as an ingredient. Those procedures that were available required special expertise to properly sample and handle this cryogenic gas. Maintaining standards of quality of the carbon dioxide used in beverages was traditionally relegated to the U.S. Compressed Gas Association (CGA), whose "quality verification levels" were incorporated into the beverage company's specification system. Then, in 1999, the International Society of Beverage Technologists (ISBT) developed the Quality Guidelines and Analytical Procedure Bibliography for Bottler's Carbon Dioxide (McLeod 2001). This was a cross-corporate effort by carbon dioxide suppliers, end-users, testing labs, and allied businesses to completely update the obsolescent guidelines that had been recognized for decades. The guidelines are only available for purchase through ISBT (www.bevtech.org), but include parameters related to health/safety, sensory, and good manufacturing practices at the supplier.

Carbon dioxide may be obtained and purified from a number of different "feed gas" sources, the majority of which are listed in Table 19.5. There are other more "exotic" sources, which are often the result of carbon dioxide being generated as a side product during an organic chemical synthesis. In addition to commercial supplies, some carbonated beverage plants produce and purify their own carbon dioxide. The most common feed-gas sources for these applications are combustion (where the flue gas is recovered, concentrated, then purified) and breweries (where the CO_2 generated from microbial metabolism is recovered and purified). Whether supplied commercially or in-house, the carbon dioxide used in carbonated soft drinks is of high quality (greater than 99.9% CO_2); in most cases, it even exceeds that of medical-grade gas.

The liquid carbon dioxide that is delivered to beverage plants is generally stored in large "bulk receivers", which are vertically or horizontally oriented steel tanks with urethane foam or vacuum insulation. In the most common arrangement, carbon dioxide is withdrawn from the liquid phase at the bottom of the tank, and vaporized by one of several methods. Due to this withdrawal, the equilibrium between vapor and liquid in the tank remains dynamic. The air gases (oxygen, nitrogen) partition into the vapor phase of the vessel, and are routinely purged to maintain the purity of the carbon dioxide within the bulk receiver. Similarly, some components preferentially partition, in trace amounts, into the liquid phase of the carbon dioxide (liquid CO_2 is an excellent solvent). Many beverage plants choose to subject the freshly vaporized carbon dioxide to one final step of purification just prior to the point of use. This is usually a simple

TABLE 19.5 Feed Gas Sources for Carbon Dioxide.

Combustion

filtration through activated carbon alone, or through a mixed adsorbent bed of carbon (to remove organic contaminants); a silica-based desiccant (to remove moisture); and a molecular sieve (to remove sulfur compounds and some oxygenates).

In addition to the quality considerations already discussed, carbon dioxide safety is a key consideration for beverage industry technologists. Carbon dioxide is not usually considered to be a toxic gas in the generally accepted sense of the term (that is, poisonous) and is normally present in the atmosphere at a concentration of approximately 0.03% (300 ppm). Under normal circumstances, CO_2 acts upon vital functions in a number of ways, including respiratory stimulation, regulation of blood circulation, and acidity of body fluids. The concentration of CO_2 in the air affects all of these. High concentrations are dangerous upon extended exposure, due to increased breathing and heart rates, and a change in the body acidity. OSHA (Occupational Safety and Health Administration) establishes regulations governing the maximum concentration of CO_2 and the time-weighted average for exposure to CO_2. These regulations should be reviewed before installation of any CO_2 equipment, and the requirements fully met during operation and maintenance.

Because CO_2 is heavier than air, it may accumulate in low or confined areas. Adequate ventilation must be provided when CO_2 is discharged into the air. At lower levels where CO_2 may be concentrated, self-contained breathing apparatus or supplied-air respirators must be used. Filter-type masks should not be used. Appropriate warning signs should be affixed outside those areas where high concentrations of CO_2 gas may accumulate, and lock-out/tag-out procedures should be followed, as appropriate (Selz 1999).

19.3 SYRUP PREPARATION

Most carbonated beverage formulas begin with a "simple syrup", which is usually a simple combination of the nutritive sweetener (sucrose, HFCS, MIS) and treated water. In some cases, it may also contain some of the salts outlined in the specific beverage document, depending on the order of addition that is required. Once the sweetener is completely dissolved, and the simple syrup is a homogeneous batch, then the flavor and remaining components are added to form the "finished syrup". All simple syrups should be filtered before being pumped to the finished syrup blending/storage tanks.

19.3.1 Using Granulated Sucrose

Accurate weighing of granulated sugar is important. Granulated sugar is normally received in bulk form or in bags. Internationally, receipt in 50- or 100-pound jute or paper bags is not uncommon. It is extremely important that the sugar received by either means should be dry and free of lumps. Moist sugar creates two immediate and serious problems:

1. Moist sugar can have high microbial counts, much of which will be yeast. Yeast is a serious problem to carbonated beverages, because it can lead to fermentation and eventual spoilage of the finished product.
2. Moist sugar makes accurate measuring difficult, because the moisture content is being weighed, in addition to the sucrose solids. This makes final control of the batch difficult and inconsistent.

TABLE 19.6 Possible Brix Errors During Simple Syrup Production.

High Brix	Low Brix
Weighing error – excess sugar	Weighing error – short sugar
Faulty scale	Faulty scale
Instrument error	Not weighing sugar bags
Too little water	Too much water
	Instrument error
	Moist sugar

Source: Delonge (1994a).

Sugar in lumps will create difficulties in making simple syrup and will take longer to dissolve. Lump sugar is usually an indication that the sugar was not fully dried during refinery production or was stored improperly (Delonge 1994a). Bulk sugar systems should never be used where faced with wet or even slightly moist sugar. It will cause "bridging" (flow restriction) in silo storage and make effective handling impossible. It is critical that any bulk sugar supply is consistently dry and that the storage environment can be controlled to assure constant low humidity. Even the most modern silo can "bridge" when faced with a moisture problem.

Granulated sugar should always be added slowly into the treated water already measured into the tank. While sugar is being added, the tank agitator should be in constant operation. The agitation should continue until the sugar is completely dissolved. After the sugar has been completely dissolved, and the simple syrup has been filtered into the blending/storage tank, the syrup is checked for sugar content (Brix). Table 19.6 outlines intuitive, but useful, reasons for off-target Brix readings.

19.3.2 Using Liquid Sugars

There are three main types of liquid sugars that are used for syrup production, as discussed earlier: liquid sucrose, medium invert sugar, and high-fructose syrups. Making simple syrup from liquid sucrose is similar to the procedure employed when using granulated sugar. The first step is to check the Brix of the liquid sucrose to find out how much water must be added to the batch to bring the Brix of the simple syrup to the level required by the formula. Most companies' beverage documents include a table that specifies how much of the liquid sucrose and additional treated water should be added to the batch based on Brix. When liquid-sucrose supplies are received at the plant, they should be accompanied by an analysis sheet comparing the tank load against the company standards.

19.3.3 Medium Invert Sugar

Medium invert sugar is resistant to microbial spoilage when being transported from supplier to plant, and while in storage. However, good sanitation procedures are still required, as well as special precautions to prohibit secondary infection. When liquid invert shipments are received at the plant, they should be accompanied by an analysis sheet comparing the tank load against standards. The formula document should include a table that specifies how much of the sweetener and additional treated water should be added to the batch based on Brix and the percent inversion. When testing for Brix in MIS

samples, a correction factor must be used on refractometer readings to compensate for the nonsucrose solids as a result of inversion.

19.3.4 Using High-Fructose Syrups

For liquid sugars, in general, a sample should be taken before the sugar is accepted, and the analysis should confirm that the material is within standards. The installation, including receiving station, pumps, air blower/ultraviolet lamp, tanks and piping/fittings, should be of approved materials (stainless steel) and in accordance with the individual beverage company's design guidelines. High-fructose syrup is subject to crystallization, so storage temperatures should be controlled (generally maintained between 75°F/24°C and 85°F/29°C), by the use of indirect heating. The receiving station is a critical point and should be fully cleaned and hot sanitized before every delivery. As with MIS, when testing for Brix in high-fructose syrup samples, a correction factor must be used on refractometer readings to correct to true Brix and compensate for the nonsucrose solids.

No matter what type of nutritive sweetener is used, once the simple syrup has been correctly prepared in the mixing tank, it should be pumped through the syrup filter into the storage tank so that the other concentrate components may be added. Most simple syrups will be in a Brix range between 60 and 65, which makes them extremely susceptible to microbial spoilage, again, with yeast the most likely culprit. Be sure to recognize and respect any time constraints included in the syrup preparation instructions. For example, a general "rule of thumb" is that simple syrup should not be kept longer than four hours before converting it to finished syrup. If hot sugar processing is used, remember to atemperate the simple syrup to ambient temperature prior to the addition of concentrate. This will help minimize thermal degradation of the flavor oils. Also, it is very important to add the individual components in the specific order detailed in the syrup preparation instructions. Incorrect order of addition can lead to a variety of problems, including changes in viscosity, flavor degradation, nutrient breakdown, and precipitation of insoluble materials in the syrup tank.

19.4 CARBONATION

Earlier in this chapter, we discussed the history, theory, and principle of introducing CO_2 gas into water to produce a carbonated beverage. We also addressed the importance of the quality of this CO_2, as well as of the treated water used to dissolve it. In this section, we will discuss the practical aspects of carbonation control.

"Mix processing" refers to the process of combining the finished syrup, treated water, and CO_2 in the correct proportions to meet beverage specifications. In addition to the proportioning function, mix processing will usually incorporate deaeration, mixing, carbonating, and cooling, depending on the manufacturer's design and the type of products being handled. The design of mix-processing systems will vary from one manufacturer to another, incorporating the features that the manufacturer feels are advantageous to controlling production.

The primary function of the carbonating unit or the carbonator is to add CO_2 to the product. It must be carbonated to the level that, after filling and closing, results in a product within the standards for beverage carbonation. Some carbonating units incorporate cooling in the same tank or unit. The product can be slightly precarbonated with CO_2

injection and then exposed to a CO_2 atmosphere directly where cooling is in progress. Other systems separate the carbonating and cooling steps. The three most common forms of carbonating technology incorporate one or a combination of the following:

1. Conventional (atmospheric exposure) introduction;
2. CO_2 injection; or
3. CO_2 eduction.

The ability of water, or beverage, to absorb CO_2 gas, is largely dependent on the efficiency of the carbonating unit (24). Other factors that influence CO_2 absorption include

1. Product type;
2. Product temperature;
3. CO_2 pressure;
4. Time and contact surface area; and
5. Air content.

If the water temperature rises, the gas pressure must be increased if the same absorption of CO_2 is to be maintained. Conversely, if the temperature of the water or beverage entering the carbonating unit drops, the CO_2 becomes more soluble, and the pressure must be decreased to keep the volumes of carbonation within standards. Automatic CO_2 controls compensate for fluctuations in temperature, pressure, and flow. This allows the carbonating unit to produce a constant CO_2 gas absorption. Such controls are standard in modern processing units, which are available as basic units, or with computer interfaces to track the variation in product temperature, pressure, flow, and final CO_2 gas volumes absorbed during operating hours.

In many ways, this is a gross oversimplification of a process that, to this day, sometimes eludes strict control. Certainly, equipment has dramatically improved over the years, but loss of CO_2 remains a significant issue in terms of overall plant productivity. New membrane carbonation systems hold great promise for continuing this evolution, by helping to carbonate, at least in theory, more precisely and accurately than ever before. It has yet to be seen if these systems will endure the economic challenges, industry acceptance, and rigors of time.

19.5 FILLING, SEALING, AND PACKING

In the most fundamental terms, this section will address the introduction of the now freshly prepared and carbonated finished beverage into the package, and sealing it in a manner so as to preserve its integrity – simple in theory, sometimes challenging in application. The bottle-filling unit includes bottle handling/transfer components, a filling machine, and a capper/crowner.

The purpose of the filler is to fill returnable and nonreturnable bottles to a predetermined level. It should do this efficiently while minimizing foaming and deliver the bottle to a crowner or closure machine to be sealed, or, in the case of cans, to the lid seamer. A discussion of the design and engineering of filling machines is beyond the scope of this text, and is normally relegated to the specific operating manuals supplied by the respective equipment

TABLE 19.7 Problems Resulting from Foaming at the Filler

Quality	Economics/Operations.
Underfilled package	Impact on filling speed
Product residue on bottle	Loss of CO_2 and product
Incorrect CO_2 level	Increased BOD (biochemical oxygen demand) to the drain (sewer surcharge)
	Increased cost of clean-up

Source: Delonge (1994b).

vendor. Carbonated beverage fillers, to prevent the loss of CO_2 from the freshly carbonated beverage, must be counterpressured. The advantage in using CO_2 gas for counterpressure purposes at the filler bowl is to reduce product air content. With can fillers, this is possible because the counterpressure gas is normally purged from the can to the atmosphere as part of the filling process. Most bottle fillers presently in use vacate the counterpressure gas back into the filler bowl as the bottle is being filled. The empty bottle moving into the sealing position (at the filling valve) already contains air. Even if the counterpressure gas is CO_2, vacating this mixture (air and CO_2) back into the filler bowl ensures that the bowl will contain (predominantly) air. This can negate the advantage of CO_2 as a counterpressure gas, and actually be wasting CO_2 to the point of an economic disadvantage. In place of CO_2, air or nitrogen are sometimes used as the counterpressure gases.

Imagine what happens when a carbonated beverage is agitated, and then quickly uncapped. Sometimes, this same type of foaming that results can occur during filling. Foaming at the filler, even in small amounts, can cause a number of problems. Some of these deal with product quality, others with economics or plant operation, and are summarized in Table 19.7 (Delonge 1994b).

The cause(s) of foaming in a filling operation can range from a simple problem that can be corrected quickly, to one requiring extensive trial and error testing. Many times, the troubleshooting exercise requires a combination of technical skill, creativity, and experience. Some causes of foaming at the filler are summarized in Table 19.8. When the problem is a single valve, or occurs for a short period of time, it is usually easy to troubleshoot and correct. Ongoing foaming problems can be extremely difficult to correct. Manuals supplied by the manufacturer of the filler/mix processor usually address troubleshooting foaming problems in detail, and should be consulted. If the problem persists, contact the filler manufacturer.

One of the problems that can result from excessive foaming at the filler, aside from the poor aesthetics of "sticky" packages, is the formation of mold colonies on the external walls of the package. This might also be evident in the thread areas of bottles when the cap is removed. Proper sealing of the newly filled package is a critical step in the processing of carbonated soft drinks. The closure can be a variety of different types, including crimp-on metal crowns on glass bottles, screw-on metal or plastic caps on plastic bottles, or a seamed lid onto a can body. Each of these applications requires different equipment, but the over-riding objectives are the same:

1. Withstand the pressure from the CO_2 in this closed system;
2. Provide the consumer with a safely sealed product, and one with tamper evidence;
3. Prevent leakage of product out of the package; and
4. Help contribute to the visual appeal of the overall package.

TABLE 19.8 Some Causes of Foaming at the Filler.

Syrup overagitation	Glass quality and configuration
Dirty bottles	Excess air of dissolved oxygen in water
Dirty filler bowl	High syrup temperatures; warm bottles
Excessively carbonated product	Too high a liquid level in bowl
Warm product (inadequate refrigeration)	Frequent start/stop operation of filler (overagitation of product)
Line leaks (air introduction)	Carbo-cooler outlet valve not opening fully
Valve failure	Incorrect bowl pressure setting
Vent tube spreading rubber – wrong position or missing	Hot or contarminated CO_2
Vent tubes – scored, missing, loose, incorrect size	Damaged snift ferrule
Inadequate drainage after washing or rinsing	Rough transfer on A-frame
Particulates in water	Silicate or carbonate scale/deposits from water
Improper carbo-cooler operation	Worn valve liquid seal (skirt)
Inadequate carbo-cooler capacity, or operating beyond capacity	Dirty valve screens
Incorrect centering cup insert	Poor/leaking counterpressure seal
Product characteristics (more common in diets)	Worn pump seals on water, syrup, or beverage transfer pumps (air education)
Incorrect setting of valve operating/snift cams	
Bent valve operating leavers	

After proper application of the closure or lid, some beverage manufacturing plants pass the bottles and cans through a warmer, which is a tunnel of water sprays of carefully controlled temperature. The purpose is to bring the temperature of the filled packages (still cold from the chilled carbonated water introduced at the mix processor) up close to ambient. The main reason for this is to prevent excessive condensation, which can lead to problems, depending on the secondary and tertiary packagings that are used.

For example, in the United States and in many countries internationally, it is common to place bottles of carbonated beverage into rigid plastic crates for transport to a retail outlet. In these instances, warming is not usually needed, because the plastic crates are essentially inert, and allow for adequate air flow and ventilation of the product. Some products, however, perhaps because of a particular marketing promotion, will shrink-wrap multiple bottles together, then place them in a cardboard case box, and then stack them on a pallet that is stretch-wrapped for structural stacking integrity. In the second example, if the bottles were not warmed after filling, there is a high probability that the excess condensation would be trapped (by the shrink wrap), absorbed by the cardboard (presenting a mold risk), and then subjected to a "green-house effect" from the poor ventilation of the stretch wrap. It becomes quickly evident that a beverage producer's job is not complete simply because the product makes it safely to a sealed container!

19.6 QUALITY CONTROL AND ASSURANCE

In this section, we will distinguish quality "control" from quality "assurance" by having control refer to testing typically performed by the beverage plant, either immediately on-site or at a local contract laboratory. "Assurance" will refer to the subject of a broader, usually centrally managed program (for example, frequent testing of the

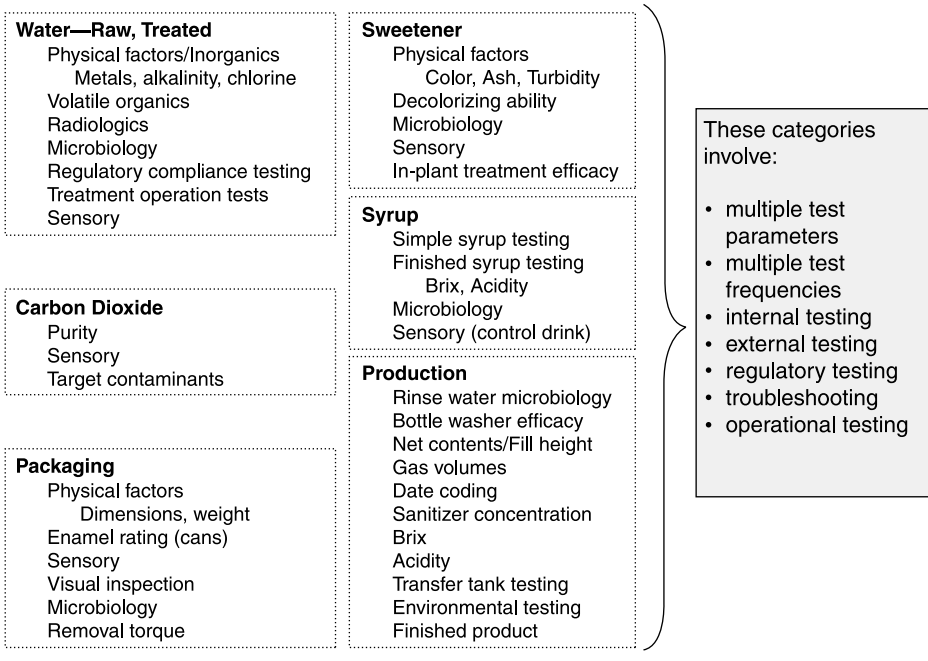

Figure 19.10 *Example of testing categories in a beverage plant quality scheme.*

product from the trade by a central corporate laboratory). Typically, the bulk of testing performed in a carbonated beverage facility falls under the category of quality control. Each company prescribes their own specific testing protocol, including the parameters to test, analytic test methods to apply, and frequency. In addition, a rigorous quality program would clearly outline the actions to be taken (and by whom) in the event that this testing demonstrates an out-of-specification situation.

Because there is no single protocol for all plants to follow, Figure 19.10 summarizes the major categories of testing to consider when evaluating a beverage plant's quality monitoring scheme. This list is by no means exhaustive, but it does provide an idea of how rigorous the monitoring and control in a beverage plant should be.

In addition to this quality control scheme, most larger beverage companies have developed formalized quality assurance schemes, which are usually under centralized corporate management. The programs generally include some auditing function to visit the production plants for compliance to standards and guidelines, and sampling of finished products from the trade. These programs vary in terms of their focus and rigor, but trade sampling provides perhaps the best representation of what the consumers in a particular market are receiving. From this perspective, the data obtained are of extreme value, and must be reviewed in concert with in-plant and external data, in order to provide the best overall picture of quality performance.

19.7 FINISHED PRODUCT

Low pH, high acidity, carbonation, and often ingredients that provide some natural antimicrobial activity (for example, d-limonene in citrus oils) – all of these combine to make

carbonated soft drinks a robust category of beverages. Of course, "robust" is a relative term, so as not to imply that carbonated beverages are completely immune to problems in the finished product. The formulas, however, go a long way in providing a margin of "designed" product safety.

In fact, for non-fruit-juice-containing carbonated beverages, the types of problems that are typically encountered in the trade are relatively few, and rarely, if ever, present a health or safety threat to the consumer. Microbiologically, we have already mentioned the possibility of having mold form where the overall moisture in the environment is not controlled. For example, remember the scenario of freshly filled bottles, moist with condensation, then shrink wrapped, palletized, and stretch wrapped. The resulting "green-house" effect could easily provide the necessary conditions in which mold could grow. In finished product, however, these beverages might contain a variety of organisms, but they will not remain viable under the conditions of the beverage. Only aciduric organisms can multiply, and these include some molds, yeasts, lactic acid bacteria, and acetic acid bacteria (Ray 2001). Of these, the clear majority of microbial problems are caused by spoilage yeast. This "spoilage" normally refers to any condition that affects the design appearance, flavor, or aroma of the product, and is usually a problem of esthetics where carbonated soft drinks are concerned.

In addition, as with any packaged products, the packaging materials can be the source of finished product problems. For example, misapplication of closures may occur, where removal torque is so high that consumers have difficulty opening the bottles. In areas of the world where returnable bottles are used, depending on their handling, they can become badly scuffed, presenting an unappealing look to the consumer.

Many problems with the finished product can be – and are – averted before the product ever leaves the beverage facility. This is due, in large part, to the diligent monitoring of the soft drink manufacturing process from beginning to end. We have already learned that the raw materials are held to high standards of quality upon receipt, and some–like water, sucrose, and carbon dioxide – are often further purified within the beverage plant itself. Then, these raw materials are combined into a finished syrup, and it is checked against standards of assembly and quality. This finished syrup is then diluted and carbonated, filled, then sealed to form the final beverage. The final product is tested chemically, microbially, and sensorially, to assure that it meets the highest standards of its trademarked brand.

This said, the summary above represents only a small portion of the quality systems that overarch most finished products, and which are clearly beyond the scope of this text. Suffice to say that many beverage companies begin to control quality as far back in the supply chain as possible – so far that some companies own their own citrus groves in order to strictly control the quality of the orange juice used in their orange-juice-containing carbonated beverages! In addition, as the principles of HACCP (Hazard Analysis and Critical Control Points) become more commonplace in the beverage industry, many bottlers and canners are voluntarily formulating their own HACCP plans to formalize the monitoring and control of their processes. All of this is done with a single, predominant end-goal in mind – to provide the consumer with a consistently high-quality, great-tasting, refreshing beverage.

20.1 INTRODUCTION

The production of alcoholic beverages is as old as history. Wine may have an archeological record going back more than 7.5 thousand years, with the early suspected wine residues dating from early to mid-fifth millennium B.C. (McGovern and others 1996). Clear evidence of intentional winemaking first appears in the representations of wine presses that date back to the reign of Udimu in Egypt, some 5000 years ago. The direct fermentation of fruit juices, such as that of grape, had doubtlessly taken place for many thousands of years before early thinking man developed beer brewing and, probably coincidentally, bread baking (Hardwick 1995). The oldest historical evidence of formal brewing dates back to about 6000 B.C. in ancient Babylonia: a piece of pottery found there, shows workers either stirring or skimming a brewing vat.

Nowadays, alcoholic beverage production represents a significant contribution to the economies of many countries. The most important beverages today are beer, wine, distilled spirits, cider, sake, and liqueurs (Lea and Piggott 1995). In Belgium ("the beer paradise"), beer is the most important alcoholic beverage, although beer consumption has declined in the last 40 years: from 11,096,717 hL in 1965 to 9,702,619 hL in 2004 (Anon. 2005a). In this time frame, wine consumption doubled from 1,059,964 to 2,471,388 hL. Another trend is the spectacular increase in water and soft drinks consumption (from 5,215,056 to 26,395,000 hL).

The principal raw materials used to brew beer are water, malted barley, hops, and yeast. The brewing process involves extracting and breaking down the carbohydrate from the malted barley to make a sugar solution (called "wort"), which also contains essential nutrients for yeast growth, and using this as a source of nutrients for "anaerobic" yeast growth. During yeast fermentation, simple sugars are consumed, releasing energy and producing ethanol and other flavoring metabolic byproducts. The major biological changes that occur in the brewing process are catalyzed by naturally produced enzymes from barley (during malting) and yeast. The rest of the brewing process largely involves heat exchange, separation, and clarification, which only produces minor changes in chemical

composition when compared to the enzyme-catalyzed reactions. Barley is able to produce all the enzymes that are needed to degrade starch, β-glucan, pentosans, lipids, and proteins, which are the major compounds of interest to the brewer. An overview of the brewing process is shown in Figure 20.1, where the input and output flows are also indicated. Table 20.1 gives a more detailed explanation of each step in the process.

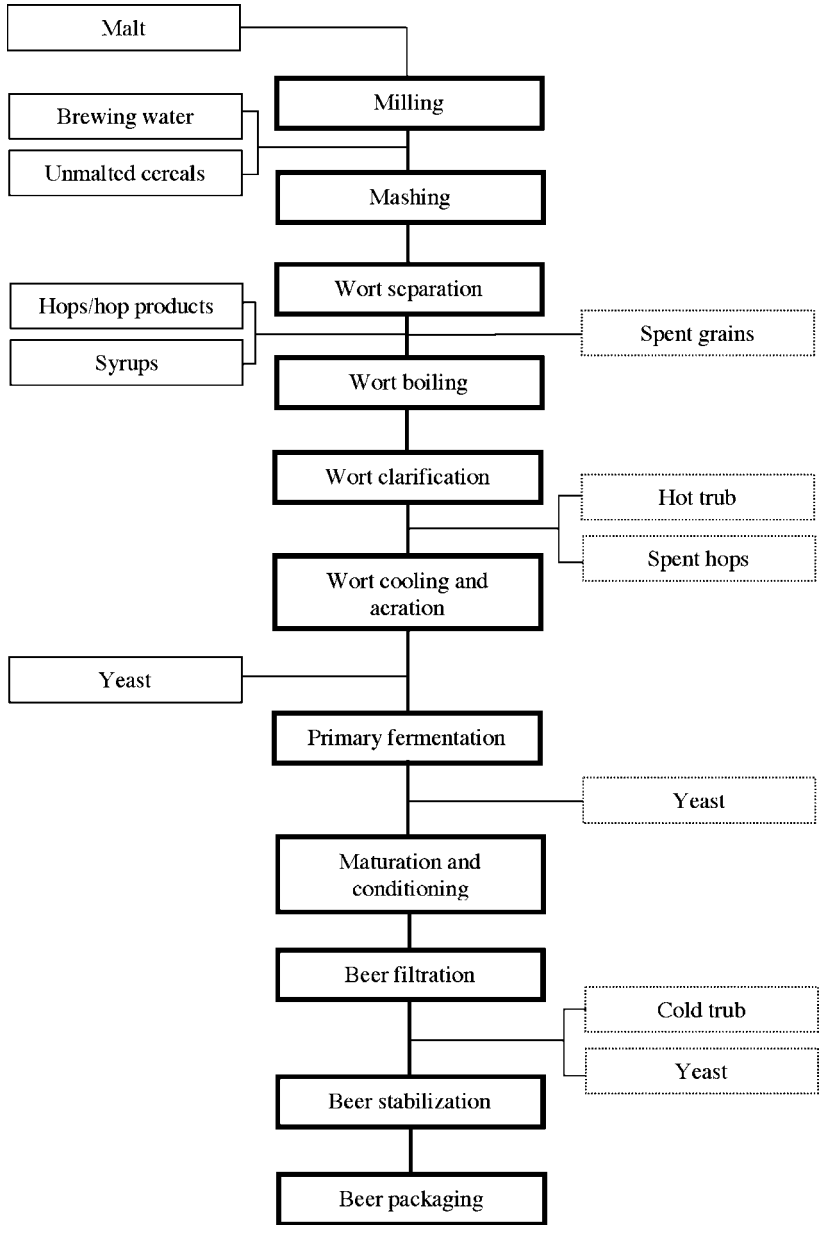

Figure 20.1 *Schematic overview of the brewing process (input flows are indicated on the left side and output flows on the right side).*

TABLE 20.1 Overview of the Brewing Processing Steps: From Barley to Beer.

Process	Action	Objectives	Time	Temperature (°C)
Malting				
Steeping	Moistening and aeration of barley	Preparation for the germination process	48 h	12–22
Germination	Barley germination	Enzyme production, chemical structure modification	3–5 days	22
Kilning	Kilning of the green malt	Ending of germination and modification, production of flavoring and coloring substances	24–48 h	22–110
Milling	Grain crushing without disintegrating the husks	Enzyme release and increase of surface area	1–2 h	22
Mashing + wort separation	Addition of warm/hot water	Stimulation of enzyme action, extraction and dissolution of compounds, wort filtration, to obtain the desired fermentable extract as quickly as possible	1–2 h	30–72
Wort boiling	Boiling of wort and hops	Extraction and isomerization of hop components, hot break formation, wort sterilization, enzyme inactivation, formation of reducing, aromatic and coloring compounds, removal of undesired volatile aroma compounds, wort acidification, evaporation of water	0.5–1.5 h	>98
Wort clarification	Sedimentation or centrifugation	Removal of spent hops, clarification (whirlpool, centrifuge, settling tank)	<1 h	100–80
Wort cooling and aeration	Use of heat exchanger, injection of air bubbles	Preparing the wort for yeast growth	<1 h	12–18
Fermentation	Adding yeast, controlling the specific gravity, removal of yeast	Production of green beer, to obtain yeast for subsequent fermentations, carbon dioxide recovery	2–7 days	12–22 (ale) 4–15 (lager)
Maturation and conditioning	Beer storage in oxygen-free tank, beer cooling, adding processing aids	Beer maturation, adjustment of the taste, adjustment of CO_2 content, sedimentation of yeast and cold trub, beer stabilization	7–21 h	−1–0
Beer clarification	Centrifugation, filtration	Removal of yeast and cold trub	1–2 h	−1–0
Biological stabilization	Pasteurization of sterile filtration	Killing or removing of microorganisms	1–2 h	62–72 (past.) −1–0 (filtr.)
Packaging	Filling of bottles, cans, casks, and kegs; pasteurization of small volumes in packings	Production of packaged beer according to specifications	0.5–1.5 h	−1 to room temperature

20.2 BREWHOUSE OPERATIONS

20.2.1 Introduction

The technology of brewing (wort production) can be classified into six unit processes: grinding of malt and adjuncts, mashing, wort filtration, wort boiling, wort clarification, and wort cooling and aeration. Figure 20.2 shows schematically the different unit operations in the brewhouse. In a classical brewhouse, the malt is milled and the grist is mixed with brewing water ("mashing in"). Mashing can be performed using the infusion method or the decoction method. In the case of using adjuncts with a high gelatination temperature, the use of an adjunct cooker is necessary. In the filter vessel or the mash filter, the liquid extract ("the wort") is separated from the insoluble material (called "the spent grains"). Next, wort is boiled in a boiling vessel. After boiling, the hot trub is removed by a whirlpool (or a sedimentation tank, or a centrifuge), and cooled using a plate heat exchanger until fermentation temperature and aerated.

The aim of the brewhouse operations is to make a malt (and adjunct) extract as efficiently as possible. During the brewing process a few chemical transformation processes occur, that is, the oxidation of polyphenols, the formation of lipid–protein complexes and the precipitation of proteins. The nitrogen and carbohydrate composition of the wort depends on the enzyme-to-substrate ratio, that is, the ratios α- and β-amylases/starch and endo-peptidases/proteins. These ratios can be adjusted by the following techniques: the use of substrates without enzyme activity (adjuncts) reduces the amount of nitrogen in wort, thermal destruction of enzymes by boiling during decoction mashing, adjusting the pH to influence the activity of the enzymes, adjusting the malt/water ratio, which has an influence on the activity of certain enzymes during mashing (e.g., proteolytic proteins are more active in a concentrated mash).

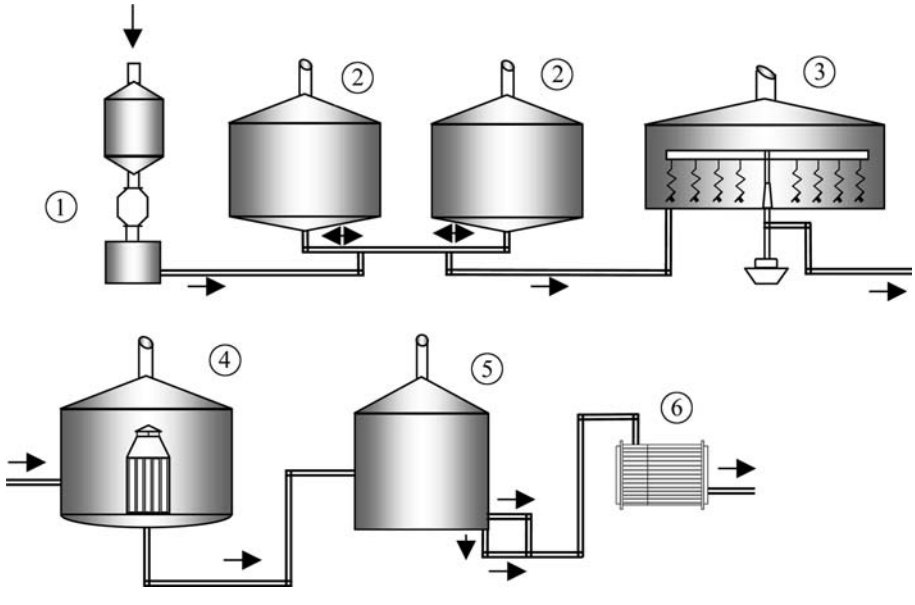

Figure 20.2 *Wort production in a classical brewhouse: 1. malt grinding, 2. mash vessels (decoction mashing), 3. wort filtration in a filter vessel, 4. wort boiling, 5. wort clarification in a Whirlpool, 6. wort cooling (heat exchanger).*

20.2.2 Malt Milling

By milling malt, the starchy endosperm will become better accessible for the malt enzymes and this will improve the extraction process. The selected milling technique depends on the methods of mashing and separation that are used. Milling should be performed in conditions that preserve the structure of the husks when a lauter or mash tun is used, as in this case the husks are needed to build up the filtration bed. The husks are more elastic and will be less damaged during milling when they are more humid. Therefore, the malt is usually made humid (called "conditioned" or "wet" milling) before it is milled. Dry or wet milling is performed in a roller mill. When modern thin-bed mash filters are used, filtration is performed using a filter cloth and intact husks are not needed. For this case, malt is milled very finely using a hammer mill. In modern mills, the milling is performed in the presence of deaerated water to avoid oxygen take-up, using a disc (Biche and others 1999; De Brackeleire and others 2000) or rotor–stator (Anon. 2004) system.

20.2.2.1 Dry Milling. Dry milling is the most popular milling technique (Kunze 1999; N.N. 1999). The degree of malt modification, the position and the type of roll surface (smooth or fluted) determine the particle distribution. Roller and hammer mills can be used for dry grinding.

Rolling mills operate by passing the malt through the narrow gap between pairs of closely spaced rotating rolls. Various roll arrangements are possible: 2, 3, 4, 5, or 6 rolls (Table 20.2). Most designs have 2 or 3 pairs with an intermediate separation stage or stages. This enables the fine material, which does not need further milling, and the husks to be separated from coarser material, which does need further milling. Oscillating (frequency of 6–12 Hz) sieves perform the separation steps. The sieves are equipped with a large number of rubber balls or other proprietary sieve cleaners. The mill with 6 rolls gives the best results and is used most frequently.

In a hammer mill, the malt is reduced in size to fine grist. A large rotating drum on which small hammers are mounted, propel the dry cereal against a striking plate. The produced fine grist is sieved at the base of the drum. The length and number of hammers, screen perforation size, and rotation speed influence the particle size of the grist, capacity, and power consumption and heat generation.

20.2.2.2 Milling with Conditioning. In this process, the malt is moisturized with cold or hot water, or steam. Moist husks are more pliable and will be less damaged in a roll mill. The temperature inside the kernel may not exceed 40°C to avoid damage to

TABLE 20.2 Types of Roller Mills.

Roll Arrangement	Capacity (kg/h/mm)	Uses	Suitability
2 rolls without sieves	1.5–2.5	Malt and cereals	Small "pub breweries" only
3 rolls without sieves	2.0–3.0	Malt and cereals	Small "pub breweries" only
4 rolls with or without sieves	2.0–6.0	Malt	Lauter tuns and mash filters
5 rolls with sieves	2.0–6.0	Malt	Lauter tuns and mash filters
6 rolls with sieves	2.0–10.0	Malt	Lauter tuns
6 rolls with sieves	1.5–8.0	Malt	Mash filters

Source: N.N. (1999).

the enzymes. The total water content increases by about 0.7%. This corresponds to an increase in water content of the husks of 1.5–1.7% and 0.3–0.5% of the endosperm. The effect of the conditioning results in an increase of the husk volume of about 10–20%, an easier separation of the grist and husks fraction, an increase in filtration rate in a lauter tun, an increased yield and attenuation, and a faster starch degradation. Conditioning can be performed using a conditioning screw where the malt is wetted when it passes through a screw conveyor.

20.2.2.3 Wet Milling. The moisture content of the husks can be raised to 20% by keeping the endosperm nearly dry in a hot water conditioning mill. This process is referred to "hot water conditioning" (Anon. 1999). In this case, the endosperm is squeezed from the husk through a single pair of rolls. After milling, mashing water is immediately added. The quantity of conditioning water depends on the malt quality, degree of modification, and achieved steeping degree.

In the "steep conditioning" process, the moisture content is raised to a much greater extent and becomes part of the mashing process. Typically, steeping lasts between 10 and 30 min at a temperature between 30 and 50°C. The temperature and duration depend on the modification and the moisture content of the incoming malt. The moisture content of the malt increases to 25–30%. The total milling and mashing-in time is in the range 30–45 min.

20.2.3 Mashing

Mashing starts with mixing the grist and brewing water (called "mashing-in"). Hydration enables the malt enzymes to become active. Today, mashing-in is part of the milling process, where it is performed in the milling equipment. Formerly, a "premasher" ("foremasher" or "grist hydrator") mixed the grist and the water on their way into the mash vessel. Deaerated water is used to minimize oxygen uptake. Typically, 2–4 hL water is used for 100 kg malt, depending on the selected brewing method and density of the produced beer.

During mashing, the malt content is solubilized by making use of the enzymes of the malt and the extract is obtained (Table 20.3). By manipulating the temperature profile and the duration of rest periods at specific temperatures, the brewer is able to influence the composition and efficiency with which the malt is extracted. The mashing operation will influence the alcohol content of the beer, the concentration of unfermented sugars in the beer, the peptide and amino acid profiles of the wort, the yeast nutrient concentration, the buffering capacity and pH of the wort and beer, the β-glucan content of the beer, and some beer physical properties such as foam, color, and clarity (Rehberger and Luther 1995).

20.2.3.1 Enzymatic Degradation Processes

Starch Degradation. Starch is degradated by α- and β-amylase, limit dextrinase, maltase, and saccharase (Table 20.3). Gelatinized starch is needed for β-amylase in order to degrade starch efficiently. Barley starch gelatinizes in the presence of amylases at 60°C. Rice starch gelatinizes at 80–85°C and thus needs to be gelatinized before it is added to the mash. Pregelatinization is performed in an adjunct cooker. The action of the α-amylases will result in a decreased viscosity of the gelatinized starch

TABLE 20.3 Active Enzymes During Mashing.

Enzyme	Optimum pH	Optimum Temperature (°C)	Inactivation Temperature (°C)	Hydrolysis Reaction	Product
			Starch Degradation		
β−Amylase	5.4−5.6	60−65	70	α-1,4 bond at the nonreducing end of starch	Maltose
α-Amylase	5.5−5.8	70−75	80	α-1,4 bond in starch	Dextrin
Limit dextrinase	5.1−5.5	55−60	65−70	α-1,6 bond in starch	Dextrin (straight chain)

("liquefaction"). The complete degradation of starch to maltose and dextrines by amylases is called saccharification. Starch breakdown must be monitored because residues of undegraded starch and dextrins cause starch hazes in beer. Starch degradation can be easily monitored by checking the color of a mixture of a mash sample and an iodine solution (iodine test): a positive starch is indicated by a blue/black color. α-Amylase is active during malting (5−10% starch degradation), but is much more active on gelatinized starch. It needs Ca^{2+} as a cofactor, and does not produce maltose during degradation. β-Amylase is present during malting, but is not active. It produces maltose, β-dextrins, glucose, and maltotriose from amylose and amylopectin. Limit dextrinase breaks the

1,6-bonds in small, branched dextrins. Its presence in malt is limited. Maltase hydrolyses maltose into glucose molecules. However, it is not active above 40°C.

Cell Wall Degradation. Cell walls are essentially composed of β-glucan and hemicellulose. Cell wall degradation starts during malting and continues during mashing by endo-β-glucanases, β-glucan solubilase, and endo-xylanase (Table 20.3). An insufficient degration of high MW β-glucan molecules results in a high viscosity and can give problems during wort and beer filtration (Meilgaard 1976). The extent of the problems can be diminished by the extent of malt modification or adding commercial β-glucanase preparations (O'Rourke 1996). An insufficient degradation of pentosans (hemicellulose) can result in filtration and haze problems (Coote and Kirsop 1976; Viëtor and other 1991; Cach and Annemüller 1995; Han and Schwarz 1996; Stewart and others 1998). Pentosans (also called arabinoxylans) can be degraded to arabinose and xylose by xylan solubilase, endo- and exo-xylanase, arabinosidase, and xylobiase (Fincher and Stone 1993; Debyser and others 1997, 1998).

Protein Degradation. Protein degradation products influence fermentation and beer flavor (lower molecular weight (MW) degradation products), palate fullness (amino acids and higher MW degradation products), color (Maillard reaction), and beer foam (higher MW degradation products). A too extensive proteolysis gives bad foam, too dark color, poor palate fullness, but a good colloidal stability. During malting and mashing, 35–40% of the total protein content is degraded. During malting 60% of the amino acids are produced, the rest during mashing. Carboxypeptidases play an important role in the production of amino acids, due to their optimal pH and temperature conditions (Table 20.3). The enzymatic breakdown of proteins occurs predominantly at 45–55°C, but does not stop even at higher temperatures. With a rest period at 45°C, more lower MW products are formed. It is necessary to supply yeast with sufficient α-amino acids for growth and metabolism. The α-amino nitrogen concentration must be at least 20 mg/100 ml wort (Kunze 1999). Worts from normally modified malts always contain sufficient α-amino acids. At 55°C, more high-MW compounds are produced. When mashing with well-modified malts, the extent of proteolysis is much less than that derived from the malting process (Lewis and others 1992). A long rest at 50°C always results in a poor foam (Kunze 1999).

20.2.3.2 Mashing Methods. Mashing is performed in a mashing vessel (also called mashing tun, mash mixer, or mash converter). Nowadays, it is constructed in stainless steel and heated with steam through semicircular pipes welded on the tun bottom and body. An agitator is used to ensure efficient and homogeneous mixing during mashing.

Possible rest periods, which are chosen at the temperature optima of the enzymes, are at the following temperatures:

- 45–50°C for proteolysis and β-glucan degradation;
- 62–65°C for maltose production (β-amylase);
- 70–75°C for saccharification (α-amylase); and
- 78°C as the final mash temperature to inactivate the carbohydrate enzymes and fix the amount of fermentable sugars.

Mashing methods can be classified into two types of processes: infusion and decoction processes.

Infusion Method. In infusion processes, the entire mash is heated up (with appropriate rest periods) to the final mashing temperature. Infusion methods can be classified as increasing temperature (German infusion method) and decreasing temperature (English infusion method) infusion processes (Fig. 20.3 shows some examples). A classical German infusion method starts with a rest period at 45–50°C (proteolysis) for 30 min. Next, the temperature is raised to 62–65°C and kept at this temperature for 30–45 min (β-amylase). The next rest period is at 70–75°C until complete saccharification (α-amylase). The process ends at 78°C. In the English infusion method, the temperature is initially raised by adding hot water to the mash. This method requires well-modified malt, because a part of the active enzymes are destroyed by the addition of hot water. An alternative English method is to perform the conversion processes at a single temperature, usually 63–65°C ("isothermal infusion mashing"). These English infusion methods are used for the production of ales (top fermentation), where both mashing and wort separation take place in the same vessel (O'Rourke 1996).

The advantages of the infusion method are that this process can be easily automated and controlled, and energy consumption is 20–30% lower than for the decoction method (Kunze 1999). Disadvantages are the rather worse iodine reaction and the possibly rather lower brewhouse yield.

Decoction Method. In decoction processes, the temperature is increased by moving part of the mash from the mash converter to the mash cooker where it is boiled (possibly also with carbohydrate rest periods in the mash cooker). By pumping it back to the remainder of the mash in the mash converter, the temperature of the total mash is increased to the next higher rest temperature.

The decoction method is traditionally used in Germany for the production of lager beer. Depending on the number of boiled mashes, decoction methods can be classified as single-, two-, and three-mash processes. Today, only the single- or two-mash processes are used. The three-mash process consumes a lot of energy and is only used for the production of some special beers. A typical two-mash scheme is shown in Figure 20.3(*c*).

The removal and boiling of the boiled mashes have the following effects (Kunze 1999):

- Less protein breakdown in the boiled mash because of more rapid heating;
- More extensive gelatinization and saccharification of the starch;
- Increased extraction of the husks;
- Increased formation of melanoidins (Maillard reaction);
- Increased removal of dimethyl sulfide (DMS);
- Reduced amounts of active enzymes in the total mash; and
- Possibly a higher brewhouse yield.

20.2.4 Wort Separation (Lautering)

During the lautering process (also called "wort separation" or "mash separation") the undissolved substances are separated from the wort. The insoluble part (spent grains) consists of the husks, the seedlings, and other insoluble material. Wort separation is a filtration process. As much of the extract as possible should be recovered during

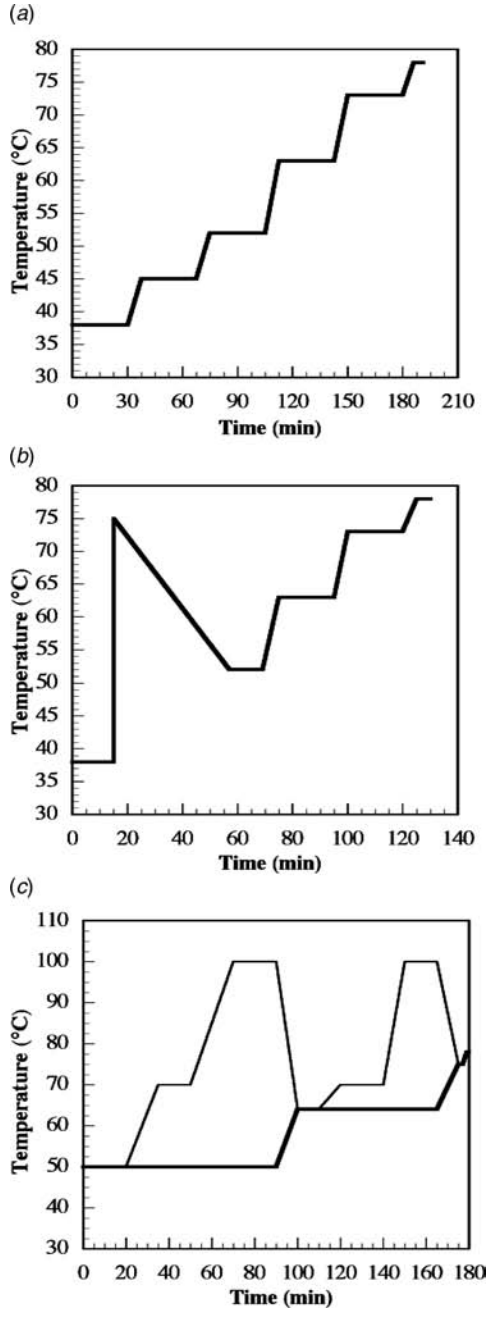

Figure 20.3 *Mashing schemes: (a) increasing infusion mashing, (b) decreasing infusion mashing, (c) two mash decoction process.*

lautering. The extraction efficiency is measured as "extract yield", which is the ratio of the mass of extract to the mass of malt or malt and adjunct (Rehberger and Luther 1995).

The filtration can be performed in a lauter tun or a mash filter. Developments in wort separation, which have been introduced over the last 15–20 years, are summarized in Table 20.4.

20.2.4.1 Mash Separation with a Lauter Tun. Today, lauter tuns are made of chrome–nickel steel and thermally insulated. A spent grain filtration layer is formed on a welded wedge wire false bottom of chrome–nickel steel, which is fixed 10–20 mm above the tun bottom. Up to 15% of the false bottom surface is composed of gaps. The lauter tun is initially filled with hot (78–80°C) water and the mash is next fed from the bottom to keep the oxygen uptake as low as possible. The loading depends on the quality of the raw material: 170–210 kg/m^2 in the case of conditioned milling and 200–280 kg/m^2 in the case of steep conditioned milling (Kunze 1999; Narziss 2005). At the bottom of the tun are runoff ports for collection of the liquid from the mash.

After filling the tun, the spent grains settle for 20–30 min and form the filtration layer (height of ~30–40 cm; 60–70 cm in the case of wet milling). A tun bottom dough, which consists of particles that have passed through, collects at first between the tun bottom and the false bottom. It is pumped back with the first cloudy wort until the withdrawn wort is clear. The first wort passes through the spent grains and is thereby filtered. Rakes cut the filtration layer in order to keep the pressure difference over the layer as low as possible. The first wort is allowed to run off until the spent grains become visible. Next, sparge water (75–78°C) is used to wash the mash and to displace the wort downwards. When the filtration operation is complete, the remaining water is drained to sewer and the spent grains are discharged.

20.2.4.2 Wort Separation with a Mash Filter. These filters perform wort separation in a thin bed (6–7 cm) process. Their basic design evolved from early inefficient units that produced high wort turbidity and solids to modern (on the market since the beginning of the

TABLE 20.4 Developments in Wort Separation.

Aim	Development
Extended beer-keeping quality	• Minimize oxygen pick up • Avoid excessive shear in stirring and transfer of mash
Increase collection gravity	• Reduce volume of lauter bottom chamber
Improve wort clarity	• Control milling procedures • Recirculation of initial worts • Sparging from inside to outside of thin compressed grain bed with new mash filter
Achieve higher extract yield	• Reuse of covered weak worts • Finer milling with new mash filters
Shorten cycle time	• Introduce new lauter knife designs and ensure balanced runoff from tun floor • Use thin bed in mash filters

1990s) fully automated units that produce up to 14 quality brews per day. A successful, modern mash filter is the Meura 2001 from the company Meura (Tournai, Belgium) (Jones 1992; Melis and Eyben 1992; Anon. 2005b). This filter consists of a fixed end frame and rear caisson, together with the side support beams form the basic framework of the machine. Within the frame is a hydraulic ram, which moves the mobile end into the open or closed position. In the closed position this compresses the plate pack composed of alternately placed polypropylene plates (polypropylene filter cloths on both sides through which the wort can flow) and polypropylene frames (elastomer membranes on both sides to compress the mash through air injection). The frames are connected via pneumatic tubing to a main compressed air header above the machine. The number of plates and frames installed and thus the length of the entire filter is determined by the required raw material capacity.

The Meura 2001 filter travels through three operation phases:

1. Filling–filtration;
2. Precompressing–sparging; and
3. Compression phase (Anon. 2005b).

During the first phase, the mash enters the filter from below and is distributed over the various chambers. When the filter is filled and the bed has started to form on the cloths, the wort will start to run bright. Once all the mash has been transferred, the transfer line is rinsed and the filter beds are precompressed. After filtration, more than 80% of the soluble sugars can be recovered. As a result of precompression and relatively "slow" sparging, the sparge rate can be as low as 2.2 hL/100 kg malt grist. Precompression of the filter beds, prior to sparging, helps to recompose the bed and makes it possible to recover most of the extract with heavy worts. In a final phase, dewatering is achieved by mechanical compression of the cakes by inflating the elasticated membranes.

20.2.5 Wort Boiling

Wort boiling is a complex process during which a wide range of chemical, physicochemical, physical, and biochemical reactions occur. Wort boiling is the most energy-intensive stage in the brewing process. Brewhouses that are equipped with old technology require a lot of energy to heat up the wort and are characterized by a long-lasting boiling process. Alternative wort-boiling technologies, such as low-pressure boiling and high-temperature wort boiling, have been studied in detail during the last decades, with a focus on the reduction of primary energy consumption. Recently, new boiling systems have been developed and commercialized (Willaert and Baron 2005). The new systems reduce energy consumption still further and are all characterized by exerting a low thermal stress on the wort during boiling. A low thermal load has a positive influence on the sensorial and foam characteristics of the produced beer. The thermal stress can be quantitatively assessed by measuring the colour, thiobarbituric number or the concentration of high-temperature indicators (Manger 2000). The thermal load can be reduced by (combining) the following measures:

- Application of the infusion mashing technique (instead of decoction mashing);
- Reduction of the heating time of the wort before boiling;
- Reduction of the boiling time;

- Reduction of the temperature during boiling and high-temperature holding periods;
- Reduction of the filling and rest time of the whirlpool;
- Reduction of the wort cooling time.

20.2.5.1 Wort Boiling Objectives. The wort has to be boiled just before it is aerated and used as the nutrient broth for alcoholic fermentation by the yeast cells. The wort boiling process aims at several objectives (see Table 20.5), as in the following.

Extraction and Isomerization of Hop Components. Bitter hops – hop cones, pellets type 90 or 45 – are added at the start of the boiling process. It is necessary to sustain a high temperature over a certain time to obtain a high isomerization yield of the α-acids. The isomerization yield depends on:

- The nature of the isohumulone (cohumulone gives the best yield);
- The duration of the boiling;
- The pH (a higher pH gives a higher yield, but the obtained bitterness at lower pH is more balanced and finer, and thus preferred);
- The humulone concentration (decreasing yield upon increasing concentration);
- Precipitation of isohumulone with the hot break;
- The use of more efficient extraction procedures (such as the use of higher temperatures);
- Size of the hop fragments (extraction rate is higher for milled hop cones or pellets).

Nowadays, the brewer can choose between different hop products. Some hop products, such as isomerized pellets, isomerized kettle or hop extracts, and reduced isomerized α-acids (i.e., tetra hydro-iso-α-acids), are already isomerized before they are used and

TABLE 20.5 Objectives of the Wort Boiling Process.

Objective	Influencing Parameters
Extraction of α-acid	Temperature, fragment size
Isomerization of α-acid	Temperature, boiling time, pH, humulone concentration
Coagulation of proteins (hot break formation)	Boiling time, nature and manner of boiling, heating system, copper shape and wort flow configuration, temperature of heating medium, wort composition (malt modification, kilning temperature, mashing temperature, pH)
Wort sterilization and inactivation of enzymes to fix the wort composition	Boiling time, temperature
Formation of reducing and aromatic compounds (Maillard reaction)	Water content, pH, oxygen, concentration, temperature, reaction (boiling) time
Formation of coloring substances	pH, parameters influencing the Maillard reaction
Removal of undesired volatile aroma compounds	Temperature, boiling time, pH, evaporation rate
Acidification of the wort	Hop addition, intensity of the Maillard reaction, alkaline phosphates and Ca^{2+} and Mg^{2+} content, malt type
Evaporation of water	Temperature, boiling time

Source: Narziss (1978), Hough and others (1982), Narziss and others (1982a), Miedoner (1986), Enari (1991), Narziss (1992), Kunze (1999).

need not be added at the wort copper, but can be applied at the end of the brewing process. By using these new hop products, it is no longer necessary to keep the wort over a "long" period at a high temperature.

Hot Break Formation. During boiling, two types of compounds are formed:

1. Compounds consisting of proteins and polyphenols, and compounds consisting of proteins and oxidized polyphenols that are insoluble in hot wort and precipitate as hot break;
2. Compounds formed from protein degradation products and polyphenols, which remain in solution during boiling and only precipitate as cold break when the wort is cooled (Kunze 1999).

Polyphenols are not directly involved in protein coagulation because protein–polyphenol complexes are based on hydrogen bondings, which have only a very weak binding energy at boiling temperatures and are unstable under these conditions (Miedaner 1986; Narziss 1992). Hot break formation is encouraged by longer boiling times, vigorous movement of the boiling wort (which improves the reaction between proteins and polyphenols), and a low pH, because the coagulation is best accomplished at the isoelectric point of the proteins. To obtain a sufficient coagulation, a pH of 5.2 is recommended (Narziss 1992; Kunze 1999). The isoelectric pH of some proteins – such as β-glubulins, δ- and ε-hordein – is very low (pH 4.9) and cannot always be realized during wort boiling. The removal of high-MW coagulable proteins is very important for the composition and the quality of the finished beer. Insufficient coagulation and removal result in a poor fermentation because the transport of substrates to and products from the yeast cells is hindered by the hot break adsorbed on the yeast cell walls. This leads to an insufficient pH drop during the primary fermentation and therefore to an incomplete elimination of proteins during the main fermentation, followed by a poor clarification during storage. This can result in a beer with a harsh bitterness ("protein bitterness") and a poor colloidal stability. The level of coagulable nitrogen in the finished wort is an important figure for the characterization of the efficiency of wort-boiling processes, and the evaluation and comparison of different boiling systems. The level of coagulable nitrogen in unboiled wort is in the range of 35–70 ppm and is reduced during boiling to 15–25 ppm with a recommended optimal value of 15–18 ppm. A low coagulable nitrogen concentration is beneficial for a good colloidal stability in the finished beer, but a too low concentration can result in head retention problems (Miedaner 1986). Protein coagulation is affected by physical and technological factors (Narziss 1992), as reviewed in Table 20.5.

Wort Sterilization and Enzyme Inactivation. Only a short boiling time is necessary to obtain a sterile solution. The microflora of the malt, hop, and other adjuncts are readily destroyed. The inactivation of residual enzymes, which survived the mashing process, is also necessary to fix the wort composition. There is only a residual activity of polyphenoloxidase and α-amylases in the wort before boiling, and a short boiling time is sufficient to denature these enzymes.

The Maillard Reaction. During wort boiling, the Maillard or nonenzymatic browning reaction is rather intensive, resulting in the production of various volatile and nonvolatile aroma compounds and colored melanoidins (brown nitrogenous polymers and

copolymers). The reaction starts with an interaction of low-MW proteins, that is, amino acids, and reducing sugars, and the Amadori rearrangement (Danehy 1986; Villamiel and others 2006). From there, a rather complex reaction network is described, including the Strecker degration. The progress of the Maillard reaction can be observed by an increase in wort color, by measuring the concentration of intermediate products (like 5-hydroxymethylfurfural (HMF), furfural, furfurylalcohol, 2-acetylfuran, 2-acetylpyrrol, and heterocyclic nitrogen compounds; Narziss and others 1983), or measuring the increase of the concentration of reductones using the "Indicator Time Test". A too intensive, uncontrolled reaction can lead to unattractive flavors in beers. The formed melanoidins are reducing compounds, but are also involved in the oxidation of higher alcohols in fresh beer, resulting in volatile aldehydes (Hashimoto 1972). Melanoidins can exert pro- and antioxidant effects (Ames 2001a). Although the structures of melanoidins isolated from foods are unknown (Ames and Nursten 1989; Ames 2001b), considerable progress has been made in recent years concerning the structures of melanoidin-like materials.

Formation of Coloring Substances. Wort boiling results in an increase in wort color: typically 4 EBC units for a light-colored beer. This increase is due to the formation of melanoidins, the caramelization of sugars and the oxidation of polyphenols. As the extent of the Maillard reaction is higher at a higher pH, the color increases with increasing pH of the wort. Thermal stress during wort boiling can also be monitored by the thiobarbituric acid coefficient (TBC), number (TBN), or index (TBI). The TBC values can also give (in combination with the coagulable nitrogen concentration) information about the expected foam stability of the produced beer (Wasmuht and Stippler 2000).

Removal of Unwanted Volatiles. During malting, *S*-methylmethionine (SMM) is formed. This compound is the precursor of dimethylsulfide (DMS), which gives a unpleasant smell and taste when present in the finished beer. At high temperatures, that is, during kilning, mashing (decoction method), and boiling, SMM is decomposed to DMS (Anness and Bamforth 1982). This DMS is very volatile and can be readily removed with the vapor during boiling. The transformation of SMM to DMS fits a first-order reaction with a half-lifetime of 30–70 min at 100°C (Narziss 1992). The formation of DMS is considerably lower at pH 5.0 compared to a pH of 5.5–5.8. This determines the lower pH limit value of the wort at the start of boiling. An optimal combination of boiling time and temperature has to be used, because when the boiling time is too low, the DMS concentration will be too high (but coagulable nitrogen can be acceptable); when the boiling time is too short, DMS concentration will also be too high (the coagulable nitrogen content can be correct) (Schwill-Miedaner and Miedaner 2001). On the other hand, a too high boiling temperature and too long boiling time will result in a too low coagulable nitrogen content.

The removal of other unwanted volatile compounds during boiling is also necessary. These volatiles can be classified into three groups: malt-derived volatiles, hop oils, and volatiles that are formed during wort boiling. Several unwanted volatiles have been detected in the vapor condensate during boiling; for example, a five-fold quantity of 2-acetylthiazole has to be evaporated (Wackerbauer 1983). Myrcene is a very volatile hop oil, which gives a harsh and unpleasant aroma. In contrast, β-caryophylene, β-farnesene, and humulene give a wanted hop oil aroma.

Acidification of the Wort. Upon boiling, the wort becomes slightly acidic (typically 0.1–0.3 pH units for a classical boiling process) due to the formation of melanoidins, the addition of hop acids, the precipitation of alkaline phosphates and the acidification

action of Ca^{2+} and Mg^{2+} ions with phosphates. The use of dark malts (intense Maillard reaction during kilning) will also give larger pH decrease compared to pale malts.

Evaporation of Water. Wort boiling results in the evaporation of water (and volatile organic components) and the concentration of the wort. During classical (conventional) atmospheric boiling 8–12% of the initial wort volume was evaporated (some breweries even boiled over 2 h with an evaporation rate of up to 18%). It has been shown that reduction of evaporation to as little as 2% can be achieved without hazard to flavor or other beer qualities such as bitterness, head retention, total nitrogen, and color (Buckee and Barrett 1982).

20.2.5.2 Energy Saving During Wort Boiling. The brewhouse is the biggest energy consumer in the brewery. The total electrical power requirements of the brewhouse accounts for 50% of the brewery requirements and 15% of the total heat energy requirements (Anon. 2001a). Since the oil crisis in 1972 and more recently since the introduction of stringent ecology laws and taxes, the reduction of the use of primary energy during wort boiling is of primary concern to the brewer. Today, various possibilities with regard to energy recuperation are available.

In the brewhouse, thermal energy is required to heat the mash and the wort, and to boil the wort. The energy required for mash and wort heating can be recovered during the wort cooling process. Cooling of the wort after boiling can be accomplished in two steps: before and after the whirlpool, as it has been shown in large-scale tests that cooling of the wort by casting out at a temperature of 89°C significantly reduces the TBC value (lower thermal stress) and improves the flavor stability of the produced beer (Coors and others 2000; Krottenthaler and Back 2001).

The recovered energy can be used for preheating and boiling of the wort, and for hot water production (Vollhalls 1994; Thüsing 2000). Energy recovery can be accomplished by reducing the boiling time, using a vapor condenser for the production of hot service water with or without wort heating, mechanical vapor compression, thermal vapor compression with or without wort heating (Fig. 20.4).

Thermal and mechanical vapor compression is mainly used in the atmospheric boiling method because the vapor compression demands calandria for larger amounts of wort. An outlet temperature of 107–108°C is required if a calandria in combination with low-pressure boiling is used. The choice of an energy recuperation system will depend on the total evaporation rate, the hot water demand and the costs for thermal and electrical energy (Thüsing 2000, 2001).

Energy Saving with Vapor Condenser. The evaporated water mass during boiling contains a high energy content. The condensation of 1 kg of steam into 1 kg of water at 100°C gives an energy of 2260 kJ. Considerable heat can be saved using a vapor condenser and an energy storage system (Fig. 20.5). Instead of a one-tank storage tank, a two-tank arrangement, one tank containing the hot water ($\pm$99°C), the other the used hot water ($\pm$80°C), of the energy storage system can also be used (Lösch and Körber 1984; Lenz 1994). Nowadays, a single-layer plate heat exchanger is used as the vapor condenser. The energy recovered by the condenser is stored in the energy saver and used to heat the lautered wort before boiling. The energy saver is a hot water displacement storage tank. The vapor condensate can be further cooled to approximately 30°C using cold water, which is normally a prerequisite for its discharge into a waste water system. The vapor condensate cooler can produce hot water at a temperature of ~85°C. Only 4–5% of the total evaporation is sufficient for the production of hot water exclusively for wort

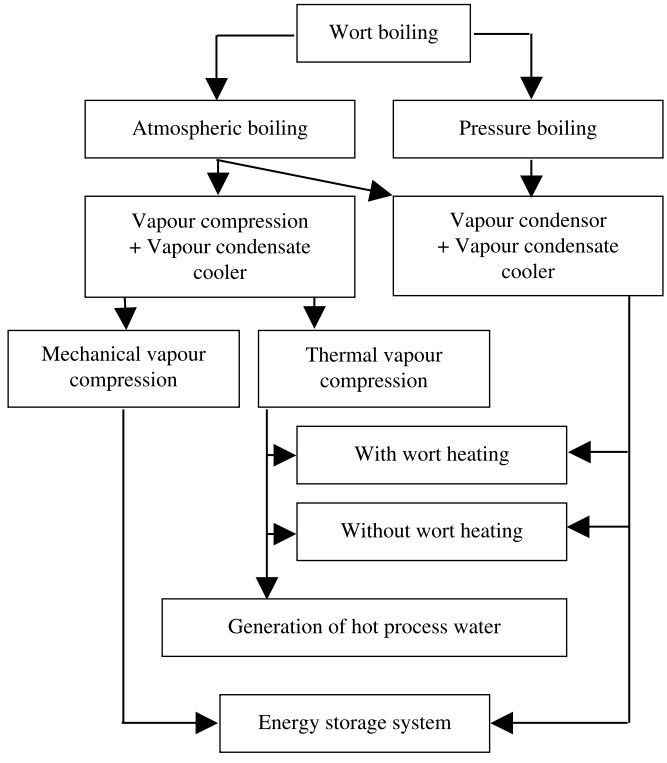

Figure 20.4 *Possibilities of energy recuperation with atmospheric or pressure boiling.*

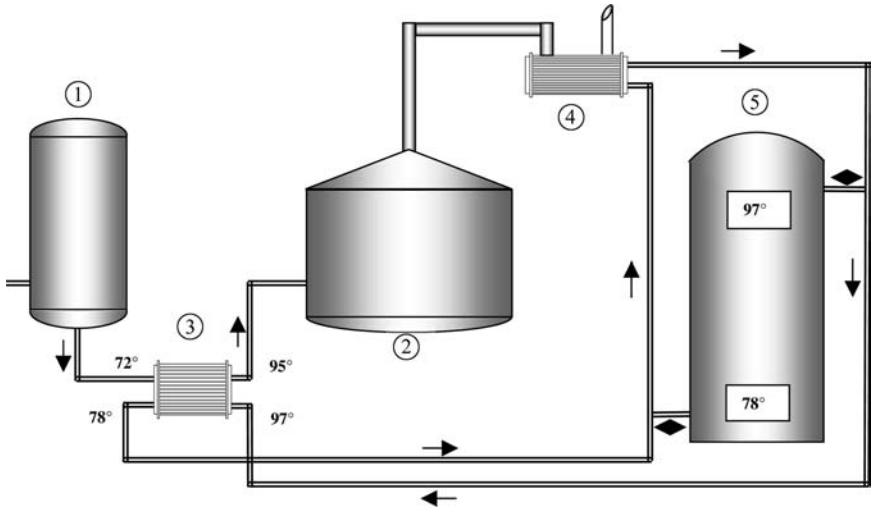

Figure 20.5 *Pressure wort copper with vapor condenser (pressureless); energy storage system and wort heating (after Vollhals, 1994); 1. wort collecting vessel, 2. wort kettle, 3. wort heater, 4. vapor condenser, 5. energy storage tank.*

heating. The same system can be used for low-pressure boiling. Low-pressure boiling works at a reduced evaporation rate compared to atmospheric boiling, which results in a lower production of hot service water. If the vapor condenser is included in the pressure sector, energy storage water at about 100°C can be produced.

Energy Saving with Vapor Compression. During atmospheric boiling, the produced vapor has a temperature of about 100°C. If this vapor is compressed to a few tenths of a bar overpressure, the temperature is raised to 102–108°C and it can be reused for heating. Vapor compression can be achieved by using a mechanical compressor or a steam jet compressor (thermocompression). The condensate, which is developed at the heater by the condensation of the vapor, leaves the cyclic process through a condensate cooler, which produces hot driving water.

Using a mechanical compressor, the vapor is compressed to an overpressure of 0.3–0.4 bar. The wort is heated to boiling temperature using fresh steam. The boiling process is maintained in operation using heat from the compressed vapor. The additional use of a vapor condenser is not possible because all the vapors are directly led back to the boiling process. Consequently, the lautered wort is not preheated when mechanical vapor compression is employed. Additional disadvantages are the complicated plant engineering, noise production, high maintenance costs, and peak electricity demands.

At thermal vapor compression, live steam from a boiler with an overpressure of at least 8 bar and up to 18 bar is fed to the steam jet pump. The vapor is sucked in and compressed to 0.1–0.4 bar overpressure. About 30–35% of the vapor is condensed in the kettle vapor condenser to produce hot water that can be used for preheating the wort. The advantages and disadvantages of using a thermal vapor compressor are summarized in Table 20.6.

20.2.5.3 Wort Boiling Systems. Today, different boiling systems are being used. Table 20.7 shows an overview. The new systems are characterized by a considerable reduced overall energy cost compared to classical systems. Investment costs depend on the system's complexity and ease of integration in the existing process. In Table 20.8, the various boiling systems are compared (classical atmospheric boiling with atmospheric venting is taken as the reference situation) with respect to thermal stress reduction,

TABLE 20.6 The Advantages and Disadvantages of Thermal Vapor Compression.

Advantages	Disadvantages
• A trouble-free, cheap, safe, and low-maintenance compressor • Low noise and vibration • Especially profitable for small and medium-sized breweries • Lower investment costs compared to mechanical vapor compression • Driven by live steam • One steam jet compressor is sufficient or any size of plant • Stepless control by injector needle valves	• Requires high steam pressure (new pipework needed) • A relative high quantity of hot process water arising • Large specific heat transfer surface with a high circulation rate (external heater needed or internal heater with recirculation pump) • A higher quantity of vapor condensate, waste, and hot water arising and more boiler feed water required compared to mechanical vapor compression

integration possibility in existing systems, obtained reduction in volatile organic compounds (VOCs) emission, achieved reduction of operation costs, and additional extra investment costs (Willaert and Baron 2005).

High-temperature boiling (HTWB) is a continuous boiling system, and the idea is quite old (Dumet 1958; Daris and others 1962; Evers 2002). At high temperatures of 130°C or 140°C, very satisfying wort analysis data can be obtained although very short boiling periods of ~5 min are used (Narziss and others 1982b; Narziss and others 1983). Narziss and others

[a]Based on the total evaporation rate.

[b]Classical atmospheric boiling with atmospheric venting is taken as the reference situation.

[c]Classical boiling vessels do not allow boiling under pressure; low-pressure boiling necessitates expensive pressure-resistant vessels.

(1991a,b) produced the best beers with a boiling temperature of 130°C and a high-temperature holding period of 180 s. The wort is heated up in three steps. In the first two steps, vapor from the flash-off chambers is reused. Considerable energy savings can be obtained due to the short boiling time and energy recovery. Alternative continuous systems have been developed, such as continuous pressure boiling in a multistage column comparable to a tray distillation tower (Krüger and Ehrlinger 1984) or the use of multiple-effect evaporators (Korek 1981).

A boiling system using microwaves was tested by the company Huppmann (Herrmann 1999; Isenberg 1999). Microwaves are produced in a separate generator. These microwaves are guided to the wort kettle via a copper waveguide and brought into the wort through the "applicator". The total wort volume was heated uniformly and no burn-on danger existed. Wort boiling trials (5 hL scale) with microwaves (4, 6, and 8% evaporation) have been compared to conventional boiling (90 min and 8% evaporation). The analysis of the obtained beers showed that the aroma was comparable to the beer obtained from the conventional boiling, although the boiling period could be reduced to 45 min (with 5% evaporation). The taste stability was rather poor for the produced "microwave beers" (Meilgaard 2001).

Wort Boiling at Low Pressure. Conventional boiling at low pressure was introduced in breweries at the end of the 1970s to decrease energy costs (Lenz 1982). The pressure is kept constant during boiling at a value of 1.08–1.21 bar (boiling temperature from 102 to 105°C). This technology has been further developed and the state of the art today is dynamic low-pressure boiling with several subsequent short phases of pressure building up and pressure release with corresponding multiple wort stripping (N.N. 2001b, Hackensellner 2001; Kantelberg and Hackensellner 2001; Schwill-Miedaner and Miedaner 2001). This technology has been commercialized by the company Huppmann (Kitzingen, Germany).

After an atmospheric preboiling phase of 3 min at 100°C, the pressure is periodically built up (1.17 bar, 104°C) and released (1.05 bar, 101°C). The boiling is ended with a post-boiling phase of 5 min at 100°C. The pressure reduction phases ensure an intensive boiling phase with stripping of wort volatiles. A total evaporation rate of 4.4–4.5% is obtained. The produced vapor is used to produce hot water and the recovered energy can be stored in a hot-water storage tank. Part of this stored energy can be used to heat up the wort before boiling. Recent results have shown that – due to the reduced thermal stress on the wort – the head retention of the produced beers increased (Anon. 2001c).

Heating up and boiling of the wort is performed using an internal boiler. Recent internal boiling systems have been designed to minimize the thermal load during heating and boiling (Hoefig 1994; Stippler and Wasmuht 1999a; Hackensellner 1999; Anon. 2001d; Kantelberg and Hackensellner 2001).

Wort Boiling in Combination with Stripping. In wort boiling, most reactions are only time/temperature dependent (Reed and Jordan 1991; Schwill-Miedaner 2002): inactivation of enzymes, the sterilization of the wort, extraction of hop compounds, isomerization of α-acids, coagulation of the protein fraction, lowering the pH, and formation of reducing and aromatic compounds. For all these reactions, no evaporation is needed. A simple hot wort stand at boiling temperature is enough to guarantee that these reactions occur. Additionally, this methodology ensures a low thermal load, which guarantees a balanced beer with good foam stability.

On the contrary, for a few specific goals evaporation is required, initially to achieve the desired gravity of the wort at the end of boiling. Secondly, the high evaporation rates generally applied are meant to eliminate unwanted volatile compounds. In classical wort boiling, evaporation ratios of 7–10% are common. Unfortunately, in conventional wort

boiling, large energy losses may occur, because a wort kettle is not necessarily designed for efficient stripping by evaporation. The effective evaporation surface per unit volume is very low, which renders the elimination of volatile compounds more difficult (Reed and Jordan 1991). For this reason a vigorous wort boil is generally required.

Recently, several new wort-boiling systems have been developed and introduced into breweries. Wort boiling and removal of unwanted volatiles (free DMS, degradation product of fat, Strecker aldehydes, and so on) are two separate processes. In this way, the thermal stress on the wort and heating costs can be reduced considerably. A wort clarification step before the stripping phase gives a better wort quality than the conventional reversed strategy where a very high thermal load was necessary during the boiling phase to avoid DMS formation during wort clarification. The removal of the unwanted volatiles can be performed at a much higher efficiency. Additionally, modern wort-boiling systems are equipped with efficient energy-recovery systems. The stripping of volatiles can be accomplished by steam, film, or vacuum stripping.

STEAM STRIPPING. Steam stripping is employed in a two-stage boiling system where volatile compounds are stripped in a "stripping column" (Baron and others 1997; Seldeslachts 1997; Bonacchelli and others 2001). In the first stage of the process, the wort is kept at wort boiling temperature in a wort kettle where no significant evaporation takes place (Fig. 20.6). The volatile compounds formed through chemical reactions and extracted from the added hops are accumulated in the wort. In the second stage, after wort clarification, the volatile compounds are eliminated, very efficiently, in the "stripping column", with steam.

FILM STRIPPING. The company Anton Steinecker Maschinenfabrik (Krones; Freising, Germany) have introduced a new boiling system, named "Merlin". The Merlin is a vessel containing a conical heating surface, which serves for boiling and evaporation (stripping) of the wort (Fig. 20.7) (Schu and Stolz 1999; Stippler and Wasmuht 1999b; Jacob and others 2001). A whirlpool positioned under the Merlin serves as a wort-holding vessel. A circulation pump is also necessary. For hop addition, the usual hop-dosing system is used. This system can also be coupled to an energy storage tank (Manger 2000; Weinzierl and others 2000; Schwill-Miedaner and Miedaner 2001).

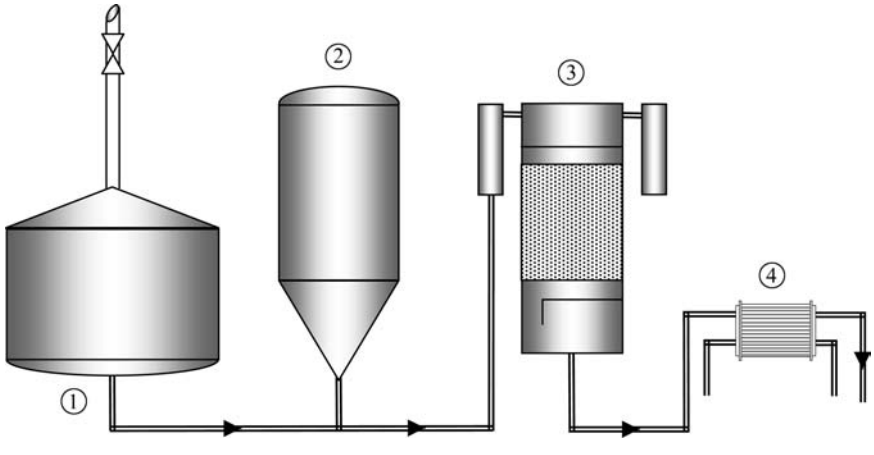

Figure 20.6 *Process layout including wort stripping (after Baron and others 1997); 1. wort kettle, 2. sedimentation tank (wort clarification), 3. wort stripper (packed with Cascade Rings from Glitsch), 4. wort cooler.*

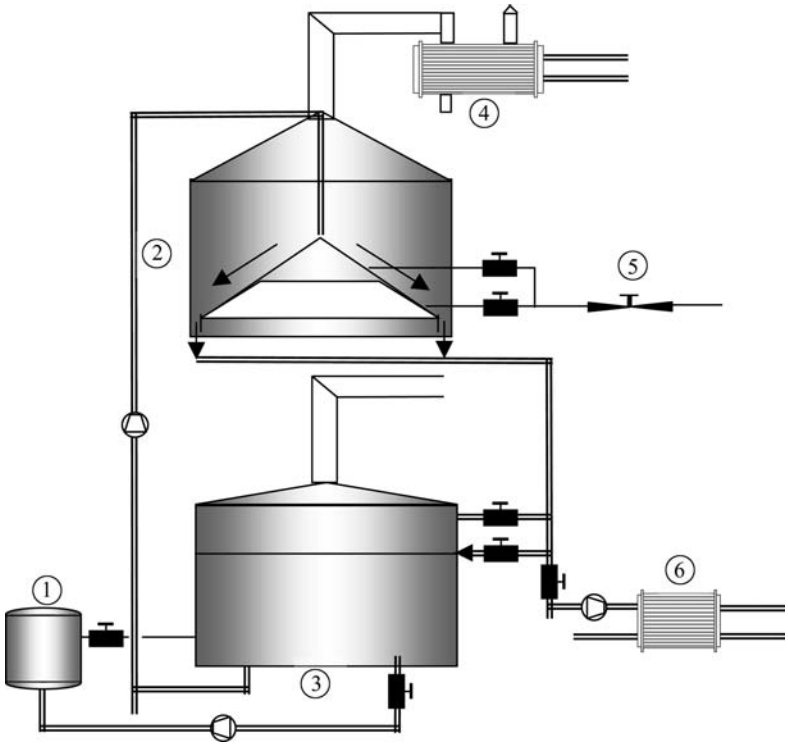

Figure 20.7 *Schematic of a brewhouse featuring Merlin and whirlpool with energy storage (after Schwill-Miedaner and Miedaner, 2001); 1. hop dosage, 2. Merlin, 3. whirlpool as collecting vessel, 4. vapor condenser, 5. steam control valve, 6. heat exchanger.*

The wort is heated until it reaches boiling temperature by pumping it in a circulation loop across the conical heating surface of the Merlin. When boiling temperature is reached in the whirlpool, a boiling cycle of 35 min starts. Next, there is a whirlpool phase of 20–30 min, followed by film stripping to remove unpleasant aroma volatiles. The stripping is accomplished by pumping the wort from the whirlpool once again across the heated surface of the Merlin on its way from whirlpool to plate cooler.

VACUUM STRIPPING

Ziemann System. The company Ziemann (Ludwigsburg, Germany) have introduced a vacuum evaporation plant, which can be installed in the brewhouse as an additional module (N.N. 2001b,e). This module is placed after the whirlpool. The combination of a relatively short boiling phase with a low evaporation rate and vacuum evaporation gives a boiling system with a low energy cost, a reduced thermal load, and sufficient unwanted volatile stripping.

The wort is boiled over 40–50 min with an existing boiling kettle (~4% evaporation). Next, the whirlpool is employed as usual. After the rest period in the whirlpool, the wort is led tangentially as a thin film through the bypass of the existing wort pipe into the

cylindroconical vacuum vessel. Undesired flavor compounds are removed during the flash evaporation process (~2% evaporation).

Nerb System. The company Nerb (Freising Attaching, Germany) introduced recently on the market the boiling system "VarioBoil" (Krottenthaler and others 2001; Anon. 2001b). This system combines atmospheric and vacuum boiling. This boiling system is composed of a wort vessel, an external boiler, an expansion evaporator with a vacuum pump, and a vapor condenser coupled to a hot-water storage tank. Additionally, vapor compression can also be used during boiling. Instead of the wort-boiling vessel, a buffer tank or whirlpool can be used.

The wort is pumped through the external boiler into the expansion vessel. The wort flows tangentially into this vessel and as a thin film from the inner surface. During boiling, the pressure is atmospheric in the expansion vessel. An outlet pump is used to pump the wort back to the wort kettle and to control the level in the expansion vessel. After the boiling process, the expansion vessel is evacuated. The wort is then pumped via the expansion vessel to the whirlpool.

Kaspar Schulz System. In the boiling system of the company Kaspar Schulz (Bamberg, Germany) (Anon. 2001f; Binkert and Haertl 2001), wort boiling is accomplished in two phases. In the first phase, the wort is kept at a temperature just below the boiling point (~97.5°C), and the second phase is a vacuum evaporation phase. A total evaporation rate of 8% is obtained. Considerable energy is saved by keeping the wort just below boiling point during the hot holding phase (because there is no evaporation energy cost).

The wort is heated in the wort kettle to 97.5°C and kept at this temperature for 60 min. The wort is stirred constantly with an impeller. The length of this hot holding period (~1% evaporation) is adjustable and depends on the isomerization yield of the α-acids and the required value of coagulable nitrogen. Next, the hot trub and hops debris are removed in a whirlpool. The clarified wort is pumped to the vacuum evaporator. An evaporation rate of 7% is obtained.

20.2.6 Wort Clarification

After boiling, it is necessary to remove the hot trub and hop debris to ensure flavor and colloidal stability of the beer and to avoid blocking of the plate heat exchanger during wort cooling. If hot trub particles are not removed, they will foul the yeast cell wall and also stimulate yeast sedimentation during fermentation. Consequently, a reduced fermentation degree will be obtained. Hot trub particles give beer a darker color, a rough trub taste, and a poor foam stability.

20.2.6.1 Spent Hops Removal. When hopping is performed with hop cones, the spent hops are removed before hot trub removal in a separate process step. Spent hops contain 5–6 L wort per kg hops. Therefore, spent hops are washed with hot water or washed and subsequently squeezed. Spent hops can be separated from the wort using the hop back or the hop strainer. In a hop back, the wort is pumped through a stirred vessel and spent hops are retained in the vessel using a sieve. For large wort volumes, a hop strainer is used. A screw conveyor just above the sieve squeezes the spent hops and "dry" spent hops are discarded.

20.2.6.2 Hot Trub Removal.

The hot trub ("coarse break", "coarse trub") particles have a size of 30–80 μm. It is composed, on average, of 40–70% proteinaceous material, 10–20% hop bitter acids, 7–8% polyphenols, 7–10% carbohydrates, 1–2% fatty acids, and varying quantities of minerals (Anon. 1999). The hot trub content of wort is typically 40–80 g/hL extract-free dry matter. This amount depends on the nitrogen content and cultivation conditions of barley, the type of mashing process, the mash filtration method, and boiling duration and intensity. The hot trub content of wort has to be decreased to less than 100 mg/L (Kunze 1999).

Different process techniques can be used to remove the hot trub from the wort. The separation processes are based on separating particles with a different density and/or size, and include sedimentation, centrifugation, and filtration techniques.

The easiest way to remove hot trub is by sedimentation by using a sedimentation tank or a whirlpool. A coolship has been used in the past as sedimentation vessel. It is a flat, rectangular, open vessel in which the wort is cast to a depth of 15–25 cm. Sedimentation takes about 0.5–2 h. This technology is still in use in Belgium for the production of lambic beers and related (fruit) beers (Gueuze, Kriek, Framboise). In this case, the wort is allowed to stand overnight until the required fermentation temperature is reached and to allow the wort to be inoculated spontaneously by the local microbiological flora, which is present in the circulating air.

The sedimentation tank is a circular vessel, usually designed with a conical bottom for easy removal of the trub. The tank is filled with hot wort and during a rest period the trub particles sediment and clarify the wort. A pivoted wort discharge pipe can be used to adjust the draw off point of the wort to just below the liquid surface. In some designs, wort can be discharged at different vessel heights. The wort–trub mixture can either be fed back to the lauter tun or can be treated separately (e.g., by centrifugation) to recover the entrained wort.

Hot trub removal in a whirlpool is one of the most elegant and economical methods. It is a cylindrical vessel into which wort is pumped tangentially. This produces a rotational flow in the vessel which causes the hot break to settle in the shape of a cone in the middle of the bottom of the vessel. Clarified wort is drawn off at the side.

Centrifugation is an effective technique to clarify the wort. The sedimentation speed is increased by increasing the sedimentation force (centrifugal vs. gravitational acceleration). The advantages of this method are that a centrifuge takes up a small space, it works continuously, emptying, cleaning, and sterilization are easy, and there are reduced wort losses (however, wort losses depend on the load of spent hop powder). The disadvantages of centrifugation are high requirements for electrical energy, noise, and relatively high maintenance costs.

Filtration is today the most used technique to remove cold trub. It can also be applied for hot trub removal. Small breweries use kieselguhr sheet filters ("plate and frame" filters). Larger breweries may use candle sieve filters that are adapted for wort clarification.

20.3 BEER FERMENTATION

20.3.1 Biochemistry of the Primary Beer Fermentation

20.3.1.1 Carbohydrate Metabolism: Ethanol Production.

Carbohydrate Uptake. Carbohydrates in wort make up 90–92% of wort solids. Wort from barley malt contains the fermentable sugars sucrose, fructose, glucose, maltose,

TABLE 20.9 Carbohydrate Composition of Worts.

Source: Adapted from Hough and others (1982).
[a]Percent of the total fermentable sugars.

and maltotriose, together with some dextrin material (Table 20.9). The fermentable sugars typically make up 70–80% of the total carbohydrate (MacWilliam 1968). The three major fermentable sugars are glucose, and the α-glucosides maltose and maltotriose. Maltose is by far the most abundant of these sugars, typically accounting for 50–70% of the total fermentable sugars in an all-malt wort. Sucrose and fructose are present in a low concentration. The unfermentable dextrins play little part in brewing. Wort fermentability may be reduced or increased by using solid or liquid adjuncts.

Brewing strains consume the wort sugars in a specific sequence: glucose is consumed first, followed by fructose, maltose, and finally maltotriose. The uptake and consumption of maltose and maltotriose is repressed or inactivated at elevated glucose concentrations. Only when 60% of the wort glucose has been taken up by the yeast will uptake and consumption of maltose start. Maltotriose uptake is inhibited by high glucose and maltose concentrations. When high amounts of carbohydrate adjuncts (e.g., glucose) or high-gravity wort are employed, the glucose repression is even more pronounced, resulting in fermentation delays (Stewart and Russell 1993).

The efficiency of brewer's yeast strains to effect alcoholic fermentation is dependent upon their ability to utilize the sugars present in wort. This ability very largely determines the fermentation rate as well as the final quality of the beer produced. In order to optimize the fermentation efficiency of the primary fermentation, a detailed knowledge of the sugar consumption kinetics, which is linked to the yeast growth kinetics, is required (Willaert 2001).

MALTOSE AND MALTOTRIOSE METABOLISM. The yeast *S. cerevisiae* transports the monosaccharides across the cell membrane using hexose transporters. There are 19, or possibly 20, genes encoding hexose transporters (Dickinson 1999). The disaccharide maltose and the trisaccharide maltotriose are transported by specific transporters into the cytoplasm, where these molecules are hydrolyzed by the same α-glucosidase, yielding two or three molecules of glucose, respectively (Panchal and Stewart 1979; Zheng and others 1994).

Maltose utilization in yeast is conferred by any one of five *MAL* loci: *MAL1* to *MAL4* and *MAL6* (Bisson and others 1993; Dickinson 1999). Each locus consists of three genes: gene 1 encodes a maltose transporter (permease), gene 2 encodes a maltase (α-glucosidase), and gene 3 encodes a transcriptional activator of the other two genes. Thus, for example, the maltose transporter gene at the *MAL1* locus is designated *MAL61*. The three genes of a *MAL* locus are all required to allow fermentation. Some authors persist in using gene designations such as for the *MAL1* locus: *MAL1T* (transporter = permease), *MAL1R* (regulator), and *MAL1S* (maltase). The five *MAL* loci each map to a different chromosome. The *MAL* loci exhibit a very high degree of homology and are telomere linked, suggesting that they evolved by translocation from telomeric regions of different chromosomes (Michels and others 1992). Because a fully functional or partial allele of the *MAL1* locus is found in all strains of *S. cerevisiae*, this locus is proposed as the progenitor of the other *MAL* loci (Chow and others 1983). Gene dosage studies performed with laboratory strains of yeast have shown that the transport of maltose in the cell may be the rate-limiting step in the utilization of this sugar (Goldenthal and others 1987). Constitutive expression of the maltose transporter gene (*MALT*) with high-copy-number plasmids in a lager strain of yeast has been found to accelerate the fermentation of maltose during high-gravity (24°P) brewing (Kodama and others 1995). The constitutive expression of *MALS* and *MALR* had no effect on maltose fermentability. Recently, it was confirmed that maltose uptake is the dominant factor controlling the rate of maltose utilization in wort (11–24°P) fermentations using an ale and lager industrial strain (Rautio and Londesborough 2003).

The control over *MAL* gene expression is exerted at three levels. The presence of maltose induces, whereas glucose represses, the transcription of *MALS* and *MALT* genes (Federoff and others 1983a,b; Needleman and others 1984). The constitutively expressed regulatory protein (*MALR*) binds near the *MALS* and *MALT* promotors and mediates the induction of *MALS* and *MALT* transcription (Cohen and others 1984; Chang and others 1988; Ni and Needleman 1990). Experiments with *MALR*-disrupted strains led to the conclusion that MalRp is involved in glucose repression (Goldenthal and Vanoni 1990; Yao and others 1994). Relatively little attention has been paid to post-transcriptional control, that is, the control of translational efficiency, or mRNA turnover, as mechanisms complementing glucose repression (Soler and others 1987). The addition of glucose to induced cells has been reported to cause a 70% increase in the lability of a mRNA population containing a fragment of *MALS* (Federoff and others 1983a). The third level of control is post-translational modification. In the presence of glucose, maltose permease is either reversibly converted to a conformational variant with decreased affinity (Siro and Lövgren 1979; Peinado and Loureiro-Dias 1986) or irreversibly proteolytically degraded depending on the physiological conditions (Lucero and others 1993; Riballo and others 1995). The latter phenomenon is called catabolite inactivation. Glucose repression is accomplished by the Mig1p repressor protein which is encoded by the *MIG1* gene (Nehlin and Ronne 1990). It has been shown that Mig1p represses the transcription of all three *MAL* genes by binding upstream of them (Hu and others 1995). The *MIG1* gene has been disrupted in a haploid laboratory strain and in an industrial polyploid strain of *S. cerevisiae* (Klein and others 1996). In the *MIG1*-disrupted haploid strain, glucose repression was partly alleviated; that is, maltose metabolism was initiated at higher glucose concentrations than in the corresponding wild-type strain. In contrast, the polyploid *Δmig1* strain exhibited an even more stringent glucose control of maltose metabolism than the corresponding wild-type strain, which could be explained by a more rigid catabolite inactivation of maltose permease, affecting the uptake of maltose.

Recently, the gene *AGT1*, which codes for an α-glucoside transporter, has been characterized (Han and others 1995). *AGT1* is found in many *S. cerevisiae* laboratory strains and maps to a naturally occurring, partially functional allele of the *MAL1* locus. Agt1p is a highly hydrophobic, postulated integral membrane protein. It is 57% identical to Mal61p (the maltose permease encoded at *MAL6*) and is also a member of the 12 transmembrane domain superfamily of sugar transporters (Nelissen and others 1995). Like Mal61p, Agt1p is a high-affinity, maltose/proton symporter, but Mal61p is capable of transporting only maltose and turanose, and Agt1p transports these two α-glucosides as well as several others including isomaltose, α-methylglucoside, maltotriose, palatinose, trehalose, and melezitose. *AGT1* expression is maltose inducible and induction is mediated by the Mal-activator.

Brewing strains of yeast are polyploid, aneuploid, or, in the case of lager strains, alloploid. Recently, Jespersen and others (1999) examined 30 brewing strains of yeast (5 ale strains and 25 lager strains), with the aim of examining the alleles of maltose and maltotriose transporter genes contained by them. All the strains of brewer's yeast examined, except two, were found to contain *MAL11* and *MAL31* sequences, and only one of these strains lacked *MAL41*. *MAL21* was not present in the five ale strains and 12 of the lager strains. *MAL61* was not found in any of the yeast chromosomes other than those known to carry *MAL* loci. Sequences corresponding to the *AGT1* gene (transport of maltose and maltotriose) were detected in all but one of the yeast strains.

The utilization of maltose or sucrose by a selection of 25 brewing, baking, or laboratory strains of *S. cerevisiae* was either repressible, constitutive or absent (Meneses and Jiranek 2002a). Overall fermentation rate of a selection of nine strains showed a good correlation with maximum specific maltose transport rate, but poor correlation with maximum maltase activity, implying that transport rather than hydrolysis of maltose was the rate-limiting step (Meneses and Jiranek 2002b). All strains were found to possess genomic sequences detectable with probes for the *MAL11*, *MAL31*, and *SUC2* invertase gene. However, the loci present and the pattern of expression of these and other *MAL* genes varied widely. From comparison of sugar utilization and gene expression patterns, constitutive maltose utilization in strain NCYC 1681 was best explained by *MAL11* expression. However, such expression of *MAL11* was not mirrored by changes in the expression of the transcriptional activator(s) (*MALx3*).

Wort maltotriose has the lowest priority for uptake by brewer's yeast cells and incomplete maltotriose uptake results in yeast fermentable extract in beer, material loss, greater potential for microbiological stability, and sometimes atypical beer flavor profiles (Stewart and Russell 1993). Maltotriose uptake from wort is always slower with ale strains than with lager strains under similar fermentation conditions. However, the initial transport rates are similar to those of maltose in a number of ale and lager strains. Elevated osmotic pressure inhibits the transport and uptake of glucose, maltose and maltotriose with maltose and maltotriose being more sensitive to osmotic pressure than glucose in both lager and ale strains. Ethanol (5% w/v) stimulated the transport of maltose and maltotriose, due in all probability to an ethanol-induced change in the plasma membrane configuration, but had no effect on glucose transport. Higher ethanol concentrations inhibited the transport of all three sugars.

Wort Fermentation. Before the fermentation process starts, wort is aerated (see Section 20.3.3.1). As a result of this aeration step, carbohydrates are degraded aerobically during

the first few hours of the fermentation process. The aerobic carbohydrate catabolism typically takes 12 h for a lager fermentation.

During the first hours of the fermentation process, oxidative degradation of carbohydrates occurs through the glycolysis and Krebs (TCA) cycle. The energy efficiency of glucose oxidation is derived from the large number of $NADH_2^+$ produced for each mole of glucose oxidized to CO_2. The actual wort fermentation produces, alcohol and carbon dioxide *via* the Embden–Meyerhof–Parnas (glycolytic) pathway. The reductive pathway from pyruvate to ethanol is important because it regenerates NAD^+. Energy is obtained solely from ATP-producing steps of the Embden–Meyerhof–Parnas pathway. During fermentation, the activity of the TCA cycle is greatly reduced, although it still serves as a source of intermediates for biosynthesis (Lievense and Lim 1982).

Lagunas (1979) observed that during aerobic growth of *S. cerevisiae*, respiration accounts for less than 10% of glucose catabolism, the remainder being fermented. Increasing sugar concentrations resulting in a decreased oxidative metabolism is known as the Crabtree effect. This was traditionally explained as an inhibition of the oxidative system by high concentrations of glucose. Nowadays, it is generally accepted that the formation of ethanol at aerobic conditions is a consequence of a bottleneck in the oxidation of pyruvate, for example, in the respiratory system (Petrik and others 1983; Rieger and others 1983; Käppeli and others 1985; Fraleigh and others 1989; Alexander and Jeffries 1990).

A reduction of ethanol production can be achieved by metabolic engineering of the carbon flux in yeast resulting in an increased formation of other fermentation products. A shift of the carbon flux towards glycerol at the expense of ethanol formation in yeast was achieved by simply increasing the level of glycerol-3-phosphate dehydrogenase (Michnick and others 1997; Nevoigt and Stahl 1997; Remize and others 1999; Dequin 2001). The *GDP1* gene, which encodes glycerol-3-phosphate dehydrogenase, has been overexpressed in an industrial lager brewing yeast to reduce the ethanol content in beer (Nevoigt and others 2002). The amount of glycerol produced by the *GDP1*-overexpressing yeast in fermentation experiments – simulating brewing conditions – was increased 5.6 times and ethanol was decreased by 18% compared to the wild-type strain. Overexpression did not affect the consumption of wort sugars and only minor changes in the concentration of higher alcohols, esters, and fatty acids could be observed. However, the concentrations of several other byproducts, particularly acetoin, diacetyl, and acetaldehyde, were considerably increased.

20.3.1.2 Metabolism of Bioflavoring Byproducts.

Yeast is an important contributor to flavor development in fermented beverages. The compounds, which are produced during fermentation, are many and varied, depending on both the raw materials and the yeast strains used. The interrelation between yeast metabolism and the production of bioflavoring byproducts is illustrated in Figure 20.8.

Biosynthesis of Higher Alcohols. During beer fermentation, higher alcohols (also called "fusel alcohols") are produced by yeast cells as byproducts and represent the major fraction of the volatile compounds. More than 35 higher alcohols in beer have been described. Table 20.10 gives the most important compounds, which can be classified into aliphatic (n-propanol, isobutanol, 2-methylbutanol (or active amyl alcohol), and 3-methylbutanol (or isoamyl alcohol)) and aromatic (2-phenylethanol, tyrosol, tryptophol) higher alcohols. Aliphatic higher alcohols contribute to the "alcoholic" or "solvent" aroma of beer, and produce a warm mouthfeel. The aromatic alcohol 2-phenylethanol has a sweet aroma and

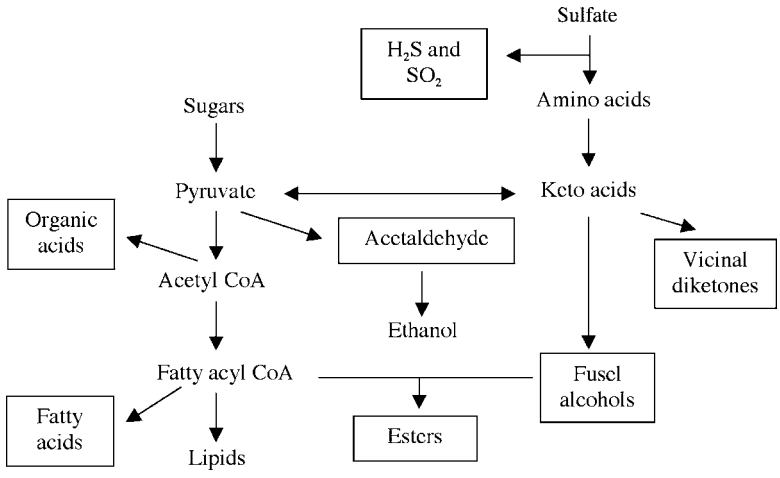

Figure 20.8 *Interrelationships between yeast metabolism and the production of flavor active compounds (Hammond 1993).*

has a positive contribution to the beer aroma, whereas the aroma of tyrosol and tryptophol are undesirable.

Higher alcohols are synthesized by yeast during fermentation via the catabolic (Ehrlich) and anabolic pathway (amino acid metabolism) (Ehrlich 1904; Chen 1978; Oshita and others 1995; Dickinson 1999). In the catabolic pathway, the yeast uses the amino acids of the wort to produce the corresponding α-keto acid via a transamination reaction. The excess oxoacids are subsequently decarboxylated into aldehydes and further reduced (alcohol dehydrogenase) to higher alcohols. This last reduction step also regenerates NAD^+.

Dickinson and co-workers looked at the genes and enzymes, that are used by *S. cerevisiae* in the catabolism of leucine to isoamyl alcohol (Dickinson and others 1997), valine to isobutanol (Dickinson and others 1998), and isoleucine to active amyl alcohol (Dickinson and others 2000). In all cases, the general sequence of biochemical reactions is similar, but the details for the formation of the individual alcohols are

TABLE 20.10 Major Higher Alcohols in Beer.

Compound	Flavor Threshold (mg/L)	Aroma or taste[b]	Concentration Range (mg/L) Bottom Fermentation	Concentration Range (mg/L) Top Fermentation
n-Propanol	600[c], 800[b]	Alcohol	7–19 (12)*[f]	20–45[i]
Isobutanol	100[c], 80–100[g], 200[b]	Alcohol	4–20 (12)[f]	10–24[i]
2-Methylbutanol	50[c], 50–60[g], 70[b]	Alcohol	9–25 (15)[a]	80–140[i]
3-Methylbutanol	50[c], 50–60[g], 65[b]	Fusely, pungent	25–75 (46)[a]	80–140[i]
2-Phenylethanol	5[a], 40[c], 45–50[g], 75[d], 125[b]	Roses, sweetish	11–51 (28)[f], 4–22[g], 16–42[h]	35–50[g], 8–25[a], 18–45[i]
Tyrosol	10[a], 10–20[e], 20[c], 100[d,g], 200[b]	Bitter chemical	6–9[a], 6–15[a]	8–12[g], 7–22[g]
Tryptophol	10[a], 10–20[e], 200[d]	Almonds, solvent	0.5–14[a]	2–12[g]

[a]Szlavko (1973), [b]Meilgaard (1975a), [c]Engan (1972), [d]Rosculet (1971), [e]Charalambous and others (1972); [f]Values in 48 European lagers, Dufour (unpublished data), [g]Reed and Nogodawithana (1991), [h]Iverson (1994), [i]Derdelinckx (unpublished data).

surprisingly different. The branched-chain amino acids are first deaminated to the corresponding α-ketoacids (α-ketoisocapric acid from leucine, α-ketoisovaleric acid from valine and α-keto-β-methylvaleric acid from leucine). There are significant differences in the way each α-ketoacid is subsequently decarboxylated. Recently, the catabolism of phenylalanine to 2-phenylethanol and of tryptophan were also studied (Dickinson and others 2003). Phenylalanine and tryptophan are first deaminated to 3-phenylpyruvate and 3-indolepyruvate, respectively, and then decarboxylated. These studies revealed that all amino acid catabolic pathways studied to date use a subtly different spectrum of decarboxylases from the five-membered family that comprises Pdc1p, Pdc5p, Pdc6p, Ydl080cp, and Ydr380wp. Using strains containing all possible combinations of mutations affecting the seven *AAD* genes (putative aryl alcohol dehydrogenases), five *ADH* and *SFA1* (other alcohol dehydrogenase) genes, showed that the final step of amino acid catabolism can be accomplished by any one of the ethanol dehydrogenases (Ahd1p, Ahd2p, Ahd3p, Ahd4p, Ahd5p) or Sfa1p (formaldehyde dehydrogenase).

In the anabolic pathway, the higher alcohols are synthesized from α-keto acids during the synthesis of amino acids from the carbohydrate source (Oshita and others 1995). The pathway choice depends on the individual higher alcohol and on the level of available amino acids available. The importance of the anabolic pathway decreases as the number of carbon atoms in the alcohol increases (Chen 1978), and increases in the later stage of fermentation as wort amino acids are depleted (MacDonald and others 1984). Yeast strain, fermentation conditions, and wort composition all have significant effects on the combination and levels of the higher alcohols that are formed (MacDonald and others 1984; Boulton and Quain 2001).

Conditions that promote yeast cell growth – such as high levels of nutrients (amino acids, oxygen, lipids, zinc ...), increased temperature and agitation – stimulate the production of higher alcohols (Landaud and others 2001). The synthesis of aromatic alcohols is especially sensitive to temperature changes. On the other hand, conditions that restrict yeast growth – such as lower temperature and higher pressure – reduce the extent of higher alcohol production (Renger and others 1992; Landaud and others 2001). Amino acid composition has a major effect on higher alcohol formation. Growth medium supplemented with valine, isoleucine and leucine induced the formation of isobutanol, amyl alcohol, and isoamyl alcohol, respectively (Äyräpää 1971; Sablayrolles and Ball 1995; Kodama and others 2001). Constitutive expression of the *BAP2* gene, which codes for the branched-chain amino acid permease Bap2p, resulted in accelerated rates of assimilation for leucine, valine, and isoleucine (Kodama and others 2001). This caused an increased production of isoamyl alcohol derived from leucine, and an increase of isobutyl alcohol derived from valine or active amyl alcohol from isoleucine was not observed. These results suggest that there are distinct but interrelated mechanisms for the production of each higher alcohol.

Biosynthesis of Esters. Esters are very important flavor compounds in beer. They have an effect on the fruity/flowery aromas (Verstrepen and others 2003a). Table 20.11 shows the most important esters with their threshold values, which are considerably lower than those for higher alcohols. The major esters can be subdivided into acetate esters and C_6–C_{10} medium-chain fatty acid ethyl esters. They are desirable components of beer when present in appropriate quantities and proportions, but can become unpleasant when in excess. Ester formation is highly dependent on the yeast strain used (Nykänen and Nykänen 1977; Peddie 1990) and on certain fermentation parameters such as temperature (Engan and Aubert 1977; Gee and Ramirez 1994; Sablayrolles and Ball 1995), specific growth rate (Gee and Ramirez 1994), pitching rate (Maule 1967; D'Amore and others 1991; Gee and

TABLE 20.11 Major Esters in Beer.

Compound	Flavor Threshold (mg/L)	Aroma	Concentration Range (mg/L) in 48 Lagers
Ethyl acetate	20–30, 30[a]	Fruity, solvent-like	8–32 (18.4)*
Isoamyl acetate	0.6–1.2, 1.2[a]	Banana, peardrop	0.3–3.8 (1.72)*
Ethyl caproate (ethyl hexanoate)	0.17–0.21, 0.21[a]	Apple–like with note of aniseed	0.05–0.3 (0.14)*
Ethyl caprylate (ethyl octanoate)	0.3–0.9, 0.9[a]	Apple-like	0.04–0.53 (0.17)*
2-Phenylethyl acetate	3.8[a]	Roses, honey, apple, sweetish	0.10–0.73 (0.54)*

Ramirez 1994) and top pressure (Anon. 2000). Additionally, the concentrations of assimilable nitrogen compounds (Hammond 1993; Calderbank and Hammond 1994; Sablayrolles and Ball 1995), carbon sources (Pfisterer and Stewart 1975; White and Portno 1979; Younis and Stewart 1998, 2000), dissolved oxygen (Anderson and Kirsop 1975a,b; Avhenainen and Mäkinen 1989; Sablayrolles and Ball 1995) and fatty acids (Thurston and others 1981, 1982) can influence the ester production rate. Fermentation of high-gravity worts results in a disproportionate synthesis of esters, particularly ethyl acetate and isoamylacetate (Anderson and Kirsop 1974, 1975a, 1975b; Casey and others 1985; Stewart 2001).

Esters are produced by yeast both during the growth phase (60%) and also during the stationary phase (40%) (Anon. 2000). They are formed by the intracellular reaction between a fatty acyl-coenzyme A and an alcohol:

$$R'OH + RCO{-}ScoA \longrightarrow RCOOR' + CoASH. \quad (1)$$

This reaction is catalyzed by an alcohol acyltransferase (or ester synthethase). Because acetyl CoA is also a central molecule in the synthesis of lipids and sterols, ester synthesis is linked to the fatty acid metabolism (see also Fig. 20.8).

Alcohol acetyltransferase (AAT) has been localized in the plasma membrane (Malcorps and Dufour 1987) and found to be strongly inhibited by unsaturated fatty acids, ergosterol, heavy metal ions, and sulfydryl reagents (Minetoki and others 1993). Subcellular fractionation studies conducted during the batch fermentation cycle demonstrated the existence of both cytosolic and membrane-bound AAT (Ramos-Jeunehomme and others 1989, 1991). In terms of controlling ester formation on a metabolic basis, it has further been shown that ester-synthesizing activity of AAT is dependent on its positioning within the yeast cell. An interesting feature of this distribution pattern is that specific rates of acetate ester formation varied directly with the level of cytosolic AAT activity (Masschelein 1997).

The *ATF1* gene, which encodes alcohol acetyltransferase, has been cloned from *S. cerevisiae* and brewery lager yeast (*S. cerevisiae uvarum*) (Fujii and others 1994). A hydrophobicity analysis suggested that alcohol acetyltransferase does not have a membrane-spanning region that is significantly hydrophobic, which contradicts the membrane-bound assumption. A Southern analysis of the yeast genomes in which the *ATF1* gene was used as a probe, revealed that *S. cerevisiae* has one *ATF1* gene, and

brewery lager yeast has one *ATF1* gene and another, homologous gene (*Lg-ATF1*). The AAT activities have been compared *in vivo* and *in vitro* under different fermentation conditions (Malcorps and others 1991). This study suggested that ester synthesis is modulated by a repression–induction of enzyme synthesis or processing, the regulation of which is presumably linked to lipid metabolism.

Ester production can be altered by changing the synthesis rate of certain fusel alcohols. Hirata and others (1992) increased the isoamyl acetate levels by introducing extra copies of the *LEU4* gene in the *S. cerevisiae* genome. A comparable *S. cerevisiae uvarum* mutant has been isolated (Lee and others 1995). The mutants have an altered regulation pattern of amino acid metabolism and produce more isoamyl acetate and phenylethyl acetate.

Isoamyl acetate is synthesized from isoamyl alcohol and acetyl coenzyme A by AAT and is hydrolyzed by esterases at the same time in *S. cerevisiae*. To study the effect of balancing both enzyme activities, yeast strains with different numbers of copies of the *ATF1* gene, and isoamyl acetate-hydrolyzing esterase gene (*IAH1*) have been constructed and used in small-scale sake brewing (Fukuda and others 1998). Fermentation profiles as well as components of the resulting sake were largely alike. However, the amount of isoamyl acetate in the sake increased with increasing ratio of AAT/Iah1p esterase activity. Therefore, it was concluded that the balance of these two enzyme activities is important for isoamyl acetate accumulation in sake mash.

The synthesis of acetate esters by *S. cerevisiae* during fermentation is ascribed to at least three acetyltransferase activities, namely alcohol acetyltransferase (AAT), ethanol acetyltransferase, and isoamyl AAT (Lilly and others 2000). To investigate the effect of increased AAT activity on the sensory quality of Chenin blanc wines and distillates from Colombar based wines, the *ATF1* gene of *S. cerevisiae* was overexpressed. Northern blot analysis indicated constitutive expression of *ATF1* at high levels in these transformants. The levels of ethyl acetate, isoamyl acetate, and 2-phenylethyl acetate increased 3- to 10-fold, 3.8- to 12-fold, and 2- to 10-fold, respectively, depending on the fermentation temperature, cultivar, and yeast used. The concentrations of ethyl caprate, ethyl caprylate, and hexyl acetate only showed minor changes, whereas the acetic acid concentration decreased by more than half. This study established the concept that the overexpression of acetyltransferase genes such as *ATF1* could profoundly affect the flavor profiles of wines and distillates deficient in aroma.

In order to investigate and compare the roles of the known *S. cerevisiae* alcohol acetyltransferases, Atf1p, Atf2p, and Lg-Atf1p, in volatile ester production, the respective genes were either deleted or overexpressed in a laboratory strain and a commercial brewing strain (Verstrepen and others 2003b). Analysis of the fermentation products confirmed that the expression levels of *ATF1* and *ATF2* greatly affect the production of ethyl acetate and isoamyl acetate. GC-MS analysis revealed that Atf1p and Atf2p are also responsible for the formation of a broad range of less volatile esters, such as propyl acetate, isobutyl acetate, pentyl acetate, hexyl acetate, heptyl acetate, octyl acetate, and phenyl ethyl acetate. With respect to the esters analyzed in this study, Atf2p seemed to play only a minor role compared to Atf1p. The *atf1 atf2* double deletion strain did not form any isoamyl acetate, showing that together, Atf1p and Atf2p are responsible for the total cellular isoamyl alcohol acetyltransferase activity. However, the double deletion strain still produced considerable amounts of certain other esters, such as ethyl acetate (50% of the wild-type strain), propyl acetate (50%), and isobutyl acetate (40%), which provides evidence for the existence of additional, as-yet-unknown ester synthases in the yeast proteome. Interestingly, overexpression of different alleles of *ATF1* and *ATF2* led

to different ester production rates, indicating that differences in the aroma profiles of yeast strains may be partially due to mutations in their *ATF* genes.

Recently, it has been discovered that the Atf1 enzyme is localized inside lipid vesicles in the cytoplasm of the yeast cell (Verstrepen 2003). Lipid vesicles are small organelles in which certain neutral lipids are metabolized or stored. This indicates that fruity esters are possibly byproducts of these processes.

Biosynthesis of Organic Acids. Important organic acids detected in beer include acetate, lactate, succinate, pyroglutamate, malate, citrate, α-ketoglutarate and α-hydroxyglutarate (Coote and Kirsop 1974). They influence flavor directly when present above their taste threshold, and by their influence on beer pH. These components have their origin in raw materials (malt, hops) and are produced during beer fermentation. Organic acids that are excreted by yeast cells, are synthesized via amino acid biosynthesis pathways and carbohydrate metabolism. In particular, they are overflow products of the incomplete Krebs cycle during beer fermentation. Excretion of organic acids is influenced by yeast strain and fermentation vigor. Sluggish fermentations lead to lower levels of excretion. Pyruvate excretion follows the yeast growth: maximal concentration is reached just before the maximal yeast growth, and is next taken up by the yeast and converted to acetate. Acetate is synthesized quickly during early fermentation and is later partially reused by the yeast during yeast growth. At the end of the fermentation, acetate is accumulated. The reduction of pyruvate results in the production of D-lactate or L-lactate (most yeast strains produce preferentially D-lactate). The highest amount of lactate is produced during the most active fermentation period.

The change in organic acid productivity by disruption of the gene encoding fumarase (*FUM1*) has been investigated and it has been suggested that malate and succinate are produced *via* the oxidative pathway of the TCA cycle under static and sake brewing conditions (Magarifuchi and others 1995). Using a NAD^+-dependent isocitrate dehydrogenase gene (*IDH1*, *IDH2*) disruptant, approximately half of the succinate in sake mash was found to be synthesized *via* the oxidative pathway of the TCA cycle in sake yeast (Asano and others 1999).

Sake yeast strains possessing various organic acid productivities were isolated by gene disruption (Arikawa and others 1999). Sake fermented using the aconitase gene (*ACO1*) disruptant contained a two-fold higher concentration of malate and a two-fold lower concentration of succinate than that made using the wild-type strain. The fumarate reductase gene (*OSM1*) disruptant produced sake containing a 1.5-fold higher concentration of succinate, whereas the α-ketoglutarate dehydrogenase gene (*KGD1*) and fumarase gene (*FUM1*) disruptants gave lower succinate concentrations. In *S. cerevisiae*, there are two isoenzymes of fumarate reductase (FRDS1 and FDRS2), encoded by the *FRDS* and *OSM1* genes, respectively (Arikawa and others 1998). Recent results suggest that these isoenzymes are required for the reoxidation of intracellular NADH under anaerobic conditions, but not under aerobic conditions (Enomoto and others 2002).

Succinate dehydrogenase is an enzyme of the TCA cycle and thus essential for respiration. In *S. cerevisiae*, this enzyme is composed of four nonidentical subunits, that is, the flavoprotein, the iron-sulfur protein, the cytochrome b_{560}, and the ubiquinone reduction protein encoded by the *SDH1*, *SDH2*, *SDH3*, and *SDH4* genes, respectively (Lombardo and others 1990; Chapman and others 1992; Bullis and Lamire 1994; Daignan-Fournier and others 1994). Sdh1p and Sdh2p comprise the catalytic domain involved in succinate oxidation. These proteins are anchored to the inner mitochondrial membrane by

Sdh3p and Sdh4p, which are necessary for electron transfer and ubiquinone reduction, and constitute the succinate:ubiquinone oxidoreductase (complex II) of the electron transport chain. Single or double disruptants of the *SDH1*, *SDH1b* (which is a homolog of the *SDH1* gene), *SDH2*, *SDH3*, and *SDH4* genes have been constructed and shown that the succinate dehydrogenase activity was retained in the *SDH2* disruptant and that double disruption of *SDH1* and *SDH2* or *SDH1b* genes is necessary to cause deficiency of succinate dehydrogenase activity in sake yeast (Kubo and others 2000). The role of each subunit in succinate dehydrogenase activity and the effect of succinate dehydrogenase on succinate production using strains that were deficient in succinate dehydrogenase, have also been determined. The results suggested that succinate dehydrogenase activity contributes to succinate production under shaking conditions, but not under static and sake brewing conditions.

Biosynthesis of Vicinal Diketones. Vicinal diketones are ketones with two adjacent carbonyl groups. During fermentations, these flavor-active compounds are produced as byproducts of the synthesis pathways of isoleucine, leucine, and valine (ILV pathway) (Fig. 20.9), and thus are also linked to amino acid metabolism (Nakatani and others 1984) and the synthesis of higher alcohols. They impart a "buttery", "butterscotch" aroma to alcoholic drinks. Two of these compounds are important in beer: diacetyl (2,3-butanedione) and 2,3-pentanedione. Diacetyl is quantitatively more important than 2,3-pentanedione. It has a taste threshold at around 0.10–0.15 mg/L in lager beer, approximately 10 times lower than that of pentanedione (Wainwright 1973).

The excreted α-acetohydroxy acids are overflow products of the ILV pathway that are nonenzymatically degraded to the corresponding vicinal diketones (Inoue and others 1968). Tetraploid gene dosage series for various *ILV* genes have been constructed and the obtained yeast strains were used to study the influence of the copy number of *ILV* genes on the production of vicinal diketones (Debourg and others 1990; Debourg 2002). It was shown that *ILV5* activity is the rate-limiting step in the ILV pathway and responsible for the overflow (Fig. 20.9). The nonenzymatic oxidative decarboxylation step is the rate limiting step and proceeds faster at a higher temperature and a lower pH (Inoue and Yamamoto 1970; Haukeli and Lie 1978). The produced amount of α-acetolactate is very dependent on the yeast strain used. The production increases with

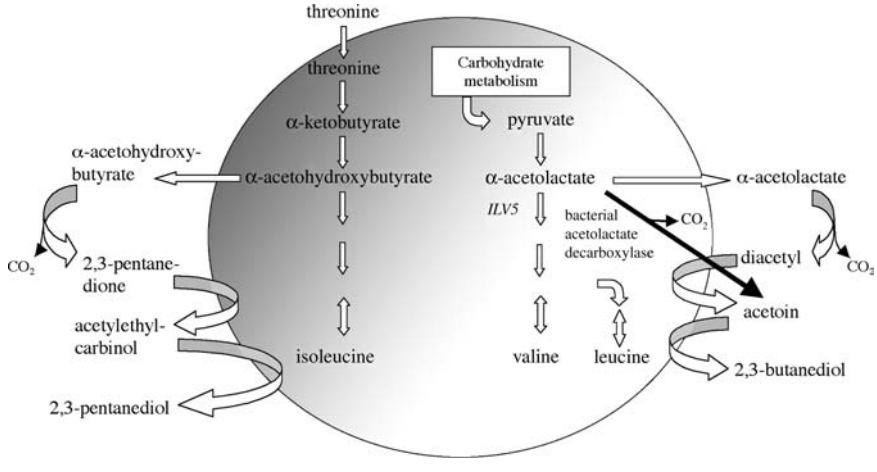

Figure 20.9 *The synthesis and reduction of vicinal diketones in S. cerevisiae.*

increasing yeast growth. For a classical fermentation, 0.6 ppm α-acetolactate is formed (Delvaux 1998). At high aeration, this value can be increased to 0.9 ppm and in cylindroconical fermentation tanks even to 1.2–1.5 ppm.

Yeast cells posses the necessary enzymes (alcohol dehydrogenase, diacetyl reductases) to reduce diacetyl to acetoin and further to 2,3-butanediol, and 2,3-pentanedione to 2,3-pentanediol (Hardwick and others 1976; Louis-Eugene and others 1988; Legeay and others 1989; Heidlas and Tressl 1990; Bamforth and Kanauchi 2004). These reduced compounds have much higher taste thresholds and have no impact on beer flavor (Van Den Berg and others 1983). The reduction reactions are yeast-strain-dependent. The reduction occurs at the end of the main fermentation and during the maturation. Sufficient yeast cells in suspension are necessary to obtain an efficient reduction. Yeast strains that flocculate early during the main fermentation need a long maturation time to reduce the vicinal diketones. Diacetyl can be complexed using SO_2. These complexes cannot be reduced, but diacetyl can again be liberated at a later stage by aldehydes. This situation is especially applicable to yeast strains that produce a lot of SO_2. Worts that are produced using much adjuncts can be low in free amino acid content. These worts can give rise to a high diacetyl peak at the end of the fermentation.

There are several strategies that can be chosen to reduce the amount of vicinal diketones during fermentation:

1. As the temperature has a positive effect on the reduction efficiency of the α-acetohydroxy acids, a warm rest period at the end of the main fermentation and a warm maturation are applied in many breweries. In this case, temperature should be well controlled to avoid yeast autolysis.
2. As the rapid removal of vicinal diketones requires yeast cells in an active metabolic condition, the addition of 5–10% Krausen (containing active, growing yeast) is a procedure that gives enhanced transformation of vicinal diketones (N.N. 2000). This procedure can lead to overproduction of hydrogen sulfide, depending upon the proportions of threonine and methionine carried forward from primary fermentation.
3. Heating up green beer to a high temperature (90°C) and holding it there for a short period (~7–10 min) to decarboxylate all excreted α-acetohydroxy acids. To avoid cell autolysis, yeast cells are removed by centrifugation prior to heating up. The vicinal diketones can be further reduced by immobilized yeast cells in a few hours (typically at 4°C) (see p. 488, Flavor maturation of green beer).
4. Adding the enzyme α-acetolactate decarboxylase (Godtfredsen and others 1984; Rostgaard-Jensen and others 1987; Hannemann 2002). This enzyme decarboxylates α-acetolactate directly into acetoin (Fig. 20.9). It is not present in *S. cerevisiae*, but has been isolated from various bacteria such as *Enterobacter aerogenes*, *Aerobacter aerogenes*, *Streptococcos lactis*, *Lactobacillus casei*, *Acetobacter aceti*, and *Acetobacter pasteurianus*. It has been shown that the addition of α-acetolactate decarboxylase from *Lactobacillus casei* can reduce the maturation time to 22 h (Godtfredsen and others 1983, 1984). An example of a commercial product is Maturex L from Novo Nordisk (Denmark) (Jensen 1993). Maturex L is a purified α-acetolactate decarboxylase produced by a genetically modified strain of *Bacillus subtilis*, which has received the gene from *Bacillus brevis*. The recommended dosage is 1–2 kg per 1000 hL wort, to be added to the cold wort at the beginning of fermentation.

5. Using genetic modified yeast strains.
   a. Introducing the bacterial α-acetolactate decarboxylase gene into yeast chromosomes (Fujii and others 1990; Suihko and others 1990; Blomqvist and others 1991; Enari and others 1992; Linko and others 1993; Yamano and others 1994; Tada and others 1995; Onnela and others 1996). Transformants possessed a very high α-acetolactate decarboxylase activity, which reduces the diacetyl concentration considerably during beer fermentation.
   b. Modifying the biosynthetic flux through the ILV pathway. Spontaneous mutants resistant to the herbicide sulfometuron methyl have been selected. These strains showed a partial inactivation of the α-acetolactate synthase activity and some mutants produced 50% less diacetyl compared to the parental strain (Gjermansen and others 1988).
   c. Increasing the flux of α-acetolactate acid isomeroreductace activity encoded by the *ILV5* gene (Dillemans and others 1987). Because α-acetolactate acid isomeroreductace activity is responsible for the rate-limiting step, increasing its activity reduces the overflow of α-acetolactate. A multicopy transformant results in a 70% decreased production of vicinal diketones (Villaneuba and others 1990), whereas an integrative transformant gives a 50% reduction (Goossens and others 1993). A tandem integration of multiple *ILV5* copies results also in elevated transciption in a polyploidy industrial yeast strain (Mithieux and Weiss 1995). Plasmid amplification of the gene products of *ILV5*, *ILV3*, or tandem *ILV5* + *ILV3* results in vicinal diketone decreases of 70, 40, and 60%, respectively, when compared to that of normal brewer's yeast (Villa and others 1995).

20.3.2 Biochemistry of Secondary Beer Fermentation

During the secondary fermentation or maturation of beer several objectives should be realized:

- Sedimentation of yeast cells;
- Improvement of colloidal stability by sedimentation of the tannin–protein complexes;
- Beer saturation with carbon dioxide;
- Removal of unwanted aroma compounds;
- Excretion of flavor-active compounds from yeast to give body and depth to the beer;
- Fermentation of the remaining extract;
- Improvement of the foam stability of the beer;
- Adjustment of the beer color (if necessary) by adding coloring substances (e.g., caramel);
- Adjustment of the bitterness of beer (if necessary) by adding hop products.

In the presence of yeast, the principal changes that occur are the elimination of undesirable flavor compounds – like vicinal diketones, hydrogen sulfide, and acetaldehyde – and the excretion of compounds enhancing the palate fullness (body) of beer.

20.3.2.1 Vicinal Diketones. In traditional fermentation lagering processes, the elimination of vicinal diketones required several weeks and determined the length of

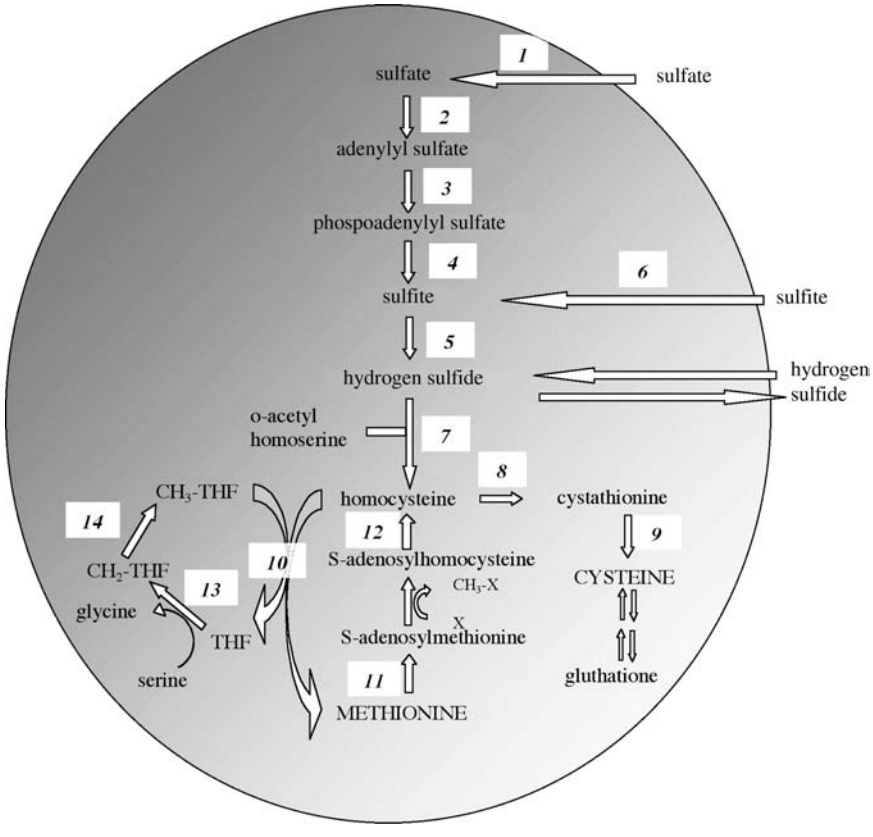

Figure 20.10 *The re-methylation, transulfuration, and sulfur assimilation pathways. Genes and enzymes catalyzing individual reactions are: 1. sulfate permease, 2. ATP sulfurylase, 3. MET14: adenylylsulfate kinase (EC 2.7.1.25), 5. MET10: sulfite reductase (EC 1.8.1.2), 6. sulfite permease, 7. MET17: O-acetylhomoserine (thiol)-lyase (EC 2.5.1.49), 8. SAM1 and SAM2: S-adenosylmethionine synthetase (EC 2.5.1.6), 12. SAH1: S-adenosylhomocysteine hydrolase (EC 3.3.1.1), 13. SHM1 and SHM2: serine hydroxymethyltransferase (SHMT; EC 2.1.2.1), 14. MET12 and MET13: methylenetetrahydrofolate reductase (MTHFR; EC 1.5.1.20). "X" represents any methyl group acceptor; THF, tetrahydrofolate; CH_2-THF, 5,10-methylenetetrahydrofolate; CH_3-THF, 5-methyltetrahydrofolate (partly adapted from Chan and Appling 2003).*

the maturation process. Nowadays, the maturation phase is much shorter because strategies are used to accelerate the removal of vicinal diketones (see above). Diacetyl is used as a marker molecule. The objective during lagering is to reduce the diacetyl concentration below its taste threshold (<0.10 mg/mL).

20.3.2.2 Hydrogen Sulfide. Hydrogen sulfide plays an important role during maturation. Hydrogen sulfide that is not incorporated into S-containing amino acids is excreted by the yeast cell during the growth phase (Fig. 20.10). The excreted amount depends on the used yeast strain, the sulfate content of the wort and the growth conditions (Romano and Suzzi 1992). At the end of the primary fermentation and during the maturation, the excess H_2S is reutilized by the yeast. A warm conditioning period at $10-12^{\circ}$C may be used to remove excessive levels of H_2S.

Brewing yeasts produce H_2S when they are deficient in the vitamin pantothenate (Walker 1998). This vitamin is a precursor of coenzyme A, which is required for metabolism of sulfate into methionine. Panthothenate deficiency may therefore result in an imbalance in sulfur–amino acid biosynthesis, leading to excess sulfate uptake and excretion of H_2S (Slaughter and Jordan 1986).

Sulfite is a versatile food additive used to preserve a large range of beverages and foodstuffs. In beer, sulfite has a dual purpose, acting both as an antioxidant and an agent for masking of certain off-flavors. Some of the flavor-stabilizing properties of sulfite are suggested to be due to complex formation of bisulfate with varying carbonyl compounds, of which some would give rise to off-flavors in bottled beer (Dufour 1991). In particular, the unwanted carbonyl *trans*-2-nonenal has received particular attention, because it is responsible for the "cardboard" flavor of some types of stale beer. It has been suggested that it would be better to use a yeast strain with reduced sulfite excretion during fermentation and to add sulfite at the point of bottling to ensure a good flavor stability (Francke Johannesen and others 1999). Therefore, a brewer's yeast disabled in the production of sulfite has been constructed by inactivating both copies of the two alleles of the *MET14* gene (which encodes for adenylylsulfate kinase). Fermentation experiments showed that there was no qualitative difference between yeast-derived and artificially added sulfite, with respect to *trans*-2-nonenal content and flavor stability of the final beer.

The elimination of the gene encoding sulfite reductase (*MET10*) in brewing strains of *Saccharomyces* results in increased accumulation of SO_2 in beer (Hansen and Kielbrandt 1996a). The inactivation of *MET2* results in elevated sulfite concentrations in beer (Hansen and Kielbrandt 1996b). Beers produced with increased levels of sulfite have shown an improved flavor stability.

The production of H_2S could be reduced by the expression of cystathione synthase genes from *S. cerevisiae* in a brewing yeast strain (Tezuka and others 1992).

20.3.2.3 Acetaldehyde. Aldehydes – in particular acetaldehyde (green apple-like flavor) – have an impact on the flavor of green beer. Acetaldehyde synthesis is linked to yeast growth. Its concentration is maximal at the end of the growth phase, and is reduced at the end of the primary fermentation and during maturation by the yeast cells. As with diacetyl, levels may be enhanced if yeast metabolism is stimulated during transfer, especially by oxygen ingress. Removal also requires the presence of enough active yeast. Fermentations with early flocculating yeast cells can result in too high acetaldehyde concentrations at the end.

20.3.2.4 Development of Palate Fullness. During maturation, the residual yeast will excrete compounds (i.e., amino acids, phosphates, peptides, nucleic acids, . . .) into the beer. The amount and quality of these excreted materials depend on the yeast concentration, yeast strain, its metabolic state, and the temperature (N.N. 2000). Rapid excretion of material is best achieved at a temperature of 5–7°C over 10 days (Van de Meersche and others 1977).

When the conditioning period is too long or when the temperature is too high, yeast cell autolysis will occur. Some enzymes are liberated (e.g., α-glucosidase), which will produce glucose from traces of residual maltose (N.N. 2000). At the bottom of a fermentation tank, the amount of α-amino-nitrogen can rise to 40–10,000 mg/L, which accounts for an increase of 30 mg/L for the total beer volume. The increase in amino acid concentration in the beer has a positive effect on the flavor fullness of the beer. Undesirable medium-chain fatty acids can also be produced in significant amounts if the maturation temperature is too

high (Masschelein 1981). Measurement of these compounds indicates the level of autolysis and permits the determination of the most appropriate conditioning period and temperature.

20.3.3 Beer Fermentation Technology

20.3.3.1 Batch Fermentation Technology. In modern breweries, the primary (main) as well as the secondary fermentation (maturation) are performed in cylindroconical tanks (CCTs). The concept of using CCTs for beer fermentation is quite old. Leopold Nathan patented CCT systems for beer fermentation in 1908 and 1927. It is only since the 1960s, however, that they have been used extensively (Maule 1986). These vessels have a number of desirable features (N.N. 2000):

- They occupy a small land area in relation to volume;
- They can be used for all beer types;
- An increased dispersal of yeast by carbon dioxide uplift allows rapid fermentation;
- Ease of pressure application, carbon dioxide collection, yeast and cold break removal and cleaning (using a CIP system);
- Efficient cooling; and
- Simplified automation.

The content of CCTs can range from 1000 to 10,000 hL. Vessels with high height-to-diameter ratios lead to increased hydrostatic pressure, which leads to overcarbonation. In vessels with a very high height-to-diameter ratio, amino acid utilization by the yeast is enhanced due to the increased fluid flow circulation via carbon dioxide evolution. This results in a beer with increased higher alcohol and decreased ester content. CCTs are made from nonrusting chrome–nickel (V2A) steel. The temperature is closely regulated using temperature sensors and cooling jackets (or cooling pockets) at different heights to remove the heat that is produced during fermentation. Direct or indirect cooling techniques can be used. In direct cooling, liquid ammonia is evaporated (which withdraws heat from the fermenting wort) in the cooling jacket. In indirect cooling, glycol is usually used as the cooling medium, which is cooled in a cooling plant using a plate heat exchanger.

To obtain a rapid start of fermentation, the wort needs to be aerated because yeast cells contain insufficient levels of sterols and unsaturated fatty acids, which need to be incorporated into the yeast cell membrane (David and Kirsop 1973; Rogers and Stewart 1973), and the synthesis of these compounds requires dissolved oxygen (O'Connor-Cox and others 1993). It has been shown that ergosterol and unsaturated fatty acids both increase in concentration as long as oxygen is present in the wort (Haukeli and Lie 1979). A maximum concentration is obtained 5–6 h after pitching, but the formation rate is dependent upon pitching rate and temperature. An interesting new alternative process is to preoxygenate the yeast cells before fermentation. Studies on lager (Aries and Kirsop 1978; Ohno and Takahashi 1986; Devuyst and others 1991; Masschelein and others 1995) and ale (Depraetere and others 2003) yeast preoxygenation have shown that sterols and unsaturated fatty acids are synthesized upon yeast preoxygenation, which results in an improved physiological condition of the yeast cells. The build-up of sterols and unsaturated fatty acids varies considerably among different lager and yeast strains (Depraetere and others 2003). Therefore, a specific preoxygenation procedure for every yeast strain is necessary to obtain successful results. Recent studies have revealed that the supplementation of

cropped yeast with the unsaturated fatty acid, linoleic acid, results in increased ratios of unsaturated fatty acids to total fatty acids and trehalose to glycogen (Moonjai and others 2000, 2002), indicating that supplementation of unsaturated fatty acids is also an interesting alternative to wort aeration.

Different devices are used to aerate the cold wort: ceramic or sintered metal candles, aeration plants employing venturi pipes, two-component jets, static mixers, or centrifugal mixers (Kunze 1999). The principle of these devices is that very small air (oxygen) bubbles are produced and quickly dissolve during turbulent mixing.

A consistent pitching (yeast addition) rate is important for uniform fermentations. Generally, brewers pitch from $10-15 \times 10^6$ viable cells/mL (Knudsen 1985; Narziss 2005) to $15-20 \times 10^6$ cells/mL (Anon. 2000) into regular 12°P wort, up to 25×10^6 cells/mL for 18°P high-gravity worts, and as low as 6×10^6 cells/mL for 9°P low-gravity wort (Knudsen 1985). A rule of thumb for many is to use one million cells per degree Plato of the wort. The yeast to be used for pitching must be checked for viability. The viability must be kept at its highest possible level (95%) for constant performance.

Using CCTs, primary fermentation and maturation can be performed in the same vessel (single-vessel processing). A typical single-vessel procedure for the production of lager beer is summarized in Table 20.12.

At the end of the primary fermentation, yeast flocculation should occur consistently. Yeast flocculation is a reversable, asexual, and calcium-dependent process in which cells adhere to form flocs consisting of thousands of cells (Stratford 1989; Bony and others 1997; Jin and Speers 1999). Many fungi contain a family of cell-wall glycoproteins (called "adhesines") that confer unique adhesion properties (Teunissen and Steensma

TABLE 20.12 Typical Single-Vessel Procedure for the Production of Lager Beer.

Time Phase	Action/Feature	Temperature	Pressure	Density
Start	Pitching with $15-20 \times 10^6$ cells/mL	7–8°C	Atmospheric	12°P
24 h	Remove trub	Increased gradually to 8–11°C	Atmospheric	
End of growth phase	Improved conversion of acetolactate to diacetyl	Increased to 12–14°C and maintained until desired diacetyl level is attained	Allowed to rise to 0.3–0.5 bar overpressure	7–5°P
Just before end of main fermentation	Cooling of the conical bottom	5°C	Increasing overpressure	
24 h after conical bottom cooling	Initial yeast removal		Increasing overpressure	
Reaching of the desired diacetyl level (start maturation)	Slow cooling of the beer	Cooled to 5–7°C	2.5–3 bar overpressure	2–2.5°P
End maturation	Second yeast removal	5–7°C	2.5–3 bar overpressure	2–2.5°P
Colloidal stabilization	Maintained for 2–3 days	−1 to −2°C	2.5–3 bar overpressure	2–2.5°P
End colloidal stabilization	Final yeast removal	−1 to −2°C	2.5–3 bar overpressure	2–2.5°P

1995; Guo and others 2000; Hoyer 2001). These molecules are required for the interactions of fungal cells with each other (flocculation and filamentation) (Teunissen and Steensma 1995; Lo and Dranginis 1998; Guo and others 2000; Viyas and others 2003), with inert surfaces such as agar and plastic (Gaur and Klotz 1997; Lo and Dranginis 1998; Reynolds and Fink 2001), and with mammalian tissues (Cormack and others 1999; Li and Palecek 2003); they are also crucial for the formation of fungal biofilms (Baillie and Douglas 1999; Reynolds and Fink 2001; Green and others 2004). The adhesin protein family in *S. cerevisiae* is responsible for its flocculation. The adhesin proteins are encoded by genes including *FLO1*, *FLO5*, *FLO9*, and *FLO10* (Verstrepen and others 2004). These proteins are called flocculins (Caro and others 1997), because they promote cell–cell adhesion to form multicellular clumps that sediment out of solution. The *FLO1*, *FLO5*, *FLO9*, and *FLO10* genes share considerable sequence homology. The member proteins of the adhesin family have a modular configuration that consists of three domains (A, B, and C) and an amino-terminal secretory sequence that must be removed as the protein moves through the secretory pathway to the plasma membrane (Hoyer and others 1998). The N-terminal domain (A) is involved in sugar recognition (Kobayashi and others 1998). The adhesins undergo several post-translational modifications. They move from the endoplasmic reticulum (ER), through the Golgi, and pass through the plasma membrane and find their final destination in the cell wall, where they are anchored by a glycosyl phosphatidylinositol (GPI) (Teunissen and others 1993; Bidard and others 1994; Hoyer and others 1998; Bony and others 1997). The GPI anchor is added to the C terminus in the ER and mannose residues are added to the many serine and threonine residues in domain B in the Golgi (Udenfriend and Kodukula 1995; Bony and others 1997; Frieman and Cormack 2003; De Groot and others 2003). The *FLO1* gene product (Flo1p) has been localized at the cell surface by immunofluorescent microscopy (Bidard and others 1995). The amount of Flo proteins in flocculent strains increases during batch yeast growth and Flo1p availability at the cell surface determines the flocculation degree of the yeast. Flo proteins are polarly incorporated into the cell wall at the bud tip and the mother – daughter neck junction (Bony and others 1997). The transcriptional activity of the flocculation genes is influenced by the nutritional status of the yeast cells as well as other stress factors (Verstrepen and others 2003). This implies that during beer fermentation, flocculation is affected by numerous parameters such as nutrient conditions, dissolved oxygen, pH, fermentation temperature, and yeast handling and storage conditions.

20.3.3.2 Beer Fermentation Using Immobilized Cell Technology. The advantages of continuous fermentation – such as greater efficiency in utilization of carbohydrates and better use of equipment – led also to the development of continuous beer fermentation processes. Since the beginning of the twentieth century, many different systems using suspended yeast cells have been developed. The excitement for continuous beer fermentation led – especially during the 1950 and 1960s – to the development of various interesting systems. These systems can be classified as:

1. Stirred versus unstirred tank reactors;
2. Single-vessel systems versus a number of vessels connected in series; and
3. Vessels that allow yeast to overflow freely with the beer ("open system") versus vessels that have abnormally high yeast concentrations ("closed" or "semiclosed" systems) (Hough and others 1982; Wellhoener 1954; Coutts 1957; Bishop 1970).

However, these continuous beer fermentation processes were not commercially successful because of many practical problems, such as the increased danger of contamination (not only during fermentation but also during storage of wort in supplementary holdings tanks, which are required because the upstream and downstream brewing processes are usually not continuous), changes in beer flavor (Thorne 1968) and a poor understanding of the beer fermentation kinetics under continuous conditions. One of the well-known exceptions is the successful implementation of a continuous beer production process in New Zealand by Morton Coutts (Dominion Breweries), which is still in use today (Hough and others 1982; Coutts 1957).

In the 1970s, there was a revival in developing continuous beer fermentation systems due to the progress in research on immobilization bioprocesses using living cells. Narziss and Hellich (1971) developed one of the first well-described ICT processes for beer production. Yeast cells were immobilized in kieselguhr (which is widely used in the brewing industry as a filter aid), and a kieselguhr filter was employed as the bioreactor (called the "bio-brew bioreactor"). This process was characterized by a very low residence time of 2.5 h, but required the addition of viable yeast and a 7-day maturation period to reduce the high concentration of vicinal diketones in the green beer. Although this result looks very good, the bio-brew bioreactor, overall, gave no satisfying results. The most serious problem was the high amount of α-acetolactate in the green beer (Narziss 1997).

Baker and Kirsop (1973) were the first to use heat treatment of green beer to considerably accelerate the chemical conversion of α-acetolactate to diacetyl. They designed a two-step continuous process. The first reactor is a packed-bed reactor also containing kieselguhr with immobilized yeast cells to perform the primary fermentation. The green beer was heated using a heating coil to accelerate the α-acetolactate conversion. It was next cooled before it entered a smaller packed-bed reactor to perform the secondary fermentation. Problems associated with this process included a gradual blocking of the packed bed and a changed beer flavor.

In 1973, the first industrial-scale process using gel (polyacrylamide, later substituted by κ-carrageenan) immobilized nonliving *Escherichia coli* cells (containing aspartase activity) to produce L-aspartic acid from fumaric acid was implemented by the company Tanebe Seiyaku in Japan (Shibatani 1996). Following the introduction of alginate gel as an entrapment matrix for living yeast cells for the production of beer by White and Portno in 1979, there was an increased level of research activity in the development of ICT processes for the production of beer. In a laboratory-scale tower fermentor, these researchers were able to produce beer with a flavor that was comparable to the control (batch fermentation with free cells). This process was operational over 7 months. It was found that gel entrapment gave protection against contaminating bacteria. Furthermore, the concentration of ethyl acetate decreased during long-term operation.

Over the last 30 years, immobilized cell technology (ICT) has been extensively examined and some designs have already reached commercial exploitation. One of the major advantage of ICT is the increased volumetric productivity due to the high volumetric cell densities of yeast in the reactor. Consequently, the fermentation process can be performed in a smaller bioreactor (decreased capital costs) with shorter residence times. Immobilized cell systems are heterogeneous systems in which considerable mass transfer limitations can occur, resulting in a changed cell yeast metabolism. Therefore, successful exploitation of ICT needs a thorough understanding of mass transfer and intrinsic yeast kinetic behavior of these systems. Technical challenges include removal of excess yeast and carbon dioxide, sustaining yeast viability, optimization of oxygen (air) feed, prevention of

microbial contamination, prevention of clogging or channeling in some bioreactor types, and regeneration of large amounts of carrier material (Linko and others 1998).

Carrier Materials. Various cell immobilization carrier materials have been tested and used for beer production/bioflavoring. Selection criteria are summarized in Table 20.13. Depending on the particular application, reactor type, and operational conditions, some selection criteria will be more appropriate. Examples of selected carrier materials for particular applications are described in Table 20.14.

In one of the first ICT processes for continuous beer fermentation, kieselguhr (diatomaceous earth) was selected as the carrier material (Narziss and Hellich 1971). Later, alginate hydrogel encapsulation became popular (White and Portno 1979; Hsu and Bernstein 1985; Onaka and others 1985; Curin and others 1987; Shindo and others 1994; Nedovic and others 1997, 2001, 2004). In addition, some new hydrogel materials were introduced, such as κ-carrageenan, pectate gels, and polyvinyl alcohol (PVA) (Mensour and others 1996; Pilkington and others 1999; Smogrovicová and Dömény 1999; Raymond and others 2004; Nedovic and others 2005). The main advantage of the hydrogel entrapment method is the attainment of extremely high cell loadings and – consequently – high fermentation rates. However, in some cases cell proliferation and activity can be limited by low mass transfer rates within the matrices. The reduced cell growth in immobilized conditions can result in an insufficient free amino nitrogen consumption and, as a consequence, an unbalanced flavor profile of the final beer (Curin and others 1987; Hayes and others 1991). This was particularly the case for immobilized cells in packed-bed

TABLE 20.13 Selection Criteria for Yeast Cell Immobilization Carrier Materials.

- High cell mass loading capacity
- Easy access to nutrient media
- Simple and gentle immobilization procedure
- Immobilization compounds approved for food applications
- High surface-area-to-volume ratio
- Optimum mass transfer distance from flowing media to center of support
- Mechanical stability (compression, abrasion)
- Chemical stability
- Highly flexible: rapid start-up after shut-down
- Sterilizable and reusable
- Suitable for conventional reactor systems
- Low shear experienced by cells
- Easy separation of cells and carrier from media
- Readily up-scalable
- Economically feasible (low capital and operating costs)
- Desired flavor profile and consistent product
- Complete attenuation
- Controlled oxygenation
- Control of contamination
- Controlled yeast growth
- Wide choice of yeast

TABLE 20.14 Some Selected Applications of Cell Immobilization Systems Used for Beer Production.

Carrier Material	Reactor Type	Reference
	Flavor Maturation	
Calcium alginate beads	Fixed-bed	Shindo and others 1994
DEAE–cellulose	Fixed-bed	Pajunen and Grönqvist 1994
Polyvinyl alcohol beads	Fixed-bed	Smogrovicová and others 2001
Porous glass beads	Fixed-bed	Linko and others 1993, Aivasidis 1996
	Alcohol-Free Beer	
DEAE–cellulose beads	Fixed-bed	Collin and others 1991, Lomni and others 1990
Porous glass beads	Fixed-bed	Aivasidis and others 1991
Silicon carbide rods	Monolith reactor	Van de Winkel and others 1991
	Acidified Wort	
DEAE–cellulose beads	Fixed-bed	Pittner and others 1993
	Main Fermentation	
Calcium alginate beads	Gas-lift	Nedovic and others 1997
Calcium pectate beads	Gas-lift	Smogrovicová and others 1997
κ-Carrageenan beads	Gas-lift	Mensour and others 1996
Ceramic beads	Fixed-bed	Inoue 1995
Gluten pellets	Fixed-bed	Bardi and others 1997
Polyvinyl alcohol beads	Gas-lift	Smogrovicová and others 2001
Porous glass beads	Fixed-bed	Virkajärvi and Krönlof 1998
Porous chitosan beads	Fluidized-bed	Unemoto and others 1998, Maeba and others 2000
Silicon carbide rods	Monolith reactor	Andries and others 1996
Spent grains	Gas-lift	Brányik and others 2002
Wood chips	Fixed-bed	Linko and others 1997, Kronlöf and Virkajärvi 1999

fermentors where high mass transfer restrictions, accumulation of carbon dioxide, nonuniform temperature profiles, flow channelling, and stagnant zones were observed during primary fermentation. Therefore, different approaches for the adaptation of immobilized systems were investigated in order to correct the final beer quality. The crucial elements were cell carrier selection and bioreactor design.

Packed-bed reactors have been selected for the production of alcohol-free or low-alcohol beers and for enhanced flavor maturation using immobilized cells. In these applications, conditions are anaerobic and yeast growth is limited. Preformed carrier materials are selected. Immobilization of cells can be by adsorption (e.g., DEAE–cellulose beads) or a combination of adsorption and entrapment (e.g., porous glass beads). These carrier materials need to be mechanically strong to withstand the high pressures in packed-bed reactors.

Recently, cheap carrier materials have been investigated as the use of these materials avoids the costly regeneration of used immobilization matrices. Wood chips have shown good performance and the use of this material has reduced the total investment cost by one-third compared to more expensive carriers (Kronlöf and others 2000).

An alternative preformed support material, based on spent grains, has been proposed recently for yeast cell immobilization for primary beer fermentation in an air-lift bioreactor (Brányik and others 2001, 2002, 2004a,b). This is an interesting carrier for cell immobilization, because spent grains are a waste byproduct of the brewing process.

Applications of Immobilized Cell Technology (ICT) in the Brewing Industry. ICT processes have been designed for different stages in the beer fermentation process, including wort acidification, bioflavoring during the secondary fermentation, primary fermentation, and fermentations for the production of alcohol-free or low-alcohol beers (for recent reviews see Branyik and others 2005; Nedovic and others 2005). The most challenging and most complex application is the combined main and secondary fermentations. A further major challenge to successfully apply ICT on an industrial scale is the control and fine-tuning of the flavor profile during a combined primary and secondary fermentation, as many parameters can have an influence on flavor formation (Willaert and Nedovic 2006).

FLAVOR MATURATION OF GREEN BEER. The objective of flavor maturation is the removal of diacetyl and 2,3-pentanedione, and their precursors α-acetolactate and α-acetohydroxybutyrate. The conversion of α-acetohydroxy acids to the vicinal diketones is the rate-limiting step. This reaction step can be accelerated by heating the beer – after yeast removal – to 80–90°C over a couple of minutes. The resulting vicinal diketones are subsequently reduced by immobilized cells into their less-flavor-active compounds.

The traditional maturation process is characterized by a near-zero temperature, low pH, and low yeast concentration, resulting in a very long maturation period of 3 to 4 weeks. Using immobilized cells, this long period can be reduced to 2 h. An ICT maturation process using a packed-bed bioreactor with DEAE–cellulose beads has been successfully integrated in the Synebrychoff Brewery (Finland) for the treatment of one million hL per year (Pajunen 1995). Alfa Laval and Schott Engineering developed a maturation system based on porous glass beads (Dillenhöfer and Rönn 1996). This system has been implemented in several breweries in Finland (Hyttinen and others 1995), Belgium, and Germany. The German company Brau & Brunnen has also shown an interest in the Alfa Laval maturation technology. In 1996, a 30,000 hL/year pilot-scale system was purchased and installed in their plant (Mensour and others 1997). The Alfa Laval maturation system has been implemented in a medium-sized German brewery (Schäff/Treuchtlingen) (Back and others 1998). The obtained beers yielded overall good analytical and sensorial results.

PRODUCTION OF ALCOHOL-FREE OR LOW-ALCOHOL BEER. The classic technology to produce alcohol-free or low-alcohol beer is based on the suppression of alcohol formation by arrested batch fermentation (Narziss and others 1992). However, the resulting beers are characterized by an undesirable wort aroma, because the wort aldehydes (especially 3-methylthiopropion aldehyde) have only been reduced to a limited degree (Collin and others 1991; Debourg and others 1994; van Iersel and others 1998; Perpète and Collin 1999; Van Nedervelde and others 1999). The reduction of these wort aldehydes can be quickly achieved by a short contact time with the immobilized yeast cells at a low temperature without undesirable cell growth and ethanol production. A disadvantage of this short contact process is the production of only a small amount of desirable esters.

Controlled ethanol production for low-alcohol and alcohol-free beers has been successfully achieved by partial fermentation using DEAE–cellulose as the carrier material, which was packed in a column reactor (Collin and others 1991; Van Dieren 1995). This technology has been successfully implemented by Bavaria Brewery (The Netherlands) to produce malt beer on an industrial scale (150,000 hL/year) (Pittner and others 1993). Several other companies, such as Faxe (Denmark), Ottakringer (Austria), and a Spanish brewery, have also implemented this technology (Mensour and others 1997). In Brewery Beck (Germany), a fluidized-bed pilot-scale reactor (8 hL/day) filled with

porous glass beads was used for the continuous production of nonalcohol beer (Aivasidis and others 1991; Breitenbücher and Mistler 1995; Aivasidis 1996). Yeast cells immobilized in silicon carbide rods and arranged in a multichannel loop reactor (Meura, Belgium), have been used to produce alcohol-free beer on a pilot scale by Grolsch Brewery (The Netherlands) and Guinness Brewery (Ireland) (Van De Winkel 1995).

Nuclear mutants of *S. cerevisiae* that are defective in the synthesis of tricarboxylic acid cycle enzymes, that is, fumarase (Kaclíková and others 1992) or 2-oxoglutarate dehydrogenase (Mockovciaková and others 1993), have been immobilized in calcium pectate gel beads and used in a continuous process for the production of nonalcoholic beer (Navrátil and others 2000). These strains produced minimal amounts of ethanol and they were also able to produce much lactic acid (up to 0.64 g/dm^3).

PRODUCTION OF ACIDIFIED WORT USING IMMOBILIZED LACTIC ACID BACTERIA. The objective of this technology is the acidification of the wort according to the "Reinheidsgebot", before the start of the boiling process in the brewhouse. An increased productivity of acidified wort has been obtained using immobilized *Lactobacillus amylovorus* on DEAE–cellulose beads (Pittner and others 1993; Meersman 1994). The pH of the wort was reduced below a value of 4.0 after contact times of 7–12 min using a packed-bed reactor in downflow mode. The produced acidified wort was stored in a holding tank and used during wort production to adjust the pH.

CONTINUOUS PRIMARY FERMENTATION. The Japanese brewery Kirin developed a multistage continuous fermentation process (Inoue 1995; Yamauchi and others 1994; Yamauchi and Kashihara 1995). The first stage is a stirred tank reactor for yeast growth, followed by packed-bed fermenters, and the final step is a packed-bed maturation column. The first stage ensures adequate yeast cell growth with the desirable free amino nitrogen consumption. Ca-alginate was initially selected as the carrier material to immobilize the yeast cells. These alginate beads were later replaced by ceramic beads ("Bioceramic®"). This system allowed beer to be produced within three to five days. This pilot-scale (100 hL) system was operational over two years in a restaurant brewery on Saipan Island (Northern Mariana Islands). The production scale was 5 hL/day, and beer of acceptable quality was produced.

The engineering company Meura (Belgium) developed a reactor configuration with a first stage with immobilized yeast cells where partial attenuation and yeast growth occurs, followed by a stirred tank reactor (with free yeast cells) for complete attenuation, ester formation, and flavor maturation (Andries and others 1996; Masschelein and Andries 1995). Silicon carbide multichannel porous rods (60% void volume) are used in the first reactor as immobilization carrier material. The porous rods are seeded with yeast cells and perfused in parallel with a recirculating feed medium. The stirred tank (second reactor) is continuously inoculated by free cells that escape from the first immobilized yeast cell reactor. The system is characterized by a simple design, which can easily be scaled up. Disadvantages are the relatively high cost of silicon carbide matrices, and lower cell growth and specific productivity in this system as compared to free cells. The immobilized reactor system has been found to be stable over a period of more than six months, producing ale and lager beer of excellent quality (Andries and others 2000).

Labatt Breweries (now InBev, Canada), in collaboration with the Department of Chemical and Biochemical Engineering at the University of Western Ontario (Canada), developed a continuous system using κ-carrageenan immobilized yeast cells in an airlift reactor (Mensour and others 1995, 1996, 1997; Pilkington and others 1999). Pilot-scale

(50 L) research showed that full attenuation was reached in 20–24 h with this system compared to 5–7 days for the traditional batch fermentation. Although the flavor profiles of the beer produced using ICT and the batch-fermented beer differed somewhat, a taste panel judged the immobilized cell product to be acceptable and, overall, similar to the conventional control fermentation product.

Hartwell Lahti and VTT Research Institute (Finland) developed a primary fermentation system using ICT on a pilot scale of 600 L/day (Kronlöf and others 1989; Kronlöf and Virkajärvi 1999). Woodchips were used as the carrier material. The results showed that fermentation and flavor formation were very similar compared to a traditional batch process, although the process time was reduced to 40 h.

Synebrychoff Brewery (Finland), in collaboration with Guinness, GEA Liquid Processing Scandinavia, and Cultor Corporation of Finland, developed a new ICT process in which the concentration of carbon dioxide is controlled in a fixed-bed reactor in such a way that the CO_2 formed is kept dissolved, and is removed from the beer without foaming problems (Andersen and others 1999). DEAE–cellulose was used as the carrier material. High-gravity beer of acceptable quality has been fermented over 20 h at a capacity of 50 L/h. Later, wood chips were used as carrier material (Pajunen and others 2001; Tapani and others 2003). Good quality beer and a constant flavor profile were achieved with a production time of 20–30 h. In a pilot plant (reactor volume of 10 hL, 12 hL/day), the fermentation process and flavor formation could be controlled by using the feed rate, recirculation rate, and fermentation temperature as control variables (Pajunen and others 2001).

A gas-lift bioreactor system, which was introduced in beer fermentation experimental studies by the research group at Belgrade University, is another promising concept for main beer fermentation (Nedovic and others 1993). Hydrogel carriers like alginate, carrageenan, and pectate demonstrated limited mechanical stability and resistence when applied in packed-bed reactors. However, these porous matrices present a good solution for yeast immobilization in gas-lift bioreactors. Laboratory- and semi-pilot-scale bioreactor systems were developed with alginate microbeads (0.8 mm in diameter) and lens-shaped PVA particles ("LentiKats^{TM}") as carriers for yeast cells (Nedovic and others 2004, 2005). Full beer attenuation in these experiments was reached within 7.5–20 h depending on solid loading (10–40%). The final beers had the desired sensory and analytical profiles.

A combined continuous immobilized system for primary fermentation and maturation has been developed and characterized (Smogrovicová and others 2001). The primary fermentation was carried out in a gas-lift bioreactor, the maturation in a packed-bed reactor. The green beer was heat-treated (to accelerate the conversion of α-acetolactate to diacetyl) before it was fed to the maturation reactor. Yeast cells were entrapped in lens-shaped PVA particles and used to perform the primary fermentation as well as the maturation. The system was stable for 2 months at a residence time of 24–36 h. The produced beer was characterized by a composition and flavor profile that was similar to that of beer produced by a classical batch fermentation.

21.1 INTRODUCTION

One of the world's greatest alcoholic drinks is whisky (whiskey). The term "whisky (whiskey)" was derived from the Gaelic "uisge beatha", equivalent to the Latin term "aqua vitae", meaning "water of life". It was invented by accident by alchemists before the eleventh century and they gave the drink this name (Gavin 1997).

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

It was reported that the Irish were drinking a form of whisky in the twelfth century, and Henry of England said that the distillation of spirit "usquebaugh" was well established in Ireland when he invaded there in 1172 (Daiches 1995). It is clear that distilling was certainly then brought from Ireland to Scotland in the early Middle Ages, although it seems to have been known in the Far East at a very early date among alchemists (Kippple and Ornelas 2000). By the end of the fifteenth century, whisky was well established in Scotland, with the first record of a commercial transaction involving the supply of whisky (aqua vitae) in the year 1494. The manufacture of whisky was brought to the United States of America in the seventeenth to eighteenth centuries and further developed to manufacture in Canada. In the early twentieth century, whisky manufacture was also brought to Japan. These five countries (Ireland, Scotland, the United States, Canada, and Japan) produce about 95% of the whisky in the world and, therefore, they are known to be the five largest international whisky-distilling countries (Tsuchiya 2000; Bathgate 2003). Many other countries are also producing whisky (Murphy 1978).

The appellation of whisky, spelled without an "e" in Scotland, Canada, and Japan, but with an "e" in Ireland and the United States, is the generic name for a distilled product made from saccharified and fermented cereal extracts.

21.2 SCOTTISH WHISKY

The word "Scotch" is, of course, a contraction of "Scottish whisky" and was first used in the mid-nineteenth century (Benitah 2002). Scotch malt whisky was well established in Scotland by the end of the fifteenth century, and approximately 700,000 kiloliters (kL) is produced per year. It is consumed in over 200 countries worldwide (Tsuchiya 2006a). There are three types of whisky in Scotland, malt whisky, grain whisky, and blended whisky.

21.2.1 Malt Whisky

Scottish malt whisky is produced by using barley, water, and peat as the raw materials. Barley locally grown in the northeast of the country was originally used. However, some of the greatest Highland distilleries today also use imported barley. Large grain two-row barley, with high starch and low protein content, is preferred.

21.2.1.1 Malting. Malting is the first step in making whisky. Malt is barley that has been persuaded to germinate by soaking in water and has then been dried by the application of heat (Daiches 1995).

The "Steeping" or soaking period in the tank is usually 2 to 3 days. The water is drained off and the grain spread out to a depth of 20–30 cm on a concrete or tiled floor in the malting house. The water content of the barley rises to approximately 43% by this soaking or steeping process. Barley begins to germinate on the malting floor and generates energy that raises the temperature. The barley is turned with rakes and wooden shovels by maltmen every 4 or 6 h in order to maintain approximately 16°C temperature and to prevent growing roots tangling each other. After 7 to 10 days, the growing stem of the barley becomes one-half to five-eighths of the length of the seed (Tsuchiya 2000).

To stop the germination, green malt is transferred to the drying kiln, which has a unique chimney (Fig. 21.1). The floor of the kiln is a drain board made of perforated iron or wire mesh. The green malt is spread on this floor at a depth of 70 cm to 1 m, depending on the design of the kiln, and dried in smoke rising from a peat fire below the floor (Tsuchiya

Figure 21.1 *Drying kiln, with its unique chimney.*

2000). Figure 21.2 shows a sample of the peat used to dry malt. Besides peat, coal and coke are often used as fuel and the barley is dried for 40–55 h until the moisture content becomes 3–4%. The peat smoke gives a special smoky flavor to the green malt and to the final product: mature whisky. A growing number of distilleries no longer do their own malting, but buy their malt ready-made from maltsters, peated to the desired degree. The kiln building is only kept as a symbol of such distilleries (Simpson 1994).

21.2.1.2 Mashing. The dried malt is moved to the malt mill and ground to fine grist consisting of husk, grits, and flour in the ratio 2 : 7 : 1 (Tsuchiya 2000). The malt grist is placed in a container known as mash tun and hot water is added. The shape and size of mash tuns vary

Figure 21.2 *Sample of peat used to dry malt.*

Figure 21.3 *Mash tun.*

and they are made from stainless steel, copper, or cast iron, usually with a lid (Fig. 21.3). Mashing or extraction of the malt is carried out three or sometimes four times with hot water, each time at a different temperature, ranging from about 60°C for the first process to 100°C for the last (Daiches 1995). Mashing with hot water dissolves the starch from the malt and also activates the amylase that decomposes the starch to maltose.

Wort (the resultant liquid) is drawn off from the base of the mash tun through the finely slotted bottom, cooled to around 20°C, and passed into fermentation vessels, or washbacks. The residual solids (draff) are removed from the floor of the mash tun and used as cattle feed (Arthur 2003).

21.2.1.3 Fermentation. The washback is made of wood or stainless steel and has a lid that incorporates a rotating blade that prevents foaming over the sides (Fig. 21.4). When the washback is two-thirds full, yeast is added in liquid or solid form to the wort and fermentation takes place at 17–35°C for 48 h (on average). The inoculated yeast converts maltose into glucose, and then alcohol and carbon dioxide (CO_2) are produced from glucose. Yeast also produce small amounts of other compounds such as a wide range of esters, aldehydes, acids, and higher alcohols. Many of these are flavor elements. The fermented wort (wash) is a sweet peaty beer-like liquid with an alcoholic content of 7–8% (Tsuchiya 2000).

21.2.1.4 Distillation. The next process, distillation, is what actually produces the whisky. Scottish malt whisky has been traditionally distilled in onion-shaped stills (pot stills), which are large copper kettles with narrow necks called lyne arms or lyne pipes that curve and enter the condenser, often located in the open air outside the still house (Simpson 2003). The shape and size of the pot still affect the quality of the whisky produced. Stills come in three basic designs, the "onion" being the most common, and the "boil-ball" and "lantern" shape (Fig. 21.5).

The way these designs are interpreted – as to capacity, height, method of heating, angle of the lyne arm, and so on – differs from one distillery to another, and varies the quantity

Figure 21.4 *Washback.*

of volatiles that will end up in the spirits (MacLean 2002; Nicol 2003). Traditional direct firing either by coal or gas to heat up the pot still is retained by many distilleries. However, a large number of distilleries have now switched to heating the stills by means of internal steam exchangers (Simpson 1994). The direct-fired wash stills have "rummagers" (revolving arms) to prevent solids in the wash sticking to the bottom of the still and scorching (Simpson 1994).

The area of copper that comes into contact with the wash and low wines is another consideration in still design. Copper dissolves easily and has a decisive influence on the quality of the spirit, as it removes sulfury or vegetable aromas by a chemical reaction (MacLean 2002).

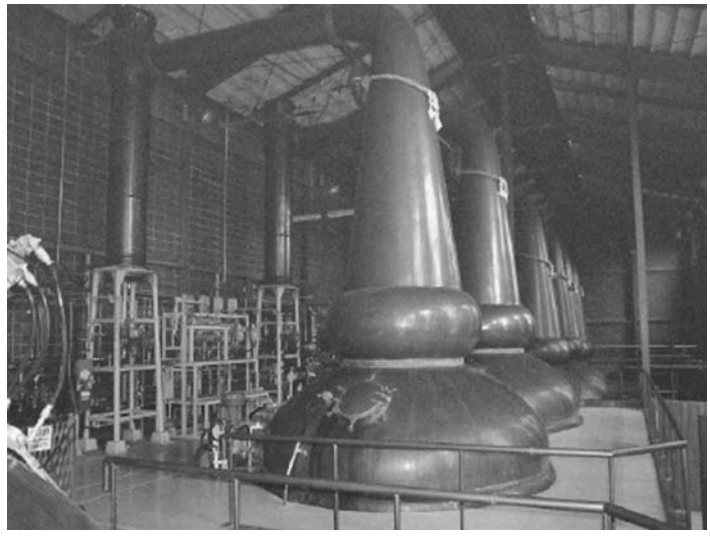

Figure 21.5 *Still.*

Because malt whisky is usually produced by double distillation, every distillery must have at least two such stills. Occasionally a third still is installed. A distillery with only one still operates the functions of wash and low wine stills in sequence.

For the first distillation, the fermented wash passes through the wash charger, into the wash still (or singling still). The charged volume is between half and two-thirds capacity, in order to allow for expansion of the wash and the froth that builds up as it is heated (MacLean 2002). When the wash in the still is heated, the alcohol (ethanol) vaporizes at a fairly low temperature (78.3°C), and passes up the neck of the still and down through the worm (coiled copper pipe) within a water jacket (worm tub or condenser). The distillate from the wash, low wine, consists of 21–24% by volume of alcohol (ABV). The first distillation is finished when the liquid left in the wash still is of no more than 1% ABV. At the end of the run, about a third of the wash will have become low wine (MacLean 2002).

As the low wine contains a large number of other volatile alcohols and oils, it must be further purified by a second distillation in the low wine still (or double/second still), which is smaller than the wash still. During the second distillation, its progress is carefully monitored by the stillman, who starts to test the spirit as soon as the condensed vapors pass through the spirit safe (Fig. 21.6).

The first distillate, called *foreshots* or *head*, is tested for the presence of impurites. When water is added, it will turn cloudy. This is called the demisting test. Foreshots are of high alcohol strength (75–80% ABV) and pungent, owing to the impurities they contain (Simpson 2003), such as the aldehyde, esters, furfurals and other compounds of hydrogen, oxygen, and carbon formed in the process of distilling the wash and known generally as congeneric, congeners, or congeries. However, they also give pot-still malt whisky its special bouquet and flavor (Daiches 1995). The foreshots are directed into the low wine charger to be redistilled with the next batch of low wines. The stillman continues to test the spirit in the spirit safe by adding water at regular intervals and checking the specific gravity. As soon as the spirit ceases to turn cloudy with the addition of water, it

Figure 21.6 *Monitoring of distillation as soon as vapors pass through the spirit safe.*

is immediately directed to the spirit receiver for collection (Arthur 2003). The spirit directed to the spirit receiver is called *hearts* or *middle cut* which consists of about 70% by volume of alcohol.

The amount of the hearts is approximately one-third of the spirit distilled. When the spirit starts to weaken, this weakened spirit, called *feints*, *after-shots*, or *tail*, is run into the feints receiver. The stillman stops collecting the spirit at the point when the alcohol content is as high as 69% by volume of alcohol for the lighter whisky character and as low as 60% for the heavier whisky character (MacLean 2002). The breadth of the cut has a profound effect on the quality of the final product. The collected feints and foreshots will be added to the next low wine for distillation. The residue in the low wine still, *spent lees*, is of no use or value and goes to waste (MacLean 2002).

21.2.1.5 Maturation. The immature spirit, called *new pot* or *new spirit*, is piped to the filling station, where it is diluted with water until its strength is reduced to 63.5% by volume of alcohol (Tsuchiya 2000). This diluted spirit is stored in casks made either from American white oak (*Quercus alba*) or European oak (*Quercus robur*) for maturation. Oakwood is thought to be desirable for maturing whisky because of its chemical complexity. The casks are secondhand, in that they have been used to store either sherry or bourbon, and in rare cases port or other wines.

Maturation of new spirits is conducted in casks stored in warehouses called "dunnage" warehouses for at least three years undisturbed. After that they can be legally called scotch whisky.

Bottling of "single malt" or "deluxe blend" whisky uses spirits matured in the cask for at least 10 to 15 years (Arthur 2003). However, there is always the danger of the whisky acquiring a slightly "woody" flavor after 15 years (Daiches 1995). Whisky maturation is influenced by factors such as the nature and history of the cask, the style of warehouse and its location, the outside microclimate of casks, and the maturation period. Oakwood facilitates oxidation, which removes harshness, increases fruitness and adds complexity (MacLean 2002). All trees suitable for making casks must be over 80 years old. Oak casks that have previously been filled with sherry give a splendid mellowing effect (color, softness, richness, and smoothness) to the mature whisky, and bourbon casks give a typically vanilla-like aroma. The process of charring of the inside walls of bourbon casks also contributes to the flavor of malt whisky. This releases vanillin into the spirits and assists in removing undesirable off-notes (Figs 21.7 and 21.8). Sherry casks are toasted rather than charred.

A small loss of spirit is expected during maturation. The smaller the cask, the faster the maturing and the larger the amount of whisky lost through absorption by the porosity of the cask wood. The degree of humidity in the warehouse where the casks lie during the maturation also affects the degree of loss of maturing whisky both in its volume and its strength. The higher the humidity, the more it loses strength (by about 4–5% ABV in ten years), and the drier, the more it loses volume (Daiches 1995). This is known as the "angel's share", a loss of 1–3% every year (Tsuchiya 2000).

Alcohol content decreases from 63.3% to around 60% and the volume becomes 80% of the initial filling after ten years' maturation. The longer whisky is matured in the cask, the more changes of color and flavor will take place. It should be noted that each cask of malt whisky from the same distillery tastes different from its neighbor, even if they came from the same still run (Simpson 1994).

Figure 21.7 *Casks.*

21.2.1.6 Bottling. Before bottling, whisky is further diluted with water until its strength is reduced to 40–60% by volume of alcohol. Soft water, free from organic and mineral impurity, is preferred for whisky production. Whisky is usually filtrated through a cellulose filter to remove fatty particles at a temperature between 4 and 10°C prior to being run into bottles (Simpson 1994). Once run into the bottles, whisky does not further mature, but some chemical changes will occur.

Single malt whisky is the product of a single distillery. When bottled, the single malt may include whisky from several years' production from the same distillery (Arthur 2003). The age shown on the bottle label means the length of the youngest whisky's maturation period. A malt whisky that is bottled from an individual cask is called single cask whisky. A vatted malt whisky is a product that is "married" together with various malt whiskies from several distilleries. A vatted malt whisky is labeled

Figure 21.8 *Casks.*

"pure malt" or "scotch malt whisky". It is impossible to determine the optimum age for whisky in general terms; so much depends on the individual case.

There are about 110 malt whisky distilleries in Scotland and about 80 to 90 distilleries are now in operation (K-Writer's Club 1998; Futagani 2000; Tsuchiya 2002). Scotch whisky is traditionally divided into Highland malts, Lowland malts, Campbeltown and Islays (Hirazawa 1990; Fikunishi 1992; Hashiguchi 2002; Hashiguchi 2003).

21.2.2 Grain Whisky

In Scotland, when whisky is produced largely from maize with a small amount of malted barley that is not dried over peat fires, it is called Scottish grain whisky. In some cases, unmalted barley is also used with the maize. The unmalted cereal is crushed and then pressure-cooked in batch cookers to gelatinize the starch so that it can be released and solubilized. Wet ground malted barley is added in an amount one-fifth of the amount of unmalted cereal, followed by hot water, and the mixture is stirred (Daiches 1995). Amylase from malted barley converts the starch to fermentable sugars, maltose. Although many distillers retain this system, there is an increasing use of continuous operation for the cooking and conversion process (Simpson 1994).

Fermentation of the wort is carried out in the same way, by the action of inoculated yeast, as in the case of making malt whisky. The fermented wort, *wash*, is pumped into the patent still or Coffey still, which distillates wins a different system from distillation using a pot still. The patent still was first invented by Robert Stein in 1826 and was improved by Aeneas Coffey in 1831. With the invention of the patent still, making whisky has become quicker, cheaper, and occurs in greater volumes. The product has no peaty flavor, for the malt had not been dried over peat fires (Daiches 1995; Tsuchiya 2000). Figure 21.9 shows a Coffey still made in Scotland, which is now running in Japan.

The patent still basically consists of two linked copper columns, 12–15 m high; these are called the analyzer and the rectifier. Each is divided horizontally into tens of chambers by perforated copper plates. Steam is led into the analyzer and proceeds up the analyzer and then through the linking pipe into the rectifier. The wash is continuously pumped into the rectifier, traveling down in a coiled copper pipe and then via the connecting wash pipe into the top of the analyzer. The heated wash moves down, chamber by chamber in the analyzer, and all the alcohol contained is vaporized before the wash reaches the base of the analyzer. The steam and alcohol vapors, which rise up through the analyzer, travel down the connecting vapor pipe (which emerges from the top of the analyzer) into the base of the rectifier. As the alcohol vapor and the steam rise up to the rectifier, chamber by chamber, the new incoming wash, coming down the rectifier in the winding pipe, is then cooled, and condensation takes place (Daiches 1995; Brander 1996; Hashiguchi 2002).

Around 95% alcohol can be obtained when the vapor is drawn off through a cooling worm to the stainless steel spirit receivers. Alcohol strength for making whisky is regulated below 94.8% by the law of Scotland (Tsuchiya 2000). The spirit is then diluted with water to around 70% by volume of alcohol, prior to being run into secondhand oak casks that were previously used for the maturation of malt whisky. The spirit-filled casks are left undisturbed in the warehouse for at least three years, the same as malt whisky (Tsuchiya 2000).

The grain whisky, being nearer to a neutral spirit than pot-still malt whisky, takes less time to mature and changes less in the maturing process. There are two types of grain whisky; one

Figure 21.9 *Coffey still.*

is a single-grain whisky produced in one distillery, and the other is that produced by vatting whiskies distilled in several distilleries. The age shown on the bottle label indicates the length of the youngest whisky's maturation period. Only eight grain distilleries are in operation; seven of these are located in Lowland Scotland (Benitah 2002).

21.2.3 Blended Whisky

A blended whisky is created from both single malts and grain whisky. Andrew Usher, of Edinburgh, pioneered blending in the early 1860s (Tsuchiya 2000). Blends are central to the Scotch whisky market, outselling malt whiskies at a ratio of around nine to one.

Blending can involve combining around 20 to 50 different malt whiskies with two to five grain whiskies to produce mild whisky with a well-balanced flavor (Daiches 1995; Hashiguchi 2002). It provides the distiller with an opportunity to create a product with unique and recognizable flavor attributes. It also enables product consistency. The proportion is 60% grain to 40% malt. The proportion of grain has risen since the early days of blending, when the ratio was more likely to be 50:50 (Daiches 1995). Deluxe blended whiskies generally contain a higher ratio of malt to grain than standard blends (Gavin 1997).

The blended whisky is left undisturbed in oak casks (generally plain oak) for 6 to 12 months in order to optimize the product quality. Some blenders "marry" the malts

and the grains separately and bring them together only in bottling. Prior to bottling, the whisky is usually diluted to market strength, caramel is added to ensure continuity of coloring, and finally the spirit is filtered to prevent cloudiness from developing when water is added by the consumer (Jaganathan and Dugar 1999). As for blends, the age (if any) stated on the label is the age of the youngest whisky in the blend.

21.3 IRISH WHISKEY

Only whiskey produced in Ireland can be called Irish whiskey. It is well known that whiskey distilling originated in Ireland. The Irish were drinking a form of whiskey in the twelfth century and their skills in whiskey-making were taken to Scotland (Daiches 1995; Gavin 1997; Hashiguchi 2002). The extra "e" in the name is traditional, but gives no special meaning (Benitah 2002).

Malt and unmalted barley are what are needed to produce the Irish malt whiskey. However, much of the current productions of Irish whiskey use oats, wheat, and rye with barley.

The size and design of Irish pot stills are quite different from Scottish pot stills. Irish stills have volumes in the range 50,000–150,000 L, whereas Scottish stills have volumes ranging from 2000 to 30,000 L. Irish stills are attached to purifiers that remove congenerics such as aldehydes, esters, furfurals and other compounds of hydrogen, oxygen, and carbon formed in the process of distilling the wash (Daiches 1995).

Irish whiskey also differs from Scotch whisky in the distillation profiles. Two separate fractions of the low wines are collected from the wash still based on differences in alcohol concentration. The weak low wines are distilled in a low wines still to obtain further fractionation, strong and weak feints. The weak feints are redistilled with the next batch of weak low wines, and the strong feints are added to the strong low wines for the third distillation.

An alcohol concentration of about 80% ABV in the new spirit is much higher than that in Scottish malt (Benitah 2002). New spirits are first reduced to 63.5% ABV before filling into secondhand bourbon, rum, and sherry casks for at least three years (usually five to seven years). These straight Irish whiskeys are then blended with grain whiskey before bottling.

The more temperate climate of Ireland produces whiskeys with a slightly spicier taste and a crisp finish (Arthur 2003). Three distilleries are now in operation (Hashiguchi 2003). Although the market for Irish whiskey is limited, it is internationally recognized as a distinct generic brand (Bathgate 2003).

21.4 AMERICAN WHISKEY

American bourbon whiskey originates from the whiskey produced in the Bourbon County in the state of Kentucky – thus the name "bourbon", in short. However, it is now common to call all whiskeys produced in the United States as bourbon. By law, bourbon must be produced from a mash of not less than 51% corn grain (usually between 70 and 90% corn), with some barley malt and rye or wheat (Takeuchi 2000; Benitah 2002).

American whiskey applies a distinctive sour mash technique in its production. Inoculation of lactic acid bacteria prevents bacterial contamination. The residue (called backset or setback) of former distillation is added prior to yeast fermentation. If no sour mash is

added at the start of fermentation, the result is called sweet-mash straight whiskey (Benitah 2002). The distillation is carried out in beer stills (column stills or patent stills), which is common to nearly all American whiskeys.

Spirits are collected at relatively low alcohol concentrations, from 64 to 70% by volume. Therefore, various flavor components are also included, and the product has a distinct aroma.

The spirit is matured for at least two years in new white-oak barrels that have been charred. Charring has been used as a means of disinfecting barrels since the early nineteenth century. In bourbons, the definite characteristics are the tones of vanillin and caramel that the whiskey takes from the wood. It is bottled at over 40% by volume of alcohol. Nine distilleries of Kentucky bourbon are now in operation, producing various brands (Tsuchiya 2006a).

Tennessee whiskey, legally classified as bourbon, is produced in the state of Tennessee using the same method as Kentucky bourbon. The new spirit is filtered through maple charcoal, prior to maturation in the barrel. It has a mellow taste.

Rye whiskey is made from a mix of grains containing a minimum of 51% rye, and straight rye whiskey is matured for at least two years in the charred white-oak barrels.

Corn whiskey is made from a mixture of grains containing a minimum of 80% corn. The product matured for at least two years in oak barrels is called straight corn whiskey (Hasiguchi 2002).

A neutral grain spirit is also made in the United States and it is exclusively used in blends. In the United States, alcohol content is expressed in terms of proof, not as a percentage of alcohol by volume (ABV). To convert proof to % ABV, simply divide by two (Benitah 2002).

21.5 CANADIAN WHISKY

Canada also produces a whisky, the Canadian whisky. Hiram Walker, in 1858, founded the first distillery, and the product was launched as Canadian Club brand in 1884 (Benitah 2002). It is produced from corn, rye, and barley malt.

When rye is used at levels over 51%, its product can be named “rye whisky”. There are two types of Canadian whisky: one is the flavoring whisky that is produced mainly from rye and the other is the base whisky that is made mainly from corn. Both are distilled in column stills. Flavoring whisky is matured in a charred barrel (new or old) and the base whisky is matured in regenerated bourbon barrels. Both are matured in small barrels (smaller than 180 Ls) for at least three years, then blended to make various brands.

Canadian whisky is characterized as flavory, light, and mild, as compared to other whiskies (Fukunishi 1992). Canadian whisky has been industrially developed to supply mainly the U.S. market. Today, there are a dozen or so distilleries across the country (Benitah 2002).

21.6 JAPANESE WHISKY

Scottish/Irish immigrants did not found the whisky industry of Japan, but Japanese and Scottish distillers have strong ties. In the 1920s, the first Japanese distillers were trained in Scotland and took their new-found knowledge to traditional sake distilleries in Japan (Arthur 2003; Bathgate 2003). The first Japanese distillery was established in 1923 in the valley of Yamazaki on the outskirts of Kyoto, and launched its first whisky in 1929. This

Figure 21.10

whisky was a blended product of malt and unmatured neutral spirit. A matured grain whisky made from North American maize has now replaced the neutral spirit in blending.

By buying into Scottish distillery operations, the Japanese distilling industry has renewed and strengthened its bonds with Scotland. Other Japanese businesses and trading houses have also participated in the growth of whisky distilling, either by setting up joint-venture companies or by importing Scotch whisky. They set out to produce the best raw materials, distilling technology, and maturing conditions required in the production of the "Scotch malt" type of whisky.

The landscape of the northern island, Hokkaido, is very similar to that of the Highlands of Scotland, with peat bogs, mountains, and cool, fresh streams, which flow over granite rocks (Simpson 1994; Bathgate 2003). Yoichi distillery of Nikka Company on the island of Hokkaido northwest of the city of Sapporo makes the most peaty of Japanese single malts (Benitah 2002).

Malt is imported mainly from Scotland, but with an increasing amount coming from Australia. Stainless-steel washbacks with cultured yeast are used for malt whisky fermentation, and distillation is conducted in traditional copper wash and spirit pot stills. North American maize used in the making of grain whisky is mashed and distilled conventionally. Malt and grain whiskies are matured in oak casks before blending, the same way as in Scotland.

The most popular brands of Japanee whiskies are blends. However, the companies Suntory, Nikka, and KIRIN have been successfully in developing single malts (Fig. 21.10). They are indeed whiskies in their own right (Benitah 2002). Seven distilleries are now in operation and the total volume of Japanese whisky production reached 70,500 kL in 2003 (Tsuchiya 2006a,b).

21.7 CONCLUSIONS

Whisky is the world's most consistently successful and popular alcoholic drink. According to documentary records, it was first commerced in Scotland in 1494. Scotland, Ireland, the United States, Canada, and Japan are now the five major whisky-producing countries. Each country has developed its own style of whisky into something approaching a fine art. Each country's particular style will remain essentially unchanged and be eternally inherited by successive generations.

Recently, "light" whiskies that have a lighter flavor, color, and body have been promoted, mainly in the U.S. and Japanese markets. The proportion of single malts to blends consumed, even in Scotland, is very small; nevertheless there is a steady rise in the availability and consumption of single malts both in Britain and in certain other countries (Daiches 1995). The promotion of single malts in the whisky market has been accompanied by the development of distillery visitor centers, complete with guide tours.

The consumption of small amounts of whisky is now considered to be healthy. Its aroma produces an effect of relaxation and contains polyphenols that act as antioxidants important in the body for the protection against free-radical damage (Goldberg and others 1999; Tsuchiya 2006a). The marketer must continue to follow consumer trends and make efforts to meet their needs.

22.1 INTRODUCTION

Rice (*Oryza sativa* L.) has been, throughout history, one of the most important foods in the human diet. It is likely that rice is the one grain that has fed more people in history than any other crop. Even today, rice grains sustain two-thirds of the world's population, although the contribution of rice is different in the developing and developed countries, and also the types of processing are quite different. Rice is the staple food of the Chinese and also 65% of the total population of India. According to the International Rice Research Institute (IRRI), rice will be the major source of food for 3.9 billion people by 2025. It is primarily consumed as milled rice, but there are also a number of products where rice is added as an

ingredient, conferring creaminess, crunchiness, and firmness. Moreover, rice-based products have often been a solution for consumers with allergenic problems.

Rice accounts for 29% of total cereal production, comparable to the production of wheat or corn. Nevertheless, its importance as a food cereal in the human diet has been calculated to be a little lower than wheat, although this assessment is reversed when only developing countries are taken into account. Rice cultivation is concentrated in developing countries, mainly in Asia, accounting for 91% of total world production (FAOSTAT 2004). China is the world's largest rice producer (31%) (Table 22.1), followed by India (20%), Indonesia (9%), and Bangladesh (7%). Rice cultivation is the principal activity and source of income in those countries, and also the central part of their diet, providing sustenance to the poor in many of those countries. Rice consumers are mainly located in Myanmar, followed by Vietnam, Bangladesh, Cambodia, and Indonesia. Rice

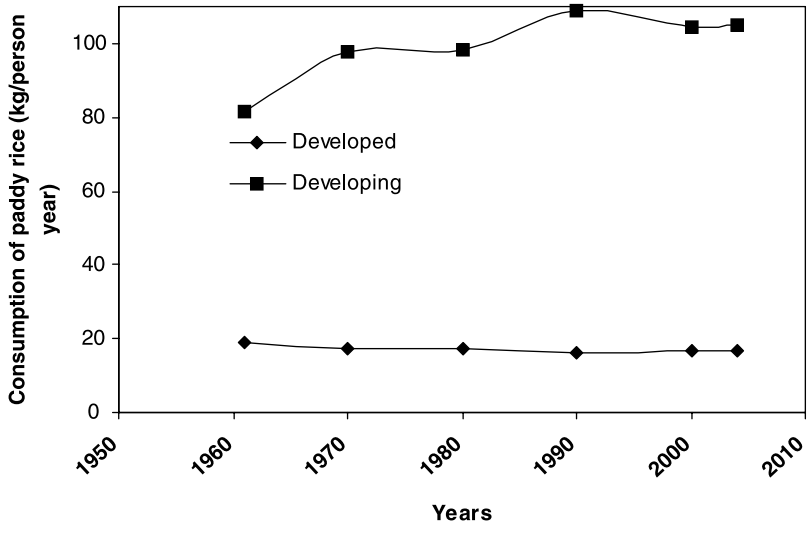

Figure 22.1 *Consumption of paddy rice in developed and developing countries.*

consumption in those countries greatly contrasts with that in the United States of America, where consumption drops to 14.1 kg per capita per year. This value is close to the average consumption of rice in the developed countries (16.1 kg per capita per year), in contrast with the 104.7 kg per capita per year of rice consumed in developing countries, which coincides with the low-income status of those countries (Fig. 22.1). In the last decade, rice consumption has experienced a steady decrease in developing countries, promoting the development of new and innovative rice-based products. In 2000, over 400 new products containing rice were launched to the market (Wilkinson and Champagne 2004), demonstrating the new initiatives for increasing rice consumption.

22.2 RICE PROCESSING

A simple flow diagram describing rice-based products is included in Figure 22.2. Rice from the field is harvested and threshed to produce the so-called paddy rice or rough rice, where the kernel is still within the hull or husk. Milling is the usual way to process rice and wheat. However, the term milling in the rice industry completely differs from the concept of wheat milling. Wheat is milled for obtaining flour, but milling of rice includes the steps of

1. Removing of the husk;
2. Stripping off the bran of the endosperm; and
3. Separating out broken kernels and other altered kernels.

All these processes drastically affect rice composition. Milling of rice is a very sophisticated process. Initially, paddy rice is cleaned through coarse screens to remove all straw, stones, and other foreign objects that are larger than the rice kernels. The same process is repeated using fine screens for removing small weed seed, sand, stones, and other objects

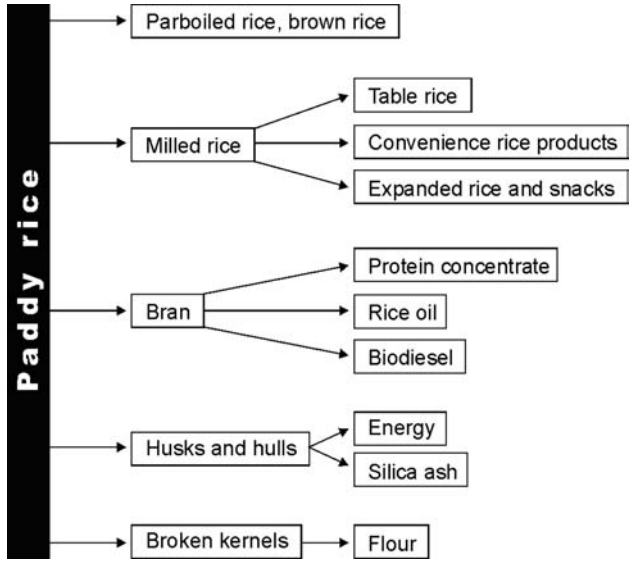

Figure 22.2

smaller than the rice kernels. Stones are separated from the rice kernels by density in specific gravity tables. After the cleaning step, the husk is removed by passing rice kernels through two spinning rubber rolls at different speeds. Brown rice is obtained after dehulling; this kernel may be eaten as is, milled into white rice, or processed for obtaining different products and byproducts. The brown color of this kernel is caused by the presence of bran layers, which are rich in minerals and vitamins.

Therefore milling of paddy rice produces milled rice, broken rice, rice bran, and hulls and husks. Numerous products with added value have been developed from rice, such as convenient rice forms like rice flour, puffed and crisped rice, breakfast cereals, and snacks (Barber and Benedito 1970; Nguyen and Tran 2000; Wilkinson and Champagne 2004).

22.3 PARBOILED RICE

Paddy rice is the principal raw material for the production of parboiled rice, which is rice that has been boiled in the husk. This rice is obtained by a process of soaking at a temperature below the gelatinization temperature of the starch, steaming with or without pressure for several minutes, and cooling and slowly drying to minimize the formation of cracks. The parboiling process changes the nutrient profile, permitting the retention of many of the natural vitamins and minerals in the kernels that diffuse from bran to endosperm, without allowing the diffusion of fat and proteins. The practice of parboiling is more than 2000 years old, and it appears to have started in India. Most parboiled rice is milled into "white" rice, although the electric power consumption and broken kernel rate are higher than those for milling untreated brown rice (Itoh and Kawamura 1991). The resulting rice is slightly yellowish, although its color intensity decreases after cooking. There are numerous patents dealing with processing parameters for obtaining parboiled rice with a high degree of whiteness, good palatability, taste, and appearance (Lay William 1972; Satake 1972; Hunnell 1974; Hayashi 1982; Itoh and Kawamura 1985; Gebhardt and Lehrack 1993; Islam and others 2002a,b).

The parboiling process shifts the nutrients, mainly thiamine, from the bran into the grain, and the starch is gelatinized (Nicholls 1947; Simpson 1951). Drying of the gelatinized starch in the grain leads to clear and harder endosperm, more resistant to breaking during milling. Parboiled rice requires longer cooking because the gelatinized starch is more resistant to water absorption. Parboiled "white" rice is nutritionally similar to brown rice, and the cooked rice is firmer and less sticky. Parboiled rice is used as a raw material for the subsequent production of canned rice, and other processed rice products, due to its stability to overcooking. Puffed-rice products are also obtained from parboiled rice subject to pressure steaming, due to its higher volume expansion.

22.4 BROWN RICE AND GERMINATED BROWN RICE

Brown rice is obtained after dehulling, owing its brown colour to the presence of bran layers, which are rich in minerals and vitamins (Fig. 22.3). Brown rice contains more nutritional components than ordinary milled rice grains, such as dietary fiber, phytic acids, E and B vitamins, and γ-aminobutyric acid (GABA). All these compounds are present in the bran layers and germ that are removed during polishing or milling (Champagne and others 1991, 1995, 2004). Despite the nutritional benefits linked to the

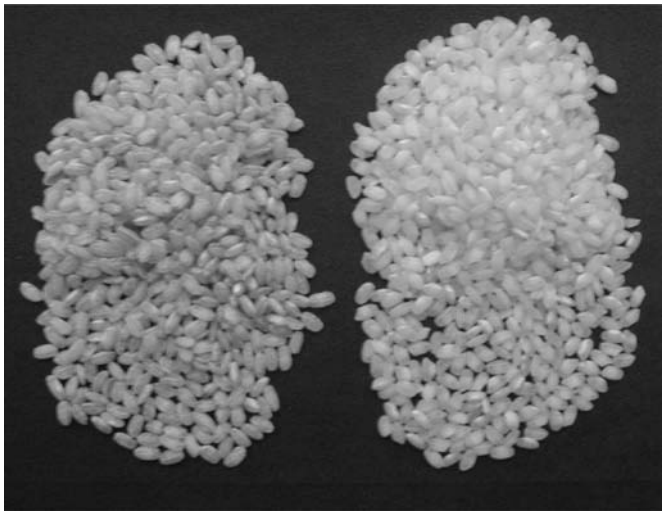

Figure 22.3 *Brown rice (left) and milled our polished rice (right). (photo by Cristina M. Rosell).*

consumption of brown rice, it is not considered suitable for table rice because it has to be cooked in a pressure rice cooker or for a longer cooking time; moreover, it has a dark appearance and hard texture. In addition, when the husk is removed from rice, the bran layer starts going rancid, contributing to the bitter taste of brown rice. Therefore, brown rice is mainly used as a medium for fermentation, or in materials for food processing.

The use of germination in grains started some decades ago and was applied to wheat and soybean (Finney 1978; Tkachuk 1979). Germinated brown rice arose following the policy of developing new value-added products from rice. In 1994, Saikusa and others found that GABA increased significantly when brown rice was soaked in water at 40°C for 8–24 h. An increase in GABA intake suppresses blood pressure, improves sleeplessness and the autonomic disorder associated with the menopausal or presenile period, or even suppressed liver damage (Tadashi and others 2000; Okada and others 2000; Jeon and others 2003). In Japan, germinated brown rice was launched to the market in 1995. Since then, germinated brown rice is increasing its popularity within the Japanesse population, and simultaneously numerous industries are emerging in Japan related to the production of germinated brown rice. During the last decade, 49 items related to germinated brown rice have been patented.

The basic procedure for obtaining pregerminated brown rice consists in the selection of good quality brown rice, which then is soaked for around 20 h at 30–40°C, changing the water a few times. This product is washed slightly before cooking, and is marketed either dry or wet, being with moisture contents of 15 and 30%, respectively. During the germination process, saccharification softens the endosperm and dormant enzymes are activated, increasing the amount of digestible compounds (Manna and others 1995). In addition, this process changes the mineral content, and results in an increase of GABA, free amino acids (Fig. 22.4), dietary fiber, inositols, ferulic acid, phytic acid, tocotrienols, magnesium, potassium, zinc, γ-oryzanol, and prolylendopeptidase inhibitor (Kayahara and Tsukahara 2000; Ohisa and others 2003; Ohtsubo and others 2005). It can be cooked in an ordinary rice cooker, obtaining a soft product with easier chewiness. Germinated brown rice is also used as a raw material for processing many different

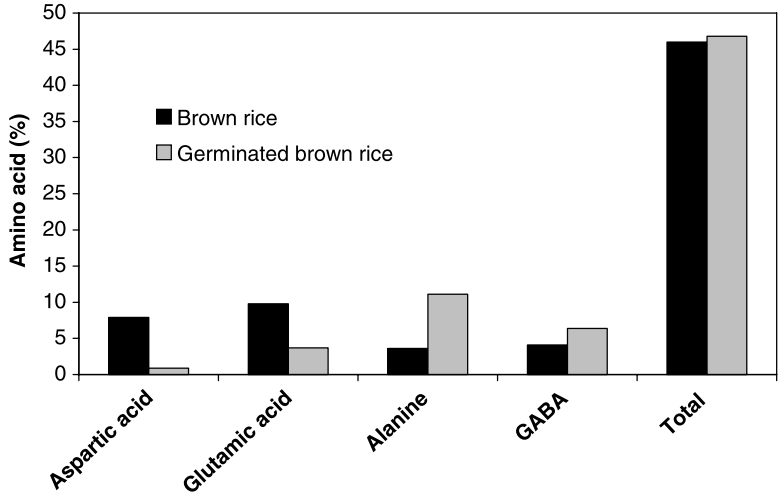

Figure 22.4 *Amino acid levels for brown rice and germinated brown rice.*

products, such as germinated brown rice balls, soup, bread, doughnuts, cookies, and rice burgers (Ito and Ishikawa 2004).

22.5 MILLED RICE

Milled rice is also known as white rice or polished rice (Fig. 22.3). Milled rice is obtained after removing the bran and germ from the brown rice. There are many machines and methods designed for milling rice, but often an abrasive system followed by frictional and polishing systems are used.

Rice milling can yield from 4 to 40% broken kernels depending on the incoming rice quality and the milling equipment. Broken kernels are removed from the whole kernels through indent graders in order to obtain high-quality table rice. Broken kernels can be further separated into various sizes according to their final use (brewing, screening, flour milling). Milled rice is usually consumed after boiling, but different techniques have been developed for the transformation of milled rice into a variety of tailored products.

Precooked rice is used for convenient rice-based products, ready to eat, where other ingredients are packed separately and mixed only after heating. These precooked rice products are packed in laminated plastic or aluminum-laminated plastic pouches and pasteurized at 120°C under pressure (Tani 1985). Steamed rices can be packed in aluminum-laminated plastic film pouches and only need to be warmed in hot water for 10–15 min. Steamed rices packed in plastic pouches, however, only need to be heated in a microwave oven for 1–2 min after puncturing of the bag. Quick-cooking rice requires significantly shorter cooking times (5 min) than the milled rice (15–25 min) (Juliano and Sakurai 1985; Luh 1991). Different technologies are suited for obtaining quick-cooking rice, like soak-boil-stem-dry methods, gelatinize-dry-puff methods, dry-heat methods, freeze-thaw methods, and freeze-drying (Roberts and others 1980; Jacops and Lin Yah 2000; Minier and others 2001). Parboiled rice can be converted to quick-cooking rice by reducing 1% of the pericarp in order to eliminate the outer water-impermeable layer.

Frozen cooked rice is packed in airtight plastic pouches and frozen in an instant in a sharp freezer. Freezing without dehydration is the most effective method for avoiding the retrogradation process. This convenient rice food is usually delivered to restaurants where they are heated in microwave ovens before being served to consumers.

Canned rice is a white product that has separate, noncohesive grains and contains a clear canning liquor. This product is consumed in the United States, Japan, the Philippines, and Taiwan. The grain is usually parboiled before canning to increase stability, and it also an acid pH (below 4.6) to reduce microbial contamination spoilage problems (Barber 1967a; Juliano and Hicks 1996).

22.6 ENRICHED OR FORTIFIED RICE

From the nutritional point of view, rice is considered an important source of energy, providing 26% of the total energy intake in developing countries and only 4% of the total energy intake in developed countries. In developing countries, rice supplies 20% of the dietary protein intake, but because of its incomplete amino-acid profile and the limited amount of micronutrients in the milled rice, there is a great problem of malnutrition where rice is a staple food. Today, different techniques for rice fortification have been developed in order to add essential vitamins and minerals to the grain (Barber 1967b; Rosell 2004; Hoffpauer and Wright 1994).

Food fortification is one way of solving nutrient deficiencies in developing countries, and so far the implementation of those programs has been very successful for correcting nutritional deficiencies within a very short period. In the developing countries, it should be taken into account that the food selected as a vehicle for the nutrient should be stable and consumed by the population at risk, and the amount of nutrient added should be sufficient to correct the possible deficiency. In general, all the rice-consuming countries have a vitamin A deficiency, which is associated with corneal lesions that can lead to partial or total blindness, and also with reduced resistance to infectious diseases, and in consequence an increased morbidity and mortality. Another deficiency associated with rice-consuming countries causes nutritional anemia due to iron deficiency, which has been linked to reduced resistance to infections and also effects on cognitive development and physiological functions in children, and in severe cases of deficiency causing maternal deaths. Iodine constitutes the third major deficiency in rice-consuming countries. This mineral is necessary for correct fetal development and also for normal physical and mental activities in adults.

There are different methods of rice fortification, one of which is the parboiling process (Nunes and others 1991). Other methods currently used are the so-called powder enrichment and grain enrichment. In powder enrichment, a preblended powder mixture of vitamins and minerals is added to the rice. For "white" parboiled rice, the blend is added immediately after milling, because the heat and moisture content of the grain surface at that moment facilitates adherence of the powder mixture. However, the nutrients supplemented in this way can be washed off if the grains are rinsed before cooking.

The grain enrichment method involves the addition of a powdered mixture of vitamins and minerals and a subsequent coating of the grain with a water-insoluble substance. Usually, grains enriched by this method contain a high nutrient concentration and are mixed in a 0.5% proportion with normal milled rice, to finally obtain an enriched

product that meets the required standard levels. Different variations of these methods have been developed in recent years; for instance, the powdered mixture can be sprayed onto the rice kernels and then fixed by the application of a water-insoluble coating such as ethanol, isopropanol, palmitic acid, or cellulose derivatives. This method has been successfully used for enriching rice with niacin, thiamin, pyridoxin, vitamin A, vitamin E, folic acid, iron, and zinc by adding alternative layers of nutrients and coatings. The most recent method consists in the development of fortified simulated rice, obtained by extrusion of rice flour in the presence of vitamins and minerals to a rice kernel shape. The fortified simulated grains are then mixed with normal milled rice. The disadvantage of this method is that the consistency of the resulting grains after cooking is different from the natural product.

22.7 EXPANDED RICE PRODUCTS AND SNACKS

Dry rice breakfast cereals include rice flakes, oven, gun, or extruder-puffed rice, shredded-rice cereals, and multigrain cereals. These products are prepared by pressure-cooking in the presence of sugar, salt, flavorings, and sufficient water. Rice flakes are prepared in a similar way to wheat and corn flakes. Rice is cooked and coated with nutritious ingredients (skimmed milk, wheat germ, wheat gluten, and so on) and is then partially dried, tempered, and passed through flaking rolls before toasting in an oven (Wilkinson and Champagne 2004). In 1951, Roberts and others presented the use of parboiled rice for the production of expanded rice products.

Rice snacks include granola, breakfast, and energy bars containing rice in their formulation (Juliano and Hicks 1996). Some snacks are designed as functional foods, with health contribution claims like cholesterol reduction. An significant number of these products have been launched targeted at children, women, and other specific groups.

22.8 BROKEN RICE

Rice kernel can be cracked in the field or during the drying or milling process. Often these cracks induce the breaking of the kernel, generating broken rice, which is removed during the milling process because it tends to get mushy during cooking, decreasing the quality of the table rice. The different sizes of broken kernels, from the largest to the smallest, are called brewing, screening, and flour milling. In some countries, broken rice is sold as it is, but at a lower price than the milled rice. Broken rice is also utilized for in the production of beer, high-fructose syrup, flour and high-protein flour, starch, maltodextrins, glucose syrup, feed for livestock, spirits, and distilled liquors.

Broken rice kernels of rice can be ground into flour using three different methods (Yen 2004). Wet grinding consists of soaking the broken kernels in water, and after draining they are ground in the presence of water, in order to reduce the amount of damaged starch. The excess water is removed by drying and the flour is again ground, yielding the wet rice flour. This product is used in the production of different Asian specialities like Japanese cake, Taiwanese cake, Indian fermented foods, and so on. Wet milling in the presence of 0.3–0.5% NaOH is used for the production of rice starch and rice maltodextrins and syrups. Semidry grinding also involves soaking, draining, and grinding without using any excess water. The semidry ground flour has similar applications to

the wet rice flour. Dry grinding is also possible; in this case broken kernels are directly ground to different sizes. Dry rice flour is used for baking, baby foods, extrusion-cooked products, and in high-protein flour.

22.9 RICE FLOUR

Rice flour is extensively used for the production of infant food formulas due to its digestibility and hypoallergenic properties. A partial acid or enzymatic (starch-hydrolyzing enzymes) hydrolysis of the rice flour is applied in order to increase the amount of free sugars, contributing to its sweet taste and consistency (Cantoni 1967).

The use of rice flour in baking has been progressively increasing, motivated by its usefulness as a wheat substitute in the dietary habits of wheat-intolerant patients. Celiac disease, first considered to be a gastrointestinal disease, is a gluten-sensitive enteropathy with genetic, immunologic, and environmental bases. Peptides released during gluten digestion are responsible for the intolerance in genetically predisposed individuals. Therefore, the only treatment is to keep their diet as gluten-free as possible. The unique cereals considered gluten-free safe are rice and corn, although rice flour is the most suitable cereal grain flour for the production of gluten-free products due to its bland taste, white color, digestibility and hypoallergenic properties (Neumann and Bruemmer 1997). In addition, other attributes such as its low protein and sodium content, low levels of prolamins and the presence of easily digested carbohydrates make the rice the selected cereal for patients suffering from celiac disease.

However, in spite of the numerous advantages of rice flour, rice proteins, compared with other plant proteins, have relatively poor functional properties for food processing. Rice proteins are extremely insoluble due to their hydrophobic nature and are unable to form the viscoelastic dough necessary to hold the carbon dioxide that is produced during proofing of yeast-leavened bread-like products. The low content of prolamins in rice flour prevents the formation of a protein network when rice flour is kneaded with water. As a consequence, the carbon dioxide produced during fermentation cannot be retained, yielding a product with a low specific volume that does not resemble the soft and open structure of wheat bread (He and Hoseney 1991).

In order to overcome this problem, different structuring agents have been added to rice bread formulation (Nishita and others 1976). Xanthan gum and carboxymethylcellulose (CMC) have been used as gluten substitutes for preparing gluten-free bread (Kulp and others 1974). Xanthan gum has been used as a gluten replacer in the preparation of cornstarch bread, yielding baked bread with a good specific volume, but a coarse crumb texture and lack of flavor (Christianson and others 1974). Among the cellulose derivatives, hydroxypropylmethylcellulose (HPMC) seems to be the best gluten substitute in rice bread formulas due to its gas retention capacity and its properties as a crumb-structuring agent (Nishita and others 1976; Ylimaki and others 1988; Gujral and others 2003a). With the addition of HPMC, it is possible to obtain rice flour dough having a similar consistency and rheological properties to those of wheat dough (Sivaramakrishnan and others 2004). Other gums such as locust bean gum, guar gum, carrageenan, xanthan gum, and agar have been tested as gluten replacers in rice flour bread, but the addition of HPMC or the combination of HPMC and carboxymethylcellulose (CMC) has resulted in the highest specific loaf volume due to their ability to trap fermented gases (Kang and others 1997; Cato and others 2004).

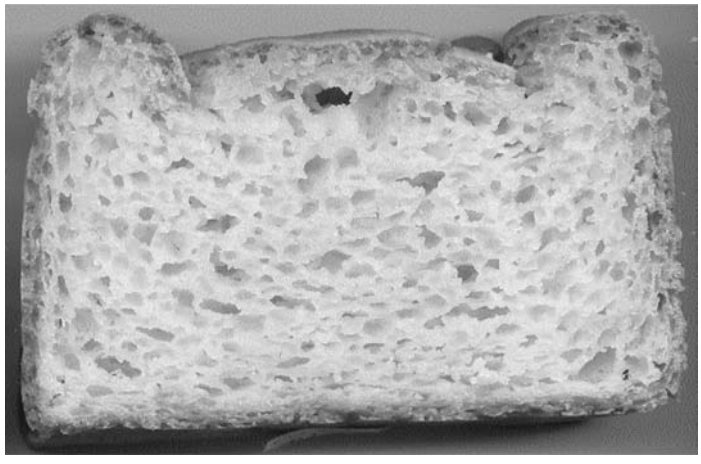

Figure 22.5 *Rice-based breed.*

Some enzymes, such as cyclodextrin glycosyl transferase, glucose oxidase, or transglutaminase, have been added to the rice bread formulation for obtaining a further improvement on the technological quality of the rice-based bread (Gujral and others 2003a,b; Gujral and Rosell 2004a,b). A chemical modification of the rice flour has also been proposed for improving its baking functionality (Nabeshima and El-Dash 2004). All the different approaches allow rice-based bread to be obtained with similar texture characteristics to wheat bread (Fig. 22.5).

Some bread specialties have been adapted for obtaining gluten-free products targeted at people suffering from gluten intolerance. This is the case for chapati, unleavened bread made from wholewheat in India. The use of different hydrocolloids (HPMC, guar gum, xanthan gum, locust bean gum) and α-amylase in the formulation of rice-flour chapati has improved the texture by maintaining its extensibility during storage (Gujral and others 2004).

A different approach for obtaining gluten-free bread concerns the use of rice flour blended with other flours and different starches (Gallagher and others 2004). Complex formulations including corn starch, brown rice, soy, and buckwheat flour have been proposed for obtaining gluten-free bread (Moore and others 2004). With these recipes, the breads were brittle after two days of storage, although that effect was reduced in the presence of dairy products like skimmed milk powder, which yielded a network-like structure resembling the gluten network in wheat bread crumb. A combination of rice flour (45%) with corn (35%) and cassava (20%) starches gave also a good gluten-free bread with uniform and well-distributed cells over the crumb, and with a pleasant flavor and appearance (Lopez and others 2004). Gluten-free breads of good quality were also obtained by lowering the amount of rice flour (17.2%) and using corn starch (74.2%) and cassava starch (8.6%) (Sanchez and others 2002). Soy protein is frequently added to gluten-free bread formulations because it improves the bread texture (Sanchez and others 2002; Sodchit and others 2003). Blends of buckwheat and rice flour in the presence of hydrogenated vegetable fat also gave gluten-free breads with good sensory acceptance (Moreira and others 2004).

In breadmaking of wheat breads, brown-rice brown flour has been used as an ingredient, although a reduction in the specific bread volume was observed (Watanabe and others

2004). Pregerminated brown rice is another alternative as bread ingredient. The substitution of pregerminated brown rice flour for wheat flour improves the bread quality and retards the staleness of bread staling (Watanabe and others 2004).

Rice cakes and crackers are increasing in popularity due to their tendency to be associated with healthy products. Rice is often used in cracker and chip production because it contributes to moisture control, texture and flow in the extruders (Wilkinson and Champagne 2004). Japanese specialties of rice cakes and crackers include senbei and arare (Nguyen and Tran 2000). In rice-cake production, the gluten network is not developed; thus it is possible to make cakes with starchy raw materials like starch from different cereals. Therefore, rice flour can be employed in the production of cakes as the main ingredient or blended with wheat flour (Bean and others 1983; Rosell and Gomez 2006). The quality of the rice cakes can also be improved by adding different proteins, like skimmed milk powder or egg proteins (Mohamed and others 1995; Mohamed and Hamid 1998). Rice flour has been used in the production of donuts. The use of rice flour led to less dough consistency and harder products with less moisture content and higher oil absorption (Shih and others 2001), but this problem could be overcome with the use of pregelatinized rice flour or acetylated rice starch (Shih and Daigle 2002). The use of rice flour has also been described in the production of cookies (Przybyla and Luh 1977; Schober and others 2003).

22.10 HULLS AND HUSK APPLICATIONS

Rice hulls and husks account for about 20% of grain weight. They are used as an energy source in some countries (Kapur and others 1996), whereas in others, they are considered as waste and used for animal feed (Gonzalez and others 1986). Different technologies have been developed for using hulls and husks, but always the application feasibility depends on the process economy. Rice husk has been used for obtaining rice husk ash or silica ash after subjecting the rice husk to a burning process. Silica ash, composed mainly of silica, is used as filler in a variety of polymeric composites employed for the production of such materials as tiles and ceramics, or even road-building materials (James and Rao 1992; Chaudhary and others 2004). Other uses include bedding material for poultry, horses, or ducks, incubation material for duck eggs, or seedbed media for vegetable production.

22.11 BRAN APPLICATIONS

Rice bran accounts for 5–8% of the paddy rice weight, and comprises germ, pericarp, aleurone cells, and seed coat. Rice bran is a byproduct of rice milling with a high content of proteins, fat, and other nutraceutical compounds. However, the presence of the enzyme lipase, which causes a rapid deterioration of lipids, obliges to inactivate the enzyme for bran stabilization. Heat treatment, low-temperature storage, chemical treatment, control of relative humidity, and simultaneous milling and extraction are different economically doubtful alternatives used in stabilizing the bran (Anon. 1985). As a consequence, rice bran has been widely used as livestock feed, boiler fuel, and for obtaining rice bran oil (Tortosa and Benedito de Barber 1978). Rice bran has been used in food as full-fat rice bran, defatted rice bran, or in the form of protein concentrates and rice bran oil. Protein concentrates from rice bran contain from 19.4 to 76.1% protein content depending

on the extraction method (Barber 1971; Barber and Maquieira 1977; Barber and others 1981; Shih 2003), and they have been incorporated into bread, beverages, confections, and weaning foods (Prakash 1996).

Rice bran contains 15–25% lipids, and the oil extracted from rice bran is unique among edible oils due to its high content of commercial and nutritional phytoceuticals such as oryzanol, lecithin, tocopherols, tocotrienols, and sterols. However, most of these compounds are removed from the rice bran oil during the refining process. Different methods of extraction have been proposed in order to recover all these compounds because of their applications in nutraceutical, pharmaceutical, and cosmoceutical preparations (Patel and Naik 2004; Danielski and others 2005). Lately, oil from rice bran has received increased attention as a possible source of renewable diesel fuel or biodiesel (Ju and Vali 2005).

Rice bran also has a direct use as a medium for screening *Saccharomyces* species or for the production of protease and milk-clotting enzymes.

Rice is one of the most consumed cereals, and its main way of consumption is as milled rice. However, the consumption decrease experienced in rice-based products over the last decades has stimulated the development of a number of different value-added rice products. Apart from the use of rice as table rice, there is a high consumption in beer production, baby foods, breakfast cereals, snacks, confections, desserts, and also in bakery products. The increased use of rice for food processing has been the result of an increasing consumer demand for more healthy products, more convenient products, and also a growing interest in a variety of ethnic products. In addition, husks, hulls, and bran are used as energy sources, fillers of polymeric composite, and raw materials for the production of nutraceuticals and protein concentrates.

23.1 INTRODUCTION

The consumption of noodles has a long history. Westerners have claimed that noodles originated from Italy. However, the Chinese claim that noodles orginated in China and were brought back to European countries on Marco Polo's return trip to his home

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

country. With the recent archeological discovery of a bowl of noodles made from a dough of broomcorn and foxtail millet dating back to the Late Neolithic era in the Qijia culture in Western China, it appears that the Chinese are winning this battle.

The term "mien (mian, or mein)" in the Chinese language is used to describe all noodle-type products (with a few exceptions in shape) made from common wheat flour as the main structural ingredient. It is wheat-based, as shown by the traditional Chinese character for noodles, which has "mia (wheat)" on one side and "mien (sheet)" on the other side of its character structure. For rice noodles, the Chinese character is written with "mi (rice)" on one side of the character structure and the other side indicates "fen (separate)", indicating that it originated from starch isolated from rice. Similar products made from mung beans and other ingredients are all grouped under the term "fen (starch-based products)", for example, "mi fen (rice noodle)", "tung fen (mung bean threads)", and "ho fen (oily rice strips)". It is assumed that "mien" and "fen" were spread from China to its neighboring countries, because the terms for noodle-like products in these countries are very similar in their sounds: for example, "men" (Japanese wheat-based noodle), "mie" (Indonesian noodles), "mee" (Malaysian noodles), "Pho" (Vietnamese rice-based noodle). Noodles made in China are traditionally continuous instead of short pieces. It is also customary to serve (continuous) noodles at birthday parties, symbolizing longevity.

The terms "noodles" and "pasta" are often used interchangeably by consumers. However, they are technically different. Western-style pasta uses durum wheat flour as the main structural ingredient, but Asian noodles are usually made from regular wheat flour. In the United States, there is a legal term (standard of identity) for "noodle", which must contain a certain proportion of egg solids. However, with an increase in the number of Asian immigrants in the United States, and their production and consumption of noodle-like products from their native countries (with some of them now produced in the United States), FDA finally accepted the term "Asian (Oriental) noodles" to describe a group of products that are similar to the American noodle, but differ in their composition and appearance with the mandate that a decsriptive or qualifying term must appear before "noodles": for example, Chinese noodles or rice noodles. Thus, in the United States, "Asian (oriental) noodles" are mostly noodle-like products produced mainly in Eastern, Southeastern, or Pacific Asian countries using common wheat flour, rice (or rice flour), or other starch materials as the main structural ingredient. Some of these products are now produced in the United States. However, there is no standard of identity for Asian noodles in the United States. This situation may change in the future and certainly differs in other countries.

Wide variations exist among the various Asian noodles in size, appearance (color and shape), ingredients, chemical properties, and methods of manufacture. In this chapter, some of these variables are introduced briefly. It should be noted that only carbohydrate-based Asian noodles are presented in this chapter. Other so-called Asian noodles, such as seaweed noodles (cut-up seaweed strips) and tofu noodles (semidry tofu strips), are not included in this chapter.

Several excellent reviews on Asian (oriental) noodle production are available. Readers should consult these references for further information (Hoseney 1994; Huang 1996a,b; Kim 1996a,b; Nagao 1996; Udesky 1988; Corke and Bhattacharya 1999; Hatcher 2000; Hou 2001; Crobie and Ross 2004; Ross and Hatcher 2005; Lu and Nip 2006). Variables affecting the production of these Asian (oriental) noodles are also studied to some extent (see following sections for further information). There is no doubt that literature in Japanese, Korean, Chinese, and other Eastern Asian languages are also available, but they are not available at the time of this work.

23.2 CLASSIFICATION OF ASIAN (ORIENTAL) NOODLES

Asian noodles vary considerably in size, appearance (color and shape), ingredients, chemical properties, and methods of manufacturing. There are several ways to classify Asian noodles. One of the classifications is based on the major ingredients used in the manufacture of these noodles (Table 23.1). The major ingredients are wheat flour, buckwheat flour, rice flour, starch of various origins, and gum. Within the wheat flour category, the noodles may or may not contain egg solids, alkaline agents, and savory flavorings. Another classification is based on the changes of starch properties during the manufacturing process (Table 23.2). The starch may stay in the natural state, partially altered or completely gelatinized, producing products that are opaque, semitranslucent, and of a cellophane-type appearance, respectively. A third classification method is based on the appearance (thickness and/or width) of the noodles. This classification is designed to standardize wheat-based noodles in China and Japan (Table 23.3).

TABLE 23.1 Classification of Asian Noodles by Major Ingredients.

Base Ingredient	Name of Noodle	Ethnic Origin	Other Ingredient(s)
Wheat flour	Gook soo	Korean	
	Kal guk su	Korean	
	Kishimen	Japanese	
	Somen	Japanese	
	Hiyamugi	Japanese	
	Udon	Japanese	
	Miswa	Filipino	
	Pancit Canton	Filipino	Coconut oil, coloring
	Egg noodle	Chinese	Egg solids
	Mein/Main	Chinese	
Buckwheat	Cha soba	Japanese	
	Soba	Japanese	
	Naeng myun	Korean	Sweet potato flour optional
Rice flour	Ban pho	Vietnam	
	Bun	Vietnam	
	Mai fun	Japanese	
	Mei fun	Chinese	
	Ho fen	Chinese	
	Pancit bihon	Filipino	
	Chantaboon	Thai	
	Rice sticks	Various cultures	
Various starches			
Mung bean	Fen si (mungbean threads)	Chinese	
	Sai fun	Chinese	
	Bun tau	Vietnam	
Sweet potato	Dang myun	Korea	Corn starch optional
	Soo foon	Malaysian	
	Harusame	Japanese	Other starches
Corn/tapioca/potato	Starch noodles	Various cultures	
Devil's tong yam	Shirataki	Japanese	
	Ito konnyaku	Chinese/Japanese	

TABLE 23.2 Classifcaion of Asian Noodles by Their Starch Properties.

Starch Properties	Noodles
Raw	Most wheat noodles except instant noodles and other deep-fried noodles
Partially gelatinized	All rice noodles
Pregelatinized	Cellophane or starch noodles
Gelatinized	Instant noodles and other deep-fried noodles

TABLE 23.3 Classification of Wheat-Based Noodles in China and Japan.

Classification	Chinese Examples	Japanese Examples
Very thin noodles	Longxu noodles (China) Yinsi mien (silver threads) (Hong Kong)	Somen
Thin noodles	Xi mien (China, Hong Kong, Taiwan)	Hiya-mugi
Flat noodles	Yangchun mien (China)	Kishi-men
	Kuan (broad) mien (China, Taiwan)	Hira-men
Standard	Not available	Udon
Wide flat noodles	Dai mien (China)	Not available
Thick noodles	Ci mien (Shanghai, China) (similar to Japanese udon)	Not available

23.3 WHEAT-BASED ASIAN NOODLES: CHARACTERISTICS AND MANUFACTURING

Wheat-based Asian noodles can be subdivided into the following major categories:

- White-salted;
- Yellow-alkaline;
- Egg noodles;
- Instant (deep-fried or dried) products; or
- Savory.

Table 23.4 compares selected chemical properties of white-salted, yellow-alkaline, instant, and savory wheat-based Asian noodles.

TABLE 23.4 Comparison of Selected Chemical Properties of Various Types of Wheat-Based Asian Noodles.

Chemical Properties	White-salted	Yellow-alkaline	Instant	Savory
Protein in wheat flour, %	8—10	10–12	8–12	10–12
Water added, %	30–35	30–35	30–36	30–35
Salt added, %	2–3	Variable	Variable	Variable
Alkaline agent(s) added	No	Yes	Yes/no	Yes/no
pH	6.5–7	9–11	6.5–7 (regular-type) 9–11 (alkaline-type)	6.5–7 (regular-type) 9–11 (alkaline-type)
Oil added, %	None	None	15–21.5 (fried-type) 1.5–1.8 (dried-type)	Variable Variable

Source: Adapted from Lu and Nip (2006).

23.3.1 Wheat-Salted Asian Noodles

The ingredients for this type of Asian noodles are common wheat flour, salt, and water, with egg solids as an optional ingredient. They have a soft elastic texture and smooth surface. Figure 23.1 is a generalized scheme for the industrial manufacture of plain wheat-based noodles in China. Products in this group are manufactured in a similar manner. These noodles vary in width and appearance considerably, with Chinese *longxu* (dragon whiskers) and *yinsi* (silver threads) noodles, and Japanese *somen* being typical examples of the very thin type of noodles (Fig. 23.2). Dried Japanese *somen* is usually wrapped with a piece of paper as a single serving quantity. Chinese *xi mien* and dried Japanese *hayamugi* are typical examples of thin noodles (Fig. 23.2). Hayamugi is always wrapped with a small piece of paper together with colored/dyed noodle pieces in a single serving bundle. Japanese *udon* and Shanghai *cu mien* (thick noodles) are examples of thick noodles

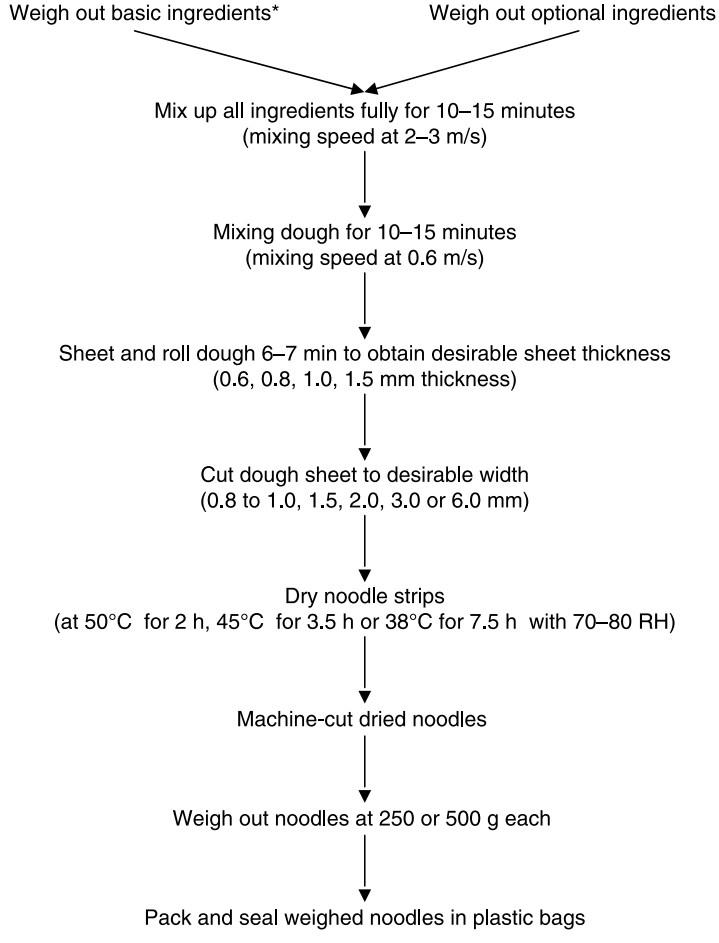

Figure 23.1 *Generalized scheme for the industrial manufacture of plain wheat-based noodles in China. *Basic ingredients: wheat flour (100 parts), water (25–32 parts dependent on gluten content of wheat flour at 30°C), salt (2–3 parts), alkaline agent (optional, 0.1 to 0.2% of flour weight). Adapted from Hou 2001, Huang 1996a,b.*

Figure 23.2 *Bundles of* somen *and* hayamugi *noodles.*

(Fig. 23.3). They are available in fresh and dried forms. Examples of flat noodles are dried Japanese *kirsimen* and *hiramen*, and Chinese *yang-chun mien* and *kuan mien* (wide noodles) (Fig. 23.3). *Dai mien* (China) and *cu mien* (China, Hong Kong, and Taiwan) are examples of wide flat noodles (Fig. 23.3).

At the household or restaurant level in China, plain noodles (such as knife-cut (pared) noodles, hand-cut noodles, cat's ear noodles, and hand-swung noodles (la mien)) can also be manufactured manually in small quantites. Although these noodles are made by hand, they have become delicacies in some areas as they are not easily produced and require some skills. They are often sold as fresh noodles, and cooked as soon as they are made. Figures 23.4 and 23.5 present the generalized schemes for the manufacture of pared, and hand-cut and cat's ear noodles, respectively. Manufacturing of hand-swung noodles

Figure 23.3 *Examples of thick noodles.*

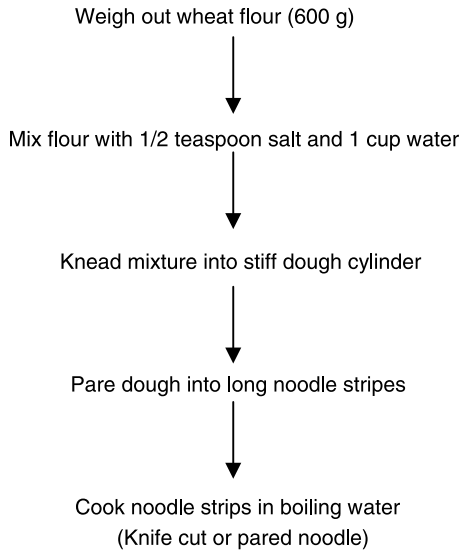

Figure 23.4 *Generalized scheme for the manufacture of pared noodles.*

or *La mien* is considered an art (Fig. 23.6), and this technique has been improved in Taiwan by applying simple devices for the stretching process instead of hand stretching/swinging (Figs 23.7 and 23.8).

In recent years, precooked, ready-to-eat *udon* in sterilized retortable pouches has been available. The cooked *udon* is sealed with water in the containers with lactic acid or sodium benzoate as preservatives, and sterilized for long-term storage.

23.3.2 Yellow-Alkaline Wheat-Based Asian Noodles

The basic ingredients for this type of noodles are common wheat flour, water, alkaline agents(s) (sodium and/or potassium carbonate), salt (optional), egg solids (optional), and yellow coloring (optional). Typical examples are Cantonese-type noodles with or without egg solids, Taiwanese-type noodles (Fig. 23.9), and *saimen* (commonly available in Hawaii). Figures 23.10 and 23.11 show generalized manufacturing processes for the production of Hong Kong or Cantonese-style alkaline noodles, and Taiwanese alkaline wheat noodles or *Yi-mien*, respectively. Addition of alkaline salts to the formulation not only alters the pH and color, but also improves the water absorption properties of the final product. It also improves the texture of the cooked product, making it chewier and with less tendency to soften and paste after cooking. The flavor of the cooked product is typical of an alkaline odor and influences its acceptance to consumers. For example, the majority of consumers in Hong Kong are used to this type of Asian (oriental) noodles. However, for most consumers in central and northern China, their preference is the common white-salted noodles. In some cases, a yellow coloring is added.

Frozen precooked *saimen* (an alkaline noodle) has also been available for many years in Hawaii. The *saimen* is precooked in water, or steamed, cooked, cooled, packaged, and sealed in plastic bags before freezing. The shelf-life of this product is good.

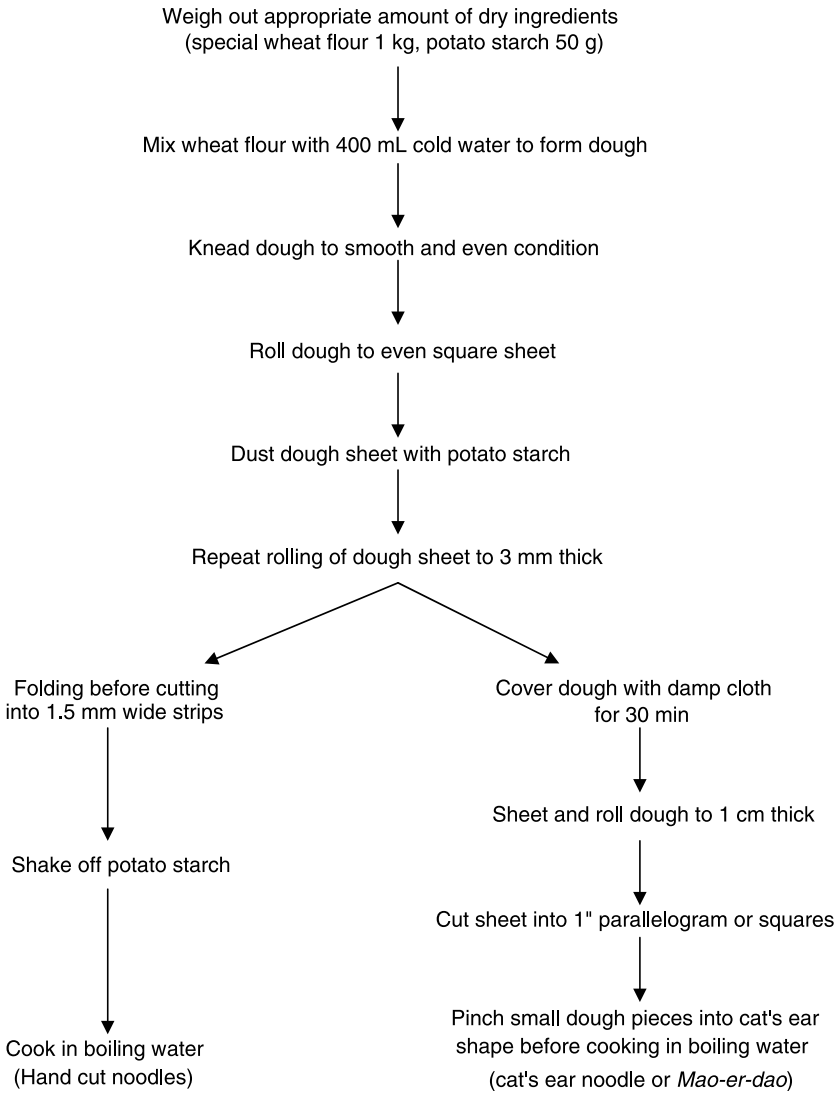

Figure 23.5 *Generalized scheme for the manufacture of hand-cut and cat's ear noodles. *1 kg of medium strength wheat flour without 10% protein, 20 g salt. **Dissolve 20 g salt in 500 ml water, water temperature at 25°C in summer and 35°C in winter. ***Dissolve 10 g sodium carbonate in 50 ml water. Adapted from Corke and Bhattacharya 1999.*

23.3.3 Egg Noodles

The use of egg soilds (whole, white, or yolk) in the manufacture of wheat-based Asian noodles has been practiced for many decades in Hong Kong and parts of China. The manufacture of whole-egg noodles (Fig. 23.12) and their consumption are fairly common practices in Hong Kong. It should be noted that egg noodles made in Hong Kong are usually bundled into an oblong or round shape (Figs 23.3 and 23.12, respectively). In some parts of China, it is common practice to add egg white and egg yolk

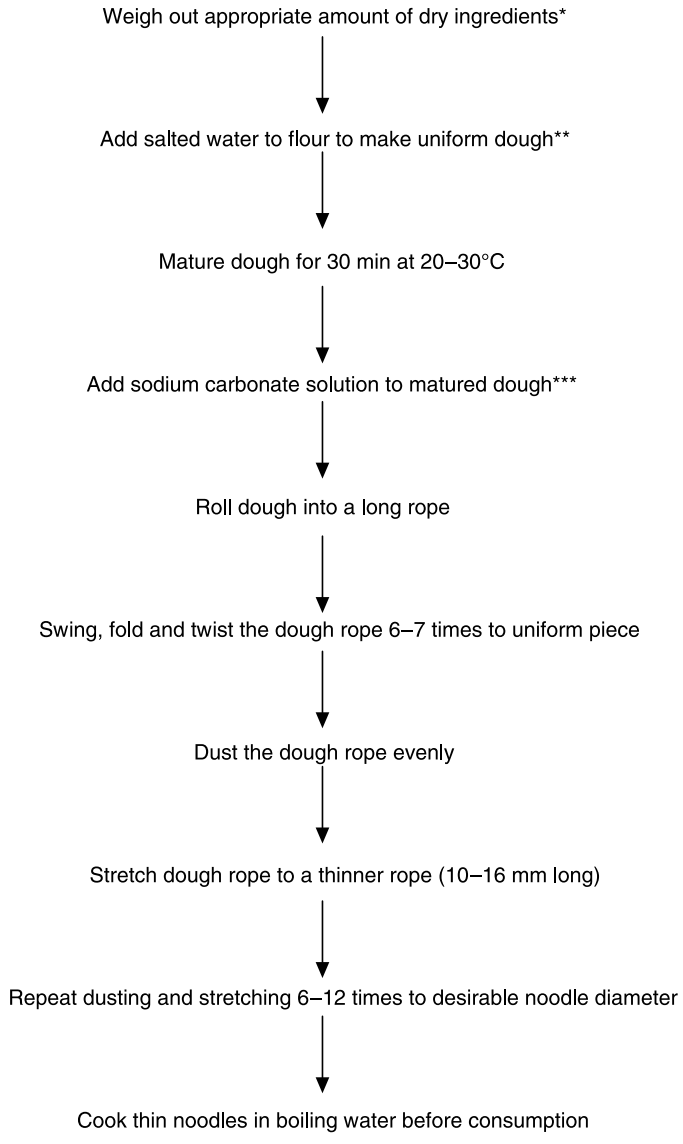

Figure 23.6 *Scheme for the manufacture of hand-swung noodles. * 1 kg of medium strength wheat flour without 10% protein, 20 g salt. ** Dissolve 20 g salt in 500 ml water, water temperature at 25°C in summer and 35°C in winter. *** Dissolve 10 g sodium carbonate in 50 ml water. Adapted from Corke and Bhattacharya 1999.*

separately to the wheat flour in the manufacture of two different wheat-based noodles (one white and the other yellow) and these two different kinds of noodles are used together in the preparation of a special bowl of noodles having two colors. The manufacture of egg noodles follows the basic manufacturing practice for dry wheat-based Asian noodles in China (Fig. 23.1). The addition of egg solids contributes to the color and textural properties of the final products. Whole-egg noodles have a rich flavor,

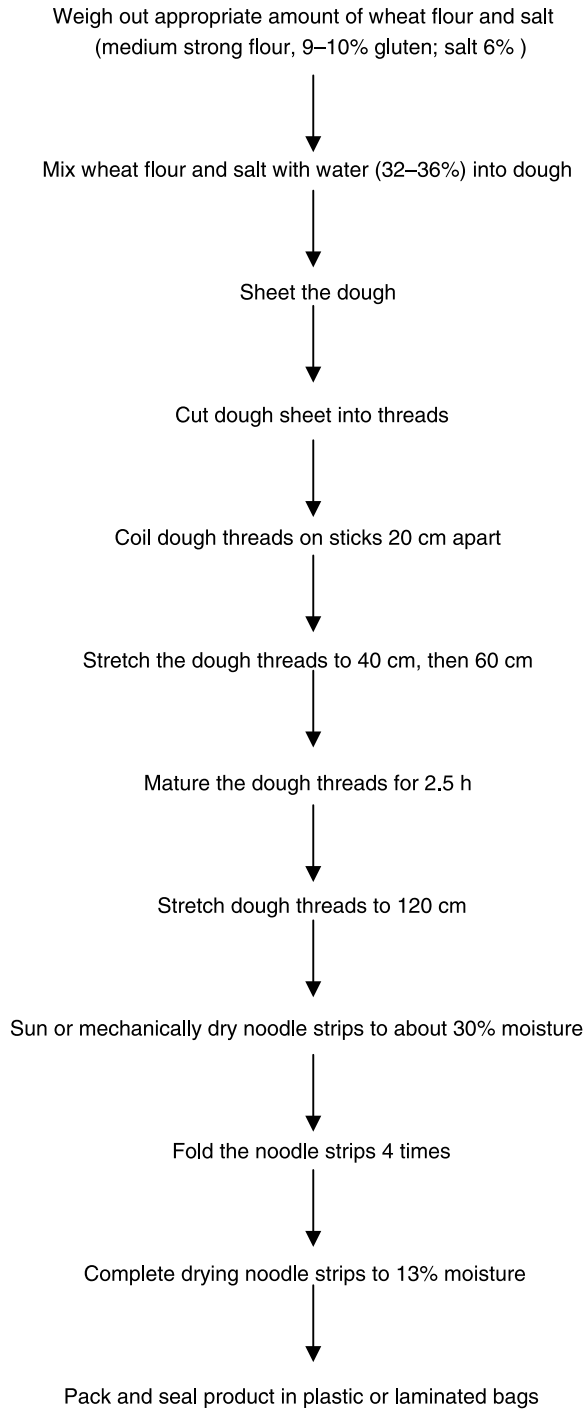

Figure 23.7 *Scheme for the manufacture of noodles using simple devices for the stretching process.*

Figure 23.8 *Simple stretching system for* La miern.

golden yellowish color, and firm and chewy texture. They stay fairly separate after cooking, especially after rinsing with cold water. The addition of egg white provides additional chewy texture and a whiter appearance, and addition of egg yolk contributes to the rich yellow color and a slightly softer texture because of the presence of lipids and lecithin in the egg yolk.

23.3.4 Instant Products

The majority of this type of products has been cooked either by deep-frying or steam-cooking and then dried following the procedure in the manufacture of regular wheat-based noodles. The starch has been gelatinized and the products can be consumed directly if

Figure 23.9 *Examples of yellow-alkaline wheat-based Asian noodles.*

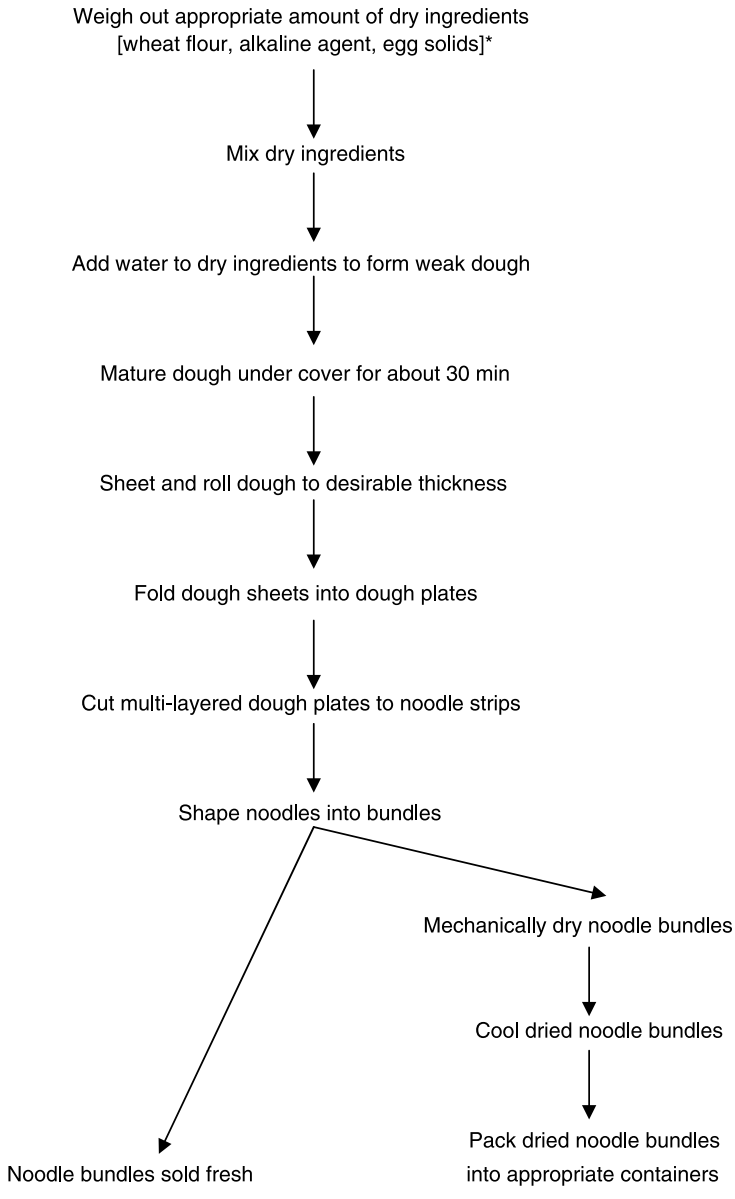

Figure 23.10 *Generalized scheme for the manufacture of Hong Kong or Cantonese-type alkaline noodles. *Alkaline agent can be sodium or potassium carbonate and egg powder can be whole egg, egg yolk or egg white. Adapted from Lu and Nip 2006.*

necessary or with minimal rehydration time in hot or boiling water. This is in contrast to the other types of Asian noodles, which require boiling in water to gelatinize the starch before consumption. Typical examples are instant noodles (such as *ramen*), and Cantonese *E-min* (deep-fried noodles) (Fig. 23.13). The American fried chow mein is a similar product. These noodles do not tend to leach out their starch as quickly as other

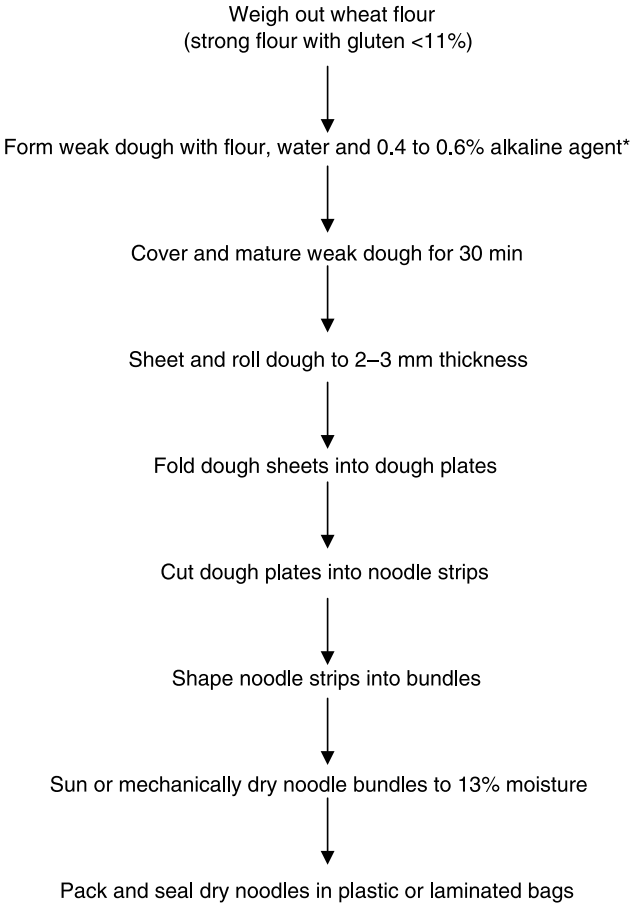

Figure 23.11 *Generalized scheme for the manufacture of Taiwanese alkaline wheat noodles. * Sodium and/or potassium carbonate. Adapted from Lu and Nip 2006.*

wheat-based noodles and have a soft but elastic texture. Their manufacturing processes are outlined in Figures 23.14 and 23.15. Traditional instant noodles are deep-fried, but now there are products that are not deep-fried, but just dried after steaming. This will satisfy consumers who do not want to have so much oil in the final products. Cantonese

Figure 23.12 *Chinese egg noodles.*

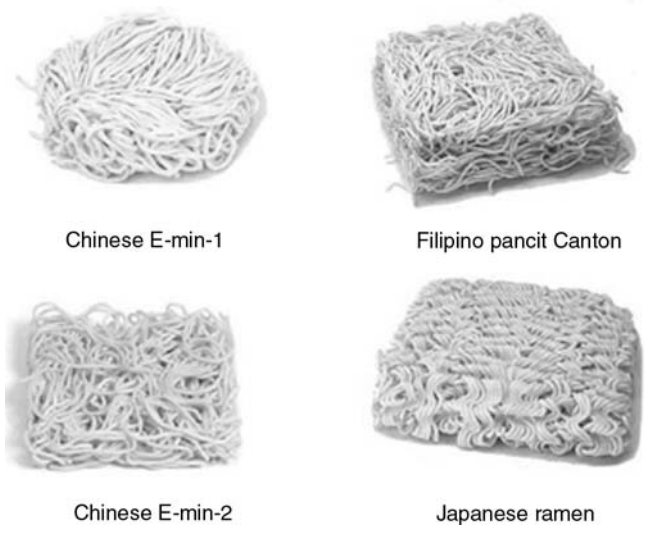

Figure 23.13 *Examples of instant noodles.*

E-min is always deep-fried, with an expansion in volume of three to four times, and it has a much longer history than instant noodles, which can be considered as an improvement of Cantonese *E-min*. It should be noted that ramen-type instant noodles (either deep-fried or dried) have a fairly compact appearance, but *E-min* has a puffed appearance (Fig. 23.13). Instant noodles are packed in cellophane pouches, or styrofoam/laminated paper cups/bowls. Recently, there are products available that contain sterilized pouches of cooked wheat-based noodles as part of the package.

23.3.5 Savory Noodles

This group of Asian noodles is considered as a specialty item. The savory flavorings may be shrimp eggs, egg yolk, egg white, whole egg, dried meat floss, tomato sauce, milk, soy milk, fish stock, chili powder, monosodium glutamate, butter, beef powder, prawn meat, L-lysine hydrochloride, chicken broth, spinach juice, or imitation flavors. They are manufactured mainly in China (including Hong Kong Special District). The manufacturing process is essentially the same as for regular dry wheat-based noodles (Fig. 23.1). The colors of these savory noodles vary according to the savory ingredients used.

The oily noodle is popular in Taiwan, southern China, and in some East Asian countries. It is unique in that oil is added to the cooked noodle to provide a special mouth-feel and it is served *al dente*. This oily, alkaline wheat-based *mien* is sometimes called *Hokkien*-type noodles. The procedures for preparing the raw *mien* are essentially the same as other alkaline wheat-based *mien*. They are then boiled once or twice, or steamed until they are completely cooked, before coating with oil and food coloring (optional). Figure 23.16 shows a generalized scheme of the manufacture of oily noodles. They are sold mainly as a fresh item and require minimal effort to prepare a dish for consumption.

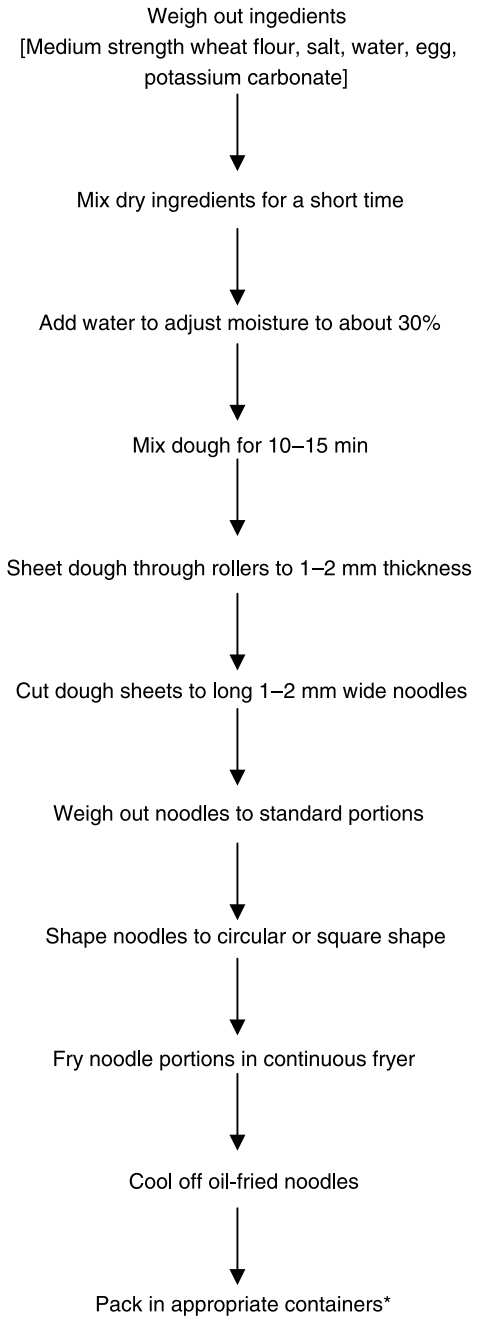

Figure 23.14 *Manufacturing process for instant noodles. * Fried noodles can be packed in cellophane bags, cardboard boxes, Styrofoam trays wrapped wrapped with cellophane, or vacuum packed in laminated pouches. Adapted from Lu and Nip 2006.*

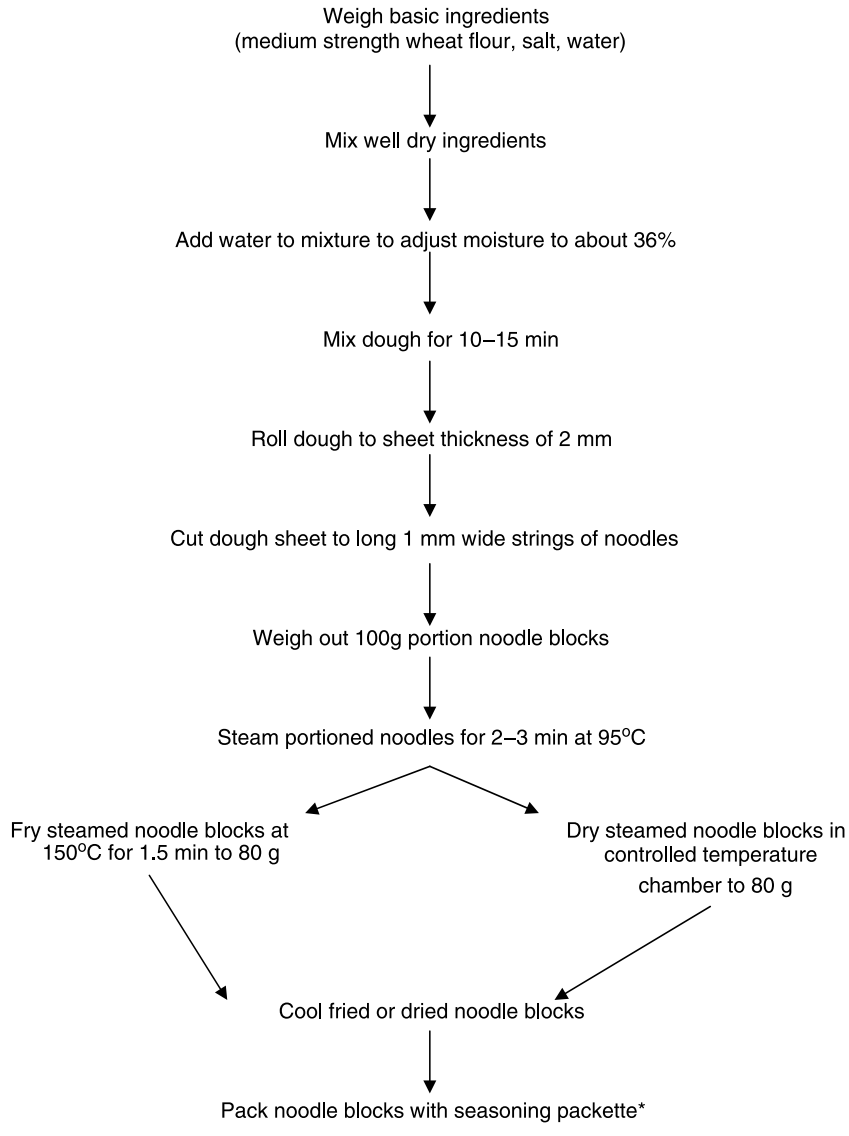

Figure 23.15 *Manufacturing process for instant noodles. *Packages may be plastic bags, or Styrofoam/plastic/laminated cups/bowls. Adapted from Lu and Nip 2006.*

23.4 BROWNISH BUCKWHEAT ASIAN NOODLES

The basic ingredients for manufacturing this type of Asian noodles are buckwheat flour, water, lime-wash or alkaline salts (optional), salt (optional), and yam flour (optional). Brownish buckwheat noodles made from 60–70 parts common buckwheat flour and 30–40 parts wheat flour have the following chemical properties:12–14% protein, 45–48% water, pH 6.5–7, and no salt or oil added. Addition of alkaline salts is optional.

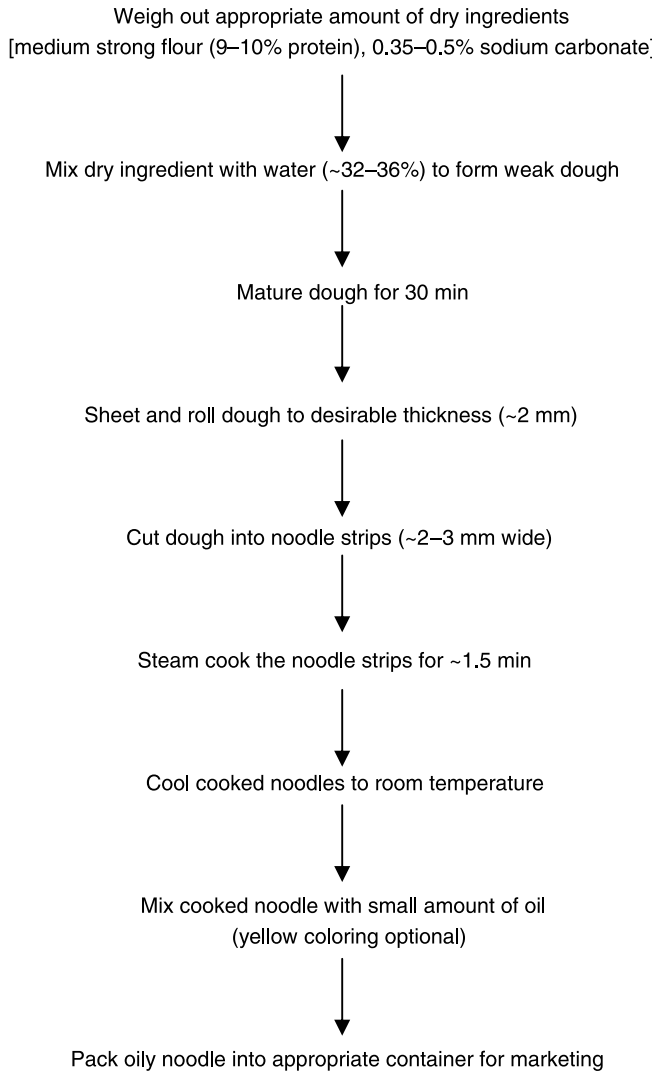

Figure 23.16 *Generalized scheme for the manufacture of oily noodles.*

Because of the absence of gluten in buckwheat, these noodles have a soft texture, but can be firm and chewy dependent on the manufacturing processes. Other ingredients such as green tea have been incorporated into some speciality buckwheat products. Dried *soba* is made by an extrusion process with uniform diameter and length. Fresh *soba* is made manually by repeated kneading and dusting of the dough to give a fairly firm chewy texture, as compared to the regular *soba* which has a fairly soft texture. Buckwheat-based Asian noodles such as *soba* are produced mainly in Japan and Korea. Typical examples are shown in Figure 23.17. They may be plain buckwheat *soba* or have flavoring added such as green tea. Buckwheat flour is also used as an optional ingredient in the manufacture of other wheat-based Asian noodles such as the cat's ear (*mou-er-dao*) noodles. Their production process is similar to regular wheat-based noodles.

Dried Japanese buckwheat soba

Korean buckwheat soba

Figure 23.17 *Examples of Buckwheat-based noodles.*

23.5 RICE-BASED ASIAN NOODLES

Rice noodles (*mi fen* or rice sticks, Fig. 23.18) differ from wheat-based Asian (oriental) noodles in that rice is the basic structural component (Table 23.1). The rice component may be wet-milled rice starch or plain rice flour. The traditional manufacture of rice noodle is a tedious procedure involving the wet milling of polished rice to remove the soluble constituents in the rice kernel, and gelatinization of the rice starch. This process also involves the problem of liquid waste disposal, although it is not high in biological oxygen demand (BOD). This procedure can be modified by using rice flour directly instead of the wet-milled rice flour, thus avoiding the liquid waste disposal problem. However, dry-milled rice flour is not the same as wet-milled rice flour (which is mainly rice starch and a small amount of rice protein), and the quality of the final product is not expected to be the same. It is generally believed that wet-milled rice flour has a

Malaysian rice sticks

Wide rice noodle

Vietnamese rice sticks

Fresh oily "ho fen"

Figure 23.18 *Examples of rice noodles.*

smoother texture after gelatinization. Figure 23.19 describes the general steps involved in the production of dry rice noodles.

Consumers should be aware that, in recent years, some manufacturers have started to replace the rice flour with other starch materials to make similar products, and still call them "rice sticks". They have similar properties, but are not as good as the original rice

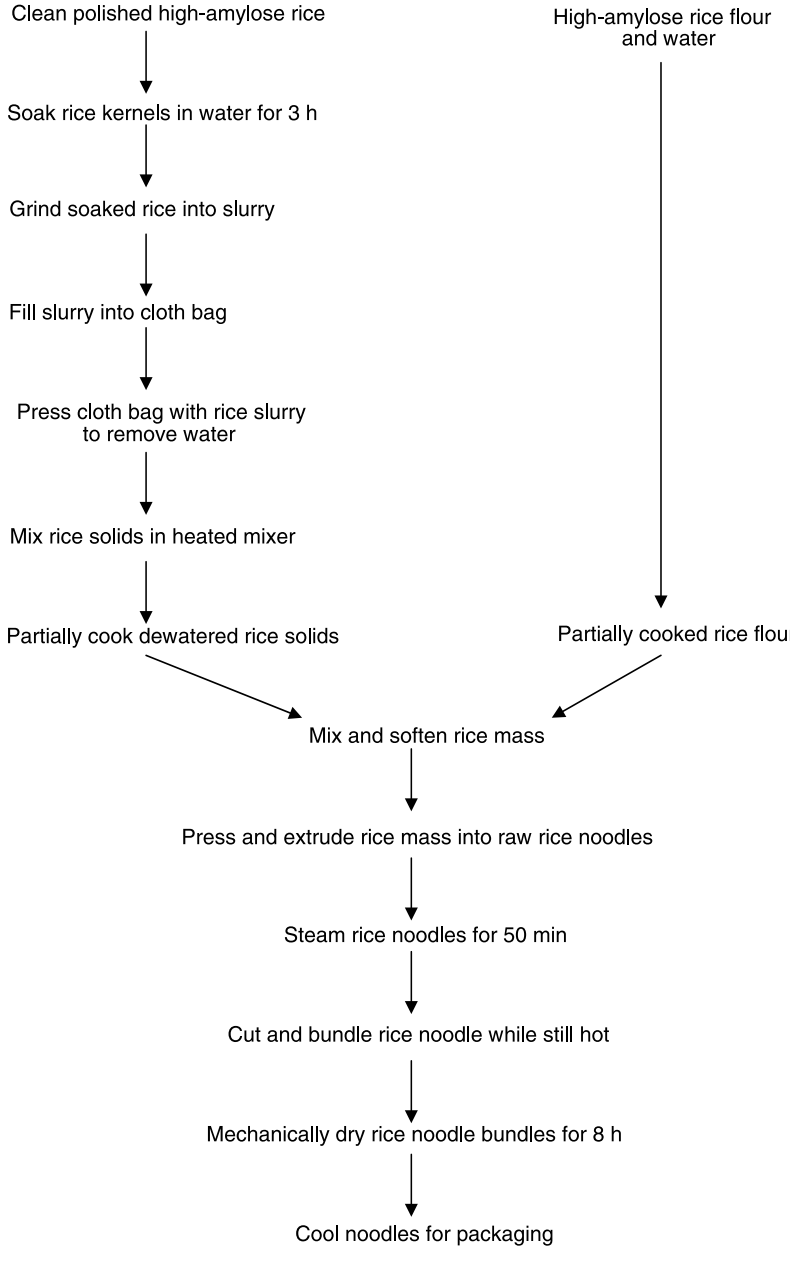

Figure 23.19 *Steps in the production of dry rice noodles.*

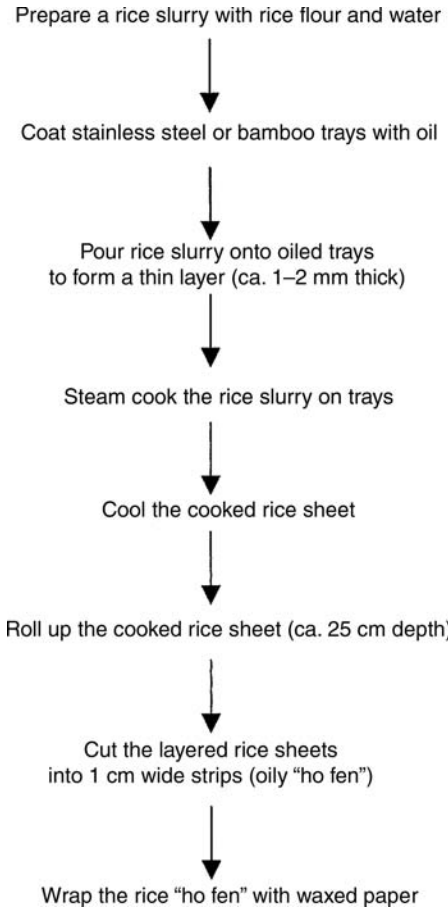

Figure 23.20 *Steps in the production of Cantonese* ho fen.

noodles (rice stick). Cost of the raw materials may be the main reason for this development. Very thin rice noodles are now made and pregelatinized by steam cooking followed by drying for the instant rice noodle market. This offers an alternative to the instant (wheat) noodle product.

The Cantonese "*ho fen* (rice stripes)" is another rice-based Asian noodle, which is an oily product. Rice-flour slurry is prepared, followed by steaming of thin layers of the slurry on oil-coated stainless trays or bamboo sheets. The gelatinized rice-flour slurry or "*fen*" is then folded into layered slabs, followed by cutting the slabs into broad strips (Fig. 23.18). Figure 23.20 describes the basic steps in the making of Cantonese "*ho fen*". They are much broader than the Chinese "hand-cut *mien*" or Japanese "*udon*". Oily rice-based "*ho fen*" is very soft and smooth in texture. The granular size of the rice flour used has a definite effect on the quality of the final product, as the difference in granular size can be detected easily. The original *ho fen* was made with wet-milled rice flour of very fine texture. However, it is much more costly to make and has a liquid waste disposal problem, as with dry rice noodles.

23.6 STARCH-BASED ASIAN NOODLES

The use of starch from various sources to manufacture products in noodle shapes has been practiced for centuries in China and subsequently spread to neighboring countries. These products are sometimes called "starch noodles" or "cellophane noodles" because of their translucent or transparent appearance before or after cooking. This transparent appearance is due to the gelatinization of starch in the manufacturing process. After drying, the product shows a translucent appearance; thus, Westerners call them "cellophane noodles". Mung bean threads or "*fen si*" or "*sai fen*", were probably the first starch noodles manufactured (Fig. 23.21). Vietnamese "*bun tau*", Korean *dang myun*, and Japanese *harusame* are similar products (Table 23.1). The best mung bean threads remain in their original shape and intact for about two days after cooking and being kept in soup. This is because of its unique starch gelling properties, which also provide very good *al dente* properties. Figure 23.22 describes the procedures used to make traditional mung bean threads. Recently, broad strips made from mainly mung bean are also available.

True (pure) mung bean threads are made from mung bean only. However, the products on the market today use other starch materials like broad beans, and other starches besides mung bean, or just plain starch only (corn starch, tapioca starch, or potato starch). Making true mung bean threads involves intensive labor and liquid waste disposal, and these are bottlenecks in the process. The liquid waste is fairly rich in nutrients as it contains all the vitamins, minerals, and proteins in the mung bean and can be used as animal feed. Attempts have also been made to recover the protein from this liquid waste. Because of these issues, it is understandable that materials other than mung bean and improvements in technology are considered. However, these products are not as good as the true mung bean threads as they become very soft, easily, upon cooking.

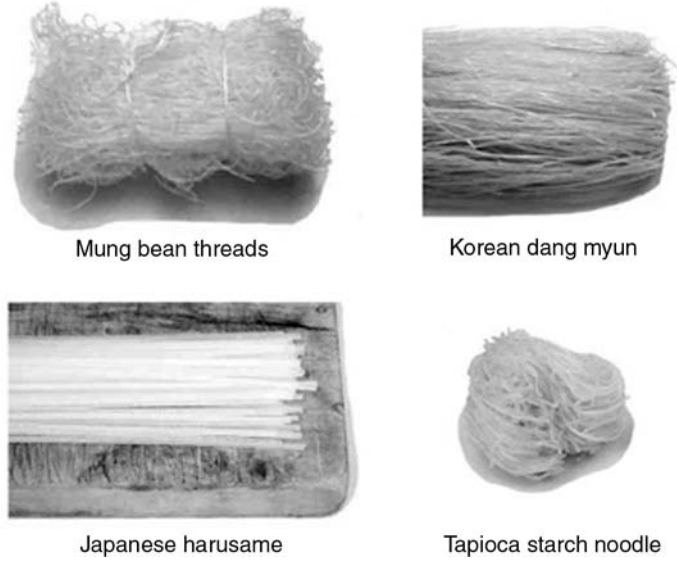

Figure 23.21 *Examples of starch-based noodles.*

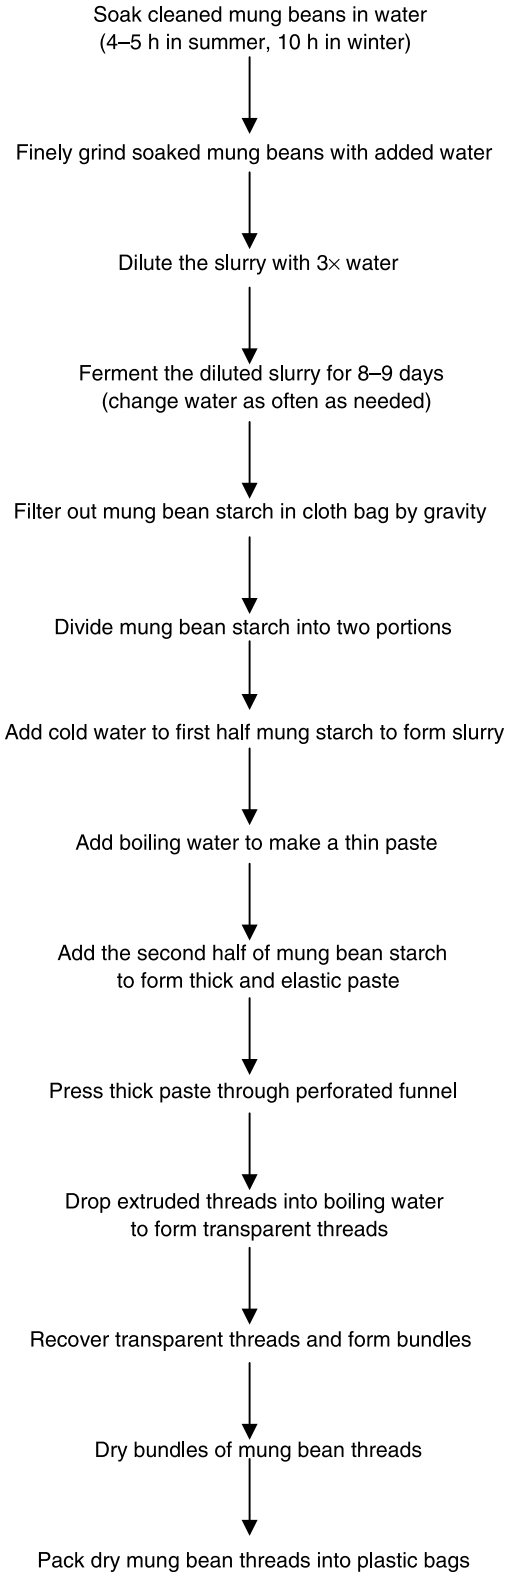

Figure 23.22 *Steps in the production of traditional mung bean threads.*

Japanese shirataki packed in water Japanese shirataki

Figure 23.23 *Japanese shirataki noodles.*

The Korean sweet potato vermicelli ("*dang myun*") is a product similar to mung bean threads, having transparency after it is cooked. Addition of other starches is also practiced. However, it is not purely colorless, but a kind of light brownish-green. It also has excellent *al dente* properties, which remain upon re-heating. They are produced as long and thick noodles. Japanese *harusame* is a similar starch noodle product, as it is also made from starches from potato, sweet potato, rice, or mung bean (Fig. 23.21).

23.7 YAM NOODLE

A very unusual Asian (oriental) noodle is the translucent Japanese "*shirataki*" noodle made from devil's tongue yam (elephant yam or konjac/konjak yam) flour. Elephant yam is used to make *Konjac/kojac* gum, a GRAS food ingredient in the United States. This *shiratake* product is marketed in a form different from others. The most common form is noodle-like, packed in liquid in a sealed container, pasteurized and kept refrigerated (Fig. 23.23). A sterilized product is also available, as are *shiratake* blocks. This product is considered a low-calorie food (only 10 calories per serving) as it utilizes mainly the gums (hydrocolloids) in the devil's tongue yam as the main structural material. Fresh elephant yam contains glucomannan (a soluble dietary fiber) and starch at a ratio of about 2 : 1. The *kojac* gum is coagulated by calcium salt(s) and the starch is gelatinized in the formation of a gel-like product with excellent water-holding capacity. It is popular in Japan and Taiwan, and also available in the oriental markets in the United States.

23.8 VARIABLES AFFECTING PRODUCT QUALITY OF ASIAN (ORIENTAL) NOODLES

In the manufacture of Asian noodles, various processing steps are applied: the selection of raw materials; mixing of ingredients to form dough, slurry, or paste; resting of dough; sheeting and rolling; extruding; shaping; pressing of slurry or paste through perforated funnels or screens; steaming, boiling, or frying; and cooling and drying. In order to be successful in the production of Asian noodles, the manufacturer has to consider, besides the processing steps, production costs, environmental issues, consumer preference, market competition, and proprietary formulations and practices.

TABLE 23.5 Variables Affecting Asian Noodle Manufacture.

Group	Variables
1. Ingredients	Amount and kinds of alkaline salts used
	Amount of coating oil used
	Amount of egg solids used
	Amount of salt used
	Buckwheat flour used
	Kinds and amount of savory ingredients used
	Kind and amount of starchy materials used
	Kinds of frying oil used
	Mung bean used
	Rice flour used (especially amylose to amylopectin ratio)
	Water quality
	Wheat flour used (especially protein content)
2. Dough quality	Rheology of dough
	Viscosity of slurry
3. Processing conditions	Cooking conditions
	Cutting actions for dough or noodle stripes
	Dough resting condition and duration
	Drying temperature, duration and condition
	Extruding condition
	Frying temperature and duration
	Mixing of ingredients
	Kneading of dough
	Relative humidity in drying chamber and environment
	Sheeting and rolling actions
	Starch extraction conditions
	Steaming temperature and duration
	Stretching actions on dough

Source: Adapted from Lu and Nip (2006).

Food technologists and scientists are more interested in the composition of ingredients, the kinds of oil used and amount absorbed, the application of food additives to prolong shelf-life, the rheology of dough, consistency of slurry, work needed to knead the dough, and others (Anon. 1995; Azudin 1998; Baik and others 1994, 1995; Bejosano and Corke 1998; Bhattcharya and Corke 1996; Crobie 1990; Dexter and others 1979; Edwards and others 1996; Galvez and others 1994; Hatcher and others 1999; Jin 1956; Kim and Seib 1993; Konik and others 1993, 1994; Lu and Kuo 1991; Lu and others 1991; Lu 1990; Miskelly and Moss 1985; Moss and others 1986, 1987; Oda and others 1980; Oh and others 1983, 1985, 1986; Ross and Hatcher 2005; Rho and others 1986; Shelke and others 1990; Toyokawa and others 1989a,b; Vadlamani and Seib 1996). The major variables that could affect the quality of Asian (oriental) noodles based on the literature published are summarized in Table 23.5. These published data do not answer all the questions a food technologist or scientist wants to ask, but will provide some indications on what is known and what needs to be studied in the future.

23.9 CONCLUSIONS

Beginning with primitive cottage-type industry, Asian noodle manufacture is now a big industry, especially for instant noodles. With the migration of various ethnic peoples to

various parts of the world and cultural exchange, it has captured the attention of consumers worldwide. It is expected that this industry will grow even further with improvement in manufacturing technology, and will be accepted further by more consumers in various regions.

24.1 INTRODUCTION

No book about dairy products is complete without a chapter dedicated to Cheddar cheese. Cheddar cheese originated in the village of Cheddar, in Somerset, England, in the nineteenth century (Banks and Williams 1997a, 2004). The term, "Cheddaring" specifies the process of piling and re-piling of blocks of warm curd into cheese vats. During the Cheddaring period of about 2 h, lactic acid increases rapidly and the proteins stretch and align, which results in the body and texture characteristic of Cheddar cheese. The first Cheddar cheese factory in the United States, other than farmhouse cheesemaking, was established in New York in 1861 (Lawrence and Gilles 1987a). The procedures for Cheddar cheese manufacture were popularized in America in 1876 by Robert McCadam, leading to the evolution of the American Cheddar cheese industry (Kosikowski and Mistry 1997a).

The United States is the largest producer of Cheddar cheese in the world. In 2001, production of Cheddar cheese in the United States exceeded 1.2 billion kg and supermarket

sales surpassed 219 million kg (IDFA 2002). Today, consumers eat approximately 4.6 kg of Cheddar cheese per capita (IDFA 2005). The greatest centers of American cheese production (including Cheddar) in 2001 were Wisconsin (1 billion kg), followed by California (723 million kg), New York (318 million kg), Minnesota (269 million kg), and Idaho (257 million kg) (IDFA 2002). Today, Idaho leads New York and Minnesota (IDFA 2005) in overall natural cheese production because of its high Italian cheese production.

Extensive modifications in Cheddar cheese manufacture have taken place with the introduction of continuous Cheddar cheese manufacturing systems in large establishments. However, regardless of advances in automation, starter cultures are always used in the manufacturing of Cheddar cheese and considerable attention is given to culture selection. The primary function of starter cultures is to produce acid during the fermentation process, but starters also contribute to cheese ripening, as their enzymes contribute to proteolysis and the formation of flavor compounds (Wallace and Fox 1997).

This chapter will describe similarities and differences among Cheddar and related hard cheeses, outline manufacturing steps involved in production, and describe technological advances in the production of cheeses in the Cheddar and Cheddar-type cheese category.

Please pass the cheese, Louise

24.2 DEFINITIONS

Cheddar cheese (FDA 2004c) is classified as a hard cheese, ranging in color from nearly white (particularly if made from goat or sheep milk) to yellow to orange (USDA 1978). Standards of identity for Cheddar include $\leq$39% moisture and $\geq$50% fat on a dry basis (FDA 2004e). Low-sodium Cheddar cheese contains not more than 96 mg of sodium per 454 g finished food.

Cheeses closely related to Cheddar include Longhorn, Colby (FDA 2004d), and Monterey Jack (FDA 2004h). Although a Cheddar is traditionally about 36.83 cm in diameter, 30.48 cm thick, and weighs between 31.75 and 35.38 kg, Longhorn is 15.24 cm in diameter (round), 33.02 cm long, and weighs 5.5 to 6 kg (USDA 1978). Longhorn is not separately defined in the Code of Federal Regulations, but it may be found commercially. Longhorn Cheddar is essentially a name that describes the round shape derived from Longhorn hoop usage during the pressing step.

Colby manufacture resembles Cheddar except that the curd is "washed" and stirred instead of matted and milled (Kosikowski and Mistry 1997a). Colby is moister, softer, and more open in texture than Cheddar. Moisture must not exceed 40% and fat in the solids must be at least 50% (FDA 2004d). Colby contains between 1.4 and 1.8% salt (USDA 1978).

Monterey, Jack or Monterey Jack cheese was first made in Monterey County, California, in 1892 (USDA 1978). Monterey is made in a similar fashion to Colby, but the procedure requires less time. Monterey contains more moisture and is softer than Cheddar and Colby (USDA 1978). Standards of identity state that Monterey must

contain not more than 44% moisture and at least 50% fat in the solids (FDA 2004h). High-moisture Jack cheese conforms to the definition and standard of identity and is subject to the requirement for label statement of ingredients prescribed for Monterey cheese, except that its moisture content is more than 44% but less than 50% (FDA 2004h). Monterey typically contains 1.5% salt (USDA 1978).

24.3 PRODUCTION OF CHEDDAR AND RELATED HARD CHEESES

Good cheese requires high-quality milk and carefully selected starter cultures. However, additional ingredients are often utilized to enhance visual appeal (annatto), coagulation properties (calcium chloride or enzymes), and flavor development (adjunct cultures or enzymes) to make great cheeses. How well the additional steps are employed determines whether or not one makes a great cheese. The following section will elaborate on individual ingredients and their function in cheesemaking.

24.3.1 Ingredients

24.3.1.1 Milk. To make high-quality cheese, producers must start with high-quality milk. Cheese quality will never be better than the starting materials. Cheddar and most Cheddar-like cheeses can be made from raw, heat-treated, heat-shocked, or pasteurized milk, nonfat milk or cream, alone or in combination (FDA 2004c). Legally, there is no distinction between raw and heat-treated/shocked milk. Because of the potential for pathogens to survive in cheese for up to 60 days, cheeses made from raw or heat-treated/shocked milk must be aged for at least 60 days at greater than 1.66°C prior to sale (FDA 2004e). Cheeses must be aged at greater than 1.66°C to ensure microbial metabolic activity and progression through the life and death cycle. Cheeses made from pasteurized milk need not be aged prior to sale. Monterey Jack cheese milk must be pasteurized because of its limited aging (FDA 2004h).

Regardless of use of heat treatment, low bacteria counts are essential for high-quality cheese, as high bacterial counts can lead to flavor and body defects. Psychrotrophic bacteria, including *Pseudomonas*, *Aeromonas*, *Flavobacterium*, *Acinetobacter*, *Bacillus*, *Micrococcus*, and other genera, can grow relatively rapidly in milk maintained at 7°C or lower (Frank and Marth 1988; Richard and Desmazeaud 2000; Banks and Williams 2004), so extended storage of milk (beyond 48 h) prior to pasteurization or cheesemaking is highly discouraged. Enzymes produced by psychrotrophs, including heat-stable lipases and proteinases, can act directly on milk proteins and lipids, reducing yield and contributing to quality defect development in the resultant cheese (Johnson 1988; Richard and Desmazeaud 2000).

Extended storage of milk prior to pasteurization and cheesemaking not only enables growth of psychrotrophic bacteria, but also encourages solubilization of colloidal calcium phosphate and a shift in caseins from the micellar to soluble state (Johnson 1988). Although soluble caseins constitute less than 15% of the total casein in normal milk directly from the udder, the proportion increases to up to 42% of total casein during storage at 4°C (Johnson 1988). Soluble calcium phosphate and casein are lost during whey drainage, which reduces cheese yield (Johnson 1988).

TABLE 24.1 Recovery of Milk Components in Cheddar Cheese.

Constituent	Percent in Cheese-Milk	Percent Recovered in Cheese
Water	87.0–88.0	4.5
Fat	3.0–4.5	92.5
Casein	3.0–4.0	96.0
Lactose	4.5–5.0	4.0
Whey protein/salts	1.2–1.8	29.0

Because approximately 90% of both fat and protein from cheese milk are captured in the cheese (Table 24.1), and these components make up 91% of the solids in cheese (Johnson 1988), detrimental effects on either component will be realized in the cheese yield and quality. Variability in milk composition is discussed in another chapter of this book. For consistency in yield and product composition, milk for Cheddar cheese is commonly standardized to a casein-to-fat ratio between 0.67 and 0.72 (Lawrence and Gilles 1987a; Banks and Williams 2004).

Somatic cells also have an impact on cheese yield. Barbano and others (1991) demonstrated that milk casein as a percentage of true protein (C%TP) and cheese yield efficiency were lower when milk somatic cell count (SCC) was high. Cheese moisture, as well as fat and protein losses in whey, increased with increased SCC (Barbano and others 1991). It was concluded that any increase in milk SCC above 100,000 cells/mL negatively affects cheese yield for milk from groups of cows with similar milk SCC (Barbano and others 1991).

Raw milk naturally contains low levels of endogenous enzymes, including alkaline phosphatase, plasmin, and lipoprotein lipase (Whitney 1988). Alkaline phosphatase (ALP) is slightly more heat stable than the most heat-resistant pathogenic microorganisms in milk. Thus, ALP is a convenient indicator of pasteurization. Indeed, the Pasteurized Milk Ordinance defines legal limits for ALP for Grade "A" pasteurized milk and bulk shipped heat-treated milk products (U.S. Department of Health and Human Services 1999 revision). ALP assays should also measure negative in cheeses made from pasteurized milk. Plasmin, which is stable at pasteurization temperature, hydrolyzes both β- and α_{s1}-casein in milk and in cheese during maturation, thus contributing to cheese maturation (Johnson 1988; Banks and Williams 2004).

The lipoprotein lipase found in milk is identical to the lipoprotein lipase in blood and represents a spillover from the mammary tissues (Weihrauch 1988). Lipoprotein lipase, if activated by severe agitation, temperature fluctuations, or other means, leads to hydrolysis of fatty acids from triacylglycerides and rancid off-flavors in milk and the subsequent cheese. Rancidity in milk may be detectable at acid degree values exceeding 1.2 meq/L (Bodyfelt and others 1988; Weihrauch 1988). Raw milk is somewhat resistant to lipase because of the protective nature of the milkfat globule membrane (Weihrauch 1988). Unlike contaminating bacterial lipases, natural milk lipase is heat labile. Heating of milk to 80°C for 20 s destroys all lipases in milk (Weihrauch 1988).

24.3.1.2 Calcium Chloride. Calcium chloride may be added to the cheese milk as a coagulation aid, in an amount not more than 0.02% (calculated as anhydrous calcium chloride) of the weight of the dairy ingredients. Addition of calcium chloride reduces

the coagulation time and increases curd firmness (Lenoir and others 2000b). Calcium added to milk is solubilized during acidification and thus lost in whey, so it does not contribute to total calcium in the final cheese.

24.3.1.3 Starter Cultures. Starter bacteria can be defined as isolates that produce sufficient acid to reduce the pH of milk to <5.3 in 6 h at $30-37^{\circ}C$, and aid in curd digestion and flavor development (Lewis 1987). Cultures selected for Cheddar cheese made throughout the world are typically "O" cultures, which are designated as cultures that produce lactic acid from lactose. The "O" type cultures are composed of *Lactococcus lactis* subsp. *lactis* and *Lactococcus lactis* subsp. *cremoris* (Harrits 1997; Strauss 1997). *L. lactis* subsp. *lactis* and *L. lactis* subsp. *cremoris* can be differentiated by their ability to grow at $40^{\circ}C$ and in the presence of salt. Whereas *L. lactis* subsp. *lactis* will grow at $40^{\circ}C$ and in the presence of 4% salt, *L. lactis* subsp. *cremoris* will not grow at $40^{\circ}C$ and will grow in the presence of salt up to a 2% concentration (Harrits 1997). The "L" type cultures consist of "O" type cultures plus the citrate-fermenting culture *Leuconostoc mesenteroides* subsp. *cremoris*, which produces flavor compounds (e.g., diacetyl) plus small amounts of carbon dioxide (Harrits 1997). "L" type cultures may also be used in the production of Colby, because an open structure is allowed in Colby (Harrits 1997). Ideally, acid should be formed quickly and at a steady rate during curd formation. Bacteriophage (phage) resistance, salt sensitivity, and protease activity (desirable flavor development) are additional selection criteria (Strauss 1997). Homofermentative starter cultures are added deliberately to initiate Cheddar cheese manufacture. The starter bacteria produce L(+)-lactate from lactose and they grow, typically attaining cell densities of 10^8 cfu/g within hours of the beginning of manufacture. L(+) refers to an optically active substance that rotates the plane of polarized light counterclockwise (also called levorotatory). The optical isomer of L(+)-lactate is D(−)-lactate. The optical isomers are mirror images of each other and result from the tetrahedral geometry around the chiral carbon center.

Production of homogeneous, high-quality Cheddar cheese requires uniform lactose fermentation, lipolysis, and proteolysis, each of which varies among bacterial strains. A relationship the exists between the extent of starter cell autolysis and the level of lipolysis during Cheddar cheese ripening (Collins and others 2003). The rate and extent of both fermentation and proteolysis depend upon temperature and salt concentration (Thomas and Pearce 1981). One of the main roles of starter bacteria is to provide a suitable environment for enzyme activity from rennet/chymosin (an acid protease) and favorable growth of secondary microflora with respect to redox potential, pH, and moisture content in cheese. Redox potential is a measure of the tendency of a system to donate or accept electrons, and indicates aerobic or anaerobic conditions. Typically, the environment inside cheese is anaerobic and reducing. Depending upon the type of culture preparation, usage rates vary between 0.75 and 1.25% for traditional bulk starter and 0.5% and 0.6% for pH controlled starter or DVS starter, respectively (Strauss 1997).

24.3.1.4 Adjunct Cultures. An adjunct culture is a one that is added, along with starter culture, for the desirable characteristics it may impart upon the cheese other than acid. Adjunct cultures are select nonstarter lactic acid bacteria (NSLAB), because not all NSLAB are desirable. Although the specific ripening mechanisms of NSLAB that contribute positively to Cheddar flavor have not been fully determined, to be successful, NSLAB adjuncts require two important features (Crow and others 2001). First, strains

must provide a balance of beneficial ripening reactions in cheese (Crow and others 2001). Secondly, strains need to be competitive against adventitious (not intentionally added) NSLAB and remain the dominant NSLAB during the ripening period (Crow and others 2001).

Lactobacillus helveticus is one species that may be added to Cheddar cheese milk for desirable cheese flavor development. *L. helveticus* species tend to be thermophilic, proteolytic, and have the ability to utilize galactose after other sugars are fermented (Harrits 1997). Because of their proteolytic capabilities, *L. helveticus* adjunct cultures have shown themselves to effectively improve the sensory quality of reduced-fat Cheddar cheese (Drake and others 1997).

24.3.1.5 Color. The recognizable yellow to orange color of Cheddar and Colby cheeses is derived from annatto, an extract from seeds of the "Lipstick tree," *Bixa orellana* (Walstra and others 1999). Annatto was first used to make cheeses appear more fat-rich, when made during seasons of the year when the milk of cows produced less colorful cheese because the cows were fed diets lower in beta-carotene. Sheep and goat milk cheeses are naturally whiter than cow milk cheeses because the beta-carotene is efficiently hydrolyzed to vitamin A in the digestive tracts of these species.

24.3.1.6 Enzymes. The Code of Federal Regulations permits the use of rennet/chymosin and/or other clotting enzymes of animal, plant, or microbial origin, as well as enzymes of animal, plant, or microbial origin, used in curing or flavor development for Cheddar cheese (FDA 2004j). Enzymes of starter, adjunct NSLAB, and adventitious NSLAB naturally contribute to flavor and body/texture development in cheeses. Kheadr and others (2003) were able to accelerate Cheddar cheese proteolysis and lipolysis using various liposome-encapsulated enzymatic cocktails. A neutral bacterial protease, acid fungal protease, and lipase were individually entrapped or mixed as cocktails and entrapped in liposomes then added to cheese milk prior to renneting (Kheadr and others 2003). Certain enzyme treatments resulted in cheeses with more mature texture and higher flavor intensity or Cheddar flavor in a shorter time compared with control cheeses (Kheadr and others 2003).

24.3.1.7 Salt. Cheddar cheese typically contains 1.6–1.8% salt (Williams and others 2000), in the form of NaCl. Salt enhances flavor, encourages syneresis, and slows or stops growth of salt-sensitive bacteria. Food-grade salt is essential to the production of safe, high-quality Cheddar cheese, and consistent salt grain size contributes to uniformity of salt concentration throughout the cheese matrix.

Investigators (Reddy and Marth 1993, 1995a,b) have demonstrated that reduced-salt, or low-salt Cheddar cheese can be made by replacing sodium chloride (NaCl) with potassium chloride (KCl) or mixtures of the two salts. Use of KCl to replace some of the NaCl for salting cheese has no detectable effect on the kinds of lactic acid bacteria, aerobic microorganisms, aerobic spores, coliforms, and yeasts and molds in cheeses when compared with control cheeses (Reddy and Marth 1993). Authors concluded that low-sodium Cheddar cheese can readily be produced without affecting its composition when one-third or more of the NaCl added to cheese curds is replaced with KCl (Reddy and Marth 1993).

24.3.1.8 Other Optional Ingredients. The Code of Federal Regulations allows the use of antimycotic agents, applied to the surface of slices or cuts in consumer-sized packages (FDA 2004a). Some of the antimycotic substances allowed by the FDA are calcium propionate (FDA 2004b), methylparaben (methyl *p*-hydroxybenzoate) (FDA

2004g), propylparaben (propyl *p*-hydroxybenzoate) (FDA 2004i), sodium benzoate (FDA 2004k), sodium propionate (FDA 2004l), and sorbic acid (FDA 2004m).

Hydrogen peroxide is allowed, if followed by a quantity of catalase preparation sufficient to eliminate the hydrogen peroxide. The weight of the hydrogen peroxide shall not exceed 0.05% of the weight of the milk (FDA 2004f) and the weight of the catalase shall not exceed 20 ppm of the weight of the treated milk (FDA 2004c).

24.3.2 Preparations for Cheesemaking

24.3.2.1 Culture Selection and/or Propagation. Culture quality is of the utmost importance in the production of high-quality cheese. Culture manufacturers commonly work closely with processing facility operators to effectively meet specific needs. Culture manufacturers continuously develop unique culture combinations for a given product. Several types of culture forms are available, including

1. Liquid (for propagation of mother culture; rarely used today);
2. Deep-frozen concentrated cultures (for propagation of bulk starter);
3. Freeze-dried concentrated cultures in powder form (for propagation of bulk starter or DRI-VAC, for preparation of mother culture); and
4. Deep-frozen or freeze-dried, superconcentrated cultures in readily soluble form for direct inoculation of the product (direct vat set, DVS).

The availability of frozen or freeze-dried cultures eliminates the need for small dairy plants to make cultures or operate a culture room (Lewis 1987). The culture room is a separate room in the dairy plant reserved for preparation and propagation of starters and an important element in production of quality cheese because it limits opportunities for contamination by airborne yeast, mold, and bacteriophage (Lewis 1987). Bacteriophage (phage) are viruses that infect specific strains of bacteria, which stresses the importance of utilizing mixed-multiple strains and starter culture rotation in cheesemaking. Proliferation of phage will result in a failure of lactic acid production, termed "stuck vat," necessitating strict sanitation and whey-handling practices to keep phage numbers to a minimum. Larger plants are typically supplied with frozen or freeze-dried cultures for the manufacture of bulk starters in aseptic bulk culture rooms (Lewis 1987). Cooling and storage conditions and shelf-lives of cultures vary. Generally, deep-frozen and freeze-dried cultures can be stored for 9–12 months at $-18^{\circ}C$ and $-45^{\circ}C$, respectively (Lewis 1987). Maintenance of consistency across cheese lots requires constancy of culture handling.

24.3.2.2 Cheese Milk Pretreatments. Centrifugal clarifier-separators are used to separate the cream and skim fractions, as well as remove solid impurities from milk prior to standardization. Cheese milk fat and protein content are commonly standardized for consistency of yield and composition. Fat may be increased with the addition of cream, and protein, particularly casein, may be increased with nonfat dry milk, skim milk, or condensed skim milk (Johnson 1988). A typical casein-to-fat ratio of between 0.67 and 0.72 may be used (Lawrence and Gilles 1987b; Banks and Williams 2004). Although cheese moisture is influenced by numerous factors during cheesemaking, higher fat levels in cheese milk are typically associated with lower moisture cheeses (Lawrence and Gilles 1987b). As a general rule, an increase of 0.05 in the casein-to-fat ratio in milk generally

results in a decrease of about 1.4% in the fat on a dry basis and an increase of about 0.8% in moisture in Cheddar cheese (Lawrence and Gilles 1980).

Most commonly in the United States, whole milk is preheated to 55–65°C in the regeneration section of the high-temperature short time (HTST) pasteurizer prior to separation. Following separation, the cream is standardized to a preset fat level and the fraction intended for standardization of milk is routed and remixed with the proper amount of skim milk to attain the desired fat and protein content. The surplus cream is directed to a separate cream pasteurizer, and the standardized milk flows through the pasteurizer.

El-Gazzar and Marth (1991) recommended the use of ultrafiltered milk for conversion into such cheeses as Cheddar, cottage, havarti, feta, brick, Colby, and Domiati because of an increase in yield of product. Ultrafiltration results in the concentration of milk proteins, with reduction in lactose and mono- and divalent cations. Additional benefits claimed for use of ultrafiltered milk in cheesemaking include reduction in costs of energy, equipment, and labor, improved consistency of cheese flavor, and the potential production of new byproducts (El-Gazzar and Marth 1991).

24.3.2.3 Homogenization. Although homogenization of cheese milk is typically not employed in the production of Cheddar cheese, research has shown that homogenization of cream may have applications to Cheddar cheese. Homogenization is most efficient when fat globules are in the liquid state, so milk is preheated in the plate heat exchanger in the regeneration section of the HTST pasteurizer, where the temperature is raised to at least 60°C prior to homogenization (Morr and Richter 1988). In a two-stage homogenizer, pressures typically range from 10 to 25 MPa in the first stage and 5 MPa in the second stage.

In a study with Cheddar cheese standardized to a casein-to-fat ratio of 0.70, Nair and others (2000) demonstrated that cheese hardness was not influenced by homogenization, and cheeses with homogenized cream had improved body and texture and flavor over controls. Cream homogenized at 6.9 MPa (first stage) and 3.5 MPa (second stage) was optimal for enhancing Cheddar cheese yield and functionality (Nair and others 2000). Metzger and Mistry (1994) demonstrated that cheese moisture and yield were higher in reduced-fat Cheddar cheeses made with homogenized cream than controls. The body and texture of reduced-fat Cheddar cheeses made from homogenized cream were improved over those for the control cheeses, which were hard, rubbery, and curdy (Metzger and Mistry 1994).

24.3.2.4 Pasteurization. The only step in the dairy processing system that guarantees the killing of pathogenic microorganisms is pasteurization. Thus, pasteurization may be considered the most critical segment of the cheese processing line. An added side-benefit of pasteurization is that it also kills many spoilage microorganisms and inactivates enzymes that may contribute to quality defects in cheese. Pasteurization contributes to consistency in product quality. Of course, strict sanitation is critical up to and beyond pasteurization to assure the safety and quality of dairy products. In HTST pasteurization, milk must be held at a temperature of at least 72°C for a minimum of 15 s to be legally pasteurized (U.S. Department of Health and Human Services 1999 Revision). In batch or low-temperature long time (LTLT) systems (uncommon in large-scale operations), milk is continuously agitated in a single tank, at a set temperature (legally at least 62.8°C) for a given time (legally at least 30 min if at 62.8°C) to guarantee inactivation of pathogens (U.S. Department of Health and Human Services 1999 Revision). Any lower temperature or shorter time than legal pasteurization means the cheese must be treated as if made from raw milk, which means products must be aged for at least 60 days at 1.66°C or higher.

Regardless of pasteurization method, cheese milk is then cooled, either to incubation temperature for selected starter cultures, or to refrigeration temperature for future applications.

Although all pathogens and most spoilage microorganisms are killed by pasteurization, potentially beneficial or flavor-producing microorganisms are also killed. And so, although cheeses made from pasteurized milk are safe, they also have less flavor than raw milk cheeses. Buchin and others (1998) studied the effects of pasteurization and fat makeup of experimental semihard cheeses with two different fat compositions. The raw-milk cheeses had more intense flavor and volatile compounds than the pasteurized milk cheeses. Raw-milk cheeses were characterized by higher amounts of numerous alcohols, fatty acids, and sulfur compounds, and pasteurized-milk cheeses were characterized by higher amounts of ketones (Buchin and others 1998). The differences were attributed to the high level of indigenous microflora in raw milk cheeses (Buchin and others 1998).

In addition to modifying milk microflora, pasteurization acts upon milk protein chemistry to influence cheese quality. Specifically, pasteurizing cheese milk influences the extent and characteristics of proteolysis during Cheddar cheese aging (Lau and others 1991). Pasteurization causes heat-induced precipitation of whey proteins upon casein micelles that results in retention of additional whey protein in the cheese beyond that which is soluble in the aqueous phase of raw-milk cheese. The presence of heat-denatured whey protein in cheese may influence the accessibility of caseins to proteases during cheese aging, a consequence of which would be differences in proteolysis during aging. These differences may be another factor that contributes to differences in flavor development in Cheddar cheese made from pasteurized and raw milk (Lau and others 1991). Temperatures higher than legal pasteurization (80°C) may be used to increase yield; however, gelling takes longer, the firming rate of the gel as well as its maximum firmness are reduced, and gel draining is more difficult and is incomplete (Lenoir and others 2000b). These factors are a consequence of denatured whey proteins, particularly β-lactoglobulin, which bind with caseins, particularly κ-casein. Indeed, a complex between β-lactoglobulin and κ-casein leads to modification in the conformation of the κ-casein chain at the chymosin cleavage site, detrimentally affecting coagulation properties (Lenoir and others 2000b). Denaturation of whey proteins is negligible at pasteurization temperatures, but reaches 10% after a treatment of 75°C for 15 s and 20% after 85°C for 30 s (Lenoir and others 2000b). Heat also decreases soluble calcium, ionized calcium, and soluble inorganic phosphorus (Lenoir and others 2000b).

24.3.3 Cheesemaking

A schematic diagram outlining the steps of cheesemaking, from fresh milk through aging cheese is shown in Figure 24.1. In large automated plants, cheesemaking is typically held to a well-timed schedule. Culture, $CaCl_2$, and color are typically added as cheese milk enters the cheese vat, after pasteurization and cooling. Chymosin is commonly added after the vat is completely filled with pasteurized milk. In pilot or small-scale operations, culture, $CaCl_2$, and color are commonly added when an entire vat of cheese milk reaches target temperature. Chymosin is added after a ripening period of 15–30 min.

24.3.3.1 Calcium Chloride Addition. If $CaCl_2$ is to be added to the cheese milk, typically 0.2% of cheese milk weight is adequate to improve coagulation properties (Kosikowski and Mistry 1997a; Lenoir and others 2000a).

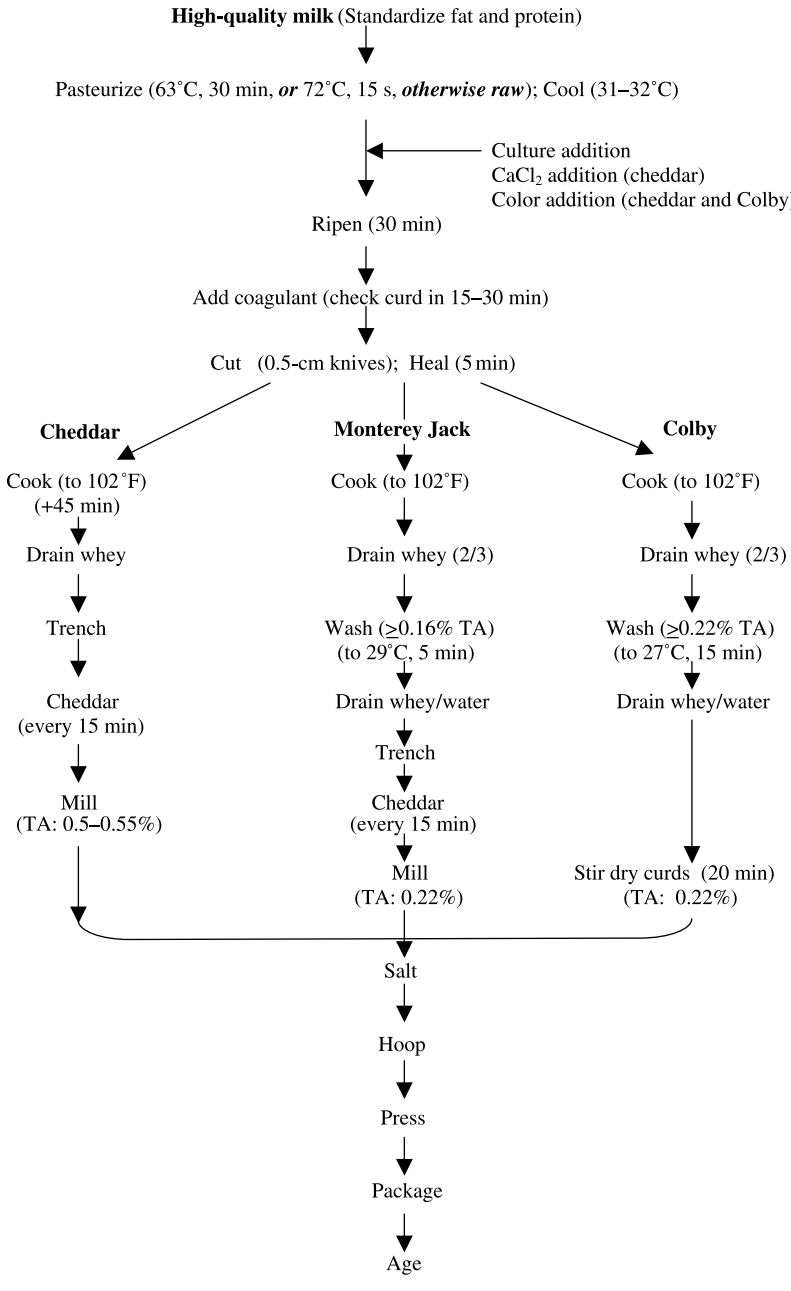

Figure 24.1 *Schematic of the steps in cheesemaking.*

24.3.3.2 Color Addition. Annatto may be added to cheese milk at a rate of approximately 66 mL per 1000 kg of milk, adjusted to desired product color (Kosikowski and Mistry 1997b). Annatto binds with protein to form a straw to orange color in the final cheese, upon a concentration that occurs with whey expulsion (syneresis).

24.3.3.3 Culture Addition. Prior to culture addition, raw or pasteurized milk must be tempered to the appropriate temperature for starter culture multiplication, approximately 26–30°C for Cheddar and related cheeses (Banks and Williams 2004). Inoculum level is defined by culture manufacturers, based upon whether the culture is DVS or bulk culture, typically from 0.5 to 5%. Cheese manufacturers may increase or decrease the amount of culture based on seasonal variation in milk composition (Lawrence and others 1999). Optional addition of adjunct culture typically varies from 0.1 to 1%.

24.3.3.4 Ripening. The titratable acidity (TA) of fresh milk is approximately 0.14–0.18, depending on composition, and pH is about 6.6–6.8. When starter culture is added, cultures need time to equilibrate to their environment (lag phase), so only a small rise in TA is noted during the 30-min ripening period. Little lactose is converted to lactic acid during the lag phase of the cultures, but TA rises steadily during the log phase of growth, during which time culture numbers increase exponentially. Even after lactic acid formation begins, little change in pH is noted because of milk's high buffering capacity, owing to the presence of proteins, citrate, and phosphate in milk.

24.3.3.5 Enzyme Addition. In fresh fluid milk, charges on the κ-casein "hairs" are negative (−), so casein micelles repel each other. With the production of acid, the charges on some κ-casein hairs begin to change to positive (+). When pH declines to near 5.2, calcium and phosphorus are solubilized and the micelle structure changes (Brulé and others 2000). At pH close to 4.6, coagulation occurs, as repulsive charges are neutralized and micelles come into contact with one another and coalesce (Brulé and others 2000). Some cheeses are made exclusively with acid coagulation (e.g., cottage cheese). Because acid development is slow, cheese make procedures that rely entirely on acid coagulation are in the order of 10–18 h in length. The cheesemaking process is accelerated by the use of coagulating enzymes.

Chymosin, originally derived from the abomasum of milk-fed calves, but now microbially or fungally derived, is the most common coagulating enzyme used in the manufacture of Cheddar and related varieties (Ramet 2000b). Chymosin is an acid protease, which means that it is more active at an acid pH than neutral or basic pH. Highest activity is observed at pH 5.5 and 42°C (Ramet 2000b). Specifically, chymosin cleaves the peptide bond Phe105–Met106, which leads to the formation of κ-para-casein (l-105) and glycomacropeptide or caseinomacropeptide (CMP, 106–169) (Brulé and others 2000). CMP is soluble in whey. When chymosin is added to milk, coagulation occurs in three steps:

1. κ-Casein hydrolysis,
2. Aggregation of destabilized micelles, and
3. Reorganization of calcium phosphate, or reticulation (Brulé and others 2000).

The coagulation process is shortened because rennet/chymosin cleaves the negatively-charged κ-casein hairs off the micelles, enabling approach and coagulation of micelles. During the coagulation process, calcium phosphate bridges form between micelles, and tighten as whey is expelled, forming a tight network of casein, which entraps some fat, water, and water-soluble components. As fermentation proceeds, Ca^{2+} are replaced by H^{+} and the casein network continues to tighten.

Approximately 5–50 mL of single-strength liquid chymosin should be used to coagulate 100 L milk (Brulé and others 2000). Chymosin should always be diluted (approximately 1 part to 40 parts water) prior to addition to the cheese vat to prevent localized coagulation. Dilution should always be done with cool (or room temperature) water immediately before adding to milk. Chymosin begins to lose its strength and activity immediately upon dilution, which is why dilution should not be done in advance. Also, chymosin is degraded by high temperatures and chlorine. Chymosin must not be overmixed into the milk because cleavage of κ-casein from casein micelle proteins begins immediately. In small operations, chymosin should only be mixed into milk for about 1 min to maximize yield. During the incubation period, the cheese vat must not be agitated or disturbed in any way, or a soft or weak curd will result and yield will be affected.

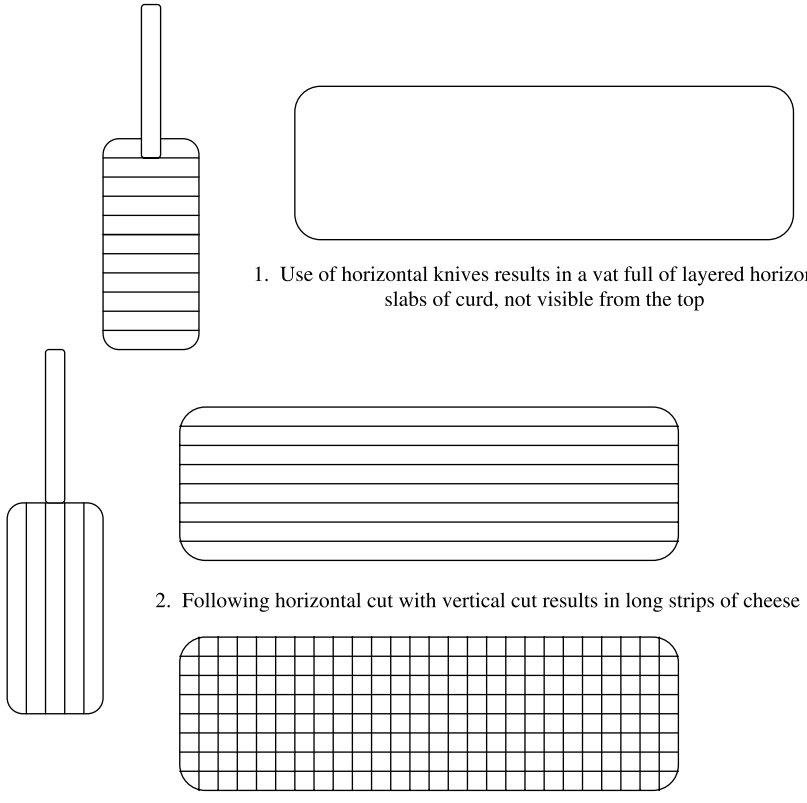
Chymosin is allowed to set the cheese for 20–30 min prior to curd testing. In large automated plants, the curd is typically not checked, and cutting begins at a set time. To check the curd, a spatula or knife may be used. A spatula works best for checking curd set because of its rounded shape. The blade is cut through the curd in a 5-cm vertical orientation and removed. The blade is then inserted at the bottom of the vertical cut, in a horizontal orientation, to form a T. The blade is pushed forward and lifted, to encourage the curd to split open. The curd is ready for cutting when the curd is firm, it breaks cleanly, and fills with clear yellow (not cloudy) whey.

24.3.3.6 Cutting. Cutting of the curd is an extremely important step in the cheesemaking process because it influences whey drainage and cheese yield (Ramet 2000a). Cutting to a consistent size, with sharp knives, is critical to minimize small curd particles (fines) that may get lost during whey drainage (Ramet 2000a). Manually, the coagulated mass of cheese is cut with harps: knives constructed of stainless steel hardware and wire spaced at regular intervals. The wires on one harp are horizontally oriented, and the other harp wires are vertically oriented. The cutting progresses in such a way that first horizontal and vertical sheets of curd are cut with the harp knives. The sheets are then cut into cubes by perpendicular cuts with the vertical harp knives (Fig. 24.2).

Large dairy plants have automated cheese vats that vary in size from 2000 to 25,000 L capacities. These cheese vats are equipped with a shaft to which agitators are attached. These agitators are designed in such a way that they cut the cheese when the shaft rotates in one direction and agitate the cubes gently when the shaft rotates in the other direction. Cheese vats are automated and allow the cheese curds to heal and cook before pumping the curds and whey onto a perforated conveyer belt where cheese curd is separated from the whey.

A schematic diagram of cheesemaking from cutting through cooking steps is shown in Figure 24.3. Cutting the coagulum increases the surface area of the curd and enhances syneresis. Upon cutting, curd particles immediately begin to expel whey and shrink, and the TA that had been rising in the cheese milk immediately drops in the whey, because the whey has lower apparent acidity, due to lower protein, citrate, and phosphate. The TA of whey will gradually increase as lactic acid is formed in the curds and released with whey during syneresis.

24.3.3.7 Healing. Freshly cut curd is fragile and shatters easily, so curds are allowed to "heal" for 5–10 min prior to agitating and cooking. A healing period is particularly important when goat Cheddar cheeses are made, because the curds are naturally more fragile than curd obtained from cow milk. During healing, a tender skin is formed



1. Use of horizontal knives results in a vat full of layered horizontal slabs of curd, not visible from the top

2. Following horizontal cut with vertical cut results in long strips of cheese

3. Only after the vertical sharp knife is used perpendicularly across the previous cuts will cubes be made out of the curds, enabling optimal syneresis

Figure 24.2 *Cutting of the curd.*

around each freshly cut curd. As the skin firms, the curd becomes more resistant to shattering and yield losses.

24.3.3.8 Cooking. The cooking process is essentially a controlled increase in curd–whey temperature. Heating allows individual curd cubes to shrink, release whey, and firm. Cooking also increases reaction rates, specifically bacteria growth and metabolism, and enzyme activity. Temperature-sensitive bacteria strains are slowed down as temperature is raised. Prior to raising the temperature of the curd–whey mixture, curds should be gently eased from the edges of the cheese vat, where they have matted. Curd cooking should begin slowly, with continual stirring of the curds. Hot water or steam may be used to increase the jacket temperature. The curd–whey mixture temperature should be raised slowly, about 2°C every 5 min until 38°C is reached (~35–45 min). Stirring speed may be increased as the curds firm, but stirring too fast will shatter curds and reduce yield. For a drier cheese, temperature should be held at 38°C for an additional 45 min, with stirring. In small or start-up facilities, whey TA should be recorded every 15 min. Regardless of plant size, good records should be kept of the entire cheesemaking procedure and final cheese quality. Failure to keep such records will reduce consistency.

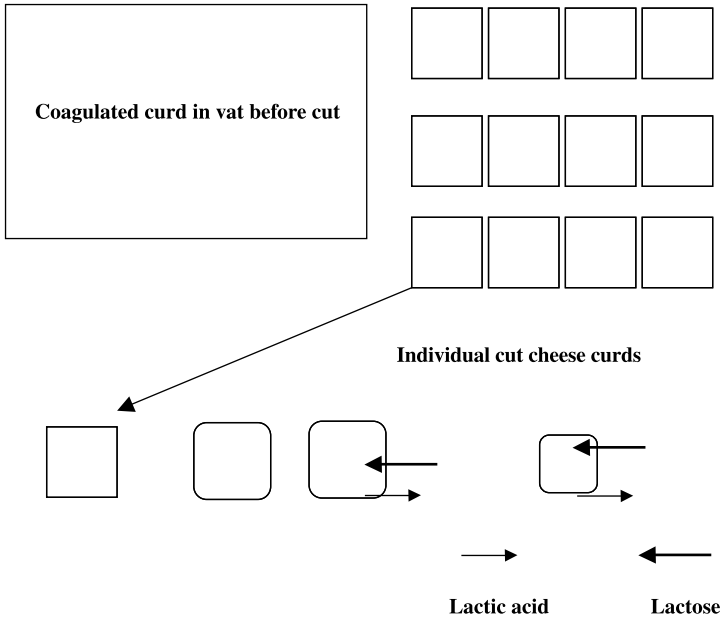


Figure 24.3 *Schematic of cheesemaking steps from cutting through cooking.*

For a short period after the curd is cut, lactose and lactic acid concentrations are at equilibrium in curd and whey. With time, the concentration of lactose drops faster in the curd than in the whey because starter bacteria concentrated in the curd deplete lactose in the curd (Fig. 24.3). As the lactose is fermented within the curd, replacement lactose diffuses into the curd from the whey (Fig. 24.3, broad arrows) (Lawrence and Gilles 1987a). As a neutral molecule, lactose diffuses easily through the matrix. Positively charged hydrogen ions exit the negatively charged curd much more slowly than lactose (Fig. 24.3, narrow arrows). As fermentation progresses, hydrogen ions are neutralized by the negatively charged proteins and phosphates. As the buffering capacity of the caseins and colloidal calcium phosphate (CCP) becomes saturated, the pH of the curd steadily drops. As pH drops, CCP is solubilized and lost into the whey.

Once cheesemaking starts, managing acid development during the cooking stage of cheese manufacture is the most important factor in the control of cheese quality (Lawrence and Gilles 1987a). Acid development determines the basic structure, moisture, final pH, and flavor of cheese (Lawrence and Gilles 1987a). As the pH drops, the body of the cheese changes from rubbery (pH 5.4) to plastic (pH 5.3–5.2) to Cheddar (pH 5.1–5.0) body and texture. When the vat TA rises too quickly, the curd will suffer an excessive loss of calcium but will not retain phosphate. The result is an increase in curd buffering capacity (Lawrence and Gilles 1987a). However, should a high TA result from an extended time between cutting and cheddaring, both calcium and phosphorus are lost in the whey (Lawrence and Gilles 1987a). The resultant cheese will have a low pH, an acid flavor, and a weak, pasty texture (Lawrence and Gilles 1987a). An objective for cheesemakers it to develop acid slowly during ripening and cooking, and more quickly during cheddaring, so that calcium phosphate is retained in the curd, as the loss of CCP alters the body and texture of the cheese (Lawrence and Gilles 1987a). Curds shrink and tighten as syneresis proceeds during the cooking process, prior to whey drainage. Approximately

75% of the whey in the curd is expelled in the time from cutting to the end of stir out. Longer stir-out times can significantly reduce moisture in cheese.

24.3.3.9 Draining. Whey may be drained entirely, in the case of Cheddar, or partially, with washing, as in the case of Colby or Monterey. In large plants, a cleaned and sanitized finishing table/vat may be aligned with the exit port of the cheese vat. The drain of the vat is opened and curds and whey are allowed to flow onto the finishing table. Alternatively, in small plants, the cheese vat may double as a finishing table. A screen is installed ahead of the finishing table drain port to prevent curd loss as the whey is drained. Whey is commonly collected in a separate reservoir.

Cheese curds should be allowed to settle into the vat or finishing table, at an even depth throughout the length, and permitted to mat for 15 min. Whey TA will rise more quickly during this interval and should be recorded every 15 min from this point forward, throughout the cheddaring process. In the largest plants, curds are delivered to a perforated conveyer belt for drainage and cheddaring, which allows formation of a sheet of curd and continuous whey drainage. The conveyer is enclosed in a tunnel. Upon drainage, in the absence of the whey bath, the curd pH will drop at a faster rate and the curds will continue to shrink and tighten. Much of the calcium is lost at drainage, particularly at low pH.

24.3.3.10 Washing. Washing is essential in Colby and Monterey production. Washing, or curd rinsing, removes lactic acid and residual lactose and lactic acid from the curd and the result is a higher pH in the final cheese. Washing is rarely included during Cheddar cheesemaking, but when it is, the duration of such rinsing is so limited that only the whey on the surface of the curds is removed (FDA 2004c).

In Colby and Monterey production, whey is drained off until the curd on the bottom of the vat is visible, then sufficient cold water is introduced to reduce the temperature of the curd–whey mixture to 27°C (Lawrence and Gilles 1987a). Rate of syneresis is slowed if cool water used, resulting in higher cheese moisture content. Long wash time removes more lactose, resulting in higher final pH of cheese. Temperature-sensitive strains may be revived if cool water used.

24.3.3.11 Cheddaring. The step known as "cheddaring" was standardized into commercial practice by Joseph Harding in 1857 (Kosikowski and Mistry 1997a). During manual cheddaring, curds are flipped and stacked at regular intervals, naturally pressed under their own weight, which enhances syneresis, yet still maintains a controllable level of moisture retention. The main purpose of cheddaring is to allow time for the acidity to increase and whey to be released (Lawrence and Gilles 1987a). Curd particles fuse into a solid mass, syneresis continues as acid builds, rennet/chymosin continues to act, and these forces cooperate to tighten the casein network. As lactic acid continues to build, curds begin to flow or stretch under the weight of piled slabs. Cheddar gains its characteristic body through the process of knitting, stretching, and orientation of the casein network during cheddaring, which requires a pH below 5.8 (Lawrence and Gilles 1987a).

In manual operations, after the cooking step is completed and curds are allowed to settle for 15 min, matted curd should be trenched, then cut into equal-sized slabs. A wide (20–30-cm) trench is made in the center of the vat to facilitate syneresis and curd stretching. Slabs should be separated as they are cut, to enable syneresis and stretching. Extra or broken curd should be placed on top of each slab, to minimize loss of fines. Slabs should be allowed to settle 15 min before the next step.

Cheddaring begins with flipping of slabs, one by one. The bottom becomes the top and the end toward the trench becomes the end toward the vat wall. Slabs should be allowed to settle 15 min before each subsequent step. The next step of cheddaring involves the flipping of one slab, followed by placing of an adjacent slab on top of the flipped slab (without flipping). This step is called "flip–stay." The process continues for every pair of slabs. After 15 min, the top slab is placed (not flipped) into an empty spot in the vat. The previous bottom slab is then flipped and placed atop the new bottom slab. This step is called "stay–flip." Cheddaring continues with flipping and stacking of slabs, alternating between "flip–stay" and "stay–flip" steps, until a whey TA of 0.35% as lactic acid is measured in a fresh sample of whey. In large plants, the process of cheddaring is automated. As the perforated conveyor mentioned previously transects a number of parallel planes during the approximately 90-min cheddaring process, the matted curds are flipped and stretched continuously in a tumbling motion.

24.3.3.12 Milling. Milling is the process of cutting the slabs into cubes about 5 cm in size, which enables more uniform salt distribution, encourages syneresis and makes hooping more convenient (Lawrence and Gilles 1987a). When curds are milled, more whey is expelled because milling greatly increases curd surface area and opens pores for syneresis. Salt distribution will be most uniform in cheese if curds are milled to a uniform size (Lawrence and Gilles 1987a). In large plants, as the mat of curd arrives at the discharge point of the perforated conveyer, it is cut to desired size in a reciprocal dice-type mill or rotary curd mill.

24.3.3.13 Salting. Milled curds of Cheddar and related hard cheeses are dry-salted rather than brine-salted. Cheese is salted because it:

1. Encourages further syneresis,
2. Inhibits further growth and metabolism of most microorganisms (thus arresting lactic acid production), and
3. Provides flavor.

Approximately 2.5 kg salt for every 100 kg of cheese curd is used. The salt is added in three equal applications and mixed for 5 min between applications. Adding salt too quickly will cause a "skin" to form on the curds, inhibiting salt absorption and syneresis. In large plants the milled cheese quantity is determined continuously by weight prior to entering the salting machine. The salter automatically calculates the salt and sifts it over the milled cheese. The pH and TA will only change slightly beyond the point of salt addition.

Salt, more specifically salt in moisture (S/M), directly influences the final pH of the cheese, growth of microganisms and overall flavor, body, and texture of cheese (Lawrence and Gilles 1987a). At S/M levels greater than 5.0, bitter flavors rarely occur (Lawrence and Gilles 1987a). Curd salted at low TA retains more salt (higher S/M) and is more plastic than curd salted at high TA (Lawrence and Gilles 1987a).

24.3.3.14 Pressing and Packaging. Pressing gives cheese its final shape, reduces openings between curd particles, promotes fusion, and releases more free whey. In small plants, Cheddar curds are pressed overnight using a batch method (Lawrence and Gilles 1987a). Pressure, approximately 1.4 atm, is applied to molds for 8–12 h at room

temperature. After one or two hours of pressing, cheeses may be flipped in the molds and lined with cheesecloth, which provides an attractive surface pattern. Large plants have a continuous "block-former" system (Lawrence and Gilles 1987a). Curds are fed into a tower under a partial vacuum, whey is siphoned off, and for a short period, mechanical pressure is applied at the base of the tower prior to packaging (Lawrence and Gilles 1987a; Banks and Williams 2004). A block former cuts 20-kg blocks from the stack at regular intervals and the blocks are transferred to a vacuum packaging system prior to aging (Banks and Williams 2004).

24.3.3.15 Aging. Aging enables flavor and texture development of hard cheeses. Nearly all residual lactose should be fermented within about 48 h. With cold storage, between 5 and 12°C, acid production slows down, but continues until limiting conditions occur (Banks and Williams 2004). Starter bacteria lyse (burst) and release proteolytic enzymes into the matrix. Residual plasmin and coagulant also contribute to proteolysis during aging. Caseins are broken down into peptides and amino acids, which yield flavor and modify cheese body/texture. Secondary fermentations can occur if NSLAB are still active, which results in further changes in flavor and body/texture. Cheeses with low S/M have a higher rate of proteolysis, resulting in a softer texture, than cheeses with high S/M (Lawrence and Gilles 1987a).

Cheddar cheese is typically aged for 3–18 months at 7–13°C, but it is not unheard of to age Cheddar for years in the case of specialty varieties (Banks and Williams 2004). Colby and Monterey are aged for shorter periods of time due to their higher moisture content and milder expected flavor.

24.4 QUALITY CONTROL

24.4.1 Shelf-life

The shelf-life of Cheddar and related cheeses is limited by quality, not safety. The quality of good Cheddar cheese improves with storage. Cheddar cheese may be removed from shelves due to flavor, body, or appearance defects. The most common flavor defects are high acid, bitter, unclean, and fermented/fruity. Common body defects are weak or crumbly body, gas holes, surface discoloration, and appearance of crystals on surfaces.

24.4.2 Evaluation

High-quality Cheddar cheese has a full, balanced nutty, sharp, but not bitter flavor. The ideal texture should be closed (no gas holes or mechanical openings), and the body should be firm, smooth and waxy (responds to moderate pressure). Colby and Monterey/Jack cheeses are similar to Cheddar, but are milder in flavor and possess a softer body. Colby and Monterey/Jack are prone to the same defects as Cheddar. However, due to higher moisture content, lower acid and salt, and higher microbial and enzymatic activity, some sensory defects may reach greater intensity and frequency in Colby and Monterey/Jack cheeses than Cheddar, particularly with extended aging.

Gas liquid chromatography (GLC) analysis of Cheddar cheese has shown that there are as many as 200 different compounds that may contribute to cheese flavor. However, flavor chemists believe that as few as 20 volatile compounds are pertinent to determination of the eventual flavor of Cheddar cheese. Cow diet, milk handling and sanitation

TABLE 24.2 Common Flavor Attributes in Hard Cheeses, Identification of Them and Their Probable Causes.

Flavor	Identification	Probable Cause
Bitter	Sometimes perceived as throbbing/piercing Sensation perceived at back of tongue Very common defect in aged Cheddar	Excessive moisture Low salt Excessive acidity Proteolytic starter culture strains Microbial contaminants Poor quality milk Plant sanitation issues
Feed	Grassy flavor	Feeding of strong flavored feeds Feeding of cattle too close to milking
Fruity/fermented	Sweet – like pineapple	Psychrotrophic *Pseudomonas fragi* may produce ethyl-butyrate and ethylhexanoate (esters) Low acidity Excessive moisture Low salt level Poor milk quality
Flat/lacks flavor	Lacks nutty flavor components Lacks typical Cheddar flavor	Lack of acid production Use of milk low in fat Excessively high cooking temperature Use of low curing temperature Too short a curing period
Heated	Sweet – like cooked flavor Reminiscent of Velveeta®	High pasteurization or cooking temperature
High acid	Excessive acid taste Unbalanced acid taste	Development of excessive lactic acid Excessive moisture Use of too much starter culture Use of high-acid milk Improper whey expulsion from curd Low salt level
Oxidized	Paperboard/cardboard Sometimes discoloration also Burnt hair aroma/flavor	Use of oxidized milk in cheesemaking Excessive exposure to UV light during aging
Rancid	Butyric, caproic, caprylic, capric acids Soapy Romano cheese aroma/flavor Baby vomit aroma	Milk lipase activity Microbial lipase activity (from contaminants) Accidental homogenization of raw milk Late lactation or mastitic milk
Sulfide	Eggy	Excessive breakdown of amino acids Only a defect when excessive for age of cheese
Unclean	Unpleasant off-flavor lingers	Microbial contamination Poor quality off-flavored or old milk Allowing off-flavored cheese to be aged Improper techniques of cheddaring
Whey taint	Combination of acid, bitter, fermented Aftertaste does not linger like unclean	Poor whey expulsion from curd Improper cheddaring techniques Failure to drain whey from piles of curd slabs
Yeasty	Ethanol aroma Yeast (bread, beer) aroma	Development of ethanol flavors by yeast contaminants Poor packaging procedures

TABLE 24.3 Common Appearance, Body and Texture Attributes in Hard Cheeses, Identification, and Their Probable Causes.

Body/Texture	Identification	Probable Cause
Corky	Dry, noncompressible Often crumbly as well	Lack of acid development Low fat
Crumbly	Falls apart while working	Excessive acid production Low moisture retention in cheese
Crystals	White crystals observed by visual examination	Tyrosine (only in aged cheese), calcium lactate, calcium citrate, calcium phosphate
Curdy	Resistant to compression	Inadequate aging conditions
Gassy	Smooth round gas holes	Contamination of cheese with CO_2-forming microorganisms
Mealy	Grainy (like corn meal)	Excessive acid production Formation of salt complexes
Open	Openings along curd lines	Improper mechanical pressing, lack of fusion between curds
Pasty	Sticky when working between fingers	High moisture retained by curd Excessive acid production
Short	Plug breaks quickly (snaps)	Excessive acid production
Weak	Plug is resistant to breaking (bends)	High moisture in cheese Excessive proteolysis

practices, milk composition, and cheese manufacturing conditions all affect cheese chemistry (Buchin and others 1998). What appears to be critical is the relative proportions of the key chemical flavor compounds in providing "balanced Cheddar flavor". Ammonia-like and sulfur-like odors and bitter taste typically occur in aged cheeses, a consequence of amino acid breakdown. Common flavor attributes encountered in Cheddar and related cheeses are included in Table 24.2. Although some attributes, such as sulfide, may be considered desirable in an aged cheese, mild cheeses are discredited for pronounced attributes.

In addition to flavor attributes, consumers look for certain functional properties in cheese (melting, grinding, slicing). Cheeses continually change during ripening, not only in flavor, but also in body/texture. Common body/texture attributes encountered in Cheddar and related cheeses are included in Table 24.3.

24.4.3 Safety

Cheddar cheese and other semihard cheeses are generally considered safe and have rarely been associated with foodborne illness outbreaks (Wood and others 1984; Johnson and others 1990; El-Gazzar and Marth 1992; Leyer and Johnson 1992). However, some pathogens can survive the cheesemaking process and during ripening. Hargrove and others (1969) demonstrated that cheese pH, rate and amount of acid produced during cheesemaking, and type and amount of starter inoculum all influence growth and survival of salmonellae in Colby and Cheddar cheeses. Raw-milk Cheddar cheese was linked to major salmonellosis outbreaks in Canada in 1982, 1984, and 1998 (Wood and others

1984; D'Aoust and others 1985; El-Gazzar and Marth 1992; Ratnam and others 1999). *Salmonella* can survive in ripening Cheddar cheese for 7–10 months (Wood and others 1984; El-Gazzar and Marth 1992). Additionally, Ryser and Marth (1969) showed that *L. monocytogenes* can survive as long as 434 days in Cheddar cheese ripened at temperatures above 1.66°C. These facts highlight the importance of using the highest quality milk and good manufacturing practices, including strict sanitation and handling procedures to prevent contamination and ensure cheese quality and safety.

24.5 TROUBLE-SHOOTING

Although poor-quality milk will always result in poor-quality cheese, even use of high-quality milk does not guarantee high-quality cheese. This section will summarize factors that influence cheese curd formation and crystal formation in Cheddar cheese.

24.5.1 No Curd or Weak Curd Formation

A weak curd can result from at least one of two main factors, namely low starter numbers or poor chymosin activity. The following factors influence the starter and chymosin activity: presence of natural inhibitors or antibiotics in the milk, residual cleaners/sanitizers on equipment, or the presence of bacteriophage in cultures or in the environment. Each factor will be discussed separately. Operator error is another reason for no curd formation. The bottom line is that personnel must be adequately trained to (1) measure appropriate levels of culture and coagulating enzyme to be added to cheese milk and (2) actually add the ingredients to the cheese milk.

24.5.2 Natural Inhibitors

Natural inhibitors in milk include lactenin L_1, L_2, and L_3, and the enzymes lysozyme and lactoperoxidase. Lactenin varies with individual animals and is inactivated by heat treatment (Desmazeaud 2000). Lysozyme attacks the glycosidic bonds found in Gram-positive bacterial cell walls, but it is unlikely to cause inhibition of lactic acid starter bacteria (Jensen 1995; Desmazeaud 2000). When supplied with hydrogen peroxide (from lactic acid bacteria in the presence of oxygen) and thiocyanate (arises from catalysis of thiosulfate or glucosides in liver), lactoperoxidase will catalyze the formation of lactococci bacteriocides (Ruden 1997), including bacteriocides that attack lactococci. Therefore, this method of preserving milk in areas with limited access to refrigeration is inappropriate for handling cheese milk. Mastitic milk naturally contains higher levels of leucocytes, which will also engulf and destroy lactic cultures (U.S. Department of Health and Human Services and others 1999 Revision).

24.5.3 Antibiotics

Every tanker load of milk must test negative for the presence of beta-lactam antibiotics (Desmazeaud 2000), however cultures can be inhibited by the presence of antibiotics at levels even lower than detectable by standard dairy lab testing methods. Lactic cultures can be inhibited by as much as 50% by 1.91 μg cloxacillin, 0.13 μg tetracycline,

0.59 μg streptomycin and as little as 0.12 μg of penicillin per mL milk (Desmazeaud 2000). Thermophilic bacteria are more resistant to streptomycin and more sensitive to penicillin than mesophilic starters (Ruden 1997).

24.5.4 Residual Cleansers/Sanitizers

Residual cleansers/sanitizers can slow a cheese vat precisely because they are intended to kill microorganisms. Quaternary ammonium compounds, or "Quats" are not appropriate for use in a cheese plant because they leave a residue on equipment that are effective against lactic acid bacteria. Quats will inhibit many starter culture strains at concentrations as low as 10 to 20 μg/mL (Ruden 1997). Other effective bactericides include organic and inorganic chlorine compounds, chlorine dioxide, iodine compounds, acid anionic sanitizers and peroxyacetic acid, but they are unstable in the presence of organic matter such as milk (Leach 1997). Regardless of sanitizer, pipelines, vats and other equipment must be allowed to drain after bactericidal treatment to prevent contamination of the cheese milk supply.

24.5.5 Bacteriophage

Bacteriophage literally means "eaters of bacteria." Bacteriophage/phage are obligate intracellular parasites that attack and replicate within specific strains of bacterial cells (Leach 1997). Bacteriophage are naturally present in the cheesemaking environment and can spread throughout a plant with poor sanitation practices. Bacteriophage are the largest single cause of slowed or failed vats of cheese (Tamime and Deeth 1980; Leach 1997). Each strain of culture has a different level of sensitivity to bacteriophage. Since it is impossible to entirely eliminate bacteriophage from a dairy plant operation, control measures must be employed. Careful selection of starter cultures, aseptic techniques for starter culture propagation, air filtration, equipment sterilization, plant sanitation, culture rotation of phage-unrelated strains, or use of phage-resistant strains are necessary techniques to control phage (Leach 1997). Starter culture rotation essentially ensures that the bacteriophage population is diluted (through the process of repeated sanitation efforts) to the point that their numbers are low enough to allow the starter culture to function normally (Desmazeaud 2000).

24.5.6 Milk Pretreatment

Excessive heating, agitation or aeration can reduce growth and acid development by lactic acid bacteria. Heating of milk to pasteurization only slightly modifies the characteristics of milk for cultures. However, temperatures above 80°C for 20 sec. induce chemical reactions that can either inhibit (by destruction of certain vitamins) or stimulate (destruction of lactoperoxidase, production of formic acid from lactose, release of non-protein-nitrogen) bacterial growth (Ruden 1997). Excessive heating of milk should be avoided, not simply because of subsequent effects on culture, but the detrimental effects on curd formation, curd moisture retention and cheese quality. Aeration or excessive agitation will slow the vat by introducing dissolved oxygen. Presence of oxygen inhibits starters since they prefer a micro-aerophilic environment (McDowall and McDowell 1939).

24.6 CRYSTAL FORMATION

The occurrence of undesirable crystals in Cheddar cheese has been documented since the 1930s (Tuckey and others 1938; McDowall and McDowell, 1939; Harper and others 1953; Conochie and others 1960; Pearce and others 1973; Washam and others 1985; Severn and others 1986), yet the problem still represents a challenge and expense to cheese manufacturers (Chou and others 2003). Cheese crystals have been identified as calcium lactate (Severn and others 1986), a racemic mixture of L(+)- and D(−)-calcium lactate (Conochie and Sutherland 1965), calcium phosphate (Dorn and Dahlberg 1942; Harper and others 1953; Conochie and others 1960), tyrosine (Harper and others 1953; Bianchi and others 1974), or mixtures of amino acids (Severn and others 1986; Dybing and others 1988; Johnson and others 1990a,b). However, most frequently the crystals in young cheese have been identified as calcium lactate (Pearce and others 1973; Blake and others 2005).

The development of CLC may result from a number of causes, including milk composition (Dybing and others 1988), cheesemaking procedure (Pearce and others 1973; Dybing and others 1988; Johnson and others 1990b; Chou and others 2003), aging temperature (Johnson and others 1990b; Somers and others 2001; Chou and others 2003), and the growth of nonstarter lactic acid bacteria (NSLAB) in cheese during aging (Dybing and others 1988).

Cheese milk lactose concentrations exceeding 4.8% lead to increased lactose in cheese, which can be used by starter or NSLAB to produce lactate in cheese and a resultant increase in calcium lactate concentrations. Dybing and colleagues (1988) concluded that casein-bound calcium is the major source of calcium in calcium lactate crystals (CLC). The investigators showed that fast acid production and high milling acidities are associated with reduced CLC formation owing to reduced concentrations of casein-bound calcium. Seasonal changes affecting milk casein and calcium affect CLC formation. A low casein to calcium ratio leads to increased amount of bound calcium in milk, contributing to increased calcium in cheese and greater predisposition to CLC formation (Khalid and Marth 1990; Williams and others 2000; Agarwal and others 2006a).

Although starter bacteria make up the majority of cheese microflora initially, NSLAB dominate the viable population in cheese for much of the ripening period (Somers and others 2001). Secondary NSLAB introduced at the cheese plant (Blake and others 2005) or during cut and wrap, may proliferate upon stimulation by warm tempering temperatures (Dybing and others 1988; Williams and others 2000). Heterofermentative NSLAB utilize a variety of substrates for growth and produce an assortment of metabolites, including both L(+)- and D(−)-lactate (Johnson and others 1990b). NSLAB that are capable of racemizing L(+)- to D(−)-lactate can contribute to CLC since D(−)-lactate is less soluble than L(+)-lactate, particularly at aging temperatures, in maturing cheese (1990b). In the early 1990s, Johnson and colleagues (Turner and Thomas, 1980; Shakeel Ur and others 2000) established correlations among CLC, D(−)-lactic acid enantiomer, and numbers of NSLAB. Cheeses with racemase-positive *Lactobacillus* developed crystals compared to cheeses without *Lactobacillus*, which did not. Cheeses aged at lower temperatures developed crystals faster when compared to cheeses aged at higher temperature. CLC were never observed on cheeses with less than 20% of the lactic acid in the D(−) form. It follows, then, that since high temperatures favor the growth of NSLAB (Johnson and others 1990b), aging cheese at high temperatures, as may be done to accelerate ripening, can result in elevated D(−)-lactate by NSLAB and induction of CLC (Linke 1958).

Additionally, aging of cheese at low temperatures may also increase CLC, due to decreased solubility of calcium lactate at a low temperature (Chou and others 2003). Chou and colleagues (2003) demonstrated that earliest and most extensive CLC occurred on cheeses aged first at higher temperatures and then stored at lower temperature. They also showed that specific NSLAB, production of D(−)-lactate, and aging temperature affect CLC in maturing Cheddar cheese (Chou and others 2003).

Elimination of racemizing NSLAB and control of storage temperature is critical to the prevention of CLC. Agarwal (2006a) and Sharma (2002) showed that, irrespective of lactose to protein ratio, contamination of cheese milk with racemizing NSLAB *L. curvatus*, may lead to CLC, particularly in combination with elevated storage temperatures. Finally, Agarwal and colleagues (2005) demonstrated that, regardless of the presence of racemizing NSLAB, CLC are more likely to form in cheeses flushed with gas than cheeses that are vacuum packaged.

More recent research (Agarwal and others 2006b) shows cheese milk composition and cheese making techniques have greater influence on the occurrence of CLC, particularly calcium L(+) lactate crystals. Increased casein concentration in cheese milk is linked to increased colloidal calcium, which solubilizes as the pH of the cheese decreases (Upreti and others 2006). If cheese is made such that it has increased residual lactose, microorganisms present in cheese will ferment residual lactose to produce excess lactic acid and decrease the pH of the cheese, encouraging solubilization of colloidal calcium previously bound to casein micelles. Increases in concentrations of soluble calcium and lactate above saturation in cheese serum during aging tends to favor development of CLC. Control of pH and whey removal prior to packaging influence the occurrence of CLC.

In summary, cleaning, sanitizing, prevention of contamination of cheese milk with lactate-racemizing NSLAB, acidification and whey removal, consistent storage temperature and vacuum packaging are encouraged to minimize CLC. Due to the prevalence and expense of the problem in the industry, additional research in the area of CLC formation is warranted.

25.1 INTRODUCTION

Approximately one-third of the cheese produced in the United States is marketed as pasteurized process cheese (Kosikowski and Mistry 1997). Why? Fast-food giants like McDonald's and Burger King rely on the consistency in flavor and melting qualities of pasteurized process cheese. Pasteurized process cheese, sometimes called processed cheese or process cheese, is convenient not only for food service, the primary user, but also retail because these cheeses are available in regular and reduced-fat varieties, chunks, cubes, spreads, loafs, slices, as well as in grated or shredded applications.

American process cheese was first developed as early as 1895 (Caric and others 1985; Kosikowski and Mistry 1997). In 1905, J.L. Kraft was making money by selling cheese from a horse-drawn delivery wagon (Kosikowski and Mistry 1997). Eleven years later, Kraft was issued a patent involving the heating of Cheddar cheese and its emulsification with alkaline salts, inaugurating American pasteurized process cheese (Kosikowski and Mistry 1997). In 1911, Swiss inventors preserved Emmental cheese by applying heat and adding emulsifying agents to form a smooth and uniform flowing mass that solidified upon cooling (Berger and others 1989). As is true today, pasteurized process cheese was initially manufactured to utilize natural cheeses that would otherwise be unmarketable, including cheese with mechanical openings, deformations, localized molds, and trimmings produced during cheese formation pressing and packaging (Caric and others 1985; Caric and Kaláb 1999).

Today, approximately 635 million kg of pasteurized process cheeses, 407 million kg of pasteurized process cheese foods and spreads, and 12 million kg of cold-pack cheese and cheese foods are produced in the United States each year, by more than 50 processing plants (IDFA 2002; Infanger 2004). Converted to per capita consumption, Americans averaged 1.9 kg pasteurized process cheese and 1.6 kg pasteurized process cheese food and spreads in 2001 (IDFA 2002). This chapter will elaborate upon similarities and differences among pasteurized process and cold-pack cheeses, outline manufacturing steps involved in production, and describe technological advances in the production of cheeses in these categories.

25.2 DEFINITIONS

The Code of Federal Regulations (CFR) defines more than 12 different kinds of pasteurized process and cold-pack cheeses, including:

- Cold-pack and club cheese;
- Cold-pack cheese food;
- Cold-pack cheese food with fruits, vegetables, or meats;
- Grated American cheese food;

- Pasteurized blended cheese;
- Pasteurized blended cheese with fruits, vegetables, or meats;
- Pasteurized process cheese;
- Pasteurized process cheese with fruits, vegetables, or meats;
- Pasteurized process pimento cheese;
- Pasteurized process cheese food;
- Pasteurized process cheese food with fruits, vegetables, or meats;
- Pasteurized cheese spread;
- Pasteurized cheese spread with fruits, vegetables, or meats;
- Pasteurized process cheese spread; and
- Pasteurized process cheese spread with fruits, vegetables, or meats (FDA 2004a).

Although different, all of the products have one thing in common: they must contain a minimum percent of natural cheese and a maximum percent of water in the composition. Characteristics of the main categories of pasteurized process and cold-pack cheeses are summarized in Table 25.1.

TABLE 25.1 Characteristics of Pasteurized Process and Cold-Pack Cheeses.

Type	Ingredients	Cooking Temperature	Composition	pH
Pasteurized process cheese	Natural cheese, water, anhydrous milk fat, cream, color, salt, flavoring, and emulsifiers	70–80°C	Moisture and fat correspond to legal limit of natural cheese	5.6–5.8
Pasteurized process cheese food	Same as process cheese, optional ingredients: skim milk, cream, whey, organic acids	79–85°C	Not $>$44% H_2O or $<$23% fat, but $>$22% fat if vegetables, fruits, or meats included	5.2–5.6
Pasteurized process cheese spread	Same as cheese food but also gums are added for water retention	88–91°C	Not $<$44% or $>$60% H_2O; not $<$20% fat; spreadable at 21°C	$\leq$5.2
Cold-pack cheese	Same as process cheese, except cheese ingredients are pasteurized or aged	Not heated	Same as natural cheese: $\leq$42% H_2O, $\geq$47% fat	$>$4.5
Cold-pack cheese food	Same as process cheese food, but allow gums, sweetening agents, inclusions; cheese must be aged or made from pasteurized milk	Not heated	$\leq$44% H_2O, $\geq$23% fat	$>$4.5

Source: CFR. Requirements for specific standardized cheese and related products. Subpart B vol. 133.

25.2.1 Pasteurized Process Cheese

The Code of Federal Regulations (FDA 2004d) defines pasteurized process cheese (PC) as "the food prepared by comminuting and mixing, with the aid of heat, one or more cheeses of the same or two or more varieties . . . for manufacturing with an emulsifying agent . . . into a homogeneous plastic mass". The CFR excludes cream cheese, Neufchatel cheese, cottage cheese, low-fat cottage cheese, cottage cheese dry curd, cook cheese, hard grating cheese, semisoft part-skim cheese, part-skim spiced cheese, and skim milk cheese from the list of permissible cheeses in PC.

Moisture content of PC is defined by whether the PC is made from one or more types of cheeses. In cases where a single variety of cheese is used, the moisture content of a PC is not more than 1% greater than the maximum moisture content prescribed by the definition and standard of identity, if any, for the variety of cheese used, but in no case is more than 43%. However, the moisture content of pasteurized process washed curd cheese or pasteurized process Colby cheese must not exceed 40%; the moisture content of pasteurized process Swiss cheese or pasteurized process Gruyere cheese must not exceed 44%; and the moisture content of pasteurized process Limburger cheese must not exceed 51% (FDA 2004d). When made from two or more varieties of cheese, the moisture content of a PC is not more than 1% greater than the arithmetical average of the maximum moisture contents prescribed by the definitions and standards of identity, if any, for the varieties of cheese used; but in no case is the moisture content more than 43%. However, the moisture content of a PC made from two or more varieties Cheddar cheese, washed curd cheese, Colby cheese, and granular cheese must not exceed 40%, and the moisture content of a mixture of Swiss cheese and Gruyere cheese must not exceed 44% (FDA 2004d).

Similarly, PC fat content is limited by the cheese(s) that compose the PC. If a single cheese variety is used, the fat content of the solids of a PC is not less than the minimum prescribed by the definition and standard of identity, if any, for the variety of cheese used, but in no case is less than 47%. However, the fat in dry matter of pasteurized process Swiss cheese must not be less than 43%, and the fat in dry matter of pasteurized process Gruyere cheese must not be less than 45%. When two or more varieties of cheese are combined, the fat content of the solids of a PC is not less than the arithmetical average of the minimum fat contents prescribed by the definitions and standards of identity, if any, for the varieties of cheese used, but in no case is less than 47%. However, the fat content of the solids of a pasteurized process Gruyere cheese made from a mixture of Swiss cheese and Gruyere cheese must not be less than 45%.

Process cheese may be smoked, or the cheese or cheeses from which it is made may be smoked, before mixing, or it may contain substances prepared by condensing or precipitating wood smoke (FDA 2004d).

25.2.2 Pasteurized Process Cheese Food

The difference between PC and pasteurized process cheese food (PCF) is primarily compositional, but the body of PCF may be notably softer and the flavor milder. PCF is allowed more water and less fat; cooking temperatures are higher and the pH is lower, and additional ingredients are allowed. Additional ingredients include skim milk, milk, cream, cheese whey, buttermilk, albumin from cheese whey, and skim milk cheese (FDA 2004e). Whey solids should not exceed 5–8% or sourness may result. PCF must not contain more than 44% moisture or less than 23% milk fat (FDA 2004e).

25.2.3 Pasteurized Process Cheese Spread

Pasteurized process cheese spreads (PCS) are similar to PC and PCF; however, the products contain more water, which makes them more spreadable. In addition to more allowable water, PCS are permitted added carbohydrates, including corn syrup solids, starches, sugars, and gums, not to exceed 0.8% by weight of the finished food (FDA 2004f). PCS must contain more than 44%, but less than 60% moisture and not less than 20% milk fat (FDA 2004f).

25.2.4 Pasteurized Process Cheese Product

Pasteurized process cheese product is a process cheese spread that may exceed the maximum moisture and/or does not meet the established minimum fat content (Dairy Management 1997).

25.2.5 Cold-Pack Cheese

The Code of Federal Regulations (FDA 2004b) defines cold-pack and club cheese as "the food prepared by comminuting, without the aid of heat, one or more cheeses of the same or two or more varieties, for manufacturing, into a homogeneous plastic mass" (FDA 2004b). The definition excludes cream cheese, Neufchatel cheese, cottage cheese, low-fat cottage cheese, cottage cheese dry curd, hard grating cheese, semisoft part-skim cheese, part-skim spiced cheese, and skim milk cheese. Further, all cheeses used in a cold-pack cheese must be made from pasteurized milk or must be held for not less than 60 days at a temperature of not less than 1.7°C before being comminuted (FDA 2004b).

Cold-pack cheeses (CPC) are composed of natural cheeses, ground finely, then mixed with vinegar or lactic, citric, acetic, or phosphoric acid, water, salt, color, and spices. The pH should not be below 4.5. Moisture must not exceed the maximum legal limit for the variety of natural cheese from which it is made, or the average of the maximum legal limits if more than one variety is used, but in no case more than 42% (FDA 2004b). However, the moisture content of a CPC made from two or more of the varieties Cheddar cheese, washed curd cheese, Colby cheese, and granular cheese is not more than 39% (FDA 2004b).

Fat in the solids must not be less than the legal minimum for the variety of natural cheese used, or the average for the legal minimum of cheeses used, but in no case less than 47% (FDA 2004b). However, the fat content of the solids of cold-pack Swiss cheese must not be less than 43% (45% if two or more varieties are used), and the fat content of the solids of cold-pack Gruyere cheese must not be less than 45%.

25.2.6 Cold-Pack Cheese Food

A cold-pack cheese food (CPF) is similar to a CPC, except a sweetening agent, such as sugar, dextrose, corn sugar, corn syrup, corn-syrup solids, glucose syrup, glucose-syrup solids, maltose, malt syrup, and hydrolyzed lactose, may be used in a quantity necessary for seasoning and to reduce water activity, which is necessary in the higher-moisture-content product. Other optional ingredients include cream, milk, skim milk, buttermilk, cheese whey, any of the foregoing from which part of the water has been removed, anhydrous milk fat, dehydrated cream, skim milk cheese for manufacturing, and albumin from cheese whey. The total weight of cheese or cheeses must constitute not

less than 51% of the weight of the finished CPF. Moisture must not exceed 44% and fat must be at least 23% in solids. If fruits, vegetables, or meats are added, the milk-fat content must be at least 22%. The pH must not be less than 4.5. Additionally, guar gum and/or xanthan gum may be used, but the total quantity must not exceed 0.3% of the weight of the finished food. When one or both such optional ingredients are used, dioctyl sodium sulfosuccinate may be used in a quantity not in excess of 0.5% by weight (FDA 2004c).

25.2.7 Cold-Pack Cheese Spread

Cold-pack cheese spreads (CPS) are not defined in the CFR, and do not have a standard of identity, but they may be found in the market. CPS may exceed the maximum moisture and/or not meet the established minimum fat content for CP and CPF. CPS are made by blending natural cheeses without the aid of heat and have a smooth spreadable body. CPS may contain herbs, spices, and other dairy ingredients, as well as gums for improving viscosity and mouthfeel, and acidulants to increase shelf-life and inhibit microbial growth.

25.3 PRINCIPLES OF PROCESSING

A schematic of the general process of pasteurized process cheese production is outlined in Figure 25.1. Ingredients and steps are detailed in the following sections.

25.3.1 Ingredients

25.3.1.1 Cheeses. Natural cheeses for pasteurized process and cold-pack cheeses are typically selected by trained personnel, based on age and quality, and combined in proportions to yield desirable flavor. When two varieties of cheese are combined, the weight of each variety of cheese is not less than 25% of the total weight of both, except that the weight of blue cheese, Nuworld cheese, Roquefort cheese, or Gorgonzola cheese is not less than 10% of the total weight of both, and the weight of Limburger cheese is not less than 5% of the total weight of both. When made from three or more varieties of cheese, the weight of each cheese is not less than 15% of the total weight of all, except that the weight of blue cheese, Nuworld cheese, Roquefort cheese, or Gorgonzola cheese is not less than 5% of the total weight of all, and the weight of Limburger cheese is not less than 3% of the total weight of all. In the case of "American cheese", these limits do not apply to the quantity of Cheddar cheese, washed curd cheese, Colby cheese, and granular cheese because such mixtures are considered as one variety of cheese (FDA 2004d). The process of cheese selection and processing will be described later in this chapter.

Enzyme-modified cheeses are natural cheeses to which proteases and/or lipases are blended to intensify cheese flavor about 10 to 30 times (Caric and Kaláb 1999). After incubating until the desired flavor is attained, enzyme-modified cheeses are packaged as a paste or dried to powder form. Enzyme-modified cheeses are especially flavorful and are used in a variety of food applications (Dairy Management 1997). Because of the long shelf-life of enzyme-modified cheeses (approximately 6 months), pasteurized process and cold-pack cheeses are a good application for them. Enzyme-modified cheeses can be used legally and help provide uniformity of cheese flavor across numerous lots of pasteurized process cheeses. Enzyme treatment also makes the cheese react better in the cooker and yields a product with superior body and texture over nonmodified

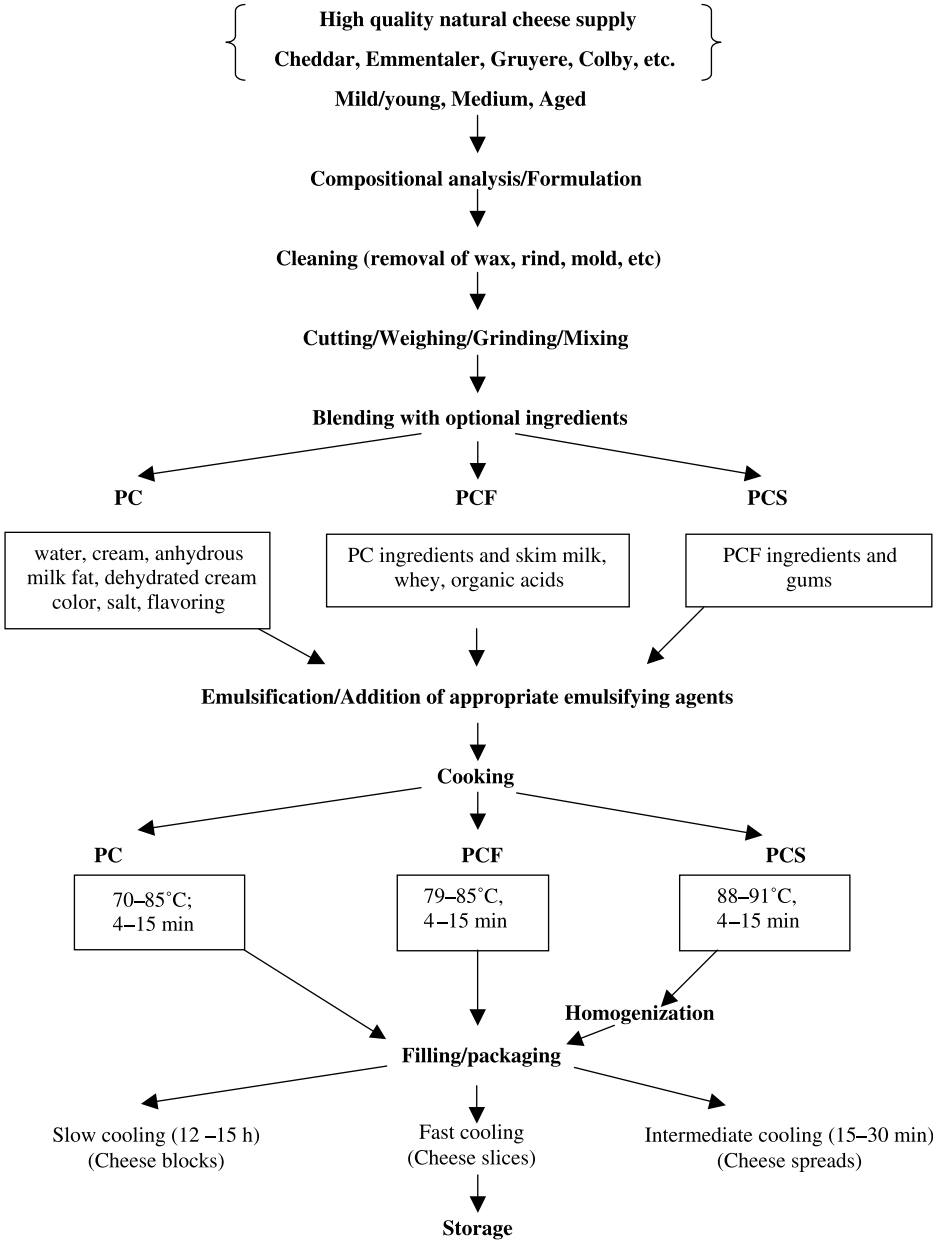

Figure 25.1 *General process steps for manufacture of pasteurized process cheese.*

cheese. After the enzymes have fulfilled their purpose (based upon target time, flavor, or chemical measure) the enzyme-modified cheese is pasteurized and the enzymes are inactivated.

25.3.1.2 Emulsifying Agents. The most common emulsifiers used in pasteurized process cheeses, foods, and spreads include various phosphate and citrate salts

TABLE 25.2 General Properties of Emulsifying Salts and Their Effect on Cheese Processing.

Property	Citrates	Ortho-phosphates	Pyro-phosphates	Polyphosphates (from 3 to 10 phosphate groups)	Aluminum Phosphates
Ion exchange (calcium sequesterization)	Low	Low	Moderate	High to very high	Low
Buffering action in pH range 5.3–6.0	High	High	Moderate	Low to very low	Nil
Para-casein dispersion	Low	Low	Very high	Very high to low	Very low
Bacteriostatic	Nil	Low	High	High to very high	Nil

Sources: Fox and others 1996; Meyer 1973.

(Table 25.2; Kosikowski and Mistry 1997). Emulsifying agents are not utilized in cold-pack cheese because no heating is involved in the process. The emulsifying agents that may be used include any one or any mixture of two or more of the following: monosodium phosphate, disodium phosphate, dipotassium phosphate, trisodium phosphate, sodium metaphosphate (sodium hexametaphosphate), sodium acid pyrophosphate, tetrasodium pyrophosphate, sodium aluminum phosphate, sodium citrate, potassium citrate, calcium citrate, sodium tartrate, and sodium potassium tartrate. The weight of the solids of emulsifying agent(s) must not exceed 3% (Kosikowski and Mistry 1997) of the weight of the PC.

Emulsifiers have many functions in pasteurized process cheeses, foods and spreads, including:

1. Removal of calcium from the protein system;
2. Peptizing, solubilizing, and dispersing proteins;
3. Hydrating and swelling proteins;
4. Emulsifying fat and stabilizing the emulsion;
5. Controlling and stabilizing pH;
6. Buffering capacity;
7. Bacteriostatic properties; and
8. Forming an appropriate structure after cooling

(Caric and others 1985; Kosikowski and Mistry 1997; Caric and Kaláb 1999). By dissolving protein, emulsifiers enable incorporation of fat, protein, and water into a uniform smooth mass (Kosikowski and Mistry 1997). Peptization also reduces the size of paracasein molecules, which creates the desired short texture of PC necessary for spreadability (Kosikowski and Mistry 1997).

Calcium-binding affinity is one of the most important functions of emulsifying agents because sequesterization of calcium improves flowability and smooth texture (Kosikowski and Mistry 1997; Caric and Kaláb 1999). Calcium-binding affinity increase in the following order:

$$\text{citrates} < \text{monophosphates (orthophosphates)} < \text{pyrophosphates} < \text{polyphosphates}$$

Differences in calcium affinity influence characteristics of the emulsification and melting properties of the final cheese (Metzger 2004). Additionally, colloidal calcium is replaced with sodium in casein micelles, which improves emulsifying characteristics and spreadability (Kosikowski and Mistry 1997). Condensed phosphates, including tetrapotassium diphosphate, disodium diphosphate, trisodium diphosphate, tetrasodium diphosphate, and so on, are particularly good at binding polyvalent cations (Berger and others 1989). They also peptize, disperse, and hydrate proteins, and promote and form stable emulsions (Berger and others 1989).

Although citrates lack bacteriostatic activity, monophosphates and polyphosphates, in particular, are quite effective against bacteria, including *Clostridium botulinum* (Caric and Kaláb 1999). Karahadian and others (1985) demonstrated that when disodium phosphate, trisodium citrate, dipotassium phosphate, tripotassium citrate, and sodium aluminum phosphate were used as single emulsifiers in PCF and PCS, they allowed toxin formation in many of the samples prepared. However, some inhibition of toxin formation was indicated for samples emulsified with disodium phosphate, and possibly trisodium citrate.

Typically, two or more emulsifiers are used in a formulation to combine desirable characteristics of each (Metzger 2004). In general, polyphosphates yield PC with better structure and keeping quality than other emulsifying agents because of their ability to solubilize calcium paracaseinate (Caric and Kaláb 1999). Pyrophosphates and orthophosphates contribute undesirable sensory attributes like tart flavor, very firm body, and calcium phosphate crystals to PC, so usage level should be minimized (Caric and Kaláb 1999). Although citrates are effective emulsifiers, they are ineffective as bacteriostatic agents (Caric and Kaláb 1999). In general, citrates are used for sliced process cheese products, whereas monophosphates, pyrophosphates, and polyphosphates are used for blocks, spreads, and sauces (Metzger 2004). Although citrates are appropriate for firm cheese with good melting properties, they are not suitable for spreadable PC because of limited creaming abilities and little tendency to absorb moisture (Meyers 1979). Monophosphates also provide good firming, buffering, and melting characteristics and are appropriate for sliced PC (Kosikowski and Mistry 1997). Short-chain polymeric phosphates (polyphosphates or condensed phosphates) provide good creaming, buffering and protein solubility attributes (Kosikowski and Mistry 1997). Long-chain polyphosphates provide firm body, but the resulting product does not melt easily because of excellent ion exchanging and protein solubility properties while having limited creaming properties (Meyers 1997).

The amount of emulsifying agents to use in a formulation varies with intact casein content; less emulsifying agent is necessary when less intact casein (aged cheese) is available (Berger and others 1989). Adding too much emulsifying agent may result in a viscous cheese with firm consistency, crystallization of emulsifying agent, oiling off, and emulsifier flavor. Using too little emulsifying agent can yield a thick, poorly flowing, nonhomogeneous mass that is difficult to pump.

25.3.1.3 Optional Ingredients. Pasteurized process cheeses, foods, and spreads may contain one or more of the allowed optional ingredients, including water, cream, anhydrous milk fat, dehydrated cream (in any combination or quantity as long as the weight of the fat derived from them is less than 5% of the weight of the PC), salt, harmless artificial coloring, spices, or flavorings (other than any that singly, or in combination with other ingredients, simulate the flavor of a cheese of any age or variety). In the

case of cold-pack cheeses, cream, anhydrous milk fat, and dehydrated cream are disallowed. Pasteurized process and cold-pack cheeses may contain an acidifying agent consisting of one or any mixture of the following: vinegar, lactic acid, citric acid, acetic acid, and phosphoric acid, as long as the pH of the PC is not below 5.3 and the pH of the finished cold-pack cheese is not below 4.5.

Although listed as an optional ingredient, water will inevitably be incorporated during the production of PC, PCF, and PCS because it is needed to hydrate and dissolve emulsifying agents (Meyer 1973). Water must be clear, free of heavy-metal contaminants, odorless, flavorless, and either sterile or nearly free of microorganisms (Meyer 1973).

Although not allowed in PC, optional ingredients allowed in PCF and PCS include various forms of non-fat milk and cheese whey. Skim milk powder, when not used in excess of 12% of the total mass, can improve the spreadability and stability of PC (Caric and Kaláb 1999). To avoid browning, total lactose content of the PC formulation should not exceed 4% (Kapoor and Metzger 2004) to 6% (Caric and Kaláb 1999). Another drawback of lactose is its tendency to form crystals when the concentration of lactose in the water phase of PC exceeds 14% (Metzger 2004), because the maximum solubility of lactose in water is 17% (Harper 1992). Whey products with reduced mineral and/or reduced lactose content are preferable because they yield PC with better flavors and color (Caric and Kaláb 1999). However, because whey proteins denature and form gels at high temperatures, they have the potential to reduce the melting quality of PC (Metzger 2004). Melting quality deteriorates when whey protein is incorporated at a rate exceeding 2% (as actual whey protein) in a formulation incorporating 45% moisture (Metzger 2004).

Gupta and Reuter (1992) demonstrated that the addition of approximately 2.2% whey protein concentrate (20% whey proteins and 5.8% lactose) in the final PCF (45% moisture) did not affect the quality of the product. Kapoor and Metzger (2004) manufactured PC, PCF, and PCS, with a control formula and a salt whey formula produced for each. The salt and water in the cheese formula were replaced with filtered and pasteurized salt whey, an underutilized natural cheese byproduct, in the salt whey formula. There were no significant differences in composition or functionality between the cheese formula and salt whey formula within each variety of processed cheese, indicating that salt whey can be used as an ingredient in PC without adversely affecting process cheese quality.

For PCS, quantities of 0.1 to 0.25% hydrocolloids (guar gum, gum arabic, gelatin, carrageen, alginate, agar and pectin) yield desirable water-binding properties and impart the smooth mouthfeel expected in these products (Berger and others 1989).

PC slices or cuts in consumer-sized packages may contain lecithin as an optional antisticking agent in an amount not to exceed 0.03% by weight of the finished product. Additionally, mold-inhibiting ingredient(s) may be used. PC may consist of not more than 0.2% (0.3% for cold-pack cheeses) by weight of sorbic acid, potassium sorbate, sodium sorbate, or any combination of two or more of these, or not more than 0.3% by weight of sodium propionate, calcium propionate, or a combination of sodium propionate and calcium propionate (FDA 2004d).

Nisin is an antimicrobial agent that is effective against most Gram-positive microorganisms, including *Clostridium* and *Bacillus* species (Meyer 1973; Berger and others 1989; Infanger 2004). Nisin is generally regarded as safe (GRAS) for process cheese applications in the United States at usage levels between 200 and 600 mg/kg (Infanger 2004). Production of Cheddar cheese with nisin-producing lactococci instead of

nisin itself, avoids the necessity of special package labeling. Zottola and others (1994) made Cheddar with nisin-producing lactococci then produced PCS and CPS with the cheese. The spreads were inoculated with pathogens and evaluated over time. Authors concluded that use of nisin-containing cheese as an ingredient in PCS or CPS could be an effective method of controlling the growth of undesirable microorganisms in these processed foods.

25.3.2 Production

25.3.2.1 Selection and Analysis. A large stock of natural cheeses, ranging from mild to sharp in flavor, is necessary for the production of pasteurized process cheeses. Experienced selectors are needed to identify flavor and body characteristics of natural cheeses to be selected for blend uniformity. Additionally, natural cheeses with microbial defects should not be selected for PC. Spore-forming, gas-producing, and pathogenic bacteria are particularly undesirable (Caric and Kaláb 1999).

Various authors recommend a variety of formulations for PC. Thomas (1977) recommended 70–75% mild natural cheese be combined with 25–30% medium to mature natural cheese. Caric and Kaláb (1999) recommended 30–40% young cheese, 50–60% mild to medium cheese, and 10% mature cheese for an elastic PC that is ideal for slices. Kosikowski and Mistry (1997) encouraged the combination of 55% young, 35% medium-aged, and 10% aged cheese for optimum firmness and slicing qualities. Essentially, the formulation is determined based on the quality and consistency desired in the final product.

One of the main factors dictating body/texture consistency is relative intact casein content. The level of intact casein influences the structure of the final cheese product, and must be considered when selecting cheeses for PC, PCF, and PCS. Only the intact casein participates in the formation of the emulsified casein network; thus, natural cheeses are selected to achieve a target amount of intact casein in the process cheese. Intact casein is highest in young cheese. PC products made with high intact protein have a long filament-like structure, which yields a product that is sliceable or rubbery, depending on the moisture content (Meyer 1973). A low intact protein content (high content of hydrolyzed peptides and amino acids), resulting from extensive proteolysis in aged cheeses, produces a short structure, appropriate for spreads (Meyer 1973). Rennet-set cheeses of only a few days old possess 90–95% intact casein. Intact casein in mold-ripened cheeses may decline to 30% within a couple of months of aging (Berger and others 1989). In Emmental, intact casein declines from about 88% after one month, to 75–80% after six months, and 70–75% after nine months of aging (Berger and others 1989). The content of intact casein in the finished product should not fall below 12% (Berger and others 1989). For block PC intended for slicing and elasticity, the natural cheeses must have predominantly high intact casein ($\geq$70%) (Meyer 1973). Intact casein can also be obtained from other dairy sources, including non-fat dry milk or milk protein concentrate (Metzger 2004). A summary of recommended combinations of raw materials for different PC products is included in Table 25.3.

A high content of young cheese in the blend will enable formation of a stable emulsion with high water-binding capacity, firm body, and good slicing properties (Thomas 1977; Caric and Kaláb 1999). However, PC with a high content of young, mild natural cheese will have less flavor than PC formulations that include aged cheese, and will exhibit a tendency to harden during storage (Caric and Kaláb 1999). A high content of aged cheese in

TABLE 25.3 Recommended Combinations of Raw Materials for Different Types of Pasteurized Process Cheeses.

Type	Young Cheese (%)	Medium-Ripe Cheese (%)	Aged Cheese (%)
Pasteurized process cheese for slicing, firm	50–60	30–40	10
Pasteurized process cheese slices	60	30	10
Pasteurized process cheese for spreading	30	50	20
Pasteurized process cheese spread	60	40	0

Source: Meyer 1973.

the PC blend will result in more highly flavored PC, good flow properties and high melting index (Thomas 1977; Caric and Kaláb 1999). However, the final product may have a sharp flavor, low emulsion stability, and soft consistency (Caric and Kaláb 1999).

Cheese stocks are analyzed for fat and moisture, then those values are used to calculate emulsifying agents, condiments (flavors), salt, water, and other ingredients to be used, so that the finished cheese will meet government regulations (Kosikowski and Mistry 1997). As there are so many formulation parameters that are important for process cheese functionality and cost, the task of creating a process cheese formulation is made much easier with the aid of a computer program that can track the important formulation parameters as well as the cost of a formula under consideration. Most process cheese manufacturers use a formulation program to assist in the formulation process and cost control (Metzger 2004).

CP cheeses are commonly served as a table spread or used by foodservice as an ingredient, because no heat treatment is given to the product during processing. According to manufacturers of process and cold-pack products, CP and CPF have fresher and more natural flavor when compared to PC (Anon. February 1999). Although selection and preparation of cheeses for use in CP and CPF are quite similar to selection for PC and related products, the major disadvantage is that cold-pack products do not have the same smooth consistency as PC. The body and consistency of CP and CPF depend on the selection of cheese ingredients and the process. Aged cheese will provide a smoother texture compared to young cheese (Anon. February 1999). Similarly, the amount of shear during CP and CPF processing will determine the particle size – the higher the shear, the smoother the product (Anon. February 1999). The pH values for CP and CPF are typically between 5.0 and 5.2 (Duitschaever and Irvine 1973). At pH values below 5.0, syneresis may occur because of proximity to the casein isoelectric point, the point of minimum hydration (Duitschaever and Irvine 1973).

25.3.2.2 Preparation. After selection for pasteurized or cold-pack applications, cheese surfaces are trimmed by scraping and cleaning (wax, rinds, mold spots discarded) (Kosikowski and Mistry 1997). A separate room from the processing floor should be used for cleaning to minimize contamination of products (Berger and others 1989). After proper cleaning, natural cheeses are pre-cut to a manageable size. Portions are shredded or otherwise reduced to about 10–20 mm in diameter, by grinding or grating, because fine particles go into solution more efficiently and completely than large ones (Meyer 1973;

Kosikowski and Mistry 1997). In the largest plants, minced cheese is weighed automatically and conveyed to the mixing vessels (Berger and others 1989).

25.3.2.3 Mixing. Prior to cooking, minced cheeses should be mixed in a vertical or horizontal mixing vessel until a homogeneous mixture is obtained (Berger and others 1989). Emulsifying agents can be added during mixing, prior to or during the cooking stage (Berger and others 1989). The pH of a PC should typically be between 5.6 and 5.8, between 5.4 and 5.6 for a PCF, and about 5.2 for a PCS (Caric and Kaláb 1999). The pH can either be adjusted with the application of acid, base, or emulsifying agent(s). At or below pH 5.0, PC becomes crumbly, while above pH 6.5, PC becomes excessively soft and microbiological problems may result (Caric and Kaláb 1999). Adjustment of pH values between 5.7 and 6.0 during manufacture is recommended for optimum elasticity and springiness of the final product (Marchesseau and others 1997). Trisodium citrate, monosodium phosphate, and disodium pyrophosphate are effective at lowering pH, and disodium phosphate, tetrasodium pyrophosphate, and polyphosphates effectively raise pH (Caric and Kaláb 1999). After blending, material is then taken to the cooker by conveyer belts, worm-feed systems, or other means.

25.3.2.4 Cooking. During cooking, cheeses and other ingredients are heated to high temperatures, in either steam-jacketed kettles or direct steam injector stainless-steel cookers to attain uniformity, safety, and to extend keeping quality. In batch processes, the blend is heated to between 70 and 95°C for 4–15 min (Meyer 1973; Kosikowski and Mistry 1997; Caric and Kaláb 1999). Temperatures of 70–75°C are needed for melting, and creaming is optimal between 80 and 90°C (Berger and others 1989). Sometimes temperatures up to 145°C are used as anaerobic bacterial spores are destroyed above 140°C (Berger and others 1989). Shorter times can be utilized for processing block PC, but longer times ensure spreadable consistency, which is needed for PCF and PCS (Berger and others 1989). Legally, PC should be heated for not less than 30 s at a temperature of not less than 65.6°C (FDA 2004d). When tested for phosphatase, the phenol equivalent of 0.25 g of PC must not be more than 3 μg (FDA 2004d).

Conventional batch-processing cookers are composed of a cast-iron supporting frame or a supporting column, two stainless-steel melting pans with matching lids fitted for steam, vacuum, or water injection, a stirrer, and a tipping mechanism (Berger and others 1989). Raw materials are added to the pan, followed by optional ingredients, then emulsifying agents (if not added at mixing) and water (Berger and others 1989). In continuous-processing cookers, equipment consists mainly of horizontal and/or vertical stainless-steel pipes inside which the cheese mass is continuously fed through single- or double-worm feeders from the input funnel to the outlet and is melted by exposure to direct steam at temperatures from 130 to 145°C for 2–3 s (Meyer 1973; Berger and others 1989; Kosikowski and Mistry 1997). In any case, time, temperature, and stirring rate must be monitored to minimize defects and ensure uniformity.

During emulsification and cooking, the critical steps involve conversion of the calcium cross-linked casein network that is present in natural cheese into a hydrated gel (Fig. 25.2). Initially, organic phosphate groups, which are covalently attached to casein, interact with calcium and inorganic phosphate, which allows several casein molecules to bind together (Metzger 2004). Because of these protein–protein interactions, and lack of interaction between fat, water, and proteins, if natural cheese is heated, it will release a large amount of free fat and water (Metzger 2004). The melted cheese in the cooker initially

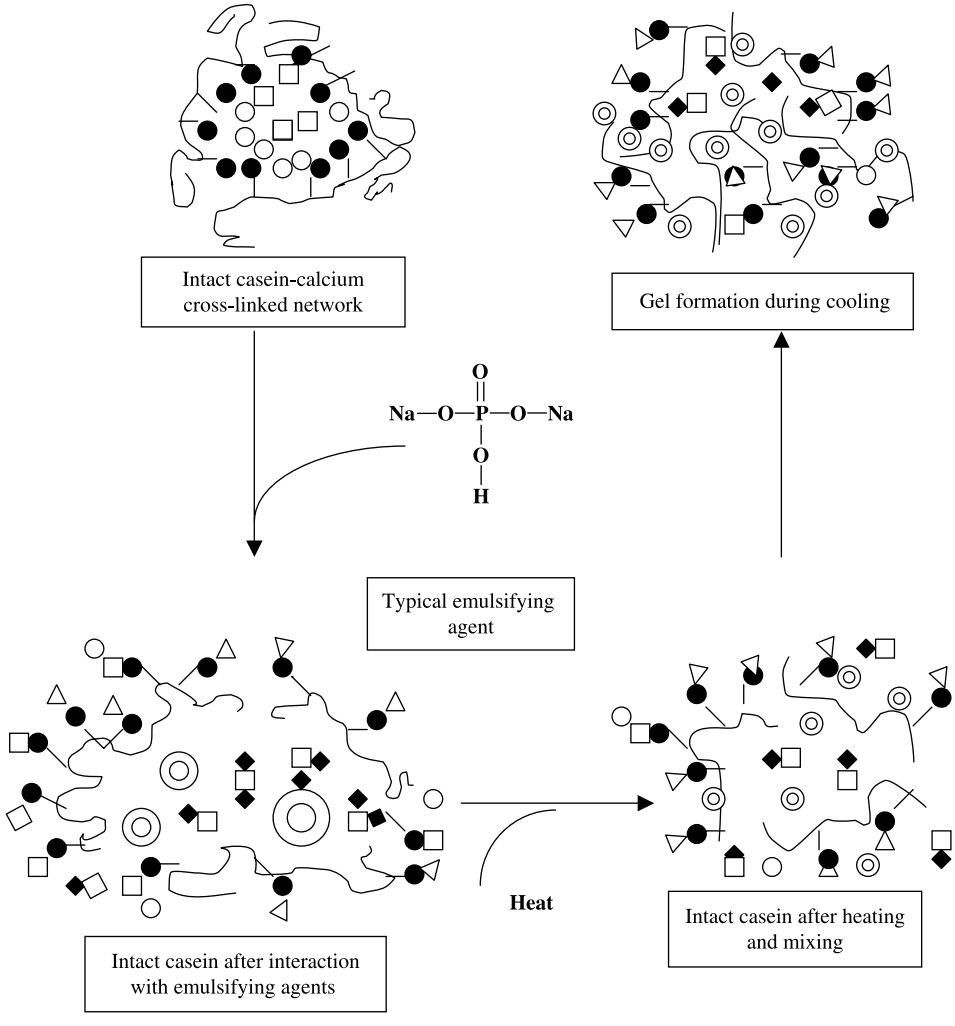

Figure 25.2 *Schematic of pasteurized process cheese emulsification; symbols represent: calcium (□), inorganic phosphate (○), organic phosphate (●), sodium ions (△), emulsifying agents (◆), and milkfat (◎) (Metzger 2004).*

separates into a fat and serum phase until the introduction of suitable emulsifying agents. The resulting upward pH shift solubilizes the protein, resurfaces the fat, and gives a smooth homogeneous mass. Some emulsifiers also peptize the protein molecule under the conditions of processing, to give a desirable short-grain texture.

When emulsifying agents are added to natural cheese, they are hydrated and release sodium ions (Fig. 25.2). The emulsifying agents contain negatively charged groups, which have the potential to interact with positively charged calcium ions, essentially pulling the calcium from the caseins (Metzger 2004). Because the casein then has free negative charges, sodium ions that were released by the emulsifying agents replace the calcium, resulting in a structural change in the previously calcium-cross-linked casein network (Fig. 25.2). The interchange between calcium and sodium ions is a critical

step. Although sodium ions act dispersively, and unwind, dissolve, and peptize proteins, calcium ions dehydrate, condense, and build larger aggregates through polymerization of polypeptides (Meyer 1973). The structural exchange results in elimination of some of the protein–protein interactions; the hydrophobic portions of caseins may interact with fat and the hydrophilic portions can interact with water (Metzger 2004).

Heat and mixing induce interactions between emulsified casein and fat and water, which results in a homogeneous melted mass (Fig. 25.2). During cooling, protein–protein interactions among emulsified casein molecules yield a cross-linked gel (Metzger 2004).

Great skill is involved in knowing when the cooking process is complete. Production of a PC with an appealing short structure with good spreading properties, from a combination of mature and young cheeses with a high level of intact protein, is referred to as "creaming" (Berger and others 1989). Production of spreadable cheese starts with a combination of natural cheeses with 60–80% intact casein (not below 50%), because short texture is desired. If a block cheese with good slicing properties is desired, proper creaming and a high proportion of young cheese with 70–90% intact casein is required. "Overcreaming" is a term describing product consistency ranging from pudding-like to solid.

Higher heat and lower pH are utilized in the production of PCF to prevent bacterial spoilage, which is accelerated at higher water activities (Kosikowski and Mistry 1997). For spreadability, PCS production requires even higher processing temperature and lower pH than PCF because of the even higher water content than PC (Kosikowski and Mistry 1997).

Other components, such as meat products, spices, fruits, or vegetables, may be added at the beginning or towards the end of the cooking process of PCS (Meyer 1973). An advantage to adding inclusions at the beginning is bacteriological safety, although adding at the end prevents shattering of susceptible fragile components (Meyer 1973). Spices are typically added at the beginning of cooking, to ensure even distribution and pasteurization (Berger and others 1989).

Cold-pack cheeses undergo no cooking step, so will not be discussed in this section. Thus, all ingredients must be pasteurized or aged $\geq 1.7^{\circ}C$ for ≥ 60 days prior to grinding, mixing, and packaging (FDA 2004b).

25.3.2.5 Homogenization. Homogenization may be employed to ensure smoothness in the final product, but it is typically reserved only for high-fat PC, PCF, or PCS products (Meyer 1973). When utilized, homogenization is carried out immediately after cooking has been completed, and certain fragile additives, such as meats and vegetables, must be added after this step (Meyer 1973). Thus, intense care should be taken to prevent post-pasteurization contamination.

25.3.2.6 Packaging and Cooling. Heating, emulsification, and unloading of the molten cheese require only a few minutes. If the process is delayed, oiling off, body thickening, browning, and other undesirable defects may result. At the proper time, the blended smooth-textured hot mass can be ejected from the cooker into hoppers or by means of a pump and pipelines, then packaged by high-speed machines that are typically housed in a separate room (Meyer 1973; Kosikowski and Mistry 1997). When the cheese becomes velvety smooth the cheese mass is ready for withdrawal at pasteurization temperature ($71^{\circ}C$) (Berger and others 1989). The smooth, molten cheese must be unloaded from the cookers and pumped into packaging hoppers quickly yet gently to prevent either a temperature drop or overcreaming (Berger and others 1989; Kosikowski and Mistry 1997).

In most facilities, filling and packaging of emulsified liquid mass is automated (Berger and others 1989). Most packaging is consumer portioned from 30 to 225 g, and block cheese is filled into 200 g to 2.5 kg portions (Berger and others 1989; Kosikowski and Mistry 1997). Cheeses are sealed in properly lacquered aluminum foil and inserted into outer packaging at up to 800 units per min (Berger and others 1989). Filled and sealed PC containers are placed in packing cases, which are then turned upside-down (to prevent bubbles) and held at room temperature for 4–6 h before cold storage.

Manufacturers have several options for producing PC in slices, including the block, roller, strip, or injection methods (Berger and others 1989). In the block method, cooled blocks are cut and packed into molded plastic pouches with or without separating foil between each slice (Berger and others 1989). In the roller method, the hot melted cheese emulsion is distributed uniformly on chilled steel rollers, where a wide thin mat of cheese, or thin bands of cold solidified cheese are formed (Meyer 1973; Kosikowski and Mistry 1997). The continuously produced strips are cut by rotary knives to consumer size, laid above each other in layers of eight or more, divided, cut, and automatically wrapped (lecithin is permitted to reduce sticking) (Meyer 1973; Kosikowski and Mistry 1997). The strip or band method is similar to the roller method, except that it employs a moving belt made of stainless steel instead of a cooling roller (Berger and others 1989). The injection method involves injection of the cheese into preshaped body foil, which is pressed flat into the shape of a slice, then cut and packaged into multipacks (Berger and others 1989). Vacuum packaging, or evacuating the air and replacing with an inert gas, prevents spoilage (Meyer 1973).

The USDA requires that PC be cooled to below 38°C within 24 h of manufacture (Zehren and Nusbaum 1992). Cooling is conducted relatively rapidly by storing portion-filled boxes on open shelves, where they can be exposed to cold air, or by immediately conveying boxes through a cooling tunnel on a belt (Berger and others 1989). The storeroom for finished products is generally maintained at temperatures between 12 and 15°C, which is cool enough to prevent further creaming (Berger and others 1989).

Cold-pack cheeses are packaged in various containers, including sausage-shaped casings, plastic or waxed cardboard cups, metal foil, and so on, which are designed to keep air out (USDA 1978).

25.4 PRODUCT ATTRIBUTES

25.4.1 Nutrition

In principle, a PC, PCF, and PCS will have the same nutritional composition as the cheese from which it was made (Berger and others 1989). Pasteurized process cheese and related products contribute high-quality protein, fat, fat-soluble and water-soluble vitamins, calcium, phosphorus, and other nutrients to the diet (Berger and others 1989). Ha and others (1989) demonstrated that conjugated linoleic acid (CLA) content of Cheddar cheese and PC were similar and approximately double the total CLA content of milk. Additionally, total CLA content of a PCS enriched with whey concentrate (Cheese Whiz™) was four to five times higher than that of PC (Ha and others 1989). CLA has been shown to exhibit anticarcinogenic activity (Ha and others 1989; Parodi 1999; Park and others 2004).

Considering the high consumption of PC, PCF, and PCS by Americans, these products may serve as good vehicles for delivering nutritive components to consumers. For instance, dairy products contribute little iron to human diets (Zhang and Mahoney 1991). By showing that consumers gave similar hedonic scores to iron-fortified (Fe-casein, Fe-whey protein, or $FECl_3$) and control cheeses Zhang and Mahoney (1991) demonstrated that it is possible to produce good-quality, iron-fortified pasteurized process Cheddar cheese.

25.4.2 Quality

A good PC has a smooth, compact body, devoid of fermentive gas holes, and a uniform color (Kosikowski and Mistry 1997). PCF is similar to PC in quality, but it has a softer body and milder flavor because of the higher water content (Kosikowski and Mistry 1997). PCS has even more water than PCF and PC, so it is even softer and more spreadable. If air cells are present, they are typically very small and are concentrated on the bottom of the package (Kosikowski and Mistry 1997). High-quality PC should have a clean, pleasant flavor and can be sliced without crumbling or sticking, and it should melt uniformly and smoothly (Kosikowski and Mistry 1997).

Of course, for quality PC, PCF, and PCS, all ingredients used in manufacture must be of high quality. Poor-quality milk fat can yield products with oxidized or rancid flavors, and poor-quality milk protein can yield PC with a bitter taste. However, use of quality ingredients does not guarantee a high-quality final product; appropriate formulation and proper manufacturing conditions are critical to quality pasteurized process cheeses, foods, and spreads. Some of the defect attributes that may be observed in pasteurized process cheese products are summarized in Table 25.4.

The major processing conditions that influence PC products are the mixing (shear) conditions, cook temperature, and cooling rate (Metzger 2004). The mixing conditions used during processing influence the interaction between the emulsified casein and fat. In general, as mixing rate and time are increased, the interactions between the emulsified casein and fat also increase. In a similar fashion, as processing temperature increases, the interactions among the hydrophobic portions of the emulsified casein and fat increase. Increasing the mixing rate or increasing the cooking temperature will typically increase the firmness but decrease the meltability of PC. During cooling, the emulsified caseins interact to form a gel, and the rate of cooling will influence the characteristics of the gel that is formed. A rapid cooling rate causes formation of a porous gel with weak cross-links, whereas a slow cooling rate produces a less porous gel with strong cross-links. A less porous gel with strong cross-links will produce a firm PC with less meltability. Consequently, a slow cooling rate will produce a firm PC with less meltability whereas a fast cooling rate will produce a softer PC with more meltability. The importance of processing conditions and cooling rate are so critical that is it is possible to take the same formulation and produce several process cheeses with completely different functionality by simply adjusting the manufacturing conditions (Metzger 2004).

25.4.3 Shelf-Life and Safety

The shelf-life of pasteurized process cheese and related products varies between 8 weeks (slices) and 20 weeks (small portions) to 1 year (tubes or cans) at room temperature (Schär and Bosset 2002). During storage, even bacteriologically stable products in good

TABLE 25.4 Common Attributes in Pasteurized Process Cheeses, Identification, and Their Probable Causes.

Attribute	Probable Cause	Prevention
Acid or bitter taste	Excess phosphates	• Minimize phosphate usage level • Natural cheese source(s) • Carefully select cheeses for base formula
Browning	Salmon or tan discoloration	• Avoid cooking above 85°C in the presence of lactose (skim or whey powder)
Crumbly	Cheese falls apart upon slicing	• Optimize moisture and emulsifier(s) levels
Crystals and/or grainy or sandy texture	Protein precipitation, or excess polyphosphates, or tyrosine crystals, or crystals of calcium diphosphate lactose or insoluble emulsifier	• Control pH to 5.2, not lower than 5.0 • Minimize phosphate usage level • Avoid use of natural cheese with crystals • Cool packaged cheeses slowly • Avoid excessive use of skim or whey powder
Firm body	Cheese does not slice smoothly due to excess polyphosphates	• Minimize polyphosphateusage level
Gassy	Physical Air bubbles introduced during processing trapped in the body of processed cheese while cooking Microbial gas formation during storage due to presence of *E. coli* or bacterial spores	• Appropriate heat treatment of pasteurized process cheese • Proper selection of cheeses(s) with low spore counts • Proper formulation (moisture levels, pH, type and amount of emulsifier(s) and NaCl, and prior treatment of condiments • Use of approved antimicrobials and/or sorbate-coated foil
Heavy body	Gummy, dense cheese body due to excess cooking	• Optimize cooking time
Leaky	Fat and water separate due to improper emulsifier and pH	• Optimize emulsifier usage and pH
Moldy flavor	Mold growth; air contamination	• Properly vacuum-seal packages
Oxidized, rancid or unclean flavor	Off-flavors resulting from natural cheese	• Avoid use of natural cheese with off-flavors
Soft body	Oily, spongy body due to excess fat, citrates, or pH	• Optimize formulation with natural cheeses and emulsifying agents
Sticky	Cheese holds to knife blade	• Control moisture to below legal limits • Reduce pH to around 5.2

Source: Meyer 1973.

packaging undergo chemical and physical aging processes that impair flavor and texture of products (Schär and Bosset 2002). A comprehensive review by Schär and Bosset (2002) details processes that occur during storage, including loss of water vapor, hydrolysis of polyphosphates, changes in ionic equilibria, formation of crystals, reactions induced by

heat-stable enzymes, nonenzymatic browning, reactions induced by light and oxygen, and interactions with packaging materials.

Thapa and Gupta (1992) reported some of the changes in sensorial and rheological properties that occur in PC and PCF during storage. Body and texture acceptability scores of PCF and PC declined slightly during storage, as the cheeses became harder and drier. Appearance acceptability scores declined as a result of increased browning during storage. Authors attributed faster flavor deterioration in PCF compared to PC to the higher moisture content of PCF, because high moisture and water activity facilitate food spoilage. Finally, the shelf-life of PCF was shortened by replacing 20% of cheese solids with whey protein concentrate.

Research has suggested promise for reduced-fat PC, PCF, and PCS. Muir and others (1997) characterized the sensory quality of 16 commercial PCS samples and showed that texture and mouthfeel were influenced by fat content. On the other hand, no evidence of differences in flavor or spreadability were associated with fat content, suggesting that formulation manipulation may be more effective at homogenizing flavor and spreadablilty than texture and mouthfeel of PCS. Moreover, Brummel and Lee (1990) were able to improve the texture of 40 and 50% reduced-fat PCS by using soluble hydrocolloids. Spreads with 15% fat and with added hydrocolloids, lambda-carrageenan (2.2%), pectin (1.7–2.2%), or low-viscosity guar (1.7%) had textures consistent with the 25% fat control. Above these gum levels, cheese-spread firmness (by Instron measure) increased while melt decreased. A 15% fat, 62% moisture cheese spread with 1.7% pectin was most like the control having 25% fat. Swenson and others (2000) characterized the effects of emulsifying agents and hydrocolloids, cook time, cook temperature, and pH on firmness, meltability, and spreadability of fat-free PCS. Incorporation of hydrocolloids resulted in increased firmness and decreased melt. Increases in cook time generally produced softer, more meltable cheeses, and increases in cook temperature decreased firmness and increased meltability and spreadability. These findings imply that reduction of fat in PC products may require manipulation of processing conditions to maximize quality.

Glass and others (1998) evaluated commercial PC slices for the ability to support the growth of four foodborne pathogens, inoculated at 10^3 cfu/g, during 4 days of storage at 30°C. *Staphylococcus aureus* levels remained relatively constant during the testing period, and were below levels that support detectable enterotoxin production. Populations of *Listeria monocytogenes*, *Escherichia coli* O157 : H7, and *Salmonella* serotypes decreased during storage. Although these results imply inherent safety of PC, PCF, and PCS, of course, post-pasteurization contamination of any kind should be minimized by using good manufacturing and handling practices to ensure safety of PC, PCF, and PCS products.

As CPC, CPF, and CPS are not heat treated or aged after manufacture, contamination of starting materials with pathogens is of major concern. Park and others (1970) contaminated CPF with *Salmonella typhimurium* and found that the pathogen survived up to 19 weeks, in the presence of preservative, if pH was not adjusted to 5.0 with acid. Ryser and Marth (1988) investigated the ability of *L. monocytogenes* to persist in various formulations of CPF manufactured with or without preservatives and/or acidifying agents. *L. monocytogenes* was unable to grow in CPF at pH 5.0–5.45, regardless of the formulation. It is not surprising that *L. monocytogenes* survived the longest in nonacidified CPF made without preservatives. *L. monocytogenes* numbers declined only 0.6–1.55 log at 4°C during the six-month shelf-life of the product. Because salt lowers the water

activity of a food, it indirectly enhances the effectiveness of preservatives; thus, the authors concluded that combining salt and preservatives in CPF at pH 5.0 can enhance destruction of *L. monocytogenes.* Of course, manufacturing CPC, CPF, and CPS with pathogen-free ingredients, under the best sanitary conditions, is of utmost importance for food safety. However, incorporation of preservatives, especially sorbic acid, and small amounts of lactic and/or acetic acid to decrease the pH to 5.0, decreases the chance for survival of *L. monocytogenes* and can provide additional assurance of safety of CPC, CPF, and CPS (Ryser and Marth 1988; Park and others 2004).

25.5 SUMMARY/CONCLUSIONS

The extended shelf-life of pasteurized process cheeses compared to natural cheeses, combined with the equivalent nutrition and enhanced convenience and consistency of these products, make pasteurized process cheese and related products popular foods in the human diet. Due to the variety of optional ingredients and advanced manufacturing practices available in the industry, plentiful opportunities exist for food scientists who wish to improve the diversity and nutritional quality of pasteurized process cheese and related products for eager consumers. With technical expertise, good sanitation practices, and creativity, great opportunities exist for a multitude of new high-quality, safe, and versatile pasteurized process cheeses and related products.

26.1 INTRODUCTION

Cottage cheese is an unripened, soft, white cooked curd cheese made from skim milk (Code of Federal Regulations 2004). Cottage cheese may be found commercially in various forms, including dry curds, creamed cottage cheese, large curd, small curd, California-style, low-fat, nonfat, no salt, or blended with fruits, chives, or other inclusions. Except in the case of dry curds, a cream dressing is added to the nonfat cottage cheese curds, to achieve the appropriate fat content for the given product identity. Both cottage cheese and creamed cottage cheese must not contain more than 80% moisture (Watrous 1997; USDA 2001). Creamed cottage cheese must contain not less than 4% milk fat, unless labeled as 2%, 1%, or nonfat cottage cheese (Watrous 1997; USDA 2001). High-quality creamed cottage cheese containing about 1% salt should have a mildly acidic, sweet, clean flavor (Bodyfelt and others 1988; Potter 2004).

Cottage cheese has been made commercially in the United States since about 1915 (Kosikowsky and Mistry 1997a) and consumption peaked (at 2.5 kg per capita) in the 1970s (IDFA 2002). Since then, sales of creamed and low-fat cottage cheese have declined from 452 million kg (2 kg per capita) in 1980, to 333 million kg in 2000 (IDFA 2002). U.S. production of cottage cheese was over 167 million kg in 2000, but since 1996, per capita sales (1.2 kg) of cottage cheese have remained nearly unchanged (IDFA 2002). Many theories have been made on why cottage cheese sales have not increased. One theory is that the success of yogurt, especially with children, has overshadowed cottage cheese. Focus by dairy companies has been on promoting fluid milk and cultured products, with little emphasis being placed on cottage cheese. Another theory is that cottage cheese has long been associated with being a diet food. That would lend itself to a smaller targeted audience and then only if they are consistently dieting. A final theory is that the uniformity of cottage cheese is inconsistent, turning away consumers. In any case, to be successful in promoting and marketing cottage cheese, expectations of product quality are the basis for the product.

26.2 PRODUCTION OF COTTAGE CHEESE

26.2.1 The Ingredients

26.2.1.1 Milk. High-quality Grade "A" skim milk must be used to make cottage cheese curds because

1. It is the law,
2. High-quality cheese cannot be made from inferior milk, and
3. Fat softens the curd (USDA 2001; Code of Federal Regulations 2004)

The United States Department of Agriculture (USDA 2001) states that "Cottage cheese shall be manufactured and packaged in accordance with the applicable requirements

contained in 7 CFR Part 58, Grading and Inspection, General Specifications for Approved Plants and Standards for Grades of Dairy Products and inspected by the AMS, Dairy Grading Branch. Alternatively, cottage cheese may be manufactured and packaged in accordance with the applicable requirements contained in the latest revision of the 'Grade A Pasteurized Milk Ordinance', Food and Drug Administration" and "Cottage cheese and dry curd cottage cheese shall comply with all applicable Federal regulations including those contained in the Food and Drug Administration's Standard of Identity for Cottage Cheese 21 CFR Part 133.128 for cottage cheese or 21 CFR Part 133.129 for dry curd cottage cheese" (U.S. Department of Health and Human Services 1999; Code of Federal Regulations 2004).

The incoming raw milk must be of high quality with regard to aroma, flavor, titratable acidity (TA, between 0.12 and 0.16), total solids, microbial counts (ideally less than 50,000 per mL), and no positive beta-lactam antibiotics test results (Potter 2004). The delicate flavor of cottage cheese will not mask quality defects in the milk. Total solids are an important component of skim milk. Normal skim solids will vary from 8.8 to 9.2% (Potter 2004). Low solids results in fragile curd, so standardizing to between 9.0 and 10.0% total solids is indicated (Potter 2004). Skim milk may be fortified with extra-grade, low-heat, spray nonfat dry milk (NFDM) or evaporated milk to increase solids and cheese yield (Kosikowski and Mistry 1997a). About 5 kg of NFDM powder is needed to raise the solids 0.5% for each 1000 kg of skim milk (Potter 2004). The NFDM should be added prior to pasteurization, and three to four hours of rehydration prior to cheesemaking is recommended for optimum yield from NFDM (Potter 2004). Reconstituted skim milk may also be used to make cottage cheese, but drainage of curd may be slowed (Kosikowski and Mistry 1997a). If the total solids level of reconstituted or fortified milk is too high, the curd will be heavy, soggy, or unnatural, with high acidity, so care must be taken in optimizing total solids (Potter 2004).

26.2.1.2 Calcium. Although not used commonly in the cottage cheese industry, calcium chloride is permitted, at a legal maximum of 0.02%, to prevent soft fragile curd (Kosikowski and Mistry 1997a).

26.2.1.3 Cultures. Ideally, cottage cheese cultures should be mesophilic homofermentative lactic acid bacteria that do not produce large quantities of diacetyl or volatile fatty acids that will be lost in the whey during curd washing (Watrous 1997). Pure cultures of *Lactococcus lactis* subsp. *lactis* or *L. lactis* subsp. *cremoris*, or a mixture of these species, satisfy these criteria. Additionally, a starter culture that combines *L. lactis* and/or *L. cremoris* plus *Leuconostoc mesenteroides* subsp. *cremoris* is suitable, as long as large amounts of carbon dioxide are not produced (Watrous 1997). *L. lactis* subsp. *diacetylactis* is generally not satisfactory for cottage cheese (Watrous 1997).

Cultures are available in a variety of forms, including conventional or pH-controlled bulk starter, and direct vat set (DVS) culture. Selection of one variety or another is influenced by plant size, volume capacity, and production scheduling. In the case of conventional bulk starter, usage rate is typically 5–7% for a 4–5 h set (Potter 2004). Either internal or external pH control bulk starter cultures can also be used for cottage cheese production (Potter 2004). Because of the higher cell population than in a conventional starter, a usage rate of 1.5–2.5% of the skim volume is appropriate for a 4–5 h set; lower inocula are used for longer sets (Watrous 1997; Potter 2004). Direct vat set cultures,

either frozen or freeze-dried, are convenient and commonly used in the industry. They are more concentrated and more expensive than bulk starters. Usage rate varies from 0.20 to 0.25% (Waltrous 1997).

An alternative to the use of cultures in the production of cottage cheese, as a time-saving device, is direct acidification. Approved acids include food-grade phosphoric, citric, and hydrochloric acids (Koslikowski and Mistry 1997a). Glucono-δ-lactone may also be used (Koslkowski and Mistry 1997a). Cottage cheeses made in this fashion require the container to be labeled with "directly set" or "curd set by direct acidification" (Kosikowski and Mistry 1997a). Directly set cottage cheeses lack the unique and complex flavors imparted by cultures. Also, depending on economic conditions in the market, the ingredients used for direct acidification may prohibit their use due to their high cost. Typically, direct acidification may cost \$0.01–0.03/kg more.

26.2.1.4 Enzymes. Although cottage cheese is an acid-set cheese and can be made entirely without the use of coagulating enzymes, modern processing facilities use chymosin (rennet) or a coagulating enzyme produced from the fermentation of *Mucor meihei*, to reduce the processing time and increase yield. The resulting cheese is also sweeter and milder in flavor (Potter 2004).

Normal usage for single-strength rennet is 1–2 mL per 4550 L (small curd) or 4–6 mL per 4550 L (large curd). Double-strength rennet is not normally recommended for use in cottage cheese manufacture, because the small amount required increases error potential. Instead, many commercial cheese companies use a prediluted rennet labeled as cottage cheese coagulator. This product is used at a rate much higher than single-strength rennet – (40–60 mL per 4550 L (small curd) or 100–120 mL per 4550 L (large curd). This will vary based on the manufacturer and desired curd texture. Coagulant must be diluted 20 to 40 times to prevent localized coagulation during addition to the milk. Dilution should be done immediately before addition to milk, to prevent inactivation by chlorine in tap water. Soft sets are preferable to firm sets in the case of cottage cheese, so lower levels of chymosin or coagulant are recommended over high levels (Potter 2004).

26.2.1.5 Cream Dressing. Cottage cheese cream dressing may be made with sweet cream or sour cream. As with the skim milk, the cream must be of prime quality. Commonly, dressings contain a combination of any of the following: whole milk, heavy sweet cream or sour cream, salt, cultured buttermilk and/or skim milk powder, and, in most products, stabilizers. The stabilizer systems typically used consist of a combination of gums, starches, emulsifiers, and phosphates (locust bean gum, guar gum, carrageenan, starch, xanthan, lecithin, and sodium and potassium phosphates). The usage rate of stabilizers in cottage cheese dressing is usually less than 0.50%. The blend may also contain a preservative such as potassium sorbate to inhibit mold growth. Each ingredient is individually labeled on the finished cottage cheese container. Stabilizer systems help the dressing adhere to the curd surface and prevent defects such as "free cream". Overuse of stabilizers will cause the finished cheese to have a "slick" mouthfeel. The level of milkfat in the cream dressing for regular cottage cheese typically ranges between 9 and 11% (Potter 2004). The fat content of the dressing is standardized with the ratio of cream to curd, as described later. A typical cream dressing may consist of 10% milk fat, 11% MSNF, 0.35% stabilizer, and 2.25% salt, for a total solids content of 23.60% (Potter 2004). For such a composition, 18.4 kg of 40% fat cream, 65.3 kg of 3.5% fat milk,

3.7 kg of NFDM, 10.0 kg of cultured whole milk (3.5% fat), 2.25 kg salt, and 0.35 kg stabilizer would be used for each 100 kg of dressing (Potter 2004). The sweet cream dressing described typically results in a cottage cheese with pH between 5.2 and 5.3, which has a short shelf-life. Cultured buttermilk may be added to the dressing in quantities up to 10%, before pasteurization, to bring the pH to or below 5.0 for the finished cheese, which extends shelf-life (Potter 2004). The dressing pH may be as low as 5.9–6.1 prior to pasteurization, but anything lower may cause the dressing to precipitate during pasteurization.

The dressing is pasteurized at 75–82°C for 30 min by the vat method or 88°C for 32 s by the high temperature short time (HTST) method (Potter 2004), then cooled to 60°C for homogenization at 2000 psi (13.77 MPa) (first stage) and 500 psi (3 MPa) (second stage). The dressing should be held, refrigerated, for 20 h to 3 days before application to curds for viscosity to develop (Potter 2004). The high temperatures impart a pleasing cooked flavor and nearly sterilize the cream dressing for an extended shelf-life (Potter 2004).

Blanchette and others (1995) demonstrated that fermenting cottage cheese dressing with probiotic bacteria, *Bifidobacterium infantis*, has potential as a product for lactose maldigestive patients. In a follow-up study, Blanchette and others (1996) found that *B. infantis* introduced into fresh cheese exhibited vigorous metabolic activity during storage for 28 days. However, consumers preferred the control cottage cheese and the cottage cheese made with the dressing fermented to pH 5.5 to the cottage cheese with added dressing fermented to pH 4.5.

26.2.1.6 Water. One thing that must not be overlooked in the production of quality cottage cheese is a reliable source of filtered, chlorinated chilled water (Potter 2004). The wash water pH should be adjusted to 5.0 with food-grade phosphoric acid and contain 8–12 ppm chlorine. Conventional washing of the curd in the cheese vat will require approximately 2.5 times as much water volume as milk volume to properly cool the cheese curd prior to creaming. It is important to wash the curd after cooking to achieve two main goals:

1. Remove excess whey and
2. Cool the curd to stop the cooking process.

The final curd temperature after washing should be between 5 and 10°C. Automatic curd-washing equipment can reduce the wash water usage by as much as 50% to achieve the same results.

One aspect of rinse water that should be considered is the source of the water. Water from reservoirs can be of inconsistent quality if the watershed flora is predominately deciduous trees. For instance, autumn runoff from such forest floors will contain extracted organic materials that react with municipal chlorine added in municipal water systems and will yield harsh flavors.

26.2.2 The Process of Cottage Cheese Making

26.2.2.1 Sanitation. For any quality product to be produced, sanitation is of utmost importance. Cleaning and sanitizing all equipment, utensils, walls, floors, and drains is critical to maintaining safety, quality, and productivity. Poor sanitation practices will lead to poor quality or shortened shelf-life, delayed fermentation of vats (due to

bacteriophage contamination) at best, and at worst, public health issues. Stainless-steel equipment and utensils are recommended for cottage cheese manufacture for their ease in cleaning and sanitizing (Potter 2004). Chlorinated alkaline cleansers are effective at removal of organic soils, especially protein, making them most useful in a cheese plant. Acid cleansers are indicated for the removal of mineral soils. Use of chlorine sanitizers is recommended over iodine sanitizers because they are more effective against bacteriophages (Potter 2004). Manufacturers should always be consulted for determination as to which cleaning and sanitizing supplies and procedures are appropriate for a given plant.

26.2.2.2 Separation. A cottage cheese plant may elect to purchase pasteurized skim milk and cream or purchase raw whole milk and separate it into skim milk and cream. Most modern facilities are equipped with in-line separators. Milk is separated prior to fortification and/or pasteurization.

26.2.2.3 Pasteurization. Legally, the skim milk for cottage cheese must be pasteurized to kill pathogens and other undesirable microorganisms that may be present in the skim milk (Potter 2004). For best quality, the skim milk for cottage cheese manufacture should be pasteurized at the minimum allowable temperature: 62.8°C for 30 min or 71.7°C for 15 s (Watrous 1997). If heated at too high a temperature, a soft, high-moisture coagulum with high acidity will result (Watrous 1997; Potter 2004). For California-style cottage cheese, pasteurization and cooking temperatures are higher than for other styles (Kosikowski and Mistry 1997a).

26.2.2.4 Homogenization. Because skim milk is used, homogenization is optional. However, homogenization is highly recommended because it helps prevent agglutination (sedimentation) and fat separation in the cheese vat if the separator is not functioning properly (Potter 2004). Homogenization pressure of 500–1000 psi (3–7 MPa) in a single-stage homogenizer is recommended (Potter 2004).

26.2.2.5 Culture Preparation. As mentioned previously, the cottage cheese maker has options for culture selection. Bulk starter culture will need to be prepared at least one day in advance of cheesemaking. Commercial bulk starter media are available and primarily contain the following: sweet whey or whey solids, nonfat dry milk, yeast extract, phosphates, and trace minerals. This preblended media replaces conventional reconstituted nonfat milk starter media and offers the advantage of concentrated starter production using pH control and also bacteriophage control. As a result of the use of these media, starter room location and construction has become easier with the use of phage-inhibitory media as compared with conventional milk starter. These media allow starter to actually be grown in the same room as the cheese vats. Although the ideal condition is to have a separate starter room with its own air-handling system, cottage cheese manufacture is feasible without one. It is good practice to incorporate filtered positive-pressure air to the starter tank to help prevent airborne bacteriophage contamination during the processing and inoculation of the starter.

Bulk starter is prepared by reconstituting the commercial medium with water to various solids levels, ranging from 6.0 to 11.0%. The reconstituted medium is then pasteurized (vat method, 85°C for 30 min, or HTST method, 95–100°C for 30–120 s). After pasteurization the medium is cooled to 25°C and inoculated with a commercial mesophilic lactic acid culture. Incubation requires 12–16 h. During incubation, the pH of the starter is

maintained or controlled through the neutralization effect of buffers or neutralizers. This is accomplished with either internally blended phosphates and/or citrates or by externally added aqueous ammonium hydroxide. Neutralization allows the culture to continue fermentation and produce a more concentrated cell concentration per volume of starter versus conventional milk starter with no pH control. Once the starter is complete, it is cooled to 5°C and can be stored and used for up to 3 to 5 days.

26.2.2.6 Culture Addition. Generally, after pasteurization, milk is cooled to set temperature, directed into the cheese vat, and immediately cultured. However, current manufacturing processes also include the use of pasteurized-milk-holding tanks to allow for continuous availability of pasteurized skim milk. Milk is pasteurized and stored cool until it is needed. It is then pumped through a heating device (that is, a triple tube or plate heat exchanger), where it is tempered to 32°C and sent to the cheese vat. This helps prevent downtime or scheduling problems with the HTST unit when vats are refilled for multiple rounds per day. Care should be taken to avoid excessive air incorporation into the milk, as cultures are facultatively anaerobic or microaerophilic. Ideal temperatures for mesophilic lactic cultures used in cottage cheese vary between 21 and 33°C, with 30–33°C being most commonly used (Kosikowski and Mistry 1997b; Watrous 1997). Selection of temperature depends on the manufacturing technique (Table 26.1). If milk is to be cultured in the evening and allowed to ferment until morning (12–16 h setting time), a temperature of 21–24°C is appropriate. If milk is to be cultured in the morning and the process is to be carried out in an 8-h period or less, the setting temperature should be 30–33°C (Watrous 1997).

In the case of conventional cottage cheese making, bulk starter should be added to the vat once the vat is at least one-half full, because the low pH (<5.0) of the starter could cause localized coagulation if added to a low volume of milk (Potter 2004). If using pH-controlled bulk starter or DVS culture, the starter can be added concurrently as the cheese vat is filled (Potter 2004).

26.2.2.7 Enzyme Addition. Diluted chymosin may be introduced into cultured milk immediately after the vat is full, or after a short incubation period (less than 30 min) (Kosikowski and Mistry 1997b). The chymosin should be mixed into the cultured milk for approximately 2 min, so it is well distributed, then the milk should remain quiescent, covered, for approximately 5 h, until the pH of the curd is 4.7–4.6 (Kosikowski and Mistry 1997b; Potter 2004). It is important that all disturbing vibrations be minimized during the setting period, because cottage cheese curd is very fragile.

26.2.2.8 Cutting. Regardless of enzyme use, cottage cheese coagulum must be cut when the curd is "ready". Cutting the curd at the proper pH is the single most important

TABLE 26.1 Processing Parameters of Different Styles of Cottage Cheese.

Process Stage	Long-Set	Intermediate-Set	Short-Set
Ripening prior to cut	12–16 h	8 h	5 h
Temperature of milk set	22°C	26.5°C	32°C
Starter addition			
Conventional	1%	2%	5%
pH Contolled	0.5%	1%	2%

factor in producing a high-quality cottage cheese, and each plant should find the optimum cutting pH for the operation then adhere to it for a consistent product (Potter 2004). Although titratable acidity (TA) is utilized widely in the production of Cheddar and other cheeses, pH is more appropriate for monitoring cheese curd formation in cottage cheese production (Potter 2004). The TA of whey at pH 4.6 will be approximately 0.42–0.60, but varies according to the solids content of the skim milk (Watrous 1997; Potter 2004). At its isoelectric point, casein is least soluble and exerts its lowest moisture-binding-capacity (Watrous 1997). At this point, cutting, stirring, and heating stimulates the curd to release moisture (Watrous 1997). Curds should be cut at a pH of 4.65–4.70 for small curd and 4.70–4.75 for large curd (Watrous 1997; Potter 2004). Cutting at pH above 4.7 typically results in a curd that is lumpy and tough, but cutting at a pH below 4.5 results in a curd that is soft and fragile (Potter 2004). Thus, each plant must monitor pH with reliable equipment, determine the optimum pH for cut, and aim for consistency.

In addition, it is good practice to do a visual check on the appearance of the coagulum by taking a sample using a "sample straw", which is used for milk sampling in bulk trucks. The test involves inserting a long sanitized straw into the curd, plugging the top of the straw with finger, and removing the loaded straw. The straw should be placed on a flat surface and slowly drag backwards as the finger is removed from the straw opening at the top. The curd is ready when it snakes across the surface, holds structure, and yields only clear whey. This method should be used in conjunction with a pH meter and not as a standalone test. Its purpose is to confirm that the coagulum firmness matches the cut pH. Information gained from this test should be used to make adjustments in the amount of coagulant to be used in future vats.

For cottage cheese curds, the coagulum should be cut with 1.3-, 1.6-, or 1.9-cm knives for small to intermediate to large curd sizes (Kosikowski and Mistry 1997b). Consistency in cutting is critical, because overly large or excessively small curds result in inconsistent curd size, moisture content, and yield losses.

26.2.2.9 Healing. Because cottage cheese curds are extremely fragile, curds must be allowed to heal, undisturbed, for 15–30 min. (Kosikowski and Mistry 1997b). Healing allows a skin to form on the surface of each curd, minimizing damage during the subsequent cooking process, which could affect cheese yield. During the healing process, whey is expelled, shrinking and firming the curd and permitting easier agitation of the curd during the cooking process.

26.2.2.10 Cooking. At the beginning of the cooking process, the curds are still fragile. A paddle should be manually used to gently and methodically ease curds apart and away from the vat walls. After the curds drop about 5 cm from the whey surface, warm water (about 5 cm) may be added to the cut curd in the vat before stirring to raise the temperature slightly (Kosikowski and Mistry 1997b; Watrous 1997). The vat jacket temperature, which is typically 10–15°C higher than the curd–whey mixture, should be raised gradually to raise the curds and whey temperature to 53°C (in winter) or 56°C (in summer), slowly (Potter 2004). A steady 1.7°C rise every 10 min is recommended (Kosikowski and Mistry 1997b). Curds may be stirred either manually or mechanically after the initial stages (30 min) of cooking in a manner that prevents both matting (too slow) and breakage (too vigorous) (Potter 2004). Improvements in vat design and agitation methods have made it unnecessary to use manual agitation. These new designs utilize a vertical stir motion as opposed to a circular one. As a result, the

curd does not go unstirred in the vat corners and the curds experience a more gentle continuous stirring action. The heating process has also been improved and heat is now added outside the cheese vat. Surface whey is drawn out of the vat and heated either by direct steam injection or tubular heat exchanger and then pumped back into the vat on the top surface. This allows the heat to be concentrated initially in the whey portion and the curd is then gently stirred up into the hot whey. A more uniform heating of the curd results with this process, as jacket heating can create localized hot spots, resulting in matting or excessive fines due to overstirring.

No acid development occurs after the vat contents reach 40°C (Watrous 1997), and starter bacteria are essentially all killed after a temperature of 53°C is attained (Potter 2004). Ideal curd firmness is attained from about 100–120 min after the initial temperature rise (Kosikowski and Mistry 1997b; Potter 2004).

Commonly today, phosphoric acid is used as an aid in cooking because it creates an imbalance between curd and whey acid (Potter 2004). Food-grade 75% phosphoric acid is added to the curd–whey mixture just after healing and initial gentle mixing (Potter 2004). Enough acid is added to reduce the pH of the vat to 4.4–4.5 when the vat temperature is 38°C, about 50–75 mL per 455 L of skim milk (Potter 2004). The acid should be diluted a minimum of 20 to 40 times with clean water before adding to the vat. Always follow safety precautions when handling phosphoric acid.

Curds can be tested for firmness after the optimum temperature is attained. Curds can be dropped from waist level (roughly 75 cm) and observed for bounce. If curds spatter instead of bounce, sufficient firmness has not yet been reached and temperature should be held for another 10–30 min. Alternatively, a clump of curds can be taken in the hand and rinsed. If they are ready for washing after squeezing, the curds should bounce back to their original shape. Both of these methods are very subjective and require a great deal of experience. Unfortunately, there is not a consistent mechanical method of analysis that will give a quick determination of curd firmness at the end of the cooking time. If the curd is too soft after cookout, the curd was cut too late and the pH at cutting should be raised in the next vat (Potter 2004). If the curd is too firm after cookout, the cut was likely too early and the opposite adjustment is indicated.

26.2.2.11 Washing. The purpose of washing the cottage cheese curds is to remove whey and cool the curd. The whey will impart an acid flavor. High-acid cottage cheese is not as desirable to most consumers as mildly acidic cottage cheese. Wash-water pH is important to cheese quality. To help minimize the growth of psychrotrophic organisms, the wash-water pH should be adjusted to a pH of 5.0 and should contain 8–12 ppm of chlorine. This pH closely matches that of the finished cheese. Wash water should be cooled to below 7°C.

Washing is accomplished using two methods: Vat and automated. To begin the vat washing process, agitation of curds is stopped and the curds are allowed to settle at the bottom of the vat. A paddle should be used to pull the curds back about 30 cm from the exit port to make way for the insertion of an inside-the-vat strainer into the exit port. Enough whey should be drained until about 10–12 cm depth of piled curd begins to show through the whey. At this time, treated wash water should be added to the rear of the vat. Enough water should be added such that the whey exiting the drain reaches approximately 50°C. At this time, the vat drain port is closed, the strainer removed, and the wash–water–whey–curd mixture agitated for 5–10 min. Rinse water is continually added until the curd temperature drops from about 53°C to 27°C.

After a temperature of about 27°C is reached, the strainer should be returned to the vat as before, and the wash-water–whey drained completely. The exit port is then closed, chilled treated water is added to the vat to the level of the previous wash-water–whey–curd level, the strainer is removed, and agitation is resumed for 5–10 min. At this point, the wash-water–curd temperature should be close to 4°C. When a single vat is used for the entire cottage cheese production, washing generally takes place in three cycles (Bylund 1995). The washings bring the temperature of the curd down to 30, 16, and 4°C, respectively (Bylund 1995). For the final drain, curds should be moved to the rear of the vat, as usual. As the wash water is drained, the curds should be trenched, or piled on two sides of the vat, and allowed to drain naturally. Complete draining takes approximately 45 min. Cream dressing must be ready for the creaming process so curds are not allowed to overdrain.

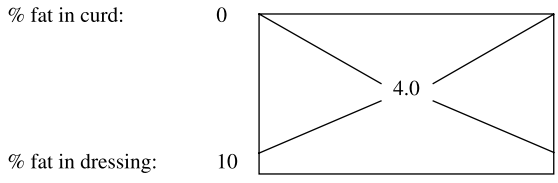
For automated curd washing, after the cook process is completed, the curd and whey mixture is pumped to a whey drainer or curd washer. The whey is separated from the curd either by a nylon or stainless-steel mesh screen and the curd is dispersed in cool wash water. Depending on the style of automated washing, it will be accomplished by using either a vertical washing tower or a horizontal washing tank. Each will result in the curd being cooled to approximately 7–10°C. The advantage of using the automated cooling is reduction in wash-water usage and also increased production and economic efficiency by allowing the washing process to occur outside of the cheese vat. The process frees up the cheese vat to be reset. The advantage of the vat washing method is better curd identity. After washing, the curd is again transferred, via pumping, to a curd drainer, where the water is removed and the curd enters a creaming vessel.

26.2.2.12 Creaming. For proper meaty cottage cheese curd texture and pleasing flavor, curds should be creamed immediately after proper draining (Potter 2004). The most common ratio of curd to cream dressing is 60:40, but it varies among manufacturers. This translates into approximately 10 L of dressing for each 100 L of skim milk set (Potter 2004). Application of pasteurized, homogenized cream dressing with 11% fat at the rate of 56 kg per 100 kg curd with normal moisture results in a highly satisfactory product (Potter 2004). If a curd with lower moisture content than the target value is produced, a lower fat (10%) dressing of higher moisture content may be used (Potter 2004).

The amount of cream dressing and curd to combine for the appropriate fat content final product can be determined by use of the "Pearson Square" method, shown in Figure 26.1. For example, if there are 100 kg of curd to be creamed and 10% fat cream dressing is available, the amount of cream necessary to give a fat content of 4% in the finished product is 66.7 kg.

As with the washing process, there are two basic methods used for creaming the curd. The first is the vat method, where dressing is added to the curd that has been rinsed and drained in the vat. This method requires skill and experience in that most cheese vats will not be on load cells and the exact amount of curd in the vat can vary from day to day. This makes it more difficult to determine the amount of cream dressing to add. Through years of experience, cheesemakers will become expert at estimating the appropriate amount of dressing needed based on appearance. Once the dressing is added, it is either stirred in by hand or by mechanical agitation.

The second method of creaming is used in conjunction with the automated washing system. Once the curd is washed it is transferred to a creaming tank. The tanks can either be vertical or horizontal depending on the type of mixing agitator. These tanks



The difference between opposite corners is calculated to determine number of parts, or component ratios. In the current example, to obtain 4% fat product, the curd and cream would be mixed at the rate of 6 parts curd and 4 parts cream dressing.

$6 / 4 = 100 / x$

$6x = 400$

$x = 66.7$ kg of 10% fat dressing, needed for 100 kg of dry curd

Proof:

66.7 kg	10% dressing contains	6.67 kg fat
100 kg	0% curd contains	0.00 kg fat
166.7 kg	4% creamed curd contains	6.67 kg fat

Figure 26.1 *Pearson square determination of cottage cheese creaming ratio.*

will be placed on load cells so the exact weight in each can be measured. Once the desired creaming ratio is calculated, the dressing is metered into the creaming tank at the same time the curd is entering. This aids in the mixing of the cream and curd and allows the operator to achieve the exact ratios of curd and cream entering the creamer.

26.2.2.13 Packaging and Shelf-Life. A good package should provide structure, visual appeal, and most importantly, protect its contents against light, oxygen, loss of moisture and aroma, and contamination (Mortensen and others 2004; Zhao 2004). Packaging materials used for fresh cheeses, including cottage cheese, may include polystyrene (PS), polypropylene (PP), polyvinyl chloride (PVC), and polyethylene (PE)/polyamide (PA) combinations, forming oxygen barriers in modified atmosphere packaged products (Mortensen and others 2004; Zhao 2004). However, vacuum-formed PS tubs are now used almost exclusively for packaging of cottage cheese because they protect the cream dressing from fat absorption and breakage (Zhao 2004). The PS tubs can also be pigmented with titanium dioxide, which provides improved light-barrier properties (Zhao 2004). A shrink-film of PP under the outer lid of the cottage cheese is effective as a tamper-evident seal, and also serves as a moisture barrier (Zhao 2004). Vinyl shrink bands are an alternative to the more costly PP seal (Zhao 2004).

Cottage-cheese shelf-life is typically about 21–28 days at 7°C (Chen and Hotchkiss 1991). The greatest enemies limiting shelf-life are microorganisms including coliforms, yeasts, molds, and psychrophiles. Acceptable initial ranges for these microorganisms are 0–10 per gram for coliforms, yeasts and molds, and up to 100 per gram for phychrophiles (Potter 2004). Contamination of cottage cheese with psychrotrophic Gram-negative bacteria such as *Pseudomonas*, *Alcaligenes*, *Proteus*, *Aerobacter*, and *Aeromonas* leads to undesirable flavors and slimy curds (Chen and Hotchkiss 1991). Yeasts and molds (*Geotrichum*, *Penicillium*, *Mucor*, *Alternaria*) cause flavor, textural, and visual spoilage (Chen and Hotchkiss 1991). Sorbate may be added to cottage cheese at a concentration of 0.25% to extend shelf-life by inhibiting yeasts, molds, and some spore-forming microorganisms, but sorbate contributes a bitter off-flavor to cottage cheese.

Some manufacturers may extend the shelf-life to 60 days with carefully controlled packaging conditions (Chen and Hotchkiss 1991). Kosikowski and Brown (1973) flushed the headspace of cottage cheese with CO_2 or N_2 and noted inhibition of yeasts, molds, and psychrotrophic bacteria. However, it was not clear if the benefit was from the gases themselves or simply the removal of O_2. Chen and Hotchkiss (1991) demonstrated that dissolved CO_2 effectively inhibits the growth of Gram-negative bacteria in creamed cottage cheese packaged in high-barrier containers. The authors did not conduct sensory evaluation. Moir and others (1993) inoculated creamed cottage cheese, pH 4.9, with pseudomonads. An atmosphere of 40% (v/v) CO_2 inhibited the growth of pseudomonads by increasing lag times and reducing growth rates. Inhibition by CO_2 was greater at the surface than in the depth of the cheese. The flavor and pH of the cheese were not affected by the CO_2. Later, Maniar and others (1994) demonstrated that cottage cheese packaged in barrier containers under modified atmospheres (100% CO_2, 75% CO_2, 25% N_2, 100% N_2) exhibited no change in psychrotrophic and lactic acid bacteria counts and exhibited satisfactory sensory characteristics after 28 days of storage at 4°C. Cheese flushed with 100% CO_2 received highest sensory scores (Maniar and others 1994). More recently, Mannheim (1996) found that an optimum headspace of about 25% (v/v) in 250 mL packages, flushed with pure CO_2, extended shelf-life of cottage cheese at 8°C by about 150%, without altering sensory properties or yielding any other negative effect. The authors stressed the importance of using high-barrier packaging material in order to maintain the proper CO_2 level in the headspace and cause its dissolution into the product (Mannheim 1996).

26.3 EVALUATION OF COTTAGE CHEESE

High-quality cottage cheese should have a clean, slightly acidic flavor with a slight buttery (diacetyl) aroma and a creamy flavor note. There should be no particular aftertaste and only a sufficiently salty taste to bring out desirable flavor (Bodyfelt and others 1988). Cottage cheese body should be somewhat like cooked chicken breast (meaty), but not overly rubbery or tough when first chewed or pressed by the tongue on the roof of the mouth. The texture should be relatively smooth throughout. The evaluator should be able to see and feel distinct curd particles that are uniform in shape and size. The creamed cheese should be white, and exhibit a moderate gloss or sheen, and the cream dressing should cling to curd particles (Fig. 26.2). Common attributes of cottage cheese, along with descriptions and probable causes for deviation from ideal are included in Tables 26.2, 26.3, and 26.4 and Figures 26.3, 26.4, and 26.5.

Figure 26.2 *Appearance of the creamed cheese.*

TABLE 26.2 Common Flavor Attributes in Cottage Cheese, Identification, and Their Probable Causes (3).

Flavor	Identification	Probable Cause
Bitter	Sometimes perceived as throbbing/piercing Sensation perceived at back of tongue	Poor quality milk Low salt Proteolytic starter culture strains Microbial contaminants Excessive acidity Plant sanitation issues
Cooked	Cooked cottage cheese may have an eggy, charred or caramel aroma or flavor	Over-heating of cream dressing Cottage cheese cream dressing is commonly cooked; not undesirable unless excessive
Feed	Grassy flavor	Feeding of strong flavored feeds Feeding of cattle too close to milking
Fruity/fermented	Sweet–like pineapple, apples or bananas	Certain strains of *L. lactis* Low acidity Low salt level Poor milk quality
Flat/lacks flavor	Lacks flavor and aroma components Lacks diacetyl or creamy flavor Reminiscient of uncreamed curd	Lack of acid production Low fat dressing

(*Continued*)

TABLE 26.2 *Continued.*

Flavor	Identification	Probable Cause
Foreign	Unlike any other off-flavor that might be anticipated in cottage cheese	Chemical sanitizers Unknown contaminant
High acid	Excessive acid taste Unbalanced acid taste	Development of excessive lactic acid Use of too much starter culture Use of high-acid milk Improper whey expulsion from curd Low salt level
High diacetyl	Diacetyl is out of balance May be associated with bitter aftertaste Harsh aroma	Excessive diacetyl production by starters Excessive diacetyl addition to dressing Imbalance among diacetyl and other flavor compounds
High salt	Unbalanced sharp or piercing taste sensation	High salt concentration in cream dressing
Lacks fine flavor	Cottage cheese smells or tastes like yogurt, is harsh, or out of balance	Improper selection of starter cultures Nonstarter lactic acid bacteria contamination
Metallic	Astringent, rusty nail-like flavor	Contamination with copper or other reactive metal
Oxidized	Paperboard/cardboard Burnt hair aroma/ flavor	Use of oxidized milk in cheesemaking Use of oxidized cream in dressing
Rancid	Butyric, caproic, caprylic, capric acids Soapy Baby vomit aroma Romano cheese aroma/flavor	Milk lipase activity Microbial lipase activity (from contaminants) Accidental homogenization of raw milk Late lactation or mastitic milk
Sweet	Sweet taste	Associated with excessive use of stabilizers in dressing
Unclean	Unpleasant off-flavor lingers	Microbial contamination Poor quality off-flavored or old milk/cream Aged cheese
Whey	Combination of acid, bitter, fermented Aftertaste does not linger like unclean	Poor whey expulsion from curd Improper curd washing techniques
Yeasty	Ethanol aroma (bread, beer)	Development of ethanol flavors by yeast Poor packaging procedures

Regional differences do exist in flavor and appearance of cottage cheese within the United States. Historically, the midwest and northwest style of curd will tend be to firmer and have a wetter appearance from the dressing, but east and west coast cottage cheese tends to have a softer curd and drier appearance with a lesser degree of curd identity. As with other cheeses, certain identified defects can be considered attributes depending on consumer preference and tastes.

TABLE 26.3 Common Body and Texture Attributes in Cottage Cheese, Identification, and Their Probable Causes (3).

Body/Texture	Identification	Probable Cause
Firm/rubbery	Resistant to compression by tongue	Over-cooking of curd Excessive acid production Improper dressing formulation
Mealy/grainy	Grainy (like corn meal) breakdown of curd during mastication	Excessive acid production Formation of salt complexes
Overstabilized	Product seems slick Curds slip between teeth Dressing may appear thick	Excessive use of stabilizers in cream dressing
Pasty	Sticky when masticating Gel-like, doughy Often associated with weak/soft	High moisture retained by curd
Weak/soft	Mushy when pressed to roof of mouth	High moisture in cheese Improper cooking of curd Improper dressing formulation

TABLE 26.4 Common Appearance and Color Attributes in Cottage Cheese, Identification, and Their Probable Causes (3).

Body/Texture	Identification	Probable Cause
Free cream	Cream dressing flows away from and does not adhere to curds	Inadequate use of stabilizers Low-solids cream dressing
Free whey	Clear yellow fluid between curd particles and separated from curd	Inadequate washing steps Low-solids cream dressing
Gassy	Excessive gas bubbles	Contamination of cheese with CO_2–forming microorganisms (or gas flush)
Lacks cream	Curd particles appear dry Curd particles lack gloss	Improper creaming ratio Excessive stabilization
Matted	Masses of curd particles are clumped	Improper curd stirring in vat
Shattered curd	High variability in shape and size of curd particles Extremely common attribute	Mechanical breakage of curd particles

26.4 SUMMARY

Cottage cheese is a very delicate and difficult product to make on a consistent basis. To make a high-quality and consistent product, the processing steps reviewed must be adhered to and refined for each manufacturer. It is essential to not only have cheesemakers know the "Hows" of making cottage cheese, but to also understand the "Whys" in the processing steps. As dairy companies continue to consolidate and increase in size and

distribution area, regional varieties of cottage cheese are disappearing. It will be important for dairy companies to establish themselves with quality products in these new markets to maintain and provide growth in cottage cheese sales.

Cheese, in general, refers to conversion of vital milk constituents from fluid to semisolid or solid form. A crucial step in cheesemaking is the coagulation of milk, resulting in curd formation. This facilitates consolidation to the solid form of most proteins and fat along with the important mineral and vitamin fractions of milk. In most cheeses, curd formation is carried out with or without fermentation by application of coagulating enzymes isolated from various biological sources. However, certain cheese varieties do not involve the use of enzymes, and the milk coagulation is triggered by an acid either generated in situ by an added culture or by direct addition to hot milk.

Figure 27.1 shows classifications of acid-coagulated cheeses. They are separated into two types according to the coagulating procedure used. In the first type, coagulation of milk at ambient temperatures is accomplished using lactic acid produced as a result of fermentation with lactic acid bacteria. Cottage cheese, quark, and cream cheese are examples of this first type of acid coagulated cheeses, and are discussed elsewhere in this book.

In the second type (directly acidified cheeses), the curd is formed by direct acidification of hot milk with food-grade acids. In general, the directly acidified cheeses are consumed in fresh or unripened form. More recently, their shelf-life has been extended by sanitary production and packaging practices to fulfill the needs of modern marketing.

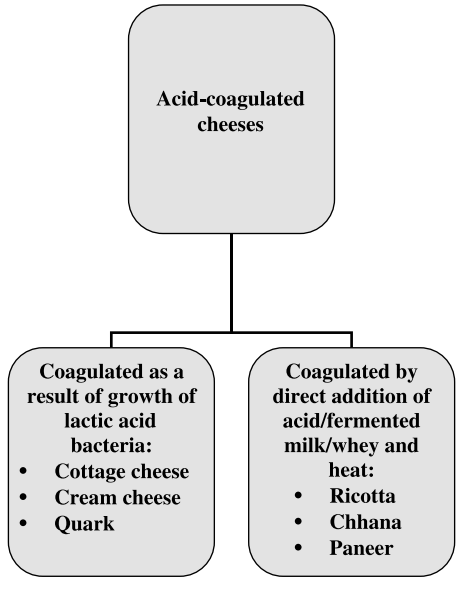

Figure 27.1 *Classifications of acid-coagulated cheeses.*

TABLE 27.1 Cheeses Made by Direct Acidification in Various Regions of the World.

Name	Country/Region	Type of Milk	Coagulants
Armavir	West Caucasus	Sheep	Sour buttermilk
Cecil	Armenia	Cow/sheep	Sour milk
Chhana	India/Bangladesh	Cow/buffalo	Lime/lemon juice/ citric acid/citric whey
Gruau de Montagne	France	Cow (whey)	Vinegar
Hudelziger/mascarpone	Switzerland	Cow (whey)	Vinegar
Kareish	Egypt	Buffalo/cow	Sour milk
Kesong Puti	Philippines	Buffalo	Vinegar
Paneer	India/Pakistan	Buffalo/cow	Citric acid/vinegar/ lime juice

Requeijao	Brazil	Cow	Sour milk
Ricotta	Italy	Cow (whey–milk blend)	Vinegar
Ziger/schottenziger	Germany, Yugoslavia	Cow (whey)	Vinegar

White, unripened cheeses derived from milk coagulation with acid under sub-boiling temperatures are known by various names in different parts of the world (Table 27.1). In spite of wide differences in their manufacturing processes, these cheeses belong to the same group. They are made from whole milk, low-fat milk, skim milk, cream, whey, or their mixtures. Milk of various species of animals may even be utilized in production of these cheeses. Depending upon its origin, curdling of hot milk may be carried out with vinegar, lactic acid, calcium lactate, lime/lemon juice, acid whey, or yogurt/fermented milk. A direct acidification procedure using citric or acetic acid has been successfully applied to produce mozzarella and pizza cheese. Table 27.2 gives approximate chemical compositions of acid-coagulated cheeses.

Cheese varieties from directly acidified milk provide a substantial proportion of the required human intake of energy and protein, and significant amounts of essential nutrients

TABLE 27.2 Approximate Composition of Directly Acidified Cheese Varieties in Comparison with Cheddar Cheese.

Cheese	pH	% Moisture	% Fat	% Protein	% Lactose	% Ash	% Salt
Ricotta (whole milk)	5.8	72	13	11	2.9	1.0	0.5 max
Ricotta (part skim milk)	5.8	74	8	12	3.2	1.1	0.5 max

such as calcium, riboflavin, magnesium, and vitamin B_{12}. High in protein and minerals but low in lactose, these cheeses offer many nutritional advantages including balancing a protein-deficient diet. As consumers are familiar with their flavor and textural attributes, no cultural barrier exists to develop or modify dietary patterns by incorporating these cheeses.

From the standpoint of commercial significance, ricotta, chhana, paneer, and Latin American white (LAW) cheeses will be discussed in this article.

27.1 RICOTTA CHEESE

Like cottage cheese, ricotta cheese is a high-moisture cheese. Ricotta is not a pressed curd type of cheese. Its composition varies depending on whether it is made exclusively from whey or from a blend of whey and milk. Originally, ricotta was produced from whey derived from mozzarella or provolone cheese production. Ricotta is now prepared from whole milk with or without addition of whey. When made from a blend of 95% sweet whey and 5% milk, ricotta contains 68–73% moisture, 16% protein, 4–10% fat, and 4% lactose.

Ricotta has a bland to slightly cooked but pleasing flavor. Its texture is soft and creamy. It is consumed as such as a spread and may be used as a replacement for cream cheese or sour cream in dips. It is basically a nonmelting cheese. Its major use is in cooking of Italian cuisine (for example, lasagna and ravioli) and confectionery.

27.1.1 Manufacturing Procedure

Most of the ricotta production is confined to a batch process. Traditionally, open kettles are used. Heating may be direct or steam jackets may provide heat transfer. Sweet whey from Italian cheese manufacture is suitable as long as its pH is 6.2 or higher. It is common to blend 10–25% milk to neutralize acid in the whey, enhance yield and curd cohesiveness. The mixture is heated in a kettle to 82–93°C, followed by the addition of a food-grade acid such as lactic, acetic, or citric acids in quantity enough to drop the pH of the mixture to 5.9–6.1. In some plants, cultured milk/whey may be used as a source of lactic acid. This pH range is crucial to maintain the sweet flavor of the cheese. As a result of heat and acidity, the proteins denature and the foam-type curd ascends to the surface. The mixture is held for 15–20 min, after which the curd is dipped with a perforated ladle and collected in a muslin bag. The bag is allowed to drip and cool in a cold room. Alternatively, the curd is drained in perforated stainless hoops and allowed to dry. The curd is soft, fragile, and grainy, and may be pressed slightly to achieve cohesiveness. The yield of ricotta is low, around 5–6%, if no milk is mixed with whey. Mechanized production for continuous manufacture of ricotta cheese involves adjustment of the pH of the whey-milk mixture to 6.9–7.1 with caustic soda, heating the blend to 88–92°C, and injecting an appropriate quantity of salt and acid in-line. Again, the target pH is 5.3–5.5. The hot acidified whey-milk blend is pumped into the bottom of a V-shaped vat and the resulting curd is mechanically collected from the top of the vat into a nylon mesh for the curd to drain. It is transferred to perforated hoops, cooled, and hot packaged for sale.

The ricottone cheese process is similar to that for ricotta, where sweet whey is blended with whole milk, skim milk, or buttermilk. The pH of the blend is adjusted to 6.1–6.2 with a starter culture or edible acid. Ricottone curd is pressed and dried for 4 weeks at 21°C to obtain dry ricotta cheese, a grating type of product.

Another variant of ricotta is mascarpone, which is made from cream (25–35% fat) by direct addition of citric or acetic acid to pH 5.0. Following drainage of whey in bags made of cloth, the cheese may be slightly salted, whipped, and formed into a cylindrical shape. Mascarpone has a creamier texture and richer flavor in comparison to ricotta. Unsalted mascarpone is used in the preparation of cakes and desserts like tiramisu.

Impastata is a starting material for pastry. It is made in a similar way to ricotta, but the curds are allowed to sink to the bottom by gentle stirring. The hot curd is drier than ricotta cheese. It is then ground into smooth dough-like material for use in confectionery.

The application of ultrafiltration technology to ricotta cheese has resulted in process improvements.

27.2 CHHANA

Chhana is a ricotta-like product in India, which is obtained from hot milk by direct acidification. According to the Indian Pure Foods Act, chhana is defined as a product obtained from cow or buffalo milk or a combination thereof by precipitation with sour milk, lactic acid, or citric acid; it should contain not more than 70% moisture, and the milk fat content should not be less then 50% of the dry matter. Skim milk chhana is the product obtained from cow or buffalo skim milk by precipitation with sour milk, lactic acid, or citric acid; it should not contain more than 70% moisture, and the milk fat content of the product should not exceed 13.0% of the dry matter.

27.2.1 Manufacturing Procedure

Production of Chhana essentially involves precipitation of casein along with fat and entrapped water-soluble components of milk (lactose, whey proteins, minerals, vitamins) by the addition of an acidulant to milk at near-boiling temperatures followed by removal of whey from the curd. Chhana is made by a batch process, but a continuous process may be adapted from the continuous process for ricotta, as described above. Figure 27.2 illustrates the sequence of steps in the manufacture of chhana. The figure also shows the relationship between chhana, paneer, and LAW cheese.

The texture of chhana varies from smooth and pasty to crumbly. It is an intermediate starting material for the preparation of indigenous Indian dairy desserts and confectionery products. The preferred milk for channa-making is cow's milk. In chhana-making, pressing of the curd is restricted to that obtained by gravity after draining of the whey in a cheesecloth/muslin bag. Longer draining time gives a hard product. Depending on its end use, chhana may be soft or hard. For example, for the confection rasogolla, soft chhana is needed, but the confection sandesh requires the hard variety. These two confections utilize the majority of chhana production, and optimum functionality is required in each case.

Chhana, like ricotta is made in kettles. Cow milk is brought to near boiling and an appropriate acidulant is quickly added to hot milk to bring the pH of the mixture to 5.4. The curd settles to the bottom and whey is removed by filtration through a strainer lined with cheesecloth. The curd is cooled in running tap water. Chhana is then utilized to make sweetmeats and other Indian confections. The coagulants used are lime or lemon juice, vinegar, citric acid, lactic acid, fermented milk, and whey. A solution of citric acid (0.5–1.5%) or lactic acid (1–2%) is appropriate to lower the pH of hot milk

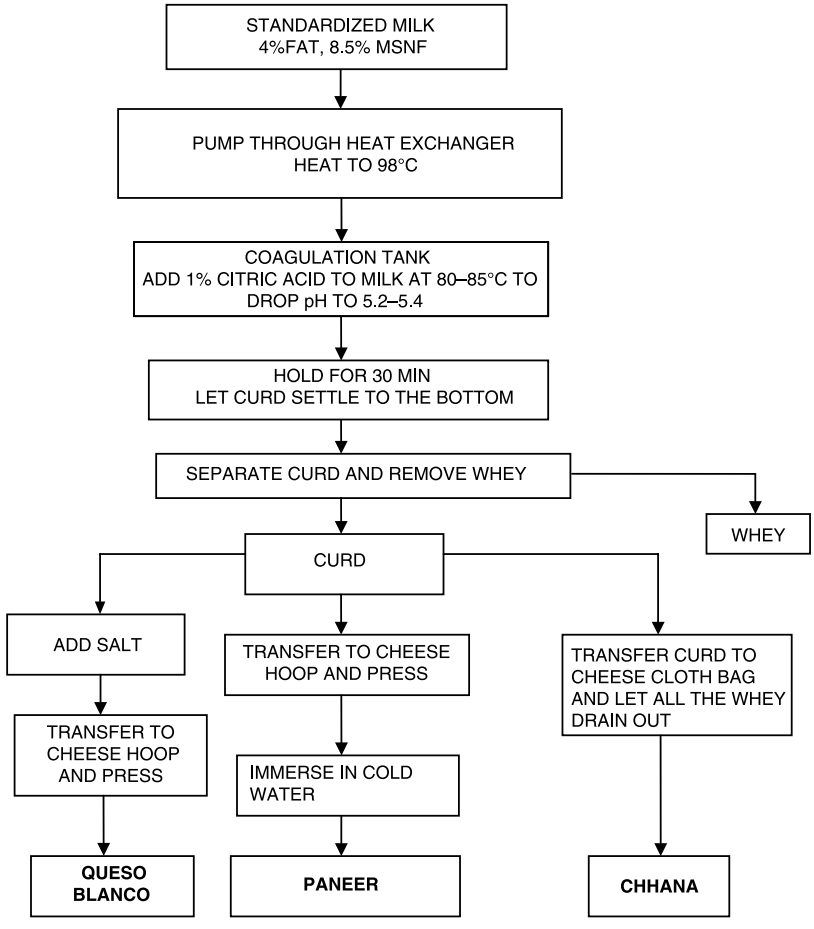

Figure 27.2 *Steps in the manufacture of chhana, paneer, and queso blanco.*

to 5.4. An interaction between the temperature of coagulation and final pH is observed in terms of obtaining the best yield and quality of chhana. For cow milk a temperature of 80°C at pH 5.4 is optimum, but for buffalo milk, 70°C at pH 5.7 is desirable. A higher coagulation temperature imparts graininess and hardness to the texture, and lower temperatures result in sticky chhana, which drains significantly slowly. Chhana is an extremely perishable food product, and at ambient temperatures, its quality deteriorates within a day or two. Therefore, soon after production, it must be used. Under refrigeration, the shelf-life is extended to six days. Two important confections based on chhana or rasogolla and sandesh.

27.2.2 Rasogolla

Rasogolla is a soft, succulent ball of chhana soaked, stored, and served in sugar syrup. Snow-white in color, it possesses a spongy, chewy body, and smooth texture. The Bureau of Indian Standards has laid down the standards for rasogolla, as shown in (Table 27.3). Its variations include rasmalai, and rajbhog. Rasogolla is prepared by

TABLE 27.3 Standard Specifications for Rasogolla.

Characteristics	
Moisture	45–55%
Milk fat	5%
Sucrose	45%
Protein	5%
Requirements for Syrup	
Acidity of syrup (mL of N/10 NaOH required to neutralize 100 mL of the syrup) (maximum)	6.0
Concentration of syrup (maximum)	55° Brix
Bacterial count, per gram (maximum)	500
Coliform count, per gram	Nil

texturization of milk protein under controlled cooking conditions in boiling syrup. This gives rasogolla an interwoven fiber-like structure. The controlled cooking in sugar syrup imparts spongy characteristics to rasogolla balls and improves their sugar-holding capacity. The unique spongy characteristic of rasogolla is typical for this dairy confection.

Rasogolla is prepared from soft, freshly made chhana, which is first manually kneaded to a smooth paste (Fig. 27.3). The paste is then portioned and rolled between palms to form balls of about 15 mm in diameter and around 10 g in weight. Each ball should have a smooth surface with no cracks. In some cases, chhana needs to be modified by mixing it with 6% arrowroot, 2% semolina, and 0.6% baking powder (of the chhana weight), and subsequently kneaded manually to a smooth paste. One kilogram of chhana typically yields 90–100 rasogollas.

27.2.2.1 Cooking Medium. For preparation of the cooking medium, three parts sugar are mixed with one part whey and two parts water. The pH is adjusted to about 6.8 with the addition of calcium hydroxide. The solution is boiled, and the scum that forms on the top is scooped off before it is subjected to further cooking. rasogolla balls are dipped in the cooking medium. The heating of the syrup is regulated to preserve the round form from cracking. The balls are cooked for about 15 min. During cooking, a small amount of water and whey solution is continuously added. This makes up for the loss of water due to evaporation. The ratio of whey and water is adjusted to maintain the pH of the medium at around 6.8 during cooking. After cooking, the balls are transferred to a container containing water at 30–35°C for stabilization of their texture and improvement of color. About 10% of the cooking solution is replaced by fresh sugar solution for the next batch of rasogollas.

27.2.2.2 Sugar Syrup. After 5–10 min of texture stabilization in water, the balls are transferred to sugar syrup. The desired sugar syrup concentration in the final product is 45–50%. This is achieved by dipping the texture-stabilized balls first in 50–60% sugar syrup for 1–2 h, followed by a second dipping in 40–50% sugar syrup. Finally, the

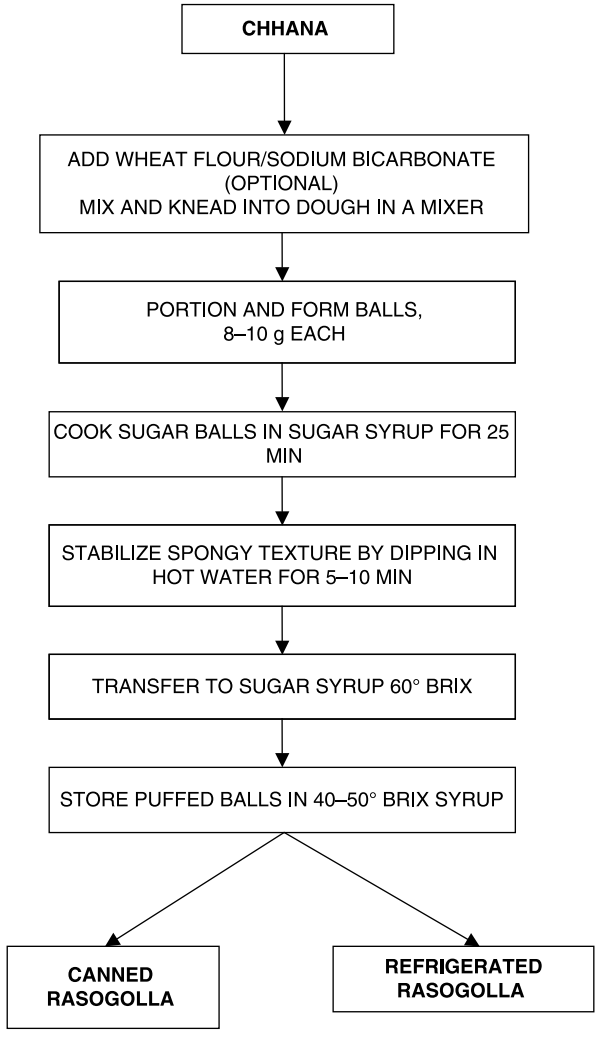

Figure 27.3 *Steps in the manufacture of rasogolla from chhana.*

product acquires the desired sugar concentration after equilibrium is reached between the sugar syrup inside the balls and outside them. To exercise better control over the sugar syrup concentration in the finished product, dipping of the texturized balls may be done in three stages. In the first stage, dipping is in a 60% sugar level, followed by second-stage dipping at 40% concentration, and final dipping at 50% concentration. Rasogollas are stored at or below 10°C to obtain a more precise sugar concentration of 45–50%.

27.2.2.3 Yield. The yield of finished rasagolla (drained) is 254 g/100 g chhana. Typically, about 90–100 rasagollas of diameter 30 mm can be made from 1 kg of chhana.

27.2.2.4 Packaging. Rasogollas are usually packaged in lacquered tin cans of 1 kg capacity, containing approximately 14 pieces. The empty containers are first sterilized

with hot air inside a closed chamber. Rasogolla balls with hot sugar syrup and permissible preservatives are filled in containers, followed by seaming, which tightly seals the lid. Sodium metabisulfite is used to maintain the white color of canned rasogollas. Containers are kept in a tub containing chilled water to create a partial vacuum by quick condensation of vapors inside the container. The shelf-life of rasogollas in tin containers is around six months.

27.2.2.5 Rasmalai. Rasmalai consists of flattened chhana patties floating in concentrated sweet milk. It has a delicate chewy/spongy texture. Chhana is kneaded into a smooth dough along with 1–4% wheat flour. The dough is portioned and rolled into balls having a smooth texture without cracks. The round balls are then flattened into patties and are processed like rasogolla. They are subsequently stored in sweetened (5–6% sugar) milk condensed to one-fourth of its volume. In many cases, milk is blended with cream.

27.2.2.6 Rajbhog. Rajbhog is also a variety of rasogolla, but is larger in size than rasogolla (about 50–60 mm in diameter). Compared to rasogolla, rajbhog balls are almost twice as large. Rajbhog is blended with saffron, which imparts an attractive golden yellow shade to it. Chhana is kneaded into a uniform dough, mixed with a small amount of saffron, and portioned and shaped into balls with hands. While shaping, a raisin or a nut is placed at the center of the ball. The balls are cooked in a 50% solution of boiling sugar syrup. Cooking is continued until a desirable body and texture is achieved. Thereafter, the balls are removed from the syrup and may be wrapped in silver foil.

27.2.3 Sandesh

Sandesh is known for its palatability, aroma, and bar-like shape. It has a firm body and smooth texture. It is a rich source of milk proteins, fat, sucrose, and fat-soluble vitamins. Three distinct varieties of sandesh are popular: soft grade (*naram-pak*), hard grade (*kara-pak*), and raw grade (*kachagolla*). The most common variety is the soft-grade sandesh. It has a soft body and smooth texture with fine grains uniformly distributed. It contains a relatively smaller amount of sugar and has higher moisture content than the hard-grade variety. *Kara-pak* has a firm body and dry appearance. Kachagolla is known for its raw chhana-like flavor, moist appearance, soft body, and coarse, grainy texture.

The production process for soft-grade sandesh is described in Figure 27.4. Chhana (30–45%) and sugar are mixed and kneaded together and heated in a shallow vessel after addition of color and flavor. The chemical profiles of commercial samples of three types of sandesh are listed in Table 27.4.

Some attempts have been made to apply extrusion technology to the manufacture of sandesh. A vented extruder with vent ports in the barrel for the volatiles and moisture to escape during the continuous process is feasible. A screw-type kneader can be used for mixing chhana and sugar to achieve the homogeneity of mixture critical for sandesh manufacture. Sandesh produced by this continuous production method has been shown to be superior in quality in comparison to the market product (Agarwal 1996). The shelf-life of sandesh produced in this process and packed in polyethylene bags was 16 days at $10 \pm 5^{\circ}C$.

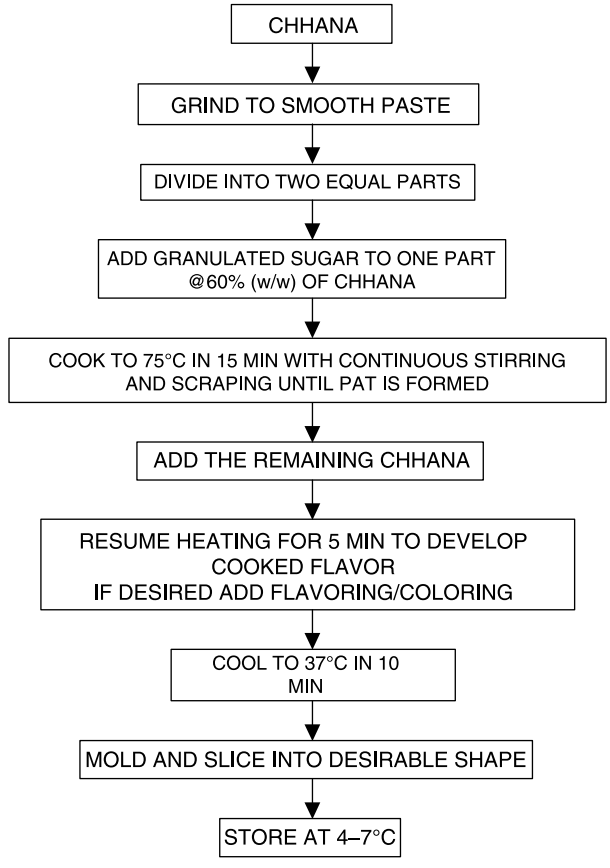

Figure 27.4 *Production process for soft–grade sandesh.*

TABLE 27.4 Physico-Chemical Attributes of Market Samples of Sandesh (Average Values Based On Market Survey).

Attribute	Soft Grade (30 samples)	Hard Grade (15 samples)	Kachagolla (15 samples)
Moisture (%)	24.1	13.4	33.9
Fat (%)	18.7	20.5	15.5
Protein (%)	16.1	16.7	12.8
Sucrose (%)	38.6	46.4	35.8
Ash (%)	1.7	1.7	1.4
Titratable acidity (% LA)*	0.88	0.82	0.7
Water-soluble acidity (% LA)*	0.35	0.22	0.19
FFA (% OA)**	0.41	0.34	0.46
Free fat (% of total fat)	68.6	80.8	56.9
Hardness (kg)	4.7	–	–
Cohesiveness	0.21	–	–
Springiness	0.30	–	–
Gumminess	1.0	–	–

*Expressed as % lactic acid.
**Expressed as % oleic acid.

27.3 PANEER

Paneer is also an acid-coagulated product of hot milk. It resembles chhana in its manufacturing procedures, but differs in that it is lightly pressed into blocks. It resembles tofu in appearance and texture, but possesses a distinct flavor of its own. Paneer is an integral part of Indian culinary preparations. Paneer offers outstanding nonmelt functionality because of its ability to withstand cooking and frying temperatures. This unique characteristic permits its use in Indian cuisine. Paneer lends itself to the preparation of fried cheese snacks. The Pure Foods Act of India requires paneer to have not more than 70% moisture and not less than 50% fat on a dry matter basis. Skim milk paneer should contain not more than 70% moisture and not more than 13% fat on a dry matter basis.

27.3.1 Manufacturing Procedure

Paneer is typically made from buffalo milk in South Asia. It is also manufactured on an industrial scale in the UK, Holland, Canada, and the United States, using cow's milk. Paneer is obtained through heat/acid coagulation of casein component of standardized milk, entrapping through various interactions almost all the fat, part of the denatured whey proteins, and colloidal salts as well as a part of the soluble milk solids (in proportion to the moisture content retained). The typical chemical composition of paneer is: 53–55% moisture, 23–26% fat, 17–18% protein, 2.0–2.5% lactose, and 1.5–2.0% minerals. Paneer is marble white in appearance with a slight spongy-body and close-knit texture. It possesses a mild sweetish-acidic nutty flavor.

The paneer production process is illustrated in Figure 27.2, and shows that blocks of paneer are obtained by pressing chhana in molds/hoops. Various steps for paneer production are discussed in the following.

27.3.1.1 Milk Standardization. The milk used for making paneer should be standardized to a fat/solids-not-fat (SNF) ratio of 1 : 1.65 in order to achieve a minimum of 50% fat in dry matter (FDM) in the finished product. To achieve this standard, the starting milk must have a minimum of 5.8% milk fat. In India, buffalo milk or blended milk is the preferred milk because it provides higher fat (6%) and SNF (9.5%) contents as compared to cow's milk. In the West, the quality of paneer made from cow's milk is quite acceptable. Cow's milk is normally blended with 0.1% calcium chloride to ensure a good yield. High-quality paneer with 42% fat (FDM) can be obtained from milk composed of 3.5% fat and 8.5% SNF. It has a soft meaty texture and a pleasant, creamy flavor. Low-fat paneer is also available, which contains fat in the range of 24% FDM. Although skim-milk paneer containing 13% FDM is feasible, the product has a chewy, rubbery and hard body.

27.3.1.2 Heat Treatment. In a typical plant, milk standardized to 5.8–6.0% fat (9.5% SNF) is heated in a plate heat exchanger from 4°C to 85–90°C and pumped into a water/steam jacketed cheese vat and allowed to cool to 70–75°C in about 10 min prior to acid blending.

27.3.1.3 Curd Formation. Industrial processes utilize citric acid as the coagulant of choice. Glacial acetic acid is also used by some manufacturers. The type and concentration of the acid and the mode of delivery and blending into the hot milk directly influence product yield and moisture retention.

Citric acid is generally used in a 1–2% solution. The preferred concentration is 1% citric acid in the coagulant, which is warmed to 70°C. Sufficient acid is gently but quickly blended with the milk (within 1 min) to drop the pH to 5.3–5.4. Normally it requires about 1.8–2.0 g of citric acid to coagulate 1 kg of milk. At this point, clear greenish-yellow whey separates out, allowing the curd to sink to the bottom.

Coagulation temperature influences the moisture content of paneer. An increase in temperature from 60 to 90°C decreases moisture in the paneer from 59 to 49%. Paneer obtained at a coagulation temperature of 70°C has the best organoleptic quality as well as the most desirable frying quality in terms of shape retention, softness, and integrity maintenance. Variation in pH of coagulation has a profound effect on processing and quality parameters. For example, the moisture content of paneer increases from 50 to 59% and the yield increases from 21 to 25% when the coagulation pH is increased from 5.1 to 5.4. Sensory quality is judged as best at pH 5.30–5.35, the recommended pH for coagulation.

27.3.1.4 Whey Drainage. The coagulated milk is allowed to separate into curd and clear whey. After 10 min, practically all the curd chunks sink to the bottom. At this point, a strainer is fitted into the outlet of the cheese vat. The whey drainage valve is then opened, and the whey flows into a surge tank partitioned by a strainer to retain any curd fines escaping from the cheese vat. Hot whey accumulates in the second section of the surge tank from where it is pumped out, cooled to 4°C, and stored in a whey tank for further processing or disposal.

27.3.1.5 Hooping. Normally, the curd is transferred to hoops lined with cheesecloth. The hoops have perforations on all sides to facilitate whey expulsion. Hoops may vary in size from 2 to 10 kg in capacity. For culinary purposes, unsalted paneer is traditionally used. Prior to placing the lid on the hoop and applying pressure, extra curd is added to facilitate block formation of paneer.

27.3.1.6 Pressing. The hoops are pressed using a hydraulic press to exert a low pressure (6.9–13.8 kPa) onto the curd. The pressing time is generally around 10–15 min after which the wrapped blocks of paneer are ejected from the hoop for quick cooling. Moisture content, shear strength, and porosity of paneer are a function of the pressing conditions. For optimum sensory quality, pressing paneer blocks at 9.8 kPa is recommended.

27.3.1.7 Cooling. The cooling of the wrapped blocks is effected by immersion in cold water (4°C) containing 3–5 ppm chlorine for 1–2 h. During dipping, paneer blocks absorb enough water to develop the typical body and texture. Another objective of dipping in cold water is to cool the blocks to less than 20°C, which facilitates handling during cutting and wrapping for retail sale. The blocks are then mechanically cut into convenient retail sizes (200 g or 500 g), and packaged into pouches made up of appropriate packaging film to maintain paneer safety and integrity during distribution and retailing.

27.3.1.8 Packaging. Various packaging materials used by manufacturers of paneer include coextruded laminates of moisture-barrier and oxygen-barrier films, polyethylene sachets, or heat-induced-shrink film. Paneer must be protected from drying out and exposure to oxygen (air) during storage. The product packaged in moisture-barrier film pouches, followed by vacuum application and heat-sealing, provides a shelf-life of over

6 months of refrigerated storage. Quick-freezing extends the shelf-life. For distribution over long distances and storage for extended periods of time, it is advantageous to freeze paneer packages.

27.3.1.9 Yield. The yield of paneer is dependent on the fat and SNF content of the starting milk, as well as on the moisture, fat, and protein retained in the paneer. A yield of 21–23 kg of paneer containing 51–54% moisture per 100 kg of buffalo milk has been achieved. This yield corresponds to a 63–67% milk solids recovery in the paneer. With cow's milk, paneer yield is around 17–18%. By the application of membrane technology (ultrafiltration), the paneer process has been improved.

27.3.1.10 Defects. Many defects in the flavor and texture quality of paneer can be traced back to the microbiological and organoleptic attributes of the starting milk. Table 27.5 shows some commonly found defects in paneer and also methods to prevent them.

27.3.1.11 Physico-Chemical Changes During Paneer Manufacture. The coagulation process in paneer manufacture occurs because of the chemical and physical changes in casein brought about by combined heat and acid treatment. This treatment leads to formation of large structural aggregates of casein from the normal colloidal dispersion of discrete casein micelles in which milk fat and coagulated serum proteins are entrapped together with whey. During formation of coagulum, major changes include the progressive removal of tricalcium phosphate from the surface of the casein and its conversion into monocalcium phosphate. Further, calcium is progressively removed from calcium hydrogen caseinate to form the soluble calcium salt and free casein.

TABLE 27.5 Defects Observed in Paneer and Measures for Their Prevention.

Defects	Preventive Measures
	Flavor
Sour	Use fresh milk having no developed acidity. Follow recommended coagulating acid concentration, temperature, and volume parameters
Oxidized/rancid	Store paneer at 4°C to avoid hydrolysis/oxidation of milk fat
Stale/foreign	Store paneer at 4°C to control microbial growth
	Body and Texture
Coarse texture	Use fresh milk. Standardize fat : SNF ratio to 1 : 1.65 Standardize coagulation temperature (70°C and pH 5.3)
Hard body	Optimize fat in milk (5–6%) Standardize coagulation, heating, and cooling conditions during manufacture
	Appearance
Dry surface	Optimize fat content of milk
Surface hardening	Avoid surface drying during manufacture Package in better moisture–barrier packaging material
Unclean	Insist on sanitary practices and use good-quality milk
Brown coloration/spots	Avoid overhead surfaces of equipment

27.3.1.12 Microstructure of Paneer. The manufacturing process and milk components, such as casein micelles, whey proteins, fat globules, lactose, and minerals, determine the texture and microstructure of paneer. Microstructure also influences some physical properties of the product such as firmness, elasticity, susceptibility to syneresis, and mouth feel. For studying the microstructure of dairy products, scanning electron microscopy (SEM) has proved to be a very useful tool, especially in tandem with other electron microscope techniques.

In paneer, the building units, namely casein micelles, are several times larger than in the starting milk. The casein micelle swells from 100 to 300 nm as a result of heat treatment to the milk. Gels prepared by coagulating the hot milk with citric acid possess a coarser structure than heat-induced milk gels. The most significant character of the gels obtained by coagulating milk heated to 90°C at pH 5.5 is the formation of a unique structure form the casein particles. Development of such a core-and-lining structure depends on the temperature at which the milk is coagulated and the final pH value.

Cow-milk paneer resembles American cottage cheese in microstructure, with a uniform density of small protein particles. In contrast, buffalo-milk paneer has more densely packed and fused protein particles. Intact fat globules with casein particles attached to the fat globule membranes are frequently seen in unfried fresh paneer. Frying in vegetable oil has a massive impact on the paneer structure. The SEM shows that compaction severely suppresses or even destroys the granularity of the protein matrix observed in unfried fresh paneer. Apart from the solid compaction of core-and-lining structure resulting from frying, the presence of deviated core-and-lining structures can also be seen at higher magnifications. Cooking in salt water restores both the granular structure and the core-and-lining structure of the protein particles.

27.4 LATIN AMERICAN WHITE CHEESES

Latin American white (LAW) or Hispanic cheeses (Queso Blanco) are found throughout Mexico, Central and South America, and the Caribbean Islands. They are known by various names (Table 27.6). These cheeses are made from whole milk, skim milk, cream, or their mixture. The use of coagulating agents varies with the type of cheese. The production process involves rennet coagulation of warm milk or curdling of hot milk with lime/lemon juice, fruit juice, or vinegar. Directly acidified cheeses include *queso del pais*, *queso de la tierra*, *queso de cincho*, and *queso sierra*. Cheeses obtained by rennet coagulation include *queso fresca*, *queso de prensa*, *queso de puna*, *queso de hoja*, *queso de matera*, and *queso pasteurizado*. They are all highly salted (salt level 2–4%) to improve their shelf-life. Generally, Hispanic cheeses are white, creamy in taste, highly salted, and acidic in flavor. They possess the body and texture of young, high-moisture cheddar and can be sliced for sandwich use.

By flavoring the LAW cheese curd with onion, garlic, caraway seeds, or hot pepper spices, an array of varieties of flavored Hispanic cheeses can be marketed. These can be used as a snack in salads, as cooking cheese in casserole dishes, grated for use in pizza and other foods, or included as an ingredient in the manufacture of processed cheese. For producing process cheese with LAW cheese (renneted), the formulation involves 2.05 kg of ground LAW cheese, 113.5 g butter, 178.8 g water, and 56.8 g disodium phosphate emulsifier. These ingredients are cooked in a steam-jacketed kettle to 70°C for 4 min. After holding for 1 min, the mixture is cooled in polyethylene-lined

TABLE 27.6 Origin and Nomenclature of Some Latin American White Cheeses.

Name	Country of Origin
Fresh Skim-Milk Cheeses	
Queso de Puna	Puerto Rico
Queso Fresco	El Salvador and Venezuela
Queso Llanero	Venezuela
Queso de Maracay	Venezuela
Queso Descremado	Costa Rica and Queso Huloso
Whole Milk/Part-Skim-Milk Cheeses	
Panela	Mexico
Queso de Prensa	El Salvador and Venezuela
Queso del Pais	Puerto Rico
Queso de la Tierra	Puerto Rico
Queso de Estera	Colombia
Queso de Crema	Panama
Grating	
Queso de Bagaces	Costa Rica

boxes. The inclusion of aged cheddar cheese for flavor gives a very desirable processed cheese. Such LAW cheese is largely consumed fresh, but can be fried with or without butter to prepare nutritious snacks of excellent eating quality. The pressed cheese is hard and crumbly, with a slightly open texture. To improve flavor, starter cultures or lipases may be incorporated prior to salting. In the treated cheese the pH drops during storage. Also, several volatile flavor compounds are generated. Consequently, the treatment leads to the development of a cheddar-like cheese flavor.

27.4.1 Manufacturing Procedure

LAW cheeses are made on farms as well as in industrial plants. The farm product is soft or semisoft cheese and is called *queso de matera* in Venezuela. The industrial product is relatively soft and is called *queso pasteurizado*. The farm cheese is made from raw milk and is highly salted (8–25% salt on wet basis). Consequently, it acquires a drier body than the industrial product. Transportation time from farm to consumer varies from days to weeks and may result in some ripening changes. In the farm cheese production, direct acidification and rennet coagulation are interchangeably used for curd formation. *Queso enchilado* is based on renneted cheese curd, which, after pressing as a 12-kg block and holding for 10 days, is immersed in chili sauce to give it a spicy, hot taste. *Queso oaxaca* is a soft cheese resembling mozzarella. Pasteurized milk, starter, and rennet are its basic materials. The curd is cooked at 39°C at a pH of 5.2. Dry salting to a level of 4–5% salt follows stretching of the curd by hand in hot water. While hot, the curd may be molded into various forms, including braided shapes; it is then cooled and packaged in plastic pouches. The methodology for LAW cheese manufacture differs in the many manufacturing countries. Variations in procedures on the farm and in industrial plants are common. A typical manufacturing procedure for LAW cheeses is shown in

Figure 27.2. The procedure is similar to paneer manufacture, except the addition of salt to the LAW cheese curd. It also differs from paneer in that the blocks of pressed cheese are not immersed in cold water.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

28.1 INTRODUCTION

Throughout history, milk products have been important elements of human nutrition in many parts of the world. Unfortunately, fresh dairy products like milk spoil relatively easily because microorganisms thrive well on them. Several obvious routes can be used to improve the keepability of these products:

- Acidification through fermentation (e.g., in yoghurt),
- Decreasing the water activity (e.g., in hard cheese),
- Pasteurization or sterilization, and
- Appropriate packing of the finished product (Shephard 2000).

These preservation techniques have been identified in many different cultures all over the world, and their implementation has resulted in a wide range of similar but slightly different local dairy products. In this chapter we will focus on acidified cheeses. Well-known examples of such products are cream cheese, cottage cheese, fromage frais, and full-fat quark (Guinee and others 1993).

The purpose of this chapter is to provide an overview on structure formation in cream-cheese-type products, which can be grouped under acidified milk protein-stabilized emulsion gels, with an emphasis on the emulsion aspects of such systems. As such, this chapter is complementary to the excellent review published earlier by Guinee and others (1993), which emphasized protein structuring in these products.

To produce a protein-stabilized emulsion gel, a fat phase has to be emulsified, for example, via homogenization, in a continuous phase. Furthermore, the emulsion has to be structured to achieve the required textural properties. Combined gelling of the continuous phase and crystallization of the dispersed phase achieve structuring of protein-stabilized emulsion gels. The firm, crystallized fat droplets will reinforce the emulsion gel by adhering to the continuous phase by means of interfacial protein.

After a brief introduction on milk proteins and emulsions, structure formation (protein denaturation, heat- and acid-induced gelling, fat crystallization, [partial] coalescence) will be reviewed in the context of cream-cheese processing (separation, heating, emulsification, acidification). The role of both dispersed and continuous phases on properties will be discussed, with emphasis on those aspects that are important in relation to cream-cheese texture (firmness, syneresis, spreadability, emulsion stability during temperature cycling) and taste.

28.2 BUILDING STRUCTURE: GELLED O/W EMULSIONS OR THE SCIENCE BEHIND CREAM CHEESE

28.2.1 Ingredients

Full-fat milk consists of water, milk protein, butterfat, lactose, colloidal calcium phosphate, and some minor components (Walstra and Jenness 1984). For industrial application, full-fat milk is often fractionated in protein-rich and fat-rich preparations, each of which can serve as the basis for further products.

Proteins in milk can be classified mainly in two groups: casein and whey protein. Casein is present in milk in the form of small protein aggregates, called casein micelles,

typically of 50–300 nm diameter. Each micelle consists of a mixture of α-, β- and κ-caseins, all proteins with relatively little secondary or tertiary structure. Various models exist for the structure of these micelles, but currently the most explanatory appears to be the version where α-casein forms the structural backbone of the micelle (linked via either direct protein–protein interactions or Ca-bridged interactions), supplemented by β-casein and colloidal calcium phosphate, and where most of the κ-casein can be found at the surface of the micelle (Horne 1998; Mellema and others 1999). The protein κ-casein is a block-polymer-like protein consisting of a relatively hydrophobic part and a relatively hydrophilic part. The hydrophobic part anchors itself in the micelle, whereas the hydrophilic part (known as the casein macropeptide, CMP, or as the glycomacropeptide, GMP, if glycosylated) acts more or less as a salted polyelectrolyte polymer brush (de Kruif and Zhulina 1996; Tuinier and de Kruif 2002). This brush stabilizes the micelles against aggregation because the charged carboxylic acid groups in the hydrophilic part of the κ-casein repel each other weakly. The stabilization is retained as long as the κ-casein remains negatively charged.

For unheated milk, the globular whey protein is in its native form and does not contribute to the aggregation behavior of the milk. Whey protein is a mixture of β-lactoglobulin (∼65%), α-lactalbumin (∼25%), and serum albumin (∼8%), which are soluble in their native forms, independent of pH. Prolonged heat treatment at sufficiently high temperatures and long duration will denature (i.e., partly unfold) the whey protein, triggering hydrophobic interactions with other proteins and interfaces, and the formation of disulfide links between whey proteins and between whey proteins and micelles. Depending on the conditions (e.g., pH) under which this heat treatment is applied, the whey protein may form separate aggregates or cover the casein micelles (Creamer and others 1978; Heertje and Pâques 1995). Such heat treatments change the pH below which milk gel formation occurs (Vasbinder and others 2001). A number of physical properties of milk proteins are summarized in Table 28.1.

Butterfat is composed of a mixture of triacylglycerols (TAGs, or triglycerides) referred to as fats and oils. The liquid phase is called the olein fraction, and does not contain any crystallized TAGs at ambient temperature. The crystalline fraction is called the stearin fraction. The amount of crystalline fat ("solid fat content" or SFC) as a function of

TABLE 28.1 Some Physical Properties of Individual Milk Proteins: Concentration by Weight in Milk Protein, Isoelectric Point *p*I, Molecular Weight M_w, and Calcium Binding Activity.

Concentration	(%)	*p*I	M_w	Calcium Binding
		Casein		
α_{S1}-casein	31	4.2–4.6	23,614	++
α_{S2}-casein	8		25,230	++
β-casein	28	4.6–5.1	23,983	+
κ-casein	10	5.3–5.8	19,023	−
		Whey Protein		
β-lactoglobulin	9.8	5.1–5.3	18,283	−
α-lactalbumin	3.7	4.2–4.5	14,176	+
BSA	1.2	4.7–5.1	66,267	−
IgG, IgM, IgA...				

BSA, borine serum albumin; Ig, Immunoglobulin.

temperature is routinely measured using NMR techniques, and is often referred to as the n-line of the fat (Gribnau 1992).

TAG crystals occur in a number of different polymorphic forms α, β′, β, that is crystal structures with different states of molecular packing (Bruijne and Bot 1999; Bot and others 2003a). The preferred polymorphic form of fat depends on the chemical composition of an individual TAG, the mixture of TAGs in the liquid oil, and the crystallization conditions. Transformations between polymorphs depend, amongst others things, on the mobility of the TAGs in the crystal and liquid phases, and the ease with which molecules fit within the new crystal lattice. In commercial fat sources like butterfat, the presence of large numbers of different species of TAGs makes crystallization behavior rather complex (Coultate 1996; Campbell and others 2002). In practice, butterfat is found to crystallize usually in the β′ form, as illustrated in Figure 28.1. Amongst the minor ingredients, the carbohydrate lactose is the most important one. Lactose contributes to the sweetness of milk. Lactose is the main nutrient for lactic acid bacteria during fermentation. Typically, milk or milk powder contains ~50% lactose on dry matter, but other milk protein preparations may contain much more (e.g., sweet whey powder) or much less (whey protein isolate) lactose. Although the solubility of lactose is sufficiently high to prevent crystallization in cream-cheese-type products under normal conditions, it can manifest itself occasionally in the form of a certain degree of grittiness of the final product.

Calcium, an important nutrient in milk, is mainly present in the micelle in the form of colloidal calcium phosphate (CCP). Calcium promotes aggregation of α-casein mainly. The concentration of CCP is an important factor determining the stability of the micelles and the buffer capacity of a protein powder.

Phospholipids are surface-active materials, and as such can be found in fat-rich fractions like cream or even buttermilk powder because these preparations contain most of the membrane material. Phospholipids compete with the protein at the interface, and may decrease the interaction between droplets and matrix in the acidified emulsion (see Section 28.2.2).

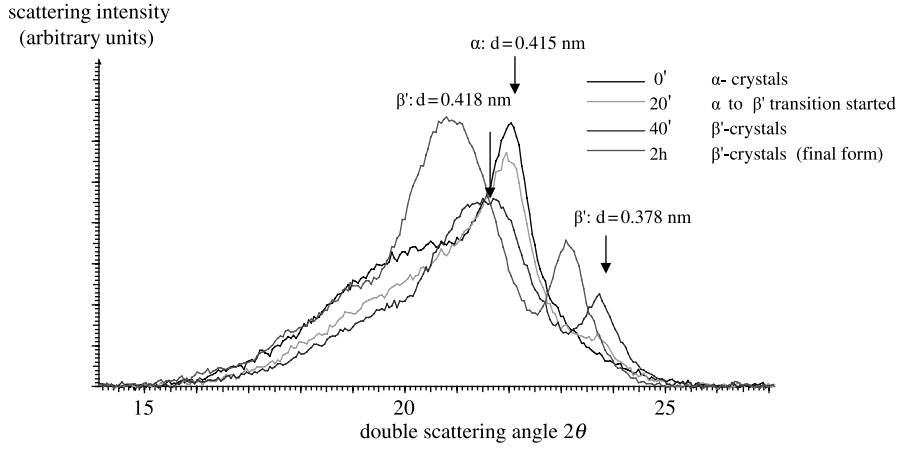

Figure 28.1 *X-ray diffractogram of a 30% butterfat model emulsion stabilized by 4% whey protein. The position of the diffraction peaks reveal the initial formation of α polymorphs, followed by the formation of β′-polymorphs over longer time scales. The vertical scale for each individual diffractogram was chosen to allow for convenient plotting (unpublished data from S. Kiokias and E.C. Roijers, Unilever Research and Development).*

Summarizing, full-fat milk can be considered the source of the two main ingredients of cream cheese: butterfat and protein. In practice, full-fat milk is not separated in butterfat and protein but centrifuged to form a fat-rich phase, cream, and a protein-rich phase, (skimmed) milk. The protein-rich phase can be processed/fractionated further to form other protein powders, such as whey protein concentrates and isolates. By mixing the fat-rich and protein-rich phases together again in different proportions, it is possible to manufacture dairy products that have completely different relative contents of fat and protein than the original full fat milk.

28.2.2 The Emulsion as a Composite Material

Cream cheese can be characterized as an (acid-protein-stabilized) o/w emulsion microstructure, in which attraction between the proteins at the surface of the butterfat droplets causes the droplets to aggregate into clusters (Fig. 28.2). Surplus protein tends to aggregate onto these clusters as well, leading to a protein network around the protein aggregates. Intense flow (shear, elongation, turbulence), as for example applied during homogenization, may lead to a (partial) collapse of this protein network onto the droplet aggregates.

As the droplets in the fat–protein aggregates usually remain present as individual droplets, the overall structure of the product can be characterized best as a composite (Fig. 28.3): a protein matrix filled with fat droplets. The dispersed phase acts as filler particles, the continuous phase as matrix. The properties of the filler phase affect the final product properties as a result of adhesion between droplet and filler phase. These effects become more important at higher filler fractions. When the interaction between filler and matrix becomes less, for example, when protein is replaced at the droplet interface by other emulsifiers, the contribution of the filler phase to the hardness becomes less

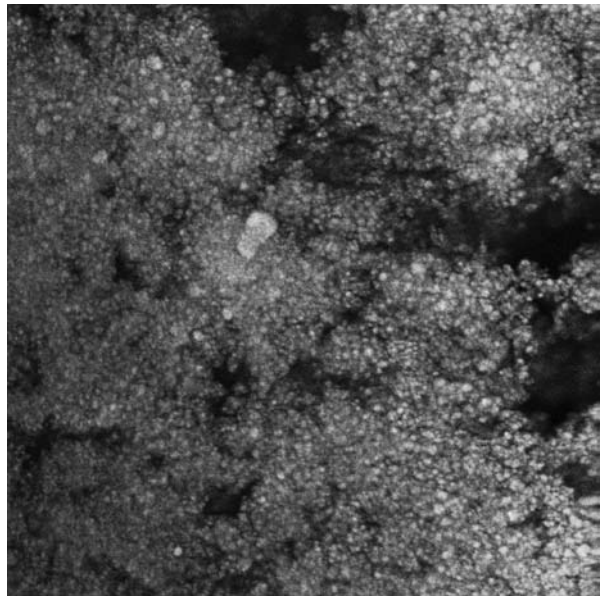

Figure 28.2 *Confocal scanning light microscopy image of the aggregated fat droplet microstructure in a commercial cream cheese. Image width 260* μm *(Image by H. van Aalst, URDV.).*

important (van Vliet and Dentener-Kikkert 1982; Reiffers-Magnani and others 1999). Effects of volume fraction, droplet size, and rigidity of the dispersed phase on composite gel strength and interaction with the continuous matrix have been investigated extensively (Jost and others 1986, 1989; Aguilera and Kessler 1988, 1989; van Vliet 1988; Langley and Green 1989; Aguilera and Kinsella 1991; Xiong and others 1991; Yost and Kinsella 1992, 1993; Aguilera and others 1993a; McClements and others 1993b; Wijmans and Dickinson 1998; Cho and others 1999; Aguilera 2000; Anton and others 2001). The spatial distribution of the dispersed phase can be expected to be important also.

Figure 28.4 shows some general dependencies of physical parameters on filler characteristics in model emulsion gels. Composite firmness tends to increase with filler concentration, and the effect is more pronounced if the filler particles are firm (Fig. 28.4*a*) (Xiong and others 1991). There are two contributions to this effect. In part, there is a direct effect of the increased hardness of the emulsion droplets (liquid oil being "soft" and crystalline fat being "hard") on the firmness of the composite. This is illustrated in Figure 28.5 by the effect of temperature on the firmness of a commercial fresh cheese, reflecting the melting of the fat phase. In part, concentration of the continuous phase plays a role (because fat occupies a larger volume and the protein in the continuous phase is more concentrated and hence forms a firmer gel; Aguilera and Kessler 1989; Aguilera and others 1993b; Dickinson and Hong 1995; Jost and others 1986). This represents an indirect effect of the fat droplets on composite strength, as it is linked to the strength of the continuous phase. Furthermore, there is an effect of the gelling-inducing processing steps, like heating (Reiffers-Magnani and others 1999) and acidification, on the composite properties of whey protein-stabilized o/w emulsions.

At a constant fat concentration, droplet size influences the strength of the composite (Fig. 28.4*b*) (Xiong and others 1991), a higher composite strength being observed with smaller droplets, independent of their physical properties. This is probably caused by the larger number of interactions between proteins at the interface and those in the continuous phase upon increasing the surface area, thus strengthening the adhesion and resulting in gel reinforcement (Ross-Murphy and Todd 1983; Langley and others 1988; van Vliet, 1988; Aguilera and Kessler 1989; Jost and others 1989; Xiong and Kinsella 1991; Yost and Kinsella 1993). This statement is only valid if the emulsifier adsorbed at the oil/water interface interacts with the continuous phase (for example, in the case of dairy gels containing milk protein as emulsifier), and if the droplets are sufficiently small to behave like (slightly deformable) hard spheres under small deformations (like the $\sim$1 μm droplets in cream cheeses). Low-molecular-weight emulsifiers tend to interact weakly with the protein in the gel network, leading to softer emulsion gels, and for this reason protein is more effective as the main emulsifier in cream cheese to achieve firmness in the final product.

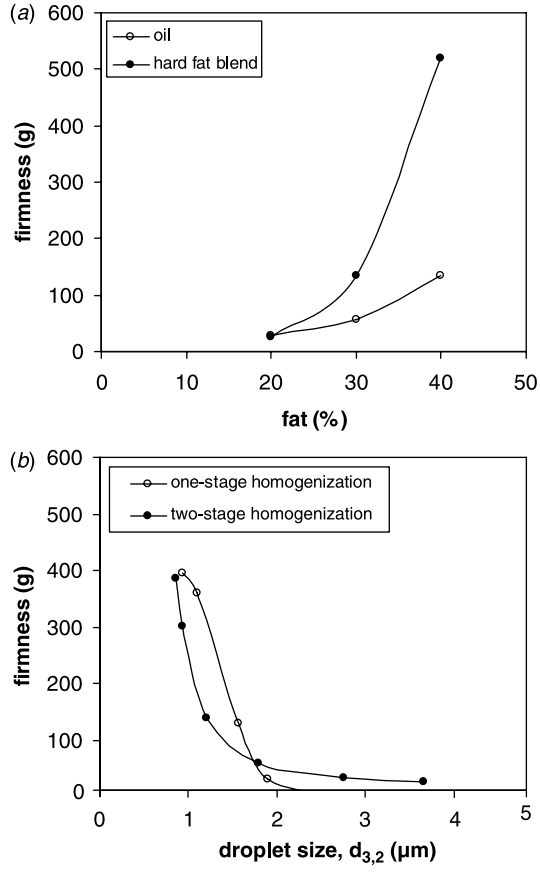

Figure 28.4 *Influence of dispersed phase of a composite, an acidified model emulsion, on firmness at 5°C as measured in a penetration test. (a) Effect of filler volume for a soft filler (oil) and hard filler (hardened vegetable fat) at roughly constant droplet size for an emulsion with 3% whey protein. (b) Effect of droplet size (i.e., different homogenization pressures) for 30% fat + 3% whey protein emulsions containing hardened vegetable fat. Two-stage homogenization involves a low-pressure second homogenization stage that tends to decluster the emulsion droplets (giving lower firmness at high first-stage homogenization pressure), but decreases the width of the droplet size distribution (giving higher firmness at low first-stage homogenization pressure).*

28.2.2.1 Emulsion Structuring by Controlling the Filler Phase

Milk Proteins as Emulsifiers. A (macro)emulsion is not a thermodynamically stable system and therefore does not form spontaneously. Creation of an oil-in-water emulsion involves dispersing oil in the form of droplets in the aqueous phase, usually under high shear conditions in a high-pressure homogenizer. The high shear stresses during this process lead to turbulence, breaking of the oil phase and formation of droplets. The droplet diameter obtained in such a process depends on the mechanical energy input per volume dispersed oil and the interfacial tension γ between the dispersed and the continuous phases (Walstra and Jenness 1984). The interfacial tension is reduced by the addition of emulsifiers, such as proteins or low-molecular-weight emulsifiers (e.g., monoglycerides, phospholipids), which contain both apolar regions that anchor to the fat phase and polar

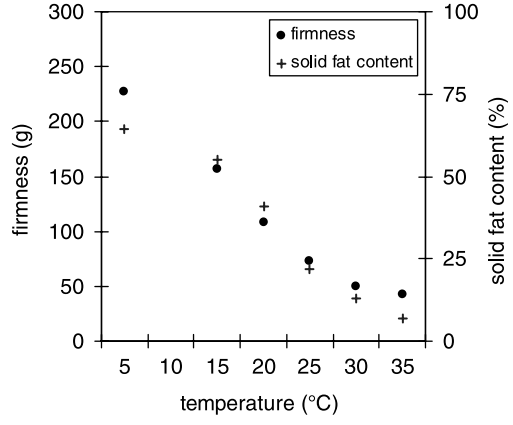

Figure 28.5 *Firmness measured by a penetration test for a commercial cream cheese as a function of temperature. Also indicated is the melting curve of butterfat (data by M.H. Schnitker, URDV).*

regions that orient towards the aqueous phase. Details on milk protein structure and behavior at the oil–water interface are given elsewhere (Leman and Kinsella 1989; Dickinson 2001).

Emulsifier functionality has two important aspects: the creation of a finely dispersed phase and the long-term stability of the emulsion. The first aspect is covered by using emulsifiers that can rapidly adsorb at the interface, and thus reduce the interfacial tension of the newly created droplet interface during stretching of the droplet in the homogenizer and subsequent break-up. This needs to be a rapid process, because it needs to be completed within the typical μs pass-through timescale for the homogenizer valve. A slower adsorption process would allow significant recoalescence of the dispersed droplets. As small molecules diffuse faster to the oil–water interface, the effectiveness of the emulsifier for making small droplets tends to reduce with increasing molecular weight (making low-molecular-weight emulsifiers more effective than proteins, for example).

Comparing different protein sources, this implies that single protein molecules like caseinate and native whey protein are more effective in emulsification than bulky casein micelles (Dickinson 1992, 1993; Euston and Hirst 2000). Droplet size was found to increase when emulsions were prepared from a range of commercial milk protein powders, micellar casein (MC), skim milk powder (SMP), and whey protein concentrate (WPC), according to WPC $<$ SMP $<$ MC (Euston and Hirst 2000). Conditions that promote protein aggregation, such as denaturation and/or acidification, reduce the effectiveness of a protein in the emulsification process.

The second aspect, however, is the long-term stability of the emulsion against partial coalescence. As a rule of thumb, it can be stated that thicker interfacial layers improve long-term stability (making low-molecular-weight emulsifiers less effective than proteins). The phospholipids occurring naturally in cream may therefore impact negatively on emulsion stability. Even within the class of milk proteins, marked differences occur in thickness of the interface: typical surface coverages for sodium and potassium caseinates and α- and β-casein are $\sim 2-3\ \mathrm{mg/m^2}$, whereas they are $\sim 10\ \mathrm{mg/m^2}$ for casein micelles (Pelan and others 1997). These differences in surface coverage should be explained as differences in interfacial thickness, and indeed sodium-caseinate-based emulsion gels are found to be less stable against (partial) coalescence during storage than emulsions made with casein micelles. The interfacial rheological properties of protein-based

interfacial layers provide an additional advantage over low-molecular-weight emulsifiers. The elastic properties of the proteins at the interface (Mellema and Isenbart 2004) also tend to prevent coalescence of the dispersed phase.

Proteins sometimes compete with fat crystals at the oil–water interface. The solid fat content in the lipid phase is known to influence the adsorption of casein proteins at the oil–water interface, as is illustrated by the decreased caseinate surface coverage in sodium-caseinate-stabilized emulsions stored below 15°C (Euston and Mayhill 2001), conditions under which large numbers of milk-fat crystals form. These crystals may induce partial coalescence as well. In this context, it should be noted that the homogeneity of the interfacial layer is important too: Denatured aggregated whey protein does not stabilize the emulsion very well (Kiokias and others 2004a; Kiokias and Bot 2005, 2006).

Emulsion Droplet Aggregation Under Neutral Conditions. Protein-stabilized oil droplets in the neutral premix may occur as either stable individual droplets or aggregated droplets (Fig. 28.6). The aggregated states are best described in terms of an interaction potential between droplets that takes into account both the electrostatic and steric interactions between protein-covered oil droplets. The interaction potential predicts attraction at short distances (short-range: van der Waals, hydrophobic), repulsion at long distances (long-range: electrostatic), and a local minimum at intermediate distances caused by steric repulsion (or interfacial elasticity) at short distances (Fig. 28.6) (Walstra and others 1996).

As a result, three states can be distinguished. If two droplets are stable and hence separated over long distances, a slight electrostatic repulsive force ensures that the droplets will remain separate. If two droplets are flocculated, and separated over intermediate distances, the attractive forces become larger than the repulsive forces and the oil phases are only prevented from touching by the protein layer covering them. The local minimum in the interaction potential is shallow and aggregation is reversible under shear. The state is referred to as clustered if the local minimum in the interaction potential is deep and aggregation is essentially irreversible, even under shear. If the short-range steric repulsion is overcome, the oil phases touch and either coalesce or partially coalesce/clump. Full coalescence is not a very common phenomenon in protein-stabilized systems, but

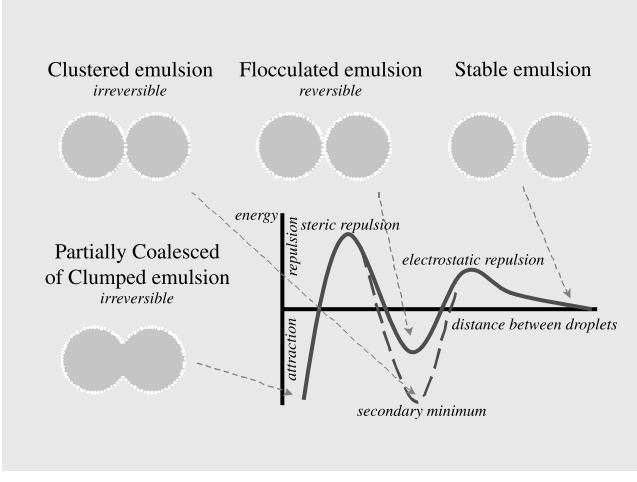

Figure 28.6 *Schematic representation of various emulsion states.*

partial coalescence may occur if the droplets have some firmness and/or contain (anisotropic) particles that are too large to be kept in one droplet, for example, upon crystallization of fat in the dispersed oil phase.

As electrostatic repulsion depends on the charge on the milk proteins, lower pH (compared to neutral pH) and higher ionic strength will reduce the height of the electrostatic repulsive barrier. For the steric repulsive barrier, besides electrostatics ("salted brush"), factors like the interfacial elastic properties and the quality (homogeneity) of the protein layer around the oil droplet are important.

Fat Structuring. As explained above, filler particles play an important role in composite properties, such as firmness and fracture properties. Concentration, size, and filler–matrix interaction effects are, however, greatly dependent on the physical properties of the particles, which are in turn linked to their crystallization behavior. Little is known about crystallization of dispersed fat in multicomponent and multiphasic systems like food products (Rousseau 2000), in contrast to crystallization in bulk oils. A better understanding of how fat behaves in such systems would open interesting perspectives to control droplet hardness and therefore composite properties (Kloek 1998).

The TAG crystallization mechanism in emulsions differs considerably from bulk crystallization. The process of crystallization consists of three stages: supercooling (or alternatively, supersaturation), nucleation, and crystal growth (Boistelle 1988). Crystallization in bulk occurs through heterogeneous nucleation involving trace impurities that provide the initial nucleation sites. Once crystallization starts, it rapidly spreads throughout the whole system by means of crystal growth and/or secondary nucleation (Sato 1988; Sato and Garti 1988; Timms 1994; Berger 1997). In emulsions, however, the lipid phase is finely dispersed in droplets and the number of impurities may be significantly less than the number of droplets, depending on the droplet size distribution in the emulsion. As a result, a considerable fraction of the fat droplets may be nucleus-free and their crystallization should occur through an alternative mechanism, such as the spontaneous formation of crystals of sufficient size to not dissolve again, known as homogeneous nucleation (McClements and others 1994; Davies and others 2000; Campbell and others 2002).

Homogeneous nucleation usually takes place well below the thermodynamic melting point, under conditions where the TAG mixture is a supercooled, metastable liquid (i.e., crystallization is thermodynamically favorable, but the required activation energy is high compared to the energy of the thermal fluctuations). Deeper cooling enhances the homogeneous nucleation rate, and therefore the fat phase in a larger fraction of the droplets will crystallize.

Alternatively, the interface can play a role. O/w emulsions contain a large interfacial area and the presence of (low-molecular-weight) emulsifiers may affect the crystallization kinetics by means of surface-induced heterogeneous nucleation as well. Emulsifiers decrease interfacial tension, making it more thermodynamically favorable for nuclei to form at the interface than in the interior of the droplets. Hence, the surface acts as a catalytic impurity promoting nucleation (Campbell 1989; Krog and Larsson 1992). This mechanism is not expected to play an important role in cream cheese, because low-molecular-weight emulsifiers are usually not added.

Finally, interdroplet heterogeneous nucleation may occur in situations in which nucleation is initiated in supercooled liquid droplets by contact with crystalline droplets of the same material, for example, crystals protruding from solid droplets and penetrating into

liquid droplets upon collision (McClements and others 1990, 1993a; Dickinson and others 1993). Interdroplet heterogeneous nucleation is promoted by high shear forces, low viscosity of the continuous phase, aggregated fat droplet state (*vs.* homogeneously distributed), high oil volume fractions, and ability of a crystal to penetrate the layer of emulsifier (possibly related to the interfacial modulus) (Mellema and Isenbart 2004). As proteins have been found to prevent interdroplet heterogeneous nucleation better than low-molecular-weight emulsifiers, this mechanism is not considered to be very important in cream-cheese-type emulsions.

Overall, the rate and degree of crystallization tends to be lower in fine o/w emulsions than in bulk, although the effect is not always large. This is illustrated in Figure 28.7, which shows a slightly lower solid fat content (expressed on fat phase) for whey protein-stabilized butterfat in oil emulsion and butterfat bulk crystallization. Incomplete crystallization will lead to lower firmness of the emulsion gel. Deeper cooling will bring the degree of crystallization in the emulsion closer to the bulk value.

28.2.2.2 Emulsion Structuring by Controlling the Continuous Phase. In composite systems like protein-stabilized emulsion gels, the continuous aqueous phase consists of a mixture of milk proteins, sugars, and salts. The textural properties of the final product are largely determined by (1) the physicochemical properties of the ingredients, (2) the order of addition, and (3) the applied processes, such as heating, acidification, and cooling.

Gelling of Milk Proteins. Casein micelles can form gels through acidification or renneting. Renneting, which induces splitting of the κ-casein at the surface of the micelle, is the basis of hard cheese formation and will not be discussed here. Acidification below ~pH 5 leads to sufficient charge neutralization in the κ-casein polyelectrolyte brush at the micelle surface to induce aggregation. The exact pH at which aggregation occurs depends on the amount of serum casein present, and therefore on temperature and the temperature–pH route taken to the point of destabilization (Vasbinder and others 2003). During acidification, the internal micellar structure weakens by the dissolution of the calcium phosphate.

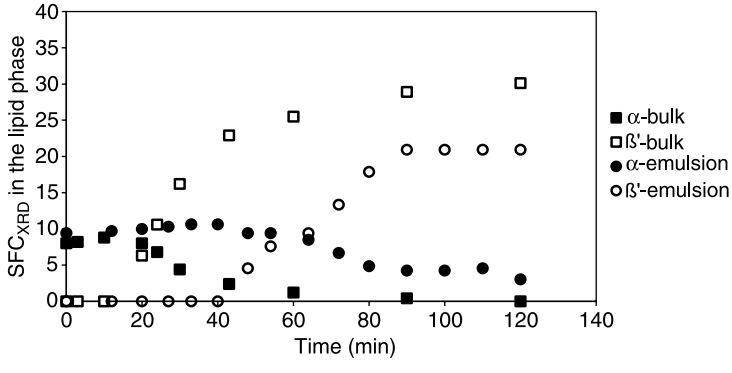

Figure 28.7 *Crystallization in 30% butterfat o/w model emulsion stabilized by pre-denatured whey protein from WPC (analysis using X-ray diffraction; filled and open symbols are derived from α and β′ polymorph peak intensities, respectively; squares and circles refer to crystallization experiments in bulk and emulsion, respectively). The comparison between crystallization in emulsion to bulk shows that modest supercooling occurs in the emulsion.*

For nonheated acid milk gels, typically a maximum in elastic modulus is found near the isoelectric point of the casein micelles (~pH 4.8), with a considerably steeper change in modulus above than below the isoelectric point. The maximum usually coincides with a steep change in water exudation from the gel, syneresis, which is much higher above the isoelectric point (Roefs and others 1990).

The mechanical properties of the casein gel are not so much determined by the mechanical properties of the micelles themselves, which are quite firm (Uricanu and others 2004), but rather by strands of micelles and thus by the properties of the connections between the micelles (Mellema 2000). The properties of the gels, such as texture and water binding, are influenced, for example, by casein concentration, presence of salts, shear forces, heat treatment, and rate of acidification. For example, increasing the rate of acidification results in gelling at a lower pH and in the formation of smaller and denser aggregates, which favors syneresis in pure casein systems. Casein gelling is discussed in more detail elsewhere (de Kruif 1998, 1999; Mellema 2000; Mellema and others 2000).

Whey proteins usually do not gel in their native state, but only after denaturation and at sufficiently high concentration. Gelling behavior of whey proteins generally follows the gelling of the main protein component, β-lactoglobulin. Upon denaturation, β-lactoglobulin exposes a reactive thiol group, which can act as an initiator for a "polymerization" reaction, during which aggregates are formed (Kella and Kinsella 1988; Kinsella and Whitehead 1989; Roefs and de Kruif 1994; Surroca and others 2002). Note that the rate of unfolding of the whey proteins can be delayed by environmental factors like the presence of lactose.

Casein and whey are present as a mixture in dairy products, which affects their gelling behavior, especially if combinations of heat treatment and acidification are applied. Upon heating at temperatures above 70°C, whey proteins denature and bind to casein micelles via hydrophobic and disulfide interactions with the κ-caseins. Heating skim milk at 90°C over 10 min leads to 40% coating of casein micelles by whey proteins (Vasbinder and others 2001), but details of the interaction depend strongly on temperature and pH (Vasbinder 2002). In milk, both β-lactoglobulin and α-lactalbumin bind to the micelle, the interactions between casein and β-lactoglobulin being limited by the number of binding sites available on the micelle surface, and the interactions between casein and α-lactalbumin being rather limited by its concentration in milk (Corredig and Dalgleish 1999). Because of this, increasing the whey/casein ratio may not necessarily result in a higher amount of whey being bound to the micelle.

The presence of denatured whey at the micelle surface increases gel firmness (Lucey and others 1998, 2000) and decreases the gelling time and increases gelling pH, because denatured whey proteins act as bridging agents between aggregating casein micelles during acidification. The resulting gel also has a more dense structure (Vasbinder and others 2001). The whey protein coating can prevent disaggregation of the micelles. Obviously, the properties of such a mixed gel are dependent on the degree of whey denaturation, with accompanying consequences on textural properties and syneresis. It appears that in heated milk gels, the reduction in elastic modulus and the decrease in syneresis below the isoelectric point of the casein micelles become less pronounced or shift to lower pH (Xiong and others 1991).

Emulsion Droplet Aggregation Under Acid Conditions. Under acid conditions like in cream cheese, the electrostatic repulsive barrier between the protein-stabilized droplets is

lowered and thus the droplets will aggregate (Fig. 28.6). Depending on the homogeneity of the protein layer around the emulsion droplets, the emulsions can be characterized as either flocculated/clustered or coalesced/clumped. An essentially flocculated emulsion is prepared if a strong protein film around the droplets is first made (e.g., by heating a properly stabilized emulsion). A clumped emulsion can be prepared from emulsions with much crystalline fat if coarse protein aggregates are first made by denaturation, followed by emulsification (Kiokias and others 2004a).

Partial coalescence is an interesting phenomenon in composite gels because the formation of a fat network by bridging of crystals from one droplet to another may help to modify textural attributes, like improved mouthfeel (Boode and Walstra 1993; Gelin and others 1994; Campbell and others 1996; Pelan and others 1997) or defects like hardening upon storage (Kiokias and others 2004a). For high-volume-fraction emulsions, like cream cheese, partial coalescence upon temperature cycling does not depend on droplet collision frequencies, because the droplets are always in close contact.

The structure of the droplet aggregates is expected to be important, but unfortunately very difficult to measure. Preliminary studies on model systems using Spin Echo Small-angle Neutron Scattering (SESANS) were done to address this (Bot and others 2006; Bot and others 2007). A priori it is expected that fine homogeneous droplet networks will result in firmer networks, much the same as in protein networks.

The mechanical properties of the emulsion gel follow the characteristics of the matrix, as was demonstrated for the behavior of an acid emulsion gel and a comparable acid milk gel as a function of pH (Xiong and others 1991). Similar trends are expected to hold true for syneresis in acid emulsions.

28.3 CREAM CHEESE PROCESSING

The traditional cream cheese production process consists typically of the following steps. A mixture of pasteurized, homogenized milk and cream is acidified via fermentation using lactic acid bacteria, which leads to aggregation of the milk protein. The aggregated milk protein, including the fat droplets contained in the protein matrix, is concentrated by separating off a liquid phase through mechanical treatment (usually centrifugation), if necessary combined with a heat treatment. The concentrated phase, the curd, can be pasteurized to inactivate the lactic acid bacteria and is usually homogenized once more before the product is filled in the final packaging (Guinee and others 1993). Usually, a sealed container and chilled storage are used to increase the shelf-life of the product. More details are provided in the following sections.

The production process is complex from a physicochemical point of view due to the presence of two irreversible steps, milk protein aggregation during acidification and separation of the whey from the curd. In addition, acidification is performed by live organisms, introducing some variability in the process.

28.3.1 Emulsification

As cream cheeses are emulsions, it is necessary to mix the dispersed phase thoroughly into the continuous phase. The efficiency of the emulsification stage depends predominantly on the power input during the emulsification process and on the interfacial tension between lipid and water phases. The proteins in the premix reduce the interfacial tension, and therefore facilitate the emulsification process. Emulsification in factory-scale cream cheese

production is achieved by intense mechanical shearing of the premix of milk and cream, usually with a high-pressure homogenizer. A homogenizer is essentially an orifice or a valve that blocks the fluid flow, causing intense shearing forces as the liquid is forced through the narrow gap. Dispersed phase droplet sizes below 1 μm can be obtained with such equipment when operating at a pressure above ~100 bar. Reduction of the dispersed liquid droplet size becomes increasingly difficult for small droplets, because the surface area in an emulsion with droplets of radius R increases as $1/R$.

Droplet sizes after homogenization can be measured routinely through low-field NMR techniques directly in the product (Goudappel and others 2001; Kiokias and others 2004b) or by static light scattering in diluted o/w emulsions (Gelin and others 1994; Bot and others 2003b).

A special phenomenon called homogenization clustering occurs in emulsions stabilized mainly by casein micelles (such as a cream cheese premix). Because micelles tend to diffuse relatively slowly, the newly created droplet interface is sometimes not covered rapidly enough by micelles from the serum phase in the break-up phase. If droplets meet again in the zone beyond the homogenization valve, this may result in a situation in which micelles stabilize two droplets at the same time and clusters of micelle-coated fat droplets are formed. This situation was already outlined in Figure 28.6, and will occur only for emulsions stabilized by relatively large particles, such as casein micelles. Homogenization clustering may lead to an increase in viscosity.

28.3.2 Acidification

Acidification is normally achieved by fermentation, which generates a wide range of subtle taste and flavor components enhancing the dairy connotation. Fermentation can either be done by thermophilic microorganisms, which show optimal activity at ~40°C, or by mesophilic microorganisms, which prefer temperatures of ~25°C. Thermophilic organisms tend to give relatively acidic yogurt-type flavors, whereas mesophilic organisms generate a wider, more subtle range of flavors. The latter tend to require longer fermentation periods, but are usually applied in cream cheese production.

Fermentation is usually performed in a batch process, but alternatives have been considered. For example, it is possible to design a continuous fermentation process in which neutral mix is added continuously to the fermentation tank, and acid mix is tapped from the tank. However, such processes have not been widely introduced as a standard because in-line control of the pH in an industrial process is notoriously difficult. Furthermore, the stability of commercial multistrain fermentation cultures over prolonged periods is not guaranteed as a result of competition among the strains.

Disadvantages of fermentation are the long periods required to achieve acidification, the fact that the period required for fermentation is never completely predictable, and the sensitivity of the fermentation cultures to phage infections.

28.3.3 Separation

The aggregated milk protein, including the fat droplets contained in the protein matrix, is concentrated by separating off a liquid phase. This allows the formation of a cream cheese with firm texture, high in milk protein but without taste defects associated with high mineral (calcium) or lactose level. Depending on the fat/protein ratio of the product, a cream-type separator or a quark-type separator may be used. Higher temperature may

be applied to facilitate the separation of the whey from the curd. Usually, it is found that the amount of dry matter in the curd decreases with decreasing pH in the pH range below the isoelectric point (Kim and Kinsella 1989).

If the milk has not been heated to denature the whey proteins, most of these proteins will still be soluble in the liquid phase and will therefore disappear with the waste stream. As an alternative to separation one could consider ultrafiltration, in which the whey protein is retained in the curd.

Before filling the curd into the final packaging, an additional high-pressure homogenization step is often applied to break up the larger protein aggregates and give the product a smoother texture.

28.3.4 Filling

Cream cheese is a relatively sensitive product in terms of microbiological stability, but the product keeps quite well if general hygienic requirements for the processing line and factory are met (see, for example, Lelieveld 1999). The product should be pasteurized, brought to a sufficiently low pH, and hygienically packed in a sealed container.

An important decision concerning process design is whether the products will be filled using hot filling or cold filling. Hot filling usually means filling the product at pasteurization temperature, sealing it, and thus using the product to pasteurize the packaging. The disadvantage of this process is that the product has to be cooled down to chilled storage temperature in the final packaging. This is a slow process and may induce product defects (e.g., condensation of water in the headspace above the product). Cold filling does not introduce these problems, but requires higher standards in packaging hygiene and in-line cooling of the product. In-line cooling (as well as heating) is usually carried out in tubular, plate, or scraped surface heat exchangers.

28.4 CREAM CHEESE PROPERTIES

The taste and textural properties of cream cheese products that are relevant for consumers may to a large extent be attributed to its composite microstructure. Important aspects are spreadability, melting in the mouth, and syneresis.

28.4.1 Spreadability

A spreadable texture can only be obtained if the product is built from microstructural elements that interact weakly and reversibly, resulting in a more or less plastic rheology. Very loosely stated, a plastic material is a solid-like material for which the deformation history (e.g., flow experienced) does not affect its current mechanical properties. In this sense, a plastic material is reminiscent of a liquid. A typical solid (e.g., a chocolate bar) would break upon application of sufficient deformation and never regain its original properties.

Few materials are really plastic, according to this description, but butter is a reasonable approximation (de Bruijne and Bot 1999; Bot and others 2003a). Cream cheese is plastic in the sense that it is built from microstructural elements (protein/fat) that interact weakly. However, the interactions between the proteins are generally not reversible and plasticity will generally be higher in products where the fat/protein ratio is higher. Besides plasticity, product hardness is of course an important factor determining the spreadability of cream cheese.

28.4.2 Melting in the Mouth

The qualitative data in Figure 28.4*a* has already indicated that the dispersed phase contributes considerably to the firmness of the product, and therefore it is logical that the melting of the butterfat in the mouth helps to soften the product. It should be realized, however, that the loss of firmness is not as extreme as in a product like butter (de Bruijne and Bot 1999; Bot and others 2003a). In butter, the continuous phase melts completely, whereas in cream cheese a considerable contribution to the viscosity can still be expected to come from the protein phase. Both the melting and the residual firmness/viscosity are illustrated in Figure 28.5. It is shown that indeed much of the firmness is lost during heating to mouth temperature, but above $\sim 30^{\circ}$C, the firmness is mostly determined by the protein network and further melting of the fat phase does not reduce the firmness any further. The end viscosity could be adapted by using more or less protein.

28.4.3 Syneresis

In a milk protein gel, 90% of the water is enclosed in the pores between the casein strands forming the network and 10% within the casein particles (van Vliet and Walstra 1994). Exudation of part of this water phase from the gel upon collapse and/or contraction of the gel matrix, a phenomenon called syneresis, occurs in most (particularly particle) gels. The process proceeds most rapidly in coarse inhomogeneous protein networks, which can be formed over time as a result of local reorganization in the milk gel (Mellema 2000). Semiquantitative descriptions of the process are based on the Darcy equation and involve the viscosity of the water phase and the geometry of the protein network through which the water phase flows (Darcy 1856; Bird and others 1960; Lucey and others 1997; de Bruijne and Bot 1999; Mellema and others 2002). The mechanisms promoting exudation of the water phase are thought to be rearrangements of the protein network ("endogeneous" exudation) and buoyant forces on continuous phase (due to density differences between exuding phase and network). In specific geometries, drainage is a possible mechanism too, for example, when a product is positioned on a grid or into the void where the product is scooped out of a consumer package.

Syneresis during cream cheese production is desirable (and can be accelerated by stirring, heating, and centrifugation). In final cream cheese products, however, syneresis is considered to be a defect, only allowed to occur to a limited extent.

There are various ways to decrease syneresis.

1. A finer, more homogeneous network has fewer large pores and therefore less syneresis. Although it is difficult to formulate a general rule because many factors play a role in network formation, this can usually be achieved by gelation at pH values away from the isoelectric point pI (due to enhanced rearrangements near pI), lower temperatures (hydrophobic interactions between caseins at higher temperatures induce aggregation), slower acidification (larger flocs as building blocks for the gel). For systems based on heated milk, however, it should be realized that the "critical" pH can actually be somewhat lower than the pI, for example, pH $\sim$ 4.
2. A firmer network tends to suffer less from rearrangements at micellar length scales, and therefore shows less syneresis. Denaturation of the whey proteins upon heating of the milk has been shown to reduce syneresis compared to unheated gels (Augustin

and others 1999; Dannenberg and Kessler 1988a,b; Lucey and others 1999, 2000), possibly due to covalent disulfide bonds and increased stability of the micelles against rearrangements.

3. An increased viscosity of the water phase reduces syneresis, for example, through the addition of low amounts of polysaccharides (Bot and Vervoort 2006).

28.5 CREAM CHEESE PROPERTIES DURING TRANSPORT AND STORAGE

During transport and storage of cream cheeses a number of undesirable changes may occur. These changes are partly due to the fact that cream cheese texture still develops after leaving the production line (fat crystallization, protein network formation) and partly to temperature fluctuations during storage and transport.

For a fresh cream-cheese-type product, microbiological stability during storage and transport is often the most critical property. To extend the shelf-life of the product before opening by the consumer ("closed shelf-life"), chilled transport and storage are usually preferred. Improper transport and storage conditions at higher temperatures for longer periods may affect keepability. Additionally, syneresis may become unacceptably high and taste may be affected (for example, by oxidation processes).

Cream cheese products also tend to be temperature cycled during consumer usage (in and out of the fridge). Sometimes this leads to partial coalescence of the fat droplets in the protein matrix, which may result in considerable post-firming of the emulsion gel. Partial coalescence may also coarsen the pores of the protein network during temperature cycling, once again leading to increased syneresis compared to noncycled samples. Acidified whey-protein-stabilized o/w emulsions based on partly crystalline fat, in which the functionality of the whey protein has been impaired before emulsification by ("pre-") heat-treatment and subsequent aggregation, form interesting model systems to investigate this effect (Kiokias and others 2004a). Such emulsions can destabilize at relatively high protein content, even under conditions at which their native neutral counterparts are still very stable.

28.6 SUMMARY

Cream cheese products are protein-stabilized emulsion gels created from water, fat, and proteins. The main processing unit operations are homogenization (emulsification), heating (pasteurization and protein denaturation), acidification (protein gelling), and cooling (fat crystallization). A broad range of microstructures can be formed with all potential composition/processing combinations. This chapter gave an overview of the basic phenomena that are involved in the production of cream cheese. The main phenomena of interest specifically relevant for the texture of cream cheeses were gel firmness, stability (syneresis of casein gel), denaturation (of whey proteins), and partial coalescence (of fat droplets).

29.1 ORIGIN

Chocolate is one of the most popular flavors in the world. It is widely used in many food products, including soups, main dishes, beverages, baked goods, and of course confectionery. Its basic ingredients are chocolate liquor, sugar, cocoa butter, and flavors. Other ingredients such as herbs, spices, milk, nuts, crisp rice, and so on, may also be added.

Under conditions of semishade, warmth, and high humidity, cacao trees (*Theobroma cacao*) have thrived and been cultivated in the Americas for at least an estimated 4000 years. It was important in Mayan and Aztec mythology and also used as currency. Originally, an unsweetened foamy beverage called *chocolatl* was served to the noble ruling class. Early Spanish explorers found that adding sugar to this bitter *chocolatl* liquid improved its flavor and soon became the rage of the Spanish nobilty. This sweetened *chocolatl* liquid then spread to Italy, Holland, France, and England.

However, this sweetened *chocolatl* beverage was very rich in fat and difficult to disperse in water. Some consumers also had difficulty in digesting it. In the early 1800s, C.J. Van Houten of Holland patented a cocoa press that could separate chocolate liquor into cocoa butter and its residue, which is processed into cocoa powder. Mr. Van Houten was also credited with inventing the Dutch Process, by alkalizing the cocoa to give it a darker color and a less acid flavor. It was found that a superior product could be made with cocoa powder when warm water replaced the cocoa butter.

Fry and Son in 1847 and Cadbury in 1849 were among the first to sell solid eating chocolate with a basic formula of chocolate liquor, sugar, and cocoa butter. The development of solid chocolate was made possible when the separation of cocoa butter from chocolate liquor resulted in an "excess" of cocoa butter. The addition of cocoa butter to chocolate liquor and sugar resulted in a smooth and creamy product. In 1875 Daniel Peter developed a method of adding condensed milk to chocolate and thus milk chocolate was born.

29.2 COCOA BEAN PRODUCTION

There are three major types of cocoa (cacao) beans: Forastero, Criollo, and Trinitario. The region where the cocoa beans are grown and its variety can greatly affect its characteristics for flavor, color, hardness of butter, and so on. Forastero beans are generally dark brown in color with a strong, bitter flavor and account for the majority of the beans. Criollo beans are the flavor beans. They are lighter in color with a mild, nutty flavor. Trinitario is basically a cross between Criollo and Forastero. The beans are blended to produce the desired end product.

Cacao trees are commercially cultivated generally within a 20° latitude of the equator with a rainfall of 45–100 in. (114–254 cm) and a temperature of 70–90°F (21–32°C). Africa (Ghana, Nigeria, Ivory Coast), South America (Brazil, Ecuador, Venezuela), the West Indies (Dominican Republic), Asia and Oceania (New Guinea, Malaysia, Indonesia) are the major producing areas.

A cacao tree will attain its full height in about 10 years. Although trees may grow to 40 ft (1200 cm) in height, they are usually pruned to 15–25 ft (450–750 cm) to facilitate harvesting. Flower clusters appear only on the trunk and main branches, with 20 to 30 fruit pods developing about five to six months later. The growth cycle is continuous, so a tree may bear leaves, blossoms, and pods simultaneously. However, the main fruiting season occurs between October and February.

The ripe pods are elliptical in form, 7–10 in. (18–25 cm) in length and 3–5 in. (8–13 cm) in diameter, containing approximately 20–50 seeds surrounded by a mucilaginous pulp. Each dried cacao bean weighs approximately 1 g. When dried, the beans from each pod weigh between $1\frac{1}{2}$ and 2 oz (42–56 g). Although yields can vary greatly, the average tree produces 20–30 pods, so each tree's output is between 2 and 3 lb (0.9–1.4 kg) of commercial cocoa beans.

Mature cacao pods turn yellow, orange, or purple in color. The pods are split open and the beans and pulp scooped out and heaped into boxes or baskets for fermentation (anaerobic and aerobic). The beans are allowed to ferment for 3–6 days, depending upon the type of beans used, batch size, temperature, and aeration. Aeration (turning) of the beans promotes bacterial activity and ensures uniform fermentation. Fermentation and drying processes have major influences on the quality of the beans used in making chocolate. The beans are subsequently dried (naturally or mechanically) to a moisture content of less than 8% to prevent mold growth, with the optimum being 6–6.5%.

Cacao beans must be cleaned before processing to produce a wholesome product with minimal microbiological risks and to remove extraneous materials. On a dry basis, the beans are approximately 87.1% nib (cotyledons), 12.0% shell, and 0.9% germ. The nib contains about 55% cocoa butter fat (Hofberger 1999b).

Cocoa beans arriving in the United States are usually inspected for mold, infestation, filth, degree of fermentation, and bean size. They are also fumigated at the ports when received. They should be stored in cool, dry, and well-ventilated warehouses to maintain quality.

29.3 COCOA BEAN PROCESSING

There are several options on how to process the cocoa bean. They all involve the removal of the shell and a roasting step. The roasting process results in the development of the flavor and aroma of the beans. There are several methods, which includes whole bean, nib, and chocolate liquor roasting. Roasting can take anywhere from 15 min to 2 h. Whichever roasting method is used, the nibs are separated from the shell (winnowing). Depending upon the degree of roast, the final nib moisture ranges from 1.5–3%.

The traditional method of roasting involves the whole bean. The beans enter a gas-fired revolving drum with various air flows and a cooling section. Temperature and length of roast will depend on equipment, flow rates, type of beans, size of beans, and the flavor desired. Cooled roasted beans will then go through a cracking step to break the nib into large pieces. Winnowing machines will use density differences and sieving to separate the nibs from the shell. Federal standards allow no more than 1.75% shell in the nib portion used for chocolate production. Cocoa-bean shells have little commercial value and are used for mulches, fertilizer, fuel, bedding, and in some cigarette blends. The germ portion is also removed because it is hard and gritty.

A common approach to roasting cocoa beans is to rapidly heat the exterior of the beans with infrared heat. The shell expands from the unheated nib portion, where it is easily removed by winnowing. The nib is then roasted in a similar manner to the whole cocoa beans. Several advantages to using this method include lower microbiological count, less fat migration to the shell portion, and better separation between the shell and nib.

The third method of roasting involves grinding raw cocoa nibs into a liquor. This liquor is then heat treated (i.e., roasted) at various times and temperatures to produce the desired finished product. This procedure is said to result in a product with uniform flavor and color. Unlike the two previous methods where large, small, and broken beans may be over- or under-roasted due to size differences, the liquor roasting method has one common heat treatment.

After roasting, the nibs are ground to a liquid state called chocolate liquor. The heat and friction from the grinding process will rupture the cell walls of the nibs to release the valuable cocoa butter. This liquor (containing approximately 55% cocoa butter) will solidify upon cooling. Nib grinding carried out using several methods, with most manufacturers using a combination of methods to obtain the desired particle size with the maximum available cocoa butter.

Micropulverizers (often called hammer mills) are the commonly used first step in the grinding process. Although they can be used to produce fine particle size liquor, other mills are often used for final size reduction. This final degree of fineness is important to maximize the amount of free cocoa butter available for viscosity reduction in chocolate, pressing of liquor into cocoa cake and butter, and particle size of the cocoa powder.

Stone mills are commonly used for final particle size reduction. They generally have three pairs of grooved "stones", with each pair progressively making the liquor finer. Each pair of stones has a stator and rotor that can be adjusted in distance. Liquor enters the center of the stones and discharges at the outer circumference to the next pair of stones.

A fine particle size may also be obtained with a ball mill. This equipment consists of a tank containing small metal or ceramic balls. Pre-ground liquor enters the bottom of the vertical tanks and is reduced in size by the rotating motion of an agitator on the balls.

A five-roll refiner is the final method that is used to reduce particle size. The ground nibs are introduced to the lower roller and move up due to the rollers rotating in alternating sequence with increasing speed.

The processing for cocoa and chocolate are essentially the same in the initial stages. The beans are cleaned, roasted, and shelled. The manufacturing of cocoa and chocolate, however, involve two separate processes (Fig. 29.1).

29.4 COCOA POWDER MANUFACTURING

Cocoa cake and cocoa butter are separated from the hot chocolate liquor by hydraulic pressing (more than 6000 psi). This cocoa butter, flowing out from the press, contains small amounts of cocoa powder, which are filtered out to maintain consistent color and flavor. The butter may be further refined, bleached, and deodorized (via steam distillation) to yield a very bland, clean-tasting cocoa butter. What is left in the

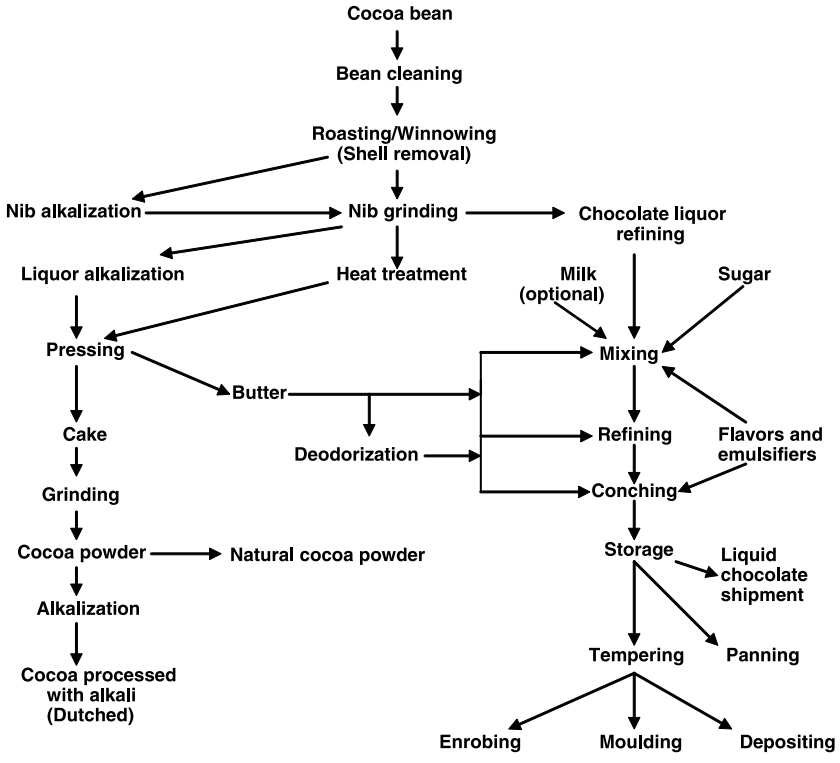

Figure 29.1 *Manufacture of cocoa and chocolate.*

press is a cake of cocoa powder (cocoa cake). The cocoa cake will generally have a fat content ranging from 10–24%. Cocoa powder is the cake ground to the desired degree of fineness – usually as 95–99% will pass through a 200-mesh screen. Powders with less than 10–12% cocoa butter are known as low-fat cocoas. Medium-fat cocoa contains 10–18% fat, and high-fat or "breakfast cocoa" has 22–24% fat. Approximately 95% of the cocoa powders on the market today are the medium-fat variety. The FDA has established Standards of Identity for various types of cocoa products (Table 29.1).

Natural cocoa is cocoa powder that has not been treated with alkali. Van Houten, in 1828, first treated cocoa with the addition of alkali; hence, it is also known as "Dutch" process cocoa. The alkalization process raises the pH of the cocoa powder from 5.2–5.6 in fermented beans to a pH of 6.8–7.5. Black cocoas, used for color, may have a pH as high as 8.5 (Minifie 1989c). FDA standards allow a maximum of 3.0% potassium carbonate per 100 lb (45 kg) of nib weight equivalent. Added alkali neutralizes acidity in the cocoa, resulting in a milder, less astringent flavor and a range of colors (from light brown to red and even black). Various formulas, equipment, and processes are used to alkalize the nibs, liquor, or powder. This allows for a wide range of cocoa powders to be produced. As such, alkalized cocoa powders are in greater demand than natural cocoa powder. Table 29.2 lists the various cocoa powder types and their applications.

TABLE 29.1 U.S. Standard of Identity for Cacoa Products, Code of Federal Regulations (CFR), Title 21, Food and Drugs.

21 CFR Reference	Product	Chocolate Liquor (%)	Milk Solids (%)	Comments
163.111	Chocolate liquor	100	0	• 50–60% fat • Optional ingredients 1 • Other names: unsweetened chocolate, bitter chocolate, baking chocolate, cooking chocolate
163.112	Breakfast cocoa		0	• 22% fat (min) • Optional ingredients 1, with the exception of butter or milk fat
163.113	Cocoa		0	• 10–22% fat • Optional ingredients in 163.112 • Other name: medium-fat cocoa
163.114	Low-fat cocoa		0	• Less than 10% fat • Optional ingredients in 163.112
163.123	Semisweet/ bittersweet chocolate	35 (min)	12 (max)	• Sweetened chocolate liquor, which may contain one or more, specified optional ingredients 2 • Traditional bittersweets 50% or more liquor
163.123	Sweet chocolate	15–35	12 (max)	• Sweetened chocolate liquor, which may contain one or more, specified optional ingredients 2
163.124	White chocolate	0	14 (min)	• 20% cacao fat (min) • 3.5% milk fat (min) • 55% nutritive carbohydrate sweetener (max)
163.130	Milk chocolate	10 (min)	12 (min)	• Sweetened chocolate liquor with dairy ingredient(s), which may contain one or more, specified optional ingredients 2
163.150	Sweet cocoa and vegetable fat coating		No limit	• Same as 163.123 except: mixture of cocoa and chocolate liquor contains a minimum of 6.8% nonfat cacao solids; contains one or more optional ingredients 3
163.153	Sweet chocolate and vegetable fat coating		12 (max)	• Same as 163.123 except that it contains one or more optional ingredients 3 (except for cocoa)
163.155	Milk chocolate and vegetable fat coating		12 (min)	• Same as 163.130 except that it contains one or more optional ingredients 3 (except for cocoa)

TABLE 29.2 Types and Applications of Cocoa Powder.

Cocoa Type	Flavor	Applications
Nonalkalized		
Natural (pH 5.2–5.7)	Mild, cocoa notes	Compounds, syrups, bakery toppings, confectionery
Alkalized		
Light Dutch (pH 6.5–7.0)	Mild, cocoa notes with mild alkali undernotes	Dairy, beverage, creams, syrups, toppings, confectionery
Red (pH 7.0–8.0)	Moderate to strong alkali notes	Bakery, dairy, beverage, cream, confectionery
Dark (pH 7.0–8.0)	Mild to moderate alkali notes	Bakery, confectionery
Black (up to pH 8.2)	Intensely unique alkali flavors	Cookies, coloring agent

29.5 CHOCOLATE MANUFACTURING

Manufacturing of dark, milk, and white chocolates involves certain basic operations: ingredient mixing, refining, conching, standardization of viscosity, and tempering. Like cocoa powders, the chocolate liquor (white chocolate uses cocoa butter only) may undergo alkalization prior to further processing. The FDA has issued Standards of Identity for milk, dark, and white chocolate (Table 29.1).

Many chocolates seen on the market will advertise something like 60% cocoa solids. This is really cocao solids, which includes cocoa butter, cocoa powder, and chocolate liquor. In general, a more intense flavor occurs with a higher percentage of cacao solids.

29.5.1 Ingredient Mixing

Chocolate liquor, sugar, cocoa butter, milk products (for milk chocolate), emulsifiers, and flavors are the basic ingredients that are blended together. The result is a paste with a rough texture and plastic consistency. It is often passed through a kneader or plasticizer to improve uniformity prior to entering the conches.

29.5.2 Refining

In order to obtain a smooth texture with increased surface area, steel rollers are used to reduce particle size of the mass to 10–40 μm. This process is called refining. The actual size will depend upon the product desired and type of chocolate, with dark chocolate generally having a smaller finished particle size. During this process the resulting mass often turns into a dry paste or powder.

The manufacture of milk chocolate is similar to that of dark chocolate. The way milk is added plays an essential part in the process. Milk solids are introduced in the form of milk powder or milk crumb, where it is dry mixed with chocolate liquor and sugar. Milk powder is produced by first concentrating liquid milk and drying it into a powder. The crumb process involves blending sweetened condensed milk and chocolate liquor. It is kneaded and dried. Crumb-based chocolates have a unique caramelized flavor based on the Maillard reaction between milk protein and sugars (Minifie 1989e; Stauffer 2000).

The term "white chocolate" has been used loosely for a number of years. It is basically milk chocolate with cocoa butter but no chocolate liquor. Cocoa butter is mixed with sugar, milk solids (a white crumb can be made from cocoa butter), emulsifiers, and flavors. Use of a

mild-flavored cocoa butter is preferred because the flavor of white chocolate is quite delicate. White chocolate is also more prone to oxidative rancidity than milk and dark chocolate.

29.5.3 Conching

After refining, the mass is transferred to large shear mixers (conches). This is the last manufacturing process where texture and flavor are affected. Time, temperature, moisture control, and shear manipulate the process. Some of the benefits of conching are (Hofberger 1999b) as follows:

- Improved rheology/reduction in viscosity (less cocoa butter needed);
- Elimination of harsh volatiles for a mellower taste;
- Removal of moisture (reduces lumping and graining);
- Improved mouthfeel (smoothes sharp particle edges).

Additional cocoa butter, flavors, and emulsifiers may be added during this process. Conching times will vary depending upon the formulation and final product desired, but can vary from 10 to 12 h up to several days. Conching temperatures range from 120 to 160°F (49–71°C), and sometimes up to 180°F (82°C). The higher conching temperature gives the final product a caramelized flavor that is different from milk crumb caramelized flavor (Minifie 1989f).

29.5.4 Viscosity

Standardization of product viscosity is one of the final steps in the manufacturing of chocolate. The development of automatic molding and enrobing equipment requires precise control over the fluidity or viscosity of the chocolate. It should be noted that the viscosity of chocolate increases with the presence of *free* moisture in chocolate. Thus, general moisture tests will not necessarily provide pertinent information for viscosity. Minute amounts of water or steam from leaking equipment, improper storage (humid conditions), and rework can affect the overall performance of the chocolate.

Chocolate is a non-Newtonian liquid in that its viscosity (internal friction of fluids) is affected by the presence of solids in suspension, as well as by temperature. Once chocolate starts to flow, its viscosity will decrease with an increase in the shear rate (Minifie 1989d; Hofberger 2000).

The United States is the only country that still uses degrees MacMichael to decribe chocolate viscosity. The MacMichael viscometer is a single-speed rotational instrument. It works on the following principle: A metal cylinder is suspended on a torsion wire, which, in turn, is immersed in a cup of chocolate at a given temperature. As the cup rotates, twisting of the wire is measured by a scale. The main drawback of the MacMichael method is its inability to provide full information on the flow properties of different chocolates.

In other parts of the world, viscosity is usually measured in centipoise. A Brookfield viscometer can determine plastic viscosity and yield values accurately. Results using a Brookfield can be converted to degrees MacMichael. Table 29.3 shows a range of chocolate viscosities and their typical applications. Viscosity alone will not indicate how the product will perform in the handling process. Two terms that help to describe flow character are yield value and plastic value. Yield value (YV) is the force required to initiate the flow of chocolate. Plastic viscosity (PV) is the force required to maintain

TABLE 29.3 Chocolate Viscosities and Their Applications.

Viscosity (in °MacMichael)	Applications
Very thin (<100°MacMichael)	Enrobing, panning, shell molding
Thin (100–125°MacMichael)	Enrobing, panning, solid molding
Medium (126–160°MacMichael)	Enrobing, hand dipping
Heavy (161–200°MacMichael)	Depositing (chips), hand dipping, molding

Source: Adapted from Hofberger (2000), Wilbur Chocolate (2003).

the flow of chocolate once it has started to move. A high YV is important in maintaining decoration marks and the prevention of "feet" on enrobed goods. A low YV is desirable for molded products to properly shake out air pockets (Minifie 1989d; Hofberger 2000).

Several factors can affect viscosity and rheology. Smaller particle size in a constant formula will give a higher viscosity. Lecithin is thus an excellent emulsifier as it exhibits both lipophilic and hydrophilic properties. The hydrophilic groups attach themselves to the water molecules on the surface of the sugar particles and reduce friction, increasing particle mobility and thus lowering viscosity (Minifie 1989d). This reduction in viscosity can also decrease the need for more expensive cocoa butter by as much as 5% (Hofberger 2000). In the United States, the addition of lecithin or other emulsifying agents is limited to 1% by weight.

29.5.5 Tempering

Tempering is the controlled cooling of melted chocolate with agitation to promote the formation of small stable fat crystals throughout the chocolate. Besides agitation, time and temperature are also critical factors in the tempering process.

Cocoa butter is a polymorphic fat in which the crystals have different characteristics, melting points, and stability. There are four major types, γ, α, β', and β, with β being the only stable form. The unstable forms will eventually recrystallize into the stable β form (Minifie 1989b; Kattenberg 2001) (Table 29.4). Stable cocoa butter crystals will provide the following desired properties (Hofberger 2001):

- Snap,
- Good gloss,
- Proper texture,
- Bloom resistance,
- Contraction for demolding, and
- Less permeable barrier (increased shelf-life).

TABLE 29.4 Polymorphic Forms of Cocoa Butter.

Form	Crystallization Temperature	Melting Range	Approximate Life
Alpha α	From gamma	70–75°F (21–24°C)	1 h
Beta β	72–92°F (22–33°C)	68–95°F (20–35°C)	Stable
Beta prime β'	32–72°F (0–22°C)	59–85°F (15–30°C)	1 month
Gamma γ	<63°F (<17°C)	Up to 63°F (17°C)	Very unstable

Source: Adapted from Cook (1982).

The cocoa butter used in chocolate manufacture will affect the physical properties of the chocolate. The origin of the bean will also affect its quality. Attributes affected include hardness, texture, mouthfeel, and melting point of the butter.

Tempering can be conducted manually or in an automatic tempering unit to form stable fat "seed" crystals. There are many types of units available using various methods to achieve the goal. In general, chocolate tempering involves heating the chocolate to approximately 110–115°F (43–46°C) to melt the fat crystals, followed by cooling with agitation to between 80 and 84°F (27–29°C), and subsequently reheating to about 86–88°F (30–31°C) before molding or coating. In general, dark chocolates are tempered about 1–2°F (0.5–1.0°C) higher than milk chocolate (Hofberger 2001). However, exact temperatures and procedures will depend upon the tempering equipment and type of chocolate used.

The four most common types of automated temperers include the following.

- *Tempering kettle*. This is primarily a batch operation where the proper temperature is maintained by a jacketed water kettle, and agitation necessary for crystallization is provided by the sweeping action of the stirrer.
- *Plate heat exchanger*. The cooling and warming cycle is accomplished when chocolate passes over a series of jacketed plates. The scraping action of the plates allows rapid growth of small crystals. This is currently the most popular and common type of temperer.
- *Screw-type temperer*. As chocolate passes through a jacketed shell, the scraping action of the screw provides the agitation necessary for seed formation. Different sections of the shell provide the proper temperatures needed.
- *Bowl-type temperer*. This method uses dry heat to melt chocolate in a rotating bowl. Chocolate is melted to ~105°F (40–41°C), and then cooled by ambient air to approximately 86°F (30°C). During this process, tempered pieces of chocolate are placed in the back half of the divided bowl to provide the proper "seed" crystal. After the chocolate is sufficiently tempered, the temperature is raised to 88–90°F (31–32°C) to prevent overtempering. This method has the advantage of not requiring external water and plumbing. Room temperatures must be kept at 73°F (23°C) or less to provide for proper tempering. These units are gaining in popularity for very small candy shops where the use of "real" chocolate is desired.

The viscosity of the chocolate increases in proportion to the increase in seeding during tempering, thus chocolate must be used fairly quickly, or carefully heated to remelt some of the seed to prevent overtempering and achieve a steady state of temper. Overtempered chocolate may cause problems such as dull finish, excessive air bubbles, and poor mold release because of reduced contraction of the chocolate. Undertempered chocolate will also have poor mold release and will have a tendency to "finger print", and have premature blooming.

Once the desired pieces of chocolate are formed, the chocolate should be cooled gradually to prevent future problems. Initial cooling temperature should be approximately 65°F (18°C) with minimal air movement. This is necessary for the continued formation of stable crystals and to prevent case hardening or the formation of a "skin". Temperatures can gradually be decreased to about 45°F (7°C) with increasing air velocity. Final cooling temperature before packing should approach that of the room temperature (about 68°F) (20°C).

One must take into consideration the heat load of the product and adjust air temperatures and velocities accordingly when sending product through a cooling tunnel. Small pieces

of chocolate will set at a faster rate than large molded blocks. The temperature on the discharge end should be higher than the dew point to prevent condensation on the chocolate. At this point, the chocolate may appear solid. But, in fact, only about 70 to 75% of the cocoa butter is crystallized. It will take about 48 h for all of the cocoa butter to crystallize. So packing and storage conditions are still an important consideration (Hofberger 2001).

29.6 PRODUCTION METHODS

29.6.1 Enrobing

The mechanized form of hand dipping is enrobing. By completely covering the center with chocolate, the shelf-life of the product may be extended. This is primarily applicable to centers that, if not covered, could be prone to moisture loss, oxidation, or microbial action.

To ensure a firm bottom, manufacturers often first pass the centers through a prebottoming step. The prebottoming step can be done with chocolate or compound coatings. The advantage of using compound coatings is that they may be set up faster and no tempering is needed. The prebottoms need to be set before entering the enrober. This is especially important when lauric-based compound coatings are used, because they will most likely eventually bloom due to fat incompatibility.

Maintaining a consistent temper in the enrober will affect the coverage and appearance of the final product. Most enrobing units today utilize active tempering/detempering equipment.

Enrobing equipment with active tempering may have either inboard or outboard tempering. For smaller operations, an inboard unit that is part of the enrober provides for an inexpensive and compact unit. For larger operations, an outboard or separate tempering unit would be more suitable. It can also be fitted with a screen to filter inclusions coming from the center mass. Both methods follow the principle of enrobing centers with a tempered coating. The excess coating is removed, detempered, and retempered before entering the enrobing process again. This helps to prevent overseeding of the chocolate in the enrober. Chocolate temper should be taken at the enrober and not at the tempering machine, where line temperatures and residence times from the tempering machine to the enrober can significantly affect the amount of seeding.

It is important that the centers entering the enrober be maintained at 70–75°F (21–24°C), and the enrobing chocolate have the desired viscosity and rheological properties. Warmer centers may lead to possible bloom problems as the heat tries to escape from the interior of the enrobed product. Cold centers may also cause blooming and cracking of the coating shell due to expansion of the center mass as it warms.

The prebottomed centers are conveyed on a wire belt through a curtain of tempered chocolate, coating the top, sides, and bottom as well. The excess coating is removed through the action of adjustable vibratory shakers and forced air blowers. The blowers will often leave a desired rippled decoration on top. Prior to transferring to the conveyor belt, the product passes over a rotating detailer rod to remove the trailing "tail" at the end of the enrobed piece. For maximum shelf-life, it is important that the centers be completely covered, with no pinholes.

29.6.2 Cooling

After enrobing, the product enters a cooling tunnel to allow the coating to harden. To avoid blooming problems, temperature changes should be gradual, and the relative humidity

properly controlled. If the dew point is lower than room temperature, moisture could condense on the product and cause sugar bloom during storage.

There are three basic types of cooling tunnels that allow for the proper crystallization of the coating:

- Convection tunnels use chilled air moving in parallel under the product belt. The cold air enters near the discharge end of the tunnel, and moves counter current to product flow, and is removed near the entrance to the cooling tunnel.
- Multizone tunnels have chilled air moving transversely to product flow in specific sections. These types of coolers allow precise temperature control and even have the capability of re-warming the product prior to discharge to prevent condensation.
- Radiant cooling tunnels utilize black matte absorption plates. They absorb the radiant heat from the chocolate that supposedly helps to prevent case hardening of the chocolate. To increase the cooling rate, many radiant tunnels also use convection air movement.

29.6.3 Depositing and Molding

Deposited and molded chocolates are popular with consumers. For molded chocolates, design detail and uniformity can be controlled to a greater extent than with enrobed chocolates. For optimal quality and throughput, it is especially important that environmental conditions and the chocolate itself be closely monitored. Environmental factors include room temperature and relative humidity, and important chocolate issues include degree of temper, temperature, rheology of the coating, and time.

Different operations will require different temper, viscosity, and rheology of the chocolate. Improperly tempered chocolate will not have the proper contraction, set-up time, gloss, and resistance to bloom. This especially affects molded chocolates in that proper viscosity and temper are crucial for the proper filling of the molds as well as the demolding operation.

29.6.3.1 Depositing. Also known as drop depositing, this operation produces the familiar chocolate chips, caps, and stars. Tempered chocolate is deposited through a multi-piston block, through a depositor plate and nozzle, and onto a moving belt.

While the chocolate is still soft, nonpareil items may be made by covering the product with nonpareil seeds. As the coating hardens in the cooling tunnel, some of the seeds adhere to the surface, with the excess seeds separated out after exiting the tunnel.

Chocolate with inclusions such as nuts and crisp rice can also be deposited onto a moving belt. Most inclusions are mixed with the chocolate before it reaches the depositor. This can be done in a batch or continuous process. One needs to consider the density of the inclusion in relation to the chocolate because less dense inclusions tend to float and denser inclusions will have a tendency to sink.

The coating should have a high viscosity to give it good stand-up qualities and inhibit flow and distortion after depositing.

29.6.3.2 Molding. The molding process can be either done manually or mechanically. The main types of molds include solid, shell, and hollow molding.

Solid Molding. Of all the types, solid molding has been around the longest and is used primarily to produce small novelty items and bars to the 10-lb (4.5-kg) blocks commonly used in the industry. Tempered chocolate by itself, or mixed with inclusions such as nuts, raisins,

crisp rice, and so on, is deposited into traditional metal or the more popular polycarbonate molds that are the reverse image of the desired end product. The molds are shaken to evenly distribute the chocolate and remove air pockets. If necessary, the mold may be scraped to remove excess chocolate before entering the cooling area. After cooling, the hardened chocolate is inverted and the mold twisted or tapped to release the product. The molds are then warmed to the appropriate temperature before returning to the depositor. This is necessary to prevent blooming of the bars and for proper set-up of the chocolate.

For solid molding, a chocolate with a low plastic viscosity (PV) is desired for the proper release of entrapped air. If inclusions are added, a medium-viscosity chocolate should keep the particulates in proper suspension.

Shell Molding. There are several types of shell molding; however, all are a fairly complex operation where a center is enclosed in a chocolate shell. The centers are usually somewhat soft, from truffles, fudges, creams, and cordial cherries to semiliquid caramels and liqueurs.

For the classic shell process, tempered chocolate is deposited in molds, vibrated to remove entrapped air, then inverted and shaken to remove most of the chocolate, leaving a thin shell. The chocolate is cooled and the filling is deposited. The mold surface and shell rim are briefly warmed before chocolate is deposited on the filling. This allows for the complete adhesion between the shell rim and the bottom coat of chocolate. The excess chocolate is scraped off and the mold is cooled, allowing the candy to fully contract. After sufficient cooling, the product is demolded and packaged.

Recent developments in shell molding equipment allow for the chocolate and filling to be produced in one depositing sequence that is commonly called a one-shot deposit. It is possible to deposit a warm homogeneous center mass such as creme fondant, caramels, truffles, and meltaways. In this process, two separate hoppers, one with chocolate and the other with the filling are deposited through concentric nozzles with precision timing to insure that the center is surrounded by chocolate. The mold is then vibrated, cooled and demolded.

Hollow Molding. With hollow molds, a mold is partially filled with chocolate, then closed and rotated on a spinner to distribute the chocolate throughout the mold. The items most commonly associated with hollow molding include novelty items such as Easter eggs, bunnies, and Santa Clauses. Hollow molding is still primarily done in batches on a spinning machine that rotates 360° through all axes. Chocolate is deposited in a two-piece mold that is then closed (with clips, hinges, or magnets) and spun. After the chocolate has cooled to the point where it no longer flows, the molds are cooled and then demolded. Chocolate used for this operation should have a low viscosity and yield value to provide a thin shell.

29.7 CONFECTIONERY COATINGS

In the United States, chocolate must conform to a certain Standard of Identity. If it does not meet the specifications, it cannot legally be called chocolate. The FDA has established Standard of Identities for cocoa products and other commonly used cocoa-based products (Table 29.1).

29.7.1 Compound Coatings (Vegetable Fat Coatings)

These are similar to real-chocolate coatings except that chocolate liquor and cocoa butter have been replaced with cocoa powder and less expensive vegetable fat, respectively. The

ingredients are dry mixed and refined to a smooth texture, with conching kept to a minimum. White and pastel compound coatings consist of vegetable fat, sugar, and dairy powder, with added flavors and colors.

The vegetable fats substituted for cocoa butter may be classified as lauric and nonlauric fats. Lauric fats are short-chained fatty acid glycerides that have physical properties similar to cocoa butter but are incompatible with cocoa butter. Examples are fractionated coconut and palm kernel oils. They have good stability, texture, and flavor release. Tempering is not needed and it is less expensive than cocoa butter. However, when exposed to lipases, especially in the presence of moisture, the free fatty acids released will have a strong soapy taste (Minifie 1989c).

The nonlauric fats are composed of longer-chain fatty acids and include hydrogenated soy, palm, and cottonseed oils. Unlike lauric fats, the nonlauric fats can be blended with up to 25% cocoa butter and chocolate liquor for a stronger flavor. Due to texture differences, the nonlaurics are used primarily for covering baked goods where a less brittle (or snap) texture is desired. Nonlauric fats are also susceptible to decomposition by lipases; however, the fatty acids liberated do not have a soapy flavor (Minifie 1989c).

29.7.2 Sugar-Free Coatings

Sugar-free coatings have been available to the food industry for over 30 years. The original versions were difficult to manufacture. With the advent of technology and health issues, the quality and quantity of sugar-free coatings and their related products have increased tremendously.

According to the FDA, a sugar-free food contains less than 0.5 g of sugars per reference serving size (US Code of Federal Regulations 2004). For most confections, the reference serving size is 40 g, so the 0.5 g/40 g equates to less than 1.25% allowed sugars. Common examples of sugars are glucose, sucrose, fructose, and lactose. Confections that are "no sugar added" generally have no added sucrose, but may contain another sugar such as lactose, which is found in milk powder.

At the present time there is no Standard of Identity for sugar-free chocolates in the U.S. Code of Federal Regulations. From a legal standpoint, this product cannot be called "chocolate". To minimize the sugar level, caseinates are often substituted for the milk as milk contains sugars in the form of lactose.

The milk powder generally used for traditional chocolates contains naturally present lactose over 50% of the nonfat dried milk. This does not meet the requirements of a sugar-free label and can only be used for "no sugar added" coatings. Sodium caseinate and to a lesser extent calcium caseinate are most commonly used as a milk replacer for sugar-free coating. Sodium caseinate at a 4–9% level will be sufficient to replace a traditional milk chocolate containing 12–20% milk solids (Hofberger 2003).

Sugar alcohols as a group have always been considered the key to making a good sugar-free coating. With the exception of xylitol and in some instances maltitol, they are often combined with high-intensity sweeteners such as aspartame, acesulfame K, and sucralose to achieve the same sweetness level as sugar-based coatings. Aspartame is more sensitive to heat and acidic conditions. Acesulfame K in high concentration can give a bitter aftertaste. Aspartame has the disadvantage of having to require a "contains phenylalanine" warning label when used (Hofberger 2003).

Most formulations using a high proportion of sugar alcohols will require a label statement of "excess consumption may have a laxative effect." If a sugar-free claim is made, it

must also include a "not a reduced calorie food" statement unless the caloric value is at least 25% less than the standard product.

29.8 CHOCOLATE BLOOM PROBLEMS

The most common problem encountered during chocolate storage is probably blooming. It is a defect that manifests itself as a grayish-white film on the surface of the product. In most instances the eating quality is not affected; however, the appearance is not very appetizing. Bloom may occur anywhere from a few hours after production to several months later (Seguine 2001). There are basically two types of bloom – sugar and fat.

29.8.1 Sugar Bloom

Sugar bloom occurs less frequently than fat bloom and its appearance may look like fat bloom. It occurs when the surface of the chocolate is exposed to moisture or high humidity and then dries out. The surface film of water dissolves some of the sugar particles in the chocolate, which then recrystallizes upon drying into a dull grayish-white haze. It commonly occurs in chocolate products emerging from a cooling tunnel into a warm and humid room. It also may occur when product is brought out of cold conditions and subjected to warmer, humid conditions without proper packaging and time to gradually bring it up to room temperature. In general, sugar bloom feels dry to the touch and does not melt, which differs from fat bloom.

29.8.2 Fat Bloom

Fat bloom is the visible accumulation of large cocoa butter crystals on the chocolate surface, which may give it a greasy surface texture that melts readily when touched. It may be accompanied by numerous mini cracks that give it a dull grayish-white appearance. These changes are primarily due to the polymorphic nature of cocoa butter and the migration of liquid fat (McCarthy and others 2003). Some factors causing chocolate bloom are listed in Table 29.5.

TABLE 29.5 Some Factors Causing Chocolate Blooming.

- Cold molds, warm to 75–80°F (24–27°C)
- Cooling tunnels/rooms that are extreme cold
- Extreme water tempertaure used in cooling/heating
- Improper formulation of centers that allow moisture or oils to migrate to the outer surface of the coating
- Introduction of foreign fats (such as coconut oil) into the chocolate
- Packaging/shrink-wrap of finished goods with heat can cause localized bloom
- Placing chocolates in cold storage before fully solidified; solidification takes 24–48 h
- Processing line equipment heaters that detemper chocolate
- Storage temperature exceeding 88–90°F (31–32°C); ideally $<$68°F ($<$20°C)
- Temperature fluctuations during storage
- Too cold or hot center mass when enrobing; ideally 70–75°F (21–24°C)
- Undertempered chocolate

Source: Adapted from Hofberger (2001).

29.9 STORAGE AND HANDLING

Like many other foods, chocolate flavor will change over time, resulting in a more balanced flavor profile. In general, most chocolates should be contained in a nonpermeable barrier for protection from oxygen, moisture, and light. Ideally, chocolate should be stored at 65–68°F (18–20°C) and less than 50% relative humidity. Dark chocolate is less prone to moisture absorption during storage than milk chocolate (Minifie 1989g; Hofberger 1999b; Urbanski 2001). As it is fat-based, it will readily absorb off-odors so chocolate should be stored in an odor-free environment. Chocolate will also pick up odors from packaging materials, printing inks, as well as odors generated from the heat sealing or shrink-wrapping process. Advances in packaging technology now include water-based cold-seal adhesives that not only eliminate the potential for heat-damaged chocolates but are also low in odor, thus eliminating or reducing the possibility for the development of off-flavors or smells (Barry 2003).

Properly stored, solid chocolate should have a shelf-life of one year of more. Chocolate can be frozen for even longer storage; however, care must be taken when bringing it back to room temperature from the frozen state to avoid condensation.

If chocolate is manufactured from clean beans under sanitary conditions, its microbial count should be low due to its low water activity (a_w) level. However, chocolates may become contaminated by some of the ingredients and equipment used, and improper storage conditions.

Moisture can be introduced into the product during its manufacture (such as equipment leaks or improperly dried equipment) or during storage under damp conditions. This may lead to mold problems. Equipment leaks will produce a high-viscosity chocolate that is readily apparent and should not be used for further processing. Moisture on the outer surface of the chocolate from improper storage conditions can also cause mold growth.

Rancidity is generally not a problem in milk and dark chocolates because of the natural antioxidant properties of undeodorized cocoa butter. Rancidity can be found on occasion in white chocolate and compound coatings and is catalyzed in the presence of air, moisture, light, heat, and some metals. With oxidative rancidity, the fats or oils exposed to air produce objectionable flavors due to the formation of aldehydes and ketones. The addition of synthetic antioxidants will help inhibit this reaction although some fats contain natural antioxidants as well (Minifie 1989g).

Hydrolytic rancidity, also known as soapy rancidity, is due to the lipid hydrolysis of fat into glycerol and fatty acids with the production of an off-flavored soapy taste. Lipases may be present in ingredients such as coconut, milk products, egg albumen, and cocoa. However, not all lipase activity will result in a soapy flavor. If possible, it is recommended that ingredients susceptible to hydrolytic rancidity be heat treated to inactivate the enzyme. Fats containing lauric acid, even a trace amount, will yield a soapy flavor. Coconut oil and palm kernel oil contain 40–50% lauric glycerides, and butter fat contains 2–6%. Cocoa butter and palm oil do not contain lauric acid (Minifie 1989g).

29.10 NUTRITIONAL VALUE

Chocolate is not a major source of dietary fat, but it does contain fat. The majority of the fat comes from cocoa butter and is composed mainly of three fatty acids: 30–37% of the monounsaturated fatty acid is oleic acid (18 : 1), 32–37% of the saturated fatty acid is stearic acid (18 : 0), and 23–30% of saturated fatty acid is palmitic acid (16 : 0). It also

Source: USDA Nutrient Database for Standard Reference (2002).

[a]Values are per 1 oz (28.35 g) unless otherwise noted.

contains 2–4% linoleic acid (Nacional de Chocolates 2003). Although stearic acid is classified as a saturated fat, it does not appear to raise cholesterol levels the way other saturated fatty acids do (Chocolate Information Center 2003a). Table 29.6 shows the USDA nutrient content of several types of chocolate.

Chocolate has also been noted recently to contain relatively high amounts of polyphenols, in particular the flavanols, catechin, and epicatechin. Polyphenols are found in the plant kingdom and exhibit antioxidant activity that is thought to reduce the risk of some human diseases. The levels found in chocolate and related products will depend upon cocoa bean variety, fermentation, and subsequent processing and formulation (Chocolate Information Center 2003b; International Cocoa Organization 2003a).

A class of alkaloid molecules known as methylxanthines (such as caffiene, theobromine, and theophylline) occurs naturally in a number of plant species. They exhibit similar pharmacological properties. They are mild stimulants and possess mild diuretic properties (About Chemistry 2001; International Cocoa Organization 2003b). A common belief is that chocolate contains a lot of caffeine. However, caffeine is the primary alkaloid in coffee, theobromine the primary alkaloid in chocolate, and theophylline the primary alkaloid in tea. A comparison of the caffeine contents in chocolate and coffee is presented (Table 29.6).

A food allergy is a reaction by the body's immune system to a substance, usually a protein, in the food. According to the National Institutes of Health, approximately seven million Americans (more children than adults) have a true food allergy. Eight food allergens account for 90% of all allergic reactions. These include milk, eggs, peanuts, tree nuts, soy, wheat, fish, and shellfish (Chocolate Manufacturers Association 2003b; National Confectioners Association 2003). An allergy to chocolate itself is uncommon; however, the addition of other ingredients may cause an allergic reaction.

Chocolate is one of the most popular flavors, enjoyed by millions of people in a variety of ways, from beverages, to main dishes, sauces, baked goods, and of course confections. Eaten in moderation it can be part of a healthful diet.

Handbook of Food Products Manufacturing. Edited by Y. H. Hui

30.1 ESTABLISHMENT INSPECTION FOR CHOCOLATE AND COCOA PRODUCTS

All information in this chapter has been modified from several public documents available at the website of U.S. Food and Drug Administration (FDA). The discussion resembles the format of teacher-student. The supervisor is describing the procedures to the inspection personnel. The objective of the presentation in this chapter is to assist the plant operation manager of a food company to become familiar with a food processing establishment inspection routinely conducted by the federal agency, FDA.

Food plant inspections are conducted to evaluate the methods, facilities, and controls used in manufacturing, storage and distribution of chocolate and chocolate products foods. Before an inspection, review FDA's guides on the general procedures. Direct special attention to the following areas when inspecting establishments processing chocolate and chocolate products.

30.1.1 Raw Materials

Insects that commonly infest cocoa beans are stored product insects representing an avoidable defect. Cocoa beans are often fumigated to kill these insect pests and cocoa bean processing effectively removes any such filth where the insects have not invaded the interior or nib portion of the bean. During inspections, determine that effective measures such as physical barriers are in place to prevent cross contamination between cocoa bean cleaning and finished product processing operations.
If cocoa beans are received in bags proceed as follows:

1. Screen a number of lots in storage by conducting a preliminary field examination. Field examine a representative number of bags in the lot. Be alert for live stored food insect pests on or around the bags including adult and larval beetles and moths. Document findings with photographs and collect samples as instructed by FDA guidelines. Extract approximately one pound of beans from each bag field examined utilizing an appropriate sized trier. Screen the beans on a number 3 sieve. Examine siftings for the presence of insects, rodent excreta and other extraneous material.
2. Composite one-hundred cocoa beans from ten to twenty bags in the lot.
3. Crack open each bean and break the interior portion (nib) of the beans into small pieces along the natural folds of the nib material. This can be accomplished with a hammer, pruning shears or pliers. Examine for mold and/or insect damage. A moldy bean is defined as any bean showing extensive mold effecting a quarter or more of the exposed nib material. Insect damaged is defined as any bean showing insects (fragments or whole insects), insect excreta, webbing or tunneling.
4. Collect an official sample for laboratory examination if field exam reveals:
   a. 2% or more moldy beans; or
   b. 2% or more insect damaged beans; or
   c. 3% or more moldy plus insect damaged beans.

If cocoa beans are received un-bagged in cargo containers obtain the subsample from random locations and levels within the container utilizing a grain probe.

If examination of raw material beans indicates the presence of internal insect damage and/or mold, document with appropriate samples, the use of those beans in the manufacture of processed chocolate products.

Determine if critical raw materials including non-fat dry milk (NFDM) and chocolate are received under a Salmonella Free Certificate.

Evaluate the firm's testing of raw materials for bacterial load, including Salmonella and other pathogens.

30.1.2 Processing

Determine in detail the firm's cocoa bean processing to include the following.

1. Precleaning: Use of magnets to remove metal.
2. Blending: Determine percent of different beans in blend.
3. Roasting: Time temperature relationship. Determine if ovens have recording thermometers.
4. Cooling: Time and to what temperature.
5. Cracking and fanning operations.
6. Milling.
7. Storage of chocolate liquor: temperature of storage tanks.

Be especially alert for avenues of contamination by water or condensation. The presence of moisture can result in conditions that can support the growth of Salmonella.

Ascertain firm's coding system.

30.1.3 Sample Collection

30.1.3.1 In-Process Sampling

1. Collect in-line samples and exhibits to document insanitary conditions which may result in contamination of the finished product with filth, mold, bacteria or other factors.
2. When the sample is collected for Salmonella and other bacterial examination, include 30-100 gram (4 oz) subs of the finished product.

30.1.3.2 Finished Product Sampling

Filth: Cocoa Beans. Take the square root of the number of bags in the lot to determine the number of subs to collect. Multiply by three to determine the number of bags to sample. Each sub will consist of 450 grams (1l b) of beans composited by collecting approximately 170 grams (1/3 lb) from each of three bags. You can sample up to a maximum of seventy-five bags which would yield twenty-five subs but in no case collect less than six subs. Fore more details, consult FDA's guidelines.

Filth: Cocoa Powder, Press Cake, Expeller. Cake, Chocolate. For microscopic filth, excess shell, etc., sample the square root of the number of bags in the lot. Collect a minimum of six and a maximum of eighteen subs each consisting of 900 grams (2 lbs) taken 340 grams (2/3 lb) from each of the three bags. Collect the subs in duplicate for

the 702(b) portion. For retail size containers, sample the square root of the number of containers in the lot with a minimum of six and a maximum of 18–900 gram (2 lb) subs.

Consult FDA guidelines for microbiological and standard sampling.

30.2 ESTABLISHMENT INSPECTION FOR CANDY WITHOUT CHOCOLATE, CANDY SPECIALTIES, AND CHEWING GUM

For these types of manufacturing establishments inspection, direct special attention to the following points.

30.2.1 Raw Materials

Egg and milk products must be pasteurized before use or otherwise treated during processing to destroy viable Salmonella microorganisms. Steps must also be taken to ensure that other raw materials susceptible to contamination by pathogenic microorganisms (i.e., gelatin, dried coconut, nuts) are free of such organisms before use unless they are pasteurized or otherwise treated before or during processing. Materials capable of supporting growth of pathogenic microorganisms must be held at appropriate temperature and relative humidity except for the period of time actually required for processing and not so long as to effect the wholesomeness of the product. Raw materials such as nuts and corn meal that are susceptible to aflatoxin contamination must comply with FDA regulations, guidelines, and action levels for poisonous or deleterious substances or be received under the supplier's guarantee of such compliance.

30.2.2 Equipment and Manufacturing Processes

Evaluate the control of foreign objects embedded or hidden within candy such as wooden splinters, glass, or otherwise dangerous articles. Processors must take every reasonable precaution to ensure that production procedures do not contribute contamination from any source. For example, strategically located magnets and/or metal detectors may be necessary to prevent contamination by metal.

30.2.2.1 Molding Starch and Trays Molding starch is often contaminated. Determine how long it has been in use. Estimate amounts and frequency that fresh starch is added. In addition, if wooden starch trays are utilized, check for splitting and/or splinters.

30.2.2.2 Scrap Candy (Rework) Evaluate the handling and reworking of scrap candy. Determine if containers used for rework can be readily distinguished from containers used for waste. Determine the source of scrap candy for rework.

30.2.2.3 Food and Color Additives Identify the slab dressing used, and estimate the amount per batch. Slab dressings are lubricants employed as release agents on such equipment as cooling tables used in the manufacture of hard candy. If mineral oil is used at a level higher than 2000 ppm (0.2%, approximately 100 g (3½ oz) per 91 kg (200 lb) batch), obtain shipments for finished product sampling.

Regulation limits the amount of alcohol that confectionery may contain to one-half of 1% by volume, and this must be derived solely from the use of flavoring extracts. However, this does not apply to confectionery designed for interstate commerce, if the sale of such confectionery is permitted under the laws of the state in which such confectionery is intended to be offered for sale.

30.2.3 Sample Collection

30.2.3.1 In-Process Sampling

Molding Starch. Collect the following subsamples when insects or rodent excreta are observed near molding starch operations:

1. One pint of starch from the starch mogul;
2. One pint of starch from starch trays in use;
3. One pint of tailings from the starch cleaner.

Scrap Candy (*Rework*). When appropriate collect exhibits and/or official samples of contaminated scrap, and describe how it is used. If contamination by filth is suspected, collect representative exhibits and/or official samples of scrap, even though no macroscopic filth is evident.

Deleterious Articles. Collect samples of products (usually 3–6 units) that have sharp pointed articles or otherwise dangerous articles embedded or hidden within candy (e.g., wooden sticks, pins, trinkets) when a potential for injury exists.

30.2.3.2 Finished Product Sampling

Mislabeled Chocolate Products. The current standards for cocoa products can be found in 21 CFR Part 163. When mislabeling is caused by a reference to chocolate, documentation should include a reference sample of the ingredient being substituted and this ingredient's quantitative formula and labeling. Be aware that FDA may issue temporary permits for test marketing of products that deviate from the standards.

Deceptive Packages. Submit specimens of flagrantly deceptive packages consisting of three filled and three empty packages with all "spacers" and fillers.

Refer to FDA guidelines for sampling filth and microbiological status.

30.3 ENFORCEMENT ACTIVITIES FOR CANDY AND SWEETENERS

The FDA rigorously enforces the law when violations are uncovered in a routine inspection. Usually, other warning signs alert the FDA to such violations. This section describe some such violations in confectionery products.

All information on these enforcement activities has been modified from public documents at the FDA's official government website.

30.3.1 Boxed Candies Recalled due to Undeclared Egg Whites and Yellow #6

FDA's Seattle District Office reported that on May 9, 2002, a chocolate company in Portland, Oregon, initiated a Class I recall of their CLASSIC 9 piece, CLASSIC 16 piece, and 12 Piece Spring Collection boxed candies due to undeclared egg whites and yellow #6. The boxed candies contained a toffee truffle with a flower decoration on top. The flower decoration contained the undeclared egg whites and yellow #6. The products were sold in retail stores and through mail order.

30.3.2 Imported Candy Seized

FDA's Southwest Import District (SWID) recommended the seizure of 192 cases of Hormigas candy that was found to be in whole or partly substituted for candy refused admission by FDA. The candy was manufactured by a company in Mexico and imported into the United States and refused admission by FDA due to filth contamination.

The U.S. Customs' special agents conducted actual seizure of the substituted merchandise. In addition to the seizure, U.S. Customs considered assessing liquidated damages against the importer for failure to redeliver the actual merchandise refused admission by FDA.

30.3.3 Konjac Candy

On October 5, 2001, FDA issued a second warning to the public concerning the serious choking hazard caused by konjac candy. FDA issued the first warning on August 17, 2001. Konjac candy is a fruit-flavored gel candies in various flavors that is imported primarily from Asia and has been linked to six deaths in children in the United States. FDA decided a second warning was warranted after consultation with experts on choking from the Consumer Product Safety Commission (CPSC). CPSC staff confirmed that these candies posed a serious choking risk, particularly to infants, children, and the elderly. FDA also issued an import alert to address the problem of importation of these candies from other countries. The agency worked with numerous firms in a nationwide recall of these candies. One firm refused to recall their candies and the product was seized by FDA following repeated attempts to get the firm to recall the candies.

FDA announced a recall by a Puerto Rico firm of 1500 cartons of Fruzel assorted Natural Fruit Jelly Candy because these products present a choking hazard. The product was distributed to wholesale and retail establishments throughout Puerto Rico under the "Neo USA" brand. The mini jelly candies came in assorted flavors. Each mini jelly cup is about the size of a single-serve coffee creamer. The candies were packaged in 16.5 g jars with 88 units per jar.

On May 17, 2002, FDA announced a recall by a firm in Bayonne, NJ, of 1197 cases of mini jelly candies (or mini cup gel candy) because these products presented a choking hazard. The product was distributed to retail establishments throughout New York, Massachusetts, Illinois, Florida, Georgia, Maryland, New Jersey, Pennsylvania, and Virginia under the "ABC" brand.

On April 25, 2002, FDA announced a recall by a company in Chicago, Illinois, of 3115 bags of mini jelly candies (or mini cup gel candy) because these products present a choking hazard. The product was distributed in bags which read in part; "Mi Costenita . . . Gelatinas Coconut Jelly" to retail establishments in Illinois, Michigan, Ohio, Indiana, Tennessee, Arkansas, Missouri, Mississippi, Kansas, Alabama, Georgia, North Carolina, and Wisconsin.

On April 25, 2002, FDA announced a recall by another company in Chicago, Illinois, of 464 cases of mini jelly candies (or mini cup gel candy) because these products present a choking hazard. The product was distributed to retail establishments throughout northern Illinois and Wisconsin under the "Jojomo" and "Naluwan" brand. The label described the product as "JM Jojomo" and "Naluwan Nata De Coco Konnyaku Jelly" in all flavors. The candy came in small creamer-sized sealed plastic cups.

On April 5, 2002, FDA announced recalls from a company in the City of Industry, California, and one in Vernon, California, of 100 cases of mini jelly candies (or mini cup gel candy) because these products present a choking hazard. The product was distributed to retail establishments throughout southern California under the "Sugarland" brand. The label described the product as "Jellyace Buko Pandan". The candy came in small sealed plastic cups.

On February 15, 2002, FDA reported a recall by an Asian company in Chicago, Illinois. These candies were distributed in Illinois, Iowa, Indiana, Kentucky, Ohio, Wisconsin, Florida, Michigan, Missouri, South Dakota, and Kansas. The three brand names included "Don Empire", another with no brand name and only Chinese characters and butterflies on the label, and "My Love and Coco". The individual serving cups were packaged in 300 g plastic bags with 30 bags per case, 510 g plastic panda-bear-shaped jars with 12 jars per case, and 1200 g round plastic jars with 6 jars per case.

There were numerous recalls of the same products sold under different brand names. Many of the recalled products were destroyed.

30.3.4 Seizure of Honey with Chloramphenicol

On August 28, 2002, FDA investigators from the New Orleans District accompanied the U.S. Marshals Service in a seizure of imported bulk, in-process, and finished-product honey located at Davidsonville, Louisiana. The product was valued at approximately $50,000,00. A sample of the imported bulk honey, collected by the New Orleans District, was tested by FDA's Denver District Laboratory and found to contain chloramphenicol at or above the level of 1 part per billion (ppb). The Louisiana Department of Agriculture and Forestry also conducted tests on samples of the imported honey and found the product contained chloramphenicol.

Chloramphenicol is a broad-spectrum antibiotic approved for use in humans with serious infections when other, less toxic, drugs are ineffective. It has not been possible to identify a safe level of human exposure to chloramphenicol due to the unpredictable dose–response on different patients. The main toxic effect of chloramphenicol in humans is the development of a type of bone marrow depression (aplastic anemia) in susceptible individuals. This condition is usually irreversible and fatal. In addition, the onset of the condition is not dose–dependent.

Prior to seizure, FDA had issued a letter to the U.S. Attorney on August 27, 2002, requesting that a Complaint for Forfeiture be filed in the U.S. District Court. The Complaint charged that the products were adulterated because they contained a food additive, namely chloramphenicol. The violations are that the products were misbranded because the label bears the statement "no additives", which is false and misleading in that the article contains the food additive chloramphenicol. There are health consequences that may result from the consumption of the article.

31.1 INTRODUCTION

Margarine was invented and patented by the French chemist, Hippolyte Mege Mouries, in 1868 as a substitute to butter. A shortage of butter due to an increasing urban population and growing army prompted this invention. The margarine was traditionally based on animal fats and the process was a relatively simple mixing process that included simultaneous cooling (Applewhite 1985; Hoffmann 1989).

Over the years the original product range has multiplied into a large variety of fat products, and since 1940 it has been possible to produce margarine in closed continuous

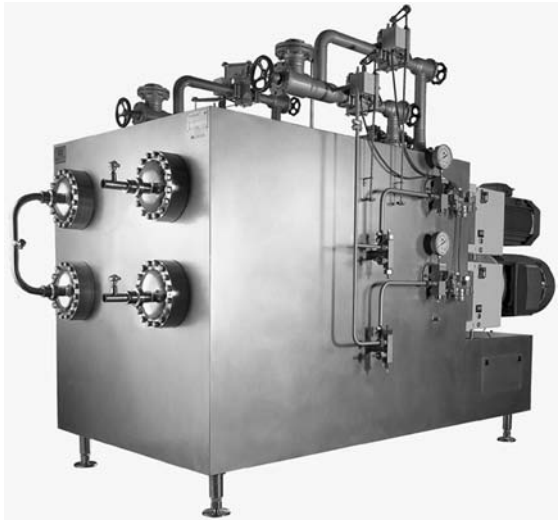

Figure 31.1 *Scraped surface heat exchanger type (1 + 1 + 1 + 1) × 250 Perfector (manufactured by Gerstenberg and Agger A/S).*

systems using scraped surface heat exchanger (SSHE) technology. Previously, margarine was mainly produced in open systems using a chilling drum. Today, both crystallization methods are still used in the industry: SSHE and drum chilling (Figs 31.1 and 31.2).

In today's market there are a range of products containing different types and amounts of fats and oils. Vegetable fats and oils are used to a great extent. After 1910 when hydrogenation came into practice in Europe, a greater variety of fats and oils was available and significant advances in the manufacturing process were made (Chrysam 1996).

The SSHE plant is by far the most flexible of the crystallization technologies in terms of crystallization of different types of fat products. The SSHE plant is designed to produce a large variety of fat products including consumer and industrial margarine, shortening, ghee, vanaspati (i.e., vegetable ghee), recombined butter, and dairy blends.

Consumer margarine includes all-purpose table margarine, soft table, reduced and low-fat spreads, and speciality products. Speciality products can be margarine containing flavours, spices, or functional ingredients.

Industrial margarine includes bakery products such as puff pastry margarine, cake and cream margarine, frying margarine, and bakery improvers.

In this chapter, the crystallization of fats and oils used for margarine and spreads production along with the processing techniques and market trends will be described.

31.2 INGREDIENTS FOR MARGARINE AND DAIRY SPREADS

Margarine and related products contain a water phase and a fat phase. Depending on the nature of the product the recipe will typically consist of a fat blend, emulsifier(s), flavour(s), colour(s), water, salt, sugar, and preservatives. Stabilizers are often added to fat spreads.

31.2.1 Fat Phase

31.2.1.1 Interchangeability of Fats and Oils. Margarine, like butter, can be characterized as a water-in-oil (w/o) emulsion in which the water phase is finely dispersed as droplets in the continuous fat phase. The fat crystals form a three-dimensional network resulting in products with properties of plastic semisolid nature (Stern and Cmolic 1976; DeMan and Beers 1987; Juriaansee and Heerttje 1988). The major ingredients in the fat phase, the fat blend, consist normally of a blend of different fats and oils. In order to achieve margarine with the desired characteristics and functionalities, the ratio of fats and oils in the fat blend is very important. The objective is to obtain a defined solid fat content (SFC) measured by NMR at various temperatures, typically ranging from 5 to 40°C (NMR). The SFC profile (Fig. 31.3) describes the amount of solid phase compared to the liquid phase at the given temperature. The SFC profile will vary according to the type of product; cup-filled margarine such as soft table margarine contains the least solids at a given temperature and puff pastry contains the highest amounts of solids (Haighton 1976; Berger 1989).

Variations might occur within each product category, because margarine manufacturers around the world have different product specifications according to application. In addition, seasonal changes might force the manufacturers to modify the oil blend formulation several times a year, shifting to harder formulations from winter to summer.

The ingredients used in the formulation of the fat blend can be derived from any animal, vegetable, or marine oil source. The choice of fats will depend on legislation, price, quality, functionality, and market demands. However, the availability of fats can be limited due to legislation, religious prohibitions, or trade barriers (Berger 1989).

As shown in Table 31.1, it is possible to divide ingredients into three main categories: liquid oils, semisolid fats, and hard stocks. Liquid source oils are today considered to be completely interchangeable as components of margarine and shortening blends due to the modern refining processes. Fat-modification processes such as fractionation,

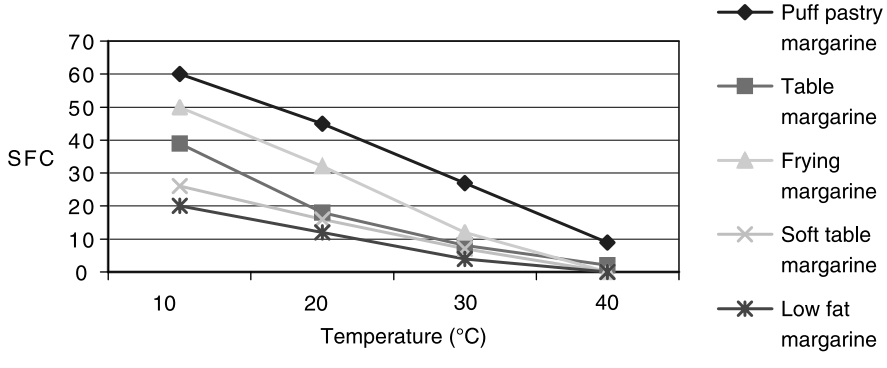

Figure 31.3 *SFC profile of selected margarine products (Gerstenberg and Agger 2001).*

TABLE 31.1 Selected Oils and Fats Grouped According to Melting Points (Berger 1989).

Liquid Oils	Semisolid Fats	Hard Stock
Unsaturated vegetable oils	Hydrogenated oils (MP: 32–34°C)	Hydrogenated oils and fats (MP > 40°C)
Palm olein	Butter fat (MP: ~34°C)	Interesterified oils and fats (MP > 40°C)
Palm kernel	Palm	Beef tallow
Coconut	Lard	Palm stearin

hydrogenation, and interesterification enable a high degree of interchangeability among fats. The modification processes produce, individually or in combination, the full range of fatty intermediates used in the manufacture of all types of margarines, and these processes enable fats to become almost completely interchangeable.

A particular product specification can be met by a large number of alternative formulations. A suitable blend can be made by combining one or more ingredients from each of the three groups (Berger 1989). By mixing the ingredients from the three groups in specific ratios, a suitable SFC profile can be met. If, for example, hydrogenated soy bean oil is used in soft table margarine and hydrogenated rapeseed is cheaper, the latter can substitute for hydrogenated soybean oil in the formulation. Thus, the producer attains the flexibility to interchange the best available and cheapest raw materials in an ever-changing market situation. The consumers are thereby certain to buy continuously a product with the same quality and price. However, certain technical limitations exist when combining one or more ingredients from the three groups. The crystallization habit or polymorphism of the fat can set limits on the proportion of the particular fat used in the blend. In addition, the crystallization rate of the fat blend is of great importance in regard to the configuration of the processing line.

31.2.1.2 Other Fat Phase Ingredients. Apart from the fat blend, the fat phase typically consists of minor ingredients such as emulsifier, lecithin, flavour, color, and antioxidants. These minor ingredients are dissolved in the fat blend before emulsification as described above.

Emulsifiers are surface-active compounds used to reduce the interfacial tension between the water and the fat phase. The emulsifier stabilizes the liquid emulsion before crystallization to secure a homogeneous product and provide fine and stable water distribution in margarine and spreads. The microbiological keeping properties in the final product are thereby improved. The most commonly used emulsifiers in margarine are distilled monoglycerides or mixtures of mono- and diglycerides. The best water-binding effect in margarine is achieved by using saturated monoglycerides (Danisco 2002c).

Soya lecithin can be used with the emulsifier to improve the effects of the emulsifier. To achieve the maximum effect of the emulsifier–lecithin system, the emulsifier is heated with the lecithin and liquid oil before the mixture is dissolved in the melted fat blend. Additionally, lecithin reduces spattering in frying margarine, and it prevents burning of sediment compounds (lactose and casein), because lecithin incorporates these compounds. Lecithin is also a good antioxidant (Bonekamp 1990; Stauffer 1996).

Fat-soluble butter flavour and color (i.e., β-carotene) are added to achieve a product that tastes and looks like butter. In addition, β-carotene has pro-vitamin A activity.

Depending on geographical region, flavors can include a large variety of taste profiles such as fermented, buttery, fatty, vanilla, sweet cream, sour, and fruity.

Antioxidants can be added in order to improve the shelf-life of the product, because these substances can delay the onset or slow the rate of oxidation. In margarine production the following antioxidants can be added to the water or fat phase according to solubility: natural tocopherols, BHA (butylated hydroxyanisole), BHT (butylated hydroxytoluene), TBHQ (tertiary butyl-hydroquinone), ascorbic acid, and ascorbic palmitate (Danisco 2002c). The use of food additives, such as emulsifiers, flavors, colors, and antioxidants, is controlled by health authorities and governmental agencies. The use and the maximum dosages permitted in food vary. Thus, local legislation should always be consulted before using food additives in food products.

31.2.2 Water Phase

The water phase differs depending on the type of margarine; thus, it has a certain influence on the finished margarine. It consists mainly of water in which the minor ingredients such as salt or brine, milk or milk protein, and preservative are dissolved. For low-fat margarine, stabilizers can be added as well as water-soluble flavor and color. For puff pastry margarine, sugar can also be added.

Salt or brine is added primarily to improve taste, but also to prevent growth of micro-organisms. In frying margarine, salt helps to prevent spattering. A content of 1% salt will minimize the growth of the majority of micro-organisms in margarine (Danisco 2002b). The salt content varies from area to area of the world. For example, in Europe a salt content of 1–1.2% is normal, whereas in South America a salt content of up to 3% is not unusual.

Milk proteins such as skim milk powder, whey powder, cream powder, or sweet butter milk powder have an oil in water (o/w) emulsifying effect. These ingredients work against the margarine w/o emulsifier system, and thus destabilize the margarine emulsion. However, this enhances the flavor release, and milk protein is added to the emulsion when producing table margarine, reduced-fat spreads, and low-fat spreads to improve the taste. Additionally, milk proteins contribute to the desired browning effect in margarine used for frying (Gerstenberg and Agger 2001).

Citric acid is used to lower pH, which has the effect of not only extending shelf-life of puff pastry margarine, but it also contributes to lift of the puff pastry (Alexandersen 1996). Other preservatives often used in margarine are benzoates and sorbates. They are most active at a pH of $\sim$4.5; this makes the advantage of their addition doubtful, because the pH in most margarine emulsions is often close to neutral. In full-fat products, preservatives are not necessary as long as the product is properly crystallized and packed. If the water droplets are finely distributed and their size is between 2 and 4 μm, the possibility of occurrence of micro-organisms is limited (Danisco 2002b).

31.3 CRYSTALLIZATION TECHNOLOGY

Fats tend to crystallize in various forms having different melting points. Each of these crystalline forms with their respective melting points is called a polymorph and the phenomenon is called polymorphism (Timms 1984, 1985).

The triglycerides exhibit, with some exceptions, three basic crystalline forms designated alpha (α), beta prime (β'), and beta (β). In general, transformations take place in the order: $\alpha \rightarrow \beta' \rightarrow \beta$. The transformations are irreversible except by melting and

recrystallization. It is possible that the transformation from one polymorphic form to another takes place in the solid state without melting. This transformation will only take place in the direction of a more stable form seeking the most compact crystal form and the lowest thermodynamic energy state possible (Sato 1988).

Different polymorphs can co-exist in the fat. These different forms show melting points depending on the cooling and heating history of the fat. Due to a so-called crystal memory, crystalline structure is preserved even though the fat is melted. This structure will affect crystallization directly, especially when the rate of cooling is high (Larsson and Friberg 1990). The polymorphic changes in the margarine may lead to a grainy structure (Merker and Wiedermann 1958; Timms 1984; Johansson and Bergenståhl 1985).

When cooling the melt, α crystals are generally formed, but this form is never stable in triglycerides and transformation to β′ is a reality. In most cases, β′ crystals are relatively slowly transformed to the stable β form. The time of transformation from one crystal form to another depends on the composition of the triglycerides and the presence of diglycerides in the fat blend (Ong and others 1995). However, some fats possess both β′ and β forms, others only either the stable β′ form with no further transition or the stable β form.

The literature states that the degree to which fats will exhibit either β or β′ tendency depends on hydrogenation and depends to a lesser extent on blending factors (Table 31.2). Also, the palmitic acid content of the fat seems to be responsible for exhibiting a particular crystal habit. Fats containing a relatively low amount of palmitic acid (C16:0), approximately 10%, seem to be β tending, whereas fats with at least 20% palmitic acid, in general, are β′. It is not only the amount of palmitic acid that seems to determine the crystal habit, but also the distribution in the glycerol molecule. For instance, lard and tallow contain approximately 24 and 25% palmitic acid, However, lard is β tending due to the high concentration of palmitic acid in the sn-2 position of the glycerol molecule, whereas tallow is β′ tending because of sn-1,3 positioning (Wiedermann 1978).

At ambient temperature, natural fats contain both a liquid and a solid phase. A phase is a state of a homogeneous matter separated from other phases by a physical barrier, and can be defined by its composition, temperature, and pressure. Phases can be solid–liquid just like ice and water, oil and fat; phases can also be solid–solid when fat has co-existing polymorphs, and liquid–liquid as in mayonnaise and salad dressing.

It is important to have knowledge about phase behavior of fats because macroscopic properties such as spreadability of margarine and butter (Narine and Marangoni 1999) can be affected when different solid phases are present. The desirable properties of margarine are closely related to the kind of crystals present; β′ crystals are the most desirable apart from a few types of shortening (Wiedermann 1978). The β′ crystals are relatively small, exhibiting a needle-like structure, and can incorporate a larger amount of liquid oil in the crystal network. β′ crystals result in a glossy surface and a smooth texture.

TABLE 31.2 Crystal Habits of Selected Fats (Wiedermann 1978).

β′ Tending Fats	β Tending Fats
Butter oil/milk fat	Canola
Coconut	Cocoa butter
Cotton seed	Corn
Modified lard	Lard
Palm	Soybean
Tallow	Sunflower

The crystallization of melted fat is the process of phase transition of molecules from liquid to solid state; the driving force is the difference between the melting point of the fat and the actual solution temperature (Grall and Hartel 1992).

The solid phase formed will consist of finely dispersed and generally microscopically sized crystals. The remaining liquid phase will fill up the interstitial space around the crystals. The crystals are interconnected by bridges and form a crystal network, also called the solid/liquid matrix (Johansson and Bergenståhl 1985; Hoffmann 1989).

The transition from the α form to the β' form takes place in the crystallization equipment. All fats tend to crystallize in the β' form when crystallization takes place in an SSHE plant. Fats that are not stable in the β' form due to its triglyceride composition will eventually transform into the β form.

31.4 MARGARINE PRODUCTION

As described in the introduction, margarine and other crystallized fat products are today produced by either the SSHE process or the traditional chilling drum process.

The chilling drum is cooled inside by ammonia or freon evaporation. A thin layer of emulsion ($\sim$0.1 mm) is placed on the cooling surface of the chilling drum; thus, cooling of the emulsion takes place rapidly without agitation. After one rotation the crystallized emulsion is scraped off as a thin film or as thin flakes. The produced flakes will have to rest in trolleys or silos in order to complete the crystallization process. After hours of resting the margarine flakes are kneaded in the vacuum kneading unit in order to achieve a margarine block exempt from air.

Because the chilling drum plant requires more space, is more labor-consuming, and less hygienic than the SSHE, the continuous SSHE is used as the crystallization method for the majority of fat products produced around the world. Today the chilling drum process finds only limited use, mainly for the production of puff pastry margarine products often containing animal fats. In the SSHE, a different and slower crystallization process takes place while the emulsion is agitated when compared to the crystallization process in a chilling drum plant. However, the complete crystallization process from melted emulsion to finished margarine or spread is faster, more hygienic, and more efficient for the SSHE process when compared to the traditional chilling drum process. Apart from the actual crystallization line, a modern manufacturing facility for margarine and related products will typically include various tanks for oil storage as well as for emulsifier, water phase, and emulsion preparation; the size and number of tanks are calculated based on daily capacity of the plant. The facility also includes a pasteurization unit and a remelting facility (Fig. 31.4).

The various oils, either as an oil blend or single oils, are stored in oil storage tanks (area 1) typically outside the production facility. Each tank is furnished with automatic temperature control and an agitator in order to secure a stable storage temperature above the melting point of the fat and to avoid fractionation of the oils, respectively.

Typically, the plant is supplied with liquid emulsifier and lecithin from the emulsifier storage tanks (area 2). Emulsifier from blocks, pellets, or flakes can also be added to the emulsifier tanks manually. All emulsifiers are preblended with liquid oil, typically in the ratio of 1 : 5 in order to ease handling and to secure homogeneous distribution of the emulsifier later in the fat phase and the emulsion. The emulsifier tanks can either be hot-water heated or heated with steam. When the emulsifier blend is ready, it awaits transfer to the premix tank.

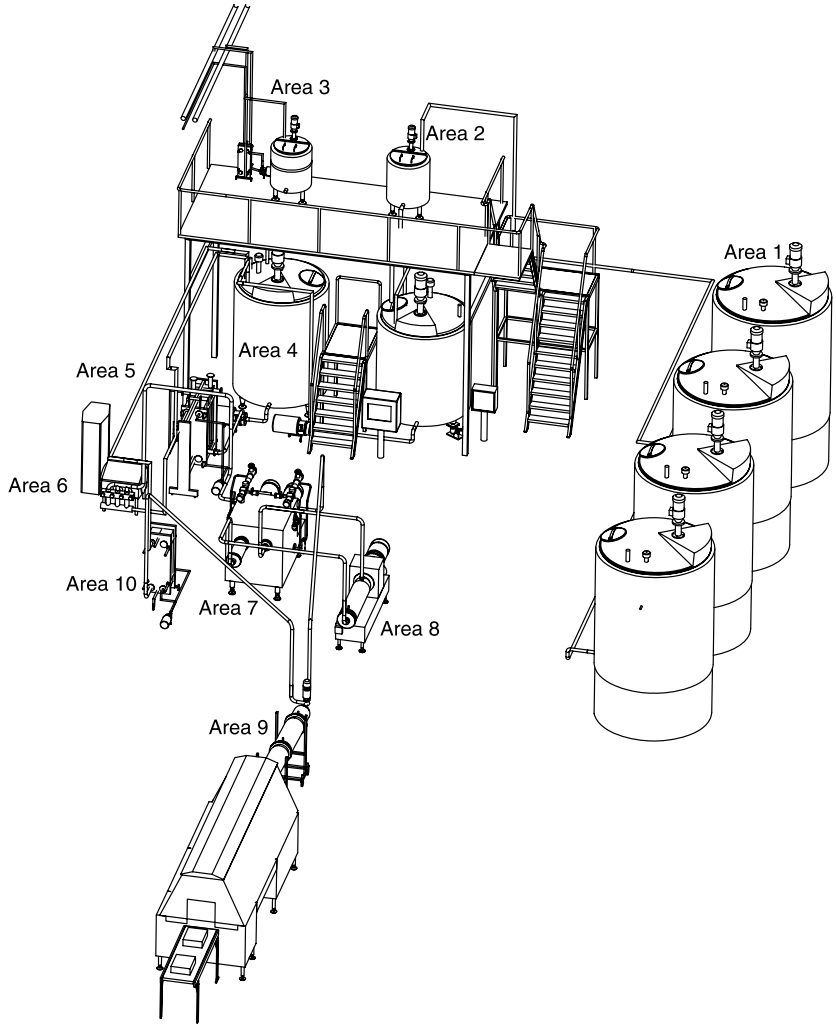

Figure 31.4 *Example of a margarine plant.*

For preparation of oil-soluble and/or water-soluble minor ingredients, smaller tanks are used. Minor ingredients such as salt, flavors, colors, preservatives, additives, antioxidants, and vitamins are dispersed later in the phases according, to solubility. The extent to which additives may be used in food as well as the maximum dosage permitted often vary from country to country. Therefore, the legal authorities should always be consulted before using additives in food products. The tanks for minor ingredients are connected to the water phase and premix tanks. The minor ingredients await the signal from the control system, which then automatically transfers the ingredients into the water phase or premix tanks.

Batching of the water phase in the water phase tank (area 3) can take place from four sources: water, milk, brine, water-soluble minor ingredients.

Water is supplied directly as sufficient pressure and capacity should be available. It must be of good drinking quality, free from harmful micro-organisms, and of an

acceptably low hardness as $CaCO_3$, that is, <100 mg/L (Bylund 1995). Normally, a water heater is included to ensure adequate temperature for dissolving the ingredients and to avoid precrystallization in the premix when the water phase is added to the oil blend.

Normally, milk is mixed using water and milk powder. This mix is dissolved, pasteurized at a temperature of at least 72°C for 15 s, and cooled to 5°C before transfer to the milk storage tank. As long as the milk has been produced from raw materials of sufficiently high quality (i.e., low number of colony forming units, CFU), and under good technical and hygienic conditions, the pasteurized milk should have a shelf-life of up to 4 days in the milk storage tank at 5°C (Bylund 1995; Larsen 2004).

Brine can be made in a locally supplied salt saturator of sufficient capacity. In order to achieve a steady flow in the salt saturator and avoid dragging unsaturated water through the saturator, a buffer tank is typically included. By using brine, the salt crystals are not present in the product, which positively affects the quality of the margarine or spread. In addition, the chilling tubes of the SSHE are very sensitive to salt, because salt is aggressive towards the coating materials used on the surface of the chilling tubes.

Minor ingredient units can be built for central preparation of water-soluble minor ingredients, and each of the units would be connected to the water tanks. The minor ingredient preblend could be dosed through a common pipe, then flushed with water and finally purged with N_2 to secure a clean pipe.

Oil and the emulsifier blend are typically metered by flow meters and/or weighed into the premix tank standing on load cells. The type of agitator used in the premix tank depends on the type of product; typically the impeller type or the anchor type are used. The agitators are specially designed to create a strong current that follows the shape of the tank. This efficient mixing assures that the product reaches everywhere in the tank and pushes the product upward, thus avoiding product dead zones. The agitator creates a uniform and controlled flow pattern for the entire batch.

Batching of emulsion takes place by transferring various oils and fats or blends to the premix tank (area 4) in which the emulsifier and other oil-soluble minor ingredients are added. When all the ingredients for the fat phase have been properly mixed, the water phase is added and the emulsion is created under intensive but controlled mixing.

When the emulsion is ready, it will automatically be transferred from the premix to the buffer tank to enable a new batch to start automatically in the premix tank. A solution with two combined premix/buffer tanks could also be an option where each tank would work as a premix tank as described above. Each tank would additionally work as a buffer tank, thus the line would be fed from one tank while a new batch would be prepared in the other.

From the buffer tank the emulsion is normally continuously pumped through the plate heat exchanger (PHE) or in some cases an SSHE for pasteurization prior to entering the crystallization line (area 5). The buffer tank receives the excess product returning from the remelt tank, remelt PHE (area 10), or remelt SSHE, which enables the remelted emulsion to be reprocessed. For very-low-fat products, the pasteurization process in the PHE might only involve the water phase, or if the complete emulsion is pasteurized it can be done in an SSHE due to the often high viscosity of the low-fat emulsion.

The emulsion is pumped to the crystallization line by means of a high-pressure piston pump (area 6). Apart from the buffer tank(s), PHE, and the high-pressure piston pump, a typical crystallization line for the production of margarine and related products consists of a high-pressure SSHE (area 7), pin rotor machine(s) (area 8), and a resting tube (area 9), as shown in Figure 31.5.

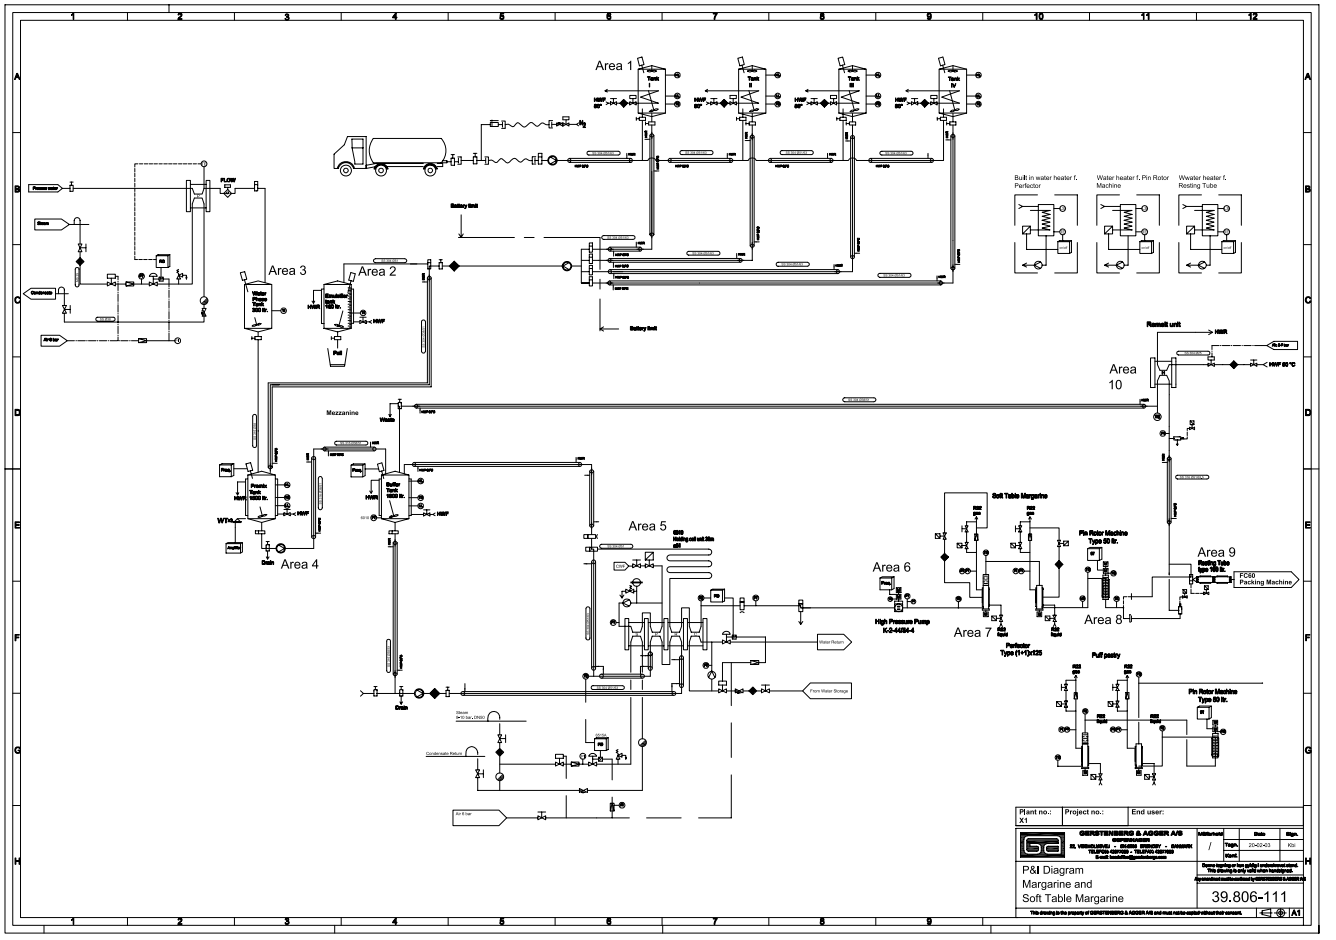

Figure 31.5 *P&I diagram of a margarine plant.*

Depending on the type of product to be manufactured, the configuration of the crystallization line (i.e., the order of the chilling tubes and the pin machines) can then be adjusted to provide the optimum configuration for the particular product. The heart of the crystallization line is the SSHE, in which the emulsion is chilled and then crystallized. As the crystallization line usually manufactures more than one specific fat product, the SSHE often consists of two or more cooling sections or chilling tubes in order to meet the requirements for a flexible crystallization line. When producing different crystallized fat products of various fat blends, flexibility is needed because the crystallization characteristics of the blends might differ from one blend to another.

After the product is chilled in the SSHE it enters the pin rotor machine where it is kneaded for a certain period of time and with a certain intensity in order to assist the promotion of plasticity and/or softness. If the product is meant to be distributed as a wrapped product it, will enter the SSHE again for a given period of time before it settles in the resting tube prior to wrapping. If the product is to be packed in cups, no resting tube is included in the crystallization line. Examples of various configurations of the crystallization line related to the type of product are shown in Figure 31.6 and will be described later in the section concerning industrial products and consumer margarine and spreads.

The crystallization process and the processing conditions have a great influence on the characteristics of the final margarine and spread products. When designing a crystallization line, it is important to identify the characteristics of the products planned to be manufactured on the line. To secure investment for the future, flexibility of the line is necessary, because the range of products of interest might change with time as well as the raw materials.

The values in Table 31.3 concerning residence time through the various units in the crystallization line are used when designing a crystallization line. These figures are also

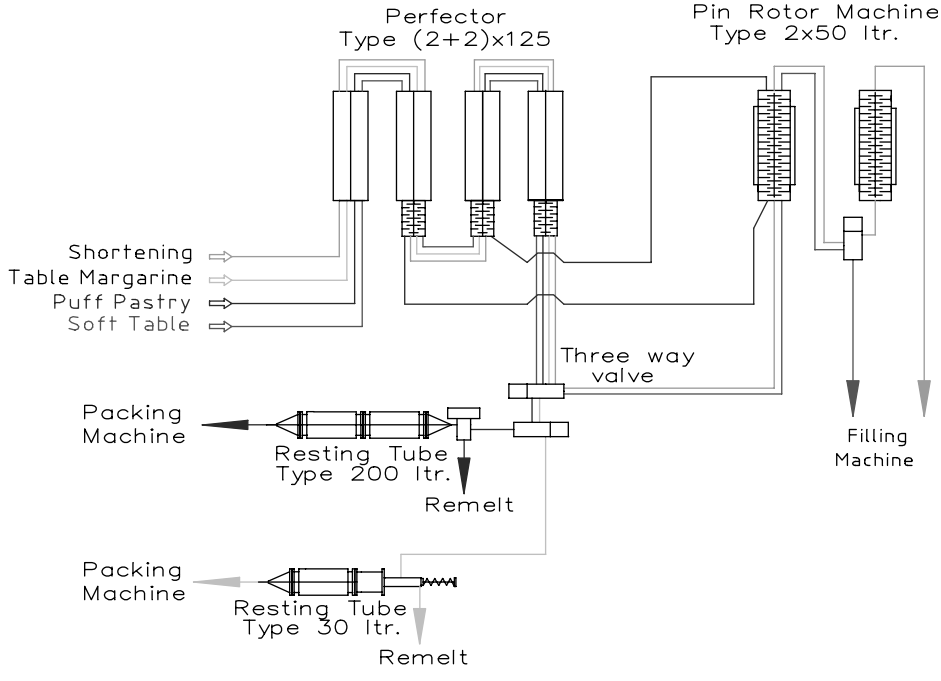

Figure 31.6 *Configuration of a flexible crystallization line (Gerstenberg and Agger 2001).*

TABLE 31.3 Recommended Processing Values for Residence Time Through Crystallization Unit Operations (Gerstenberg 2002, 2004).

Product	Pin Machine (% Volume/Time)	Resting Tube (% Volume/Time)	Capacity (%)
Puff pastry margarine	5–6	10–15	40–70
Cake and cream margarine	1–4	2	90–110
Table margarine	1–2	1–2	100
Soft table margarine	3–4	–	100–110
Low fat spreads	3–4	–	50–90

used in order to find the optimum processing parameters when manufacturing margarine and spreads products. When producing soft table margarine, lines are typically operated at full capacity. The cooling surface of the SSHE determines the capacity or product throughput of the margarine line. If the SSHE is designed to give 3000 kg/h soft table margarine, as a rule of thumb the volume of the pin rotor machine will be 3–4% of the throughput, meaning 90–120 L. The specific volume of pin rotor machine used depends on the type of soft table margarine and is decided individually from plant to plant.

The HPP feeding pump is not shown, but the SSHE, intermediate crystallizers (I/C), pin rotor machines (PRM), and resting tubes (RT) are shown in Figure 31.6. These are the necessary units to produce a large number of margarine and spread products. In this case a $(2+2)\times 125$ Perfector (manufactured by Gerstenberg and Agger A/S, Denmark) is used as SSHE and this type has a nominal capacity of 750 kg/h/tube measured by 80% margarine. Thus, the line can manufacture 3000 kg/h. It is named "2 + 2" because each cooling section has two chilling tubes, and "125" because the diameter of the chilling tube is 125 mm. Each chilling tube has a cooling surface of 0.42 m^2, resulting in 1.68 m^2 for the complete line (Gerstenberg and Agger 2004). The actual capacity of the line is determined by the cooling surface available and the type of product being manufactured.

In the Perfector, the emulsion is cooled and the crystallization process is initiated when the warm liquid emulsion meets the cold cooling surface on the inner wall of the SSHE. The emulsion is subsequently kneaded in small kneading units, I/C, mounted directly on the Perfector shaft or in the larger volume PRM. In these kneading units the secondary nucleation is promoted along with the plastic secondary bonds. In the PRM a rise in temperature will occur due to the release of heat of crystallization and mechanical heat. Typically, if the product is filled in cups or bag-in-box, the PRM will be included in the line prior to the filling machine as shown with soft table margarine, for example. If the product is packed or wrapped, the last step in the crystallization line will be the RT, as shown for table margarine.

Thus, the configuration suggestions shown in Figure 31.6 used in connection with the recommended figures in Table 31.3 provide a good foundation for optimal processing conditions. In the following section, characterization of various crystallized fat products will be described.

31.5 INDUSTRIAL PRODUCTS

Industrial products include shortenings and bakery margarine. Shortenings are defined as 100% fat products and will not be described in this chapter. Bakery margarine includes

products such as puff pastry margarine, cake margarine, and cream margarine. These products typically exhibit a fat content of 60–80% with the high-fat products still being most common.

Puff pastry margarine or puff pastry butter is used for the production of puff pastry and various baked products, which are characterized by a flaky structure of good volume and uniform appearance (Kun and Ong 1986). The flakiness depends partly on the plasticity of the roll-in puff pastry margarine, because the margarine in connection with a basic dough is rolled and folded several times in order to produce a thin product containing multiple, alternate dough/margarine layers. In order to achieve baked products with a flaky structure, formation of thin films of gluten that trap water vapor and carbon dioxide from fermentation is necessary. The thin films of gluten can form a three-dimensional structure. To prevent this from occurring, the laminates must be separated by continuous sheets of fat. Thus, the fat works as a barrier between the basic dough layers and prevents these from joining during the layering procedure. To function as a barrier the fat should not be absorbed by the dough layers and it must remain as a continuous film throughout the procedure.

The main demands of puff pastry margarine and butter are plasticity and firmness, because soft and oily margarine tends to be absorbed by the dough, and hard and brittle margarine is difficult to stretch during the abovementioned layering procedure. In both cases the baking performance will be affected negatively (Larsen 2004).

From Tables 31.3 and Figure 31.6 it can be noted that puff pastry margarine or butter is produced at a lower capacity (throughput rate). The content of solids is relatively high at usage temperature (high SFC profile), as it is important that the margarine is in its solid form during the layering procedure and before the baking process. The relatively high amounts of solids at given temperatures result in a need for more cooling energy in order to achieve crystallized products at packing. In addition, longer kneading time in the pin rotor machine(s) and SSHE is needed to achieve the plasticity and firmness of the product; therefore, a longer residence time is needed in the crystallization line. Typically, puff pastry margarine is produced with the configuration shown in Figure 31.6. The PRM is positioned between the two cooling sections in order to give the fat time to crystallize without cooling, but while kneading, which results in maximum plasticity in the product.

Traditionally, hydrogenated fats were used to produce puff pastry margarine, but palm oil and its fractions are now used to a great extent to minimize trans fatty acid content. It is additionally reported in the literature that puff pastry margarine based on palm oil shows excellent plasticity (deMan and deMan 1994). In some areas of the world where animal fats are still natural to use and available at favorable prices, beef tallow can be used for the production of puff pastry margarine. Also, interesterified blends can be used for the production of puff pastry margarine with success. However, the abovementioned recommended processing figures with regard to residence time and configuration have to be reconsidered, because margarine made by these blends tends to become greasy easily (Kirkeby 2003).

Cake and cream margarine can be covered as one, because often the same margarine is used for both of these applications. For example, this type of margarine is used in pound cake, short cake, and filling or decoration cream.

Cake margarine should exhibit a short structure in order to ensure that the final baked products have good crumb structure. The function of cake margarine is to prevent the formation of the gluten network as described under puff pastry margarine.

At usage temperature, cake margarine should consequently be soft and easy to incorporate into the batter in order to apply optimal stability to the finished products. Hereby, the fat will coat the individual flour particles and prevent these from forming the gluten network.

Firmer and more plastic cake margarine is used in cookie production where no air is incorporated into the batter (Danisco 2002a). Easy incorporation of the fat into the batter is still important and a certain plasticity of the margarine is necessary in order for the cookie to keep its shape and not spread out before baking.

At usage temperature, cream margarine should exhibit a short structure like cake margarine and the consistency should allow a large volume of air to be sufficiently finely incorporated and maintained. The cream must not collapse or separate on standing. Tempering is utilized to obtain the correct consistency.

From Table 31.3 it can be noted that cake and cream margarine can be produced with relatively low or high amounts of PRM volume. As a rule of thumb, packed cake and cream margarines require a lower amount of PRM volume positioned between the cooling sections and will settle in the RT before packing. Cake and cream margarine that is filled in boxes needs the PRM between the cooling sections for the plasticity but also at the end prior to the filling machine for plasticity and uniform filling.

It is generally accepted that lauric oils such as coconut and palm kernel oil (containing lauric acid) provide good whipping properties. These oils crystallize quickly due to a relatively steep melting profile or SFC profile, and they form small crystals in margarine, which ensures a homogeneous product. Additionally, the fat blend contains a certain proportion of higher melting fat and liquid oil in order to achieve strength in the crystal network and easy whipping ability, respectively. The whipping ability has been shown to be inhibited by fat blends containing a large number of triglycerides with similar fatty acid chain length such as hydrogenated rapeseed and hydrogenated sunflower oil. These fats also transform easily into the β crystal form. Interesterified fats can be used for cake and cream margarine (Danisco 2002a).

Industrial margarine is evaluated according to application. Margarine used for baking is typically subjectively evaluated for plasticity, and objective baking tests are used that involve a standard baking method imitating the application. Margarine used for creaming purposes is evaluated for creaming performance. Margarine is whipped with sugar according to a standardized procedure and the ability to incorporate air is calculated by weighing the known volume. Low specific volume is ideal.

Flavour is important for all types of margarines. In the case of margarine used for baking, the flavor has to exhibit certain heat stability or carry-through in order not to disappear completely during baking. Special carry-through flavor systems exhibiting a butter-like taste with necessary heat stability are on the market. Flavors for cream margarine usually have a light delicate butter experience (Danisco 2002a).

31.6 CONSUMER MARGARINE, SPREADS, AND DAIRY SPREADS

Consumer margarine, spreads, and dairy spreads cover a range of semifirm to soft products such as table margarine, soft table margarine, and low-fat spreads. Margarine is by definition a product containing 80% fat, whereas spreads are defined as products with a fat content lower than 80%. Reduced-fat spread contains approximately 60% fat, low-fat spread contains 40%, and very-low-fat spread has the range 20–35% fat content. Dairy spreads are defined as products containing a significant amount of butter or butter fat.

Table margarine is used in households or in food service as a substitute for butter in applications that include spreading on bread, baking, and pan frying, for example. Table margarine is typically marketed in a block format, often wrapped in foil or paper; the block format necessitates that this product be relatively firm in consistency in order to shape. However, a certain plasticity is necessary due to the multipurpose nature of the product. Depending on the climate or season, firmer and softer variations occur around the world. In Figure 31.3 it can be seen that table margarine does not show a straight SFC profile due to the fact that the product needs to melt relatively fast in the mouth. In addition, the product should exhibit a certain firmness and plasticity; thus, table margarine is formulated to have relatively high amounts of solids at 15°C.

According to Figure 31.6 and Table 31.3 table margarine is produced at nominal capacity without the PRM. However, the PRM is replaced by I/Cs in this case. The I/Cs shown in Figure 31.6 each have a volume of 15 L; thus, the total kneading volume in the crystallization line is 45 L, corresponding to 1.5% of the line. The I/Cs could be replaced by one, 50-L PRM in order to have the possibility of altering the rotation speed of the kneading unit. A relatively small volume of RT is needed due to the fact that the blends normally used for table margarine crystallize fast and only need a short time to firm prior to extrusion or packing.

Traditionally, the higher melting portion of the margarine fat blend consists mainly of partially hydrogenated vegetable oil. In general, hydrogenated fats crystallize relatively faster than unhydrogenated fats and provide the finished margarine with the required characteristics (Yap and others 1989). However, during the hydrogenation process, various trans fatty acids are formed and at present these isomers are thought to be nutritionally undesirable. Several studies seem to indicate a correlation between a certain intake of these isomers and the risk of cardiovascular diseases. The main direct sources of trans fatty acids in the human diet are margarine and crystallized fat products. Indirect sources are contributed by products such as baked products, fried foods, and so on (Mattson and Grundy 1985; Boyeens and others 1988; National Research Council 1989; Mensink and Katan 1990; Emken 1991; London 1991; Nestel and others 1992; Mensink and others 1992a,b; Willet and others 1993; Wood and others 1993; Ascherio 1994; Danish Nutrition Council 1994; Judd and others 1994).

However, it is possible to replace the trans-fatty-acid-containing, partially hydrogenated fats by fractionated or interesterified intermediates. These fats will still fall into the two main groups of semisolid and hard stock fats as shown in Table 31.1. Due to the abovementioned trans fatty acid issue, the majority of the larger margarine producers around the world have shifted from high to low or non-trans-fatty-acid-containing blends; legislation in Denmark, for example, states a 1% limit of trans fatty acids (Watkins 2004). Today, palm oil, palm oil fractions, and interesterified blends are used to a great extent in the production of margarine.

Soft table margarine is used mainly for spreading on bread. It is a softer version of table margarine, and consequently contains a larger amount of liquid oil and exhibits a lower SFC profile. Soft table margarine is spreadable directly from the refrigerator but should still have a certain texture. Soft table margarine is relatively easy to produce; however, a large variety of soft products containing functional ingredients are on the market and these products can have special processing demands. An example would be production of a spreadable product containing stanolesters (Holmström 1997), which are claimed to lower the cholesterol levels in the blood of humans by 14% at a daily intake of 2 g. Initially manufactured and sold on the Finnish market, similar products are now available

in many countries around the world where heath claims associated with margarine products are not restricted by legislation.

Soft table margarine is usually produced by applying PRM at the end of the processing line as shown in Figure 31.6. This process step ensures that excess heat of crystallization is removed, which prevents the margarine from becoming brittle. The PRM at the end also ensures a uniform filling in the cup. However, if the soft table margarine is made by a high-liquid–low-solid blend, it can be advantageous to place the PRM between the two cooling sections avoid mechanically overworking the margarine prior to filling.

Low-fat margarine is mainly used for spreading on bread, but reduced-fat spread can additionally be used as traditional table margarine. Production of reduced fat spread is very similar to the already mentioned table and soft table margarine. The trend towards reduced- and low-fat products can be explained by an increasing interest from consumers due to an increasing awareness of their fat intake (Merker and Wiedermann 1958).

Low-fat margarine exhibits a higher water content than 80% margarine, which sets special demands on the emulsifier system and processing. The emulsifier should be able to bind large amounts of water in order to obtain a stable product with a narrow water droplet distribution; this results in a spread with a long microbiological shelf-life. However, a too narrow water droplet distribution is not necessarily an advantage, because this tight emulsion will affect the taste impression. Therefore, milk protein is often added to low-fat spreads, because they destabilize the emulsion and act as an o/w component that results in a more open emulsion. In order to control the emulsion when milk protein is present, hydrocolloids are added (Chrysam 1996; Gerstenberg and Agger 2001; Danisco 2002d).

There is a wide range of hydrocolloids, stabilizers, or textural ingredients on the market for use in margarine and dairy spreads. Water-binding capacity and sensory properties have to be considered when the manufacturer chooses a stabilizer.

Gelatine has a bland taste and melts at body temperature like a typical table margarine oil blend. For these reasons it has been preferred by many manufacturers for years. However, in recent years margarine manufacturers have been reluctant to use gelatine due to its association with bovine spongiform encephalopathy (BSE) and possible other considerations like kosher or lifestyle issues. Alginates, carrageenans, pectins, and starches all have a good water-binding effect and give stable emulsions, but all leave different taste impressions. Additionally, various mixtures of the abovementioned stabilizers are on the market, offering margarine producers a great variety of stabilizer systems.

Low-fat spreads are produced at different capacities as shown in Table 31.3. Although capacities are desired, some emulsions are so sensitive to shear forces that capacity must be decreased to avoid emulsion separation. Low-fat spreads are usually made with high-liquid–low-solid blends and the PRM is often positioned between the two cooling sections for the same reasons as described in the section concerning low-fat spreads. However, for some low-fat emulsions the optimal configuration of the crystallization line is obtained by having the PRM at the end of the line prior to the filling machine. The filling temperature of low-fat spreads is relatively higher than for soft table margarine, for example, due to the higher viscosity of the low-fat emulsion. If the filling temperature is too low, the final product may become brittle and crumbly, with free water as a result (Gerstenberg and Agger 2001; Danisco 2002d).

Dairy spreads cover products containing butter and vegetable oils and/or vegetable fats at various ratios with a total fat content less than 80%. Typically, dairy blends will cover the product group of 80% fat products, and the dairy spreads will cover the product groups

of reduced fat (60% fat) and low fat (40% fat) (Merker and Wiedermann 1958). Dairy blends have been on the market in northern Europe since 1969 (Merker and Wiedermann 1958; Mortensen 2001), but today the products are sold all over the world. Dairy blends were initially developed in order to meet consumers' demands for butter-flavored products spreadable directly from the refrigerator.

Dairy blends are produced batchwise in a butter churn or via a continuous process in a butter-making machine. This method has the disadvantage that it is difficult if not impossible to produce dairy spreads with a lower fat content than 60%. The dairy blends produced by this method exhibit a consistency very similar to butter, but tend to be softer as liquid oil has been added (i.e., lower SFC profile). However, in this chapter, only dairy blends and dairy spreads produced by margarine technology will be described.

Dairy blends are used domestically for spreading on bread, baking, and pan frying, whereas dairy spreads are mainly used for spreading on bread due to the higher water content. Dairy spreads can be a challenge to produce using SSHE technology with respect to obtaining plastic texture. However, the challenges can be minimized by optimizing the fat blend. For example, this can be done by adding anhydrous milk fat (AMF) to the blend instead of only depending on butter and/or cream as the fat phase. Apart from the butter fat and liquid vegetable oil, some dairy blends and spreads contain partially hydrogenated oil or interesterified fat.

When producing dairy blends and spreads in the SSHE plant, margarine technology is used. The fats for the fat blend are melted and the liquid oil, including possible emulsifiers, is added along with the water phase. The products are produced according to the configuration shown in Figure 31.6 and Table 31.3 for similar margarine products. However, the maximum recommendation values in regard to kneading volume are normally implemented in order to obtain products with a satisfactory texture and plasticity. Often it is necessary to reduce capacity (throughput) as well.

Apart from the margarine method, other processing methods are also used in the industry today. These processes can include a combination of the traditional butter manufacturing process and the SSHE process (Merker and Wiedermann 1958; Jensen and Kirkeby 2003).

Consumer margarine and dairy spreads are all evaluated according to the same parameters, because these products are used for the same purposes. Appearance, texture, spreadability, taste, and shelf-life are normally the most important parameters in regard to consumer margarine and spreads. However, an antispattering test is normally conducted for consumer products such as table margarine, reduced-fat spread, and dairy spreads that are used for frying. For low-fat spreads the free water stability is additionally evaluated.

The appearance of margarine and spreads is described by evaluating the following characteristics of the surface of the product: shiny, greasy, dull, dry, even, uneven. It is important that the product appears attractive. Thus, filling or packing has to be performed satisfactorily.

Texture is evaluated by describing the hardness and plasticity of the product. There are objective analyses available for measuring hardness and plasticity such as the Texture Analyser (Stable Micro Systems, UK) (Stable Micro Systems 2004). However, more simple and subjective methods are still in use around the world.

Spreadability is a very important quality parameter for consumer margarine, spreads, and dairy spreads. The homogeneity, consistency, gloss when spreading, sandiness, and free water can also be determined. The stability of the products can be described by a spreadability test that involves the spreading of a sample with a knife on cardboard in

order to imitate the spreading on a piece of bread. The abovementioned parameters can therefore be easily observed. The risk of free water is usually limited to low-fat spreads.

Taste is relatively important for all products, and as a general rule the taste impression of low-fat spreads should be similar to their related full-fat products in terms of melt down and flavor release. As described earlier, taste preferences differ around the world; thus, melt down and flavor release are individually described as fast, average, or slow.

Shelf-life can be determined in terms of microbiological or oxidative shelf-life. Also, for some products a stability test can determine the shelf-life. The microbiological shelf-life is increased with smaller water droplets. Oxidative shelf-life is increased by using high-quality oils and fats, and is further improved by adding antioxidants to the fat phase (Danisco 2002d).

31.7 PROCESSING AND PRODUCT TRENDS

New products are introduced into the market every year, and these products may require processing developments in order to be successfully produced. Demand for low- and non-trans-FA products seems to be of worldwide interest. In North America the concern is more focused on low- and non-trans-FA products due to the traditional use of partially hydrogenated soybean in margarine. Europe has a demand for genetically modified organism (GMO) free products and functional foods, and there is also demand for low-fat butter spreads. In South America interest is high for very-low-fat spreads (20% fat content). For environmental and economical reasons, production of cartonless butter products is of interest for the butter-producing countries and methods are available on the market today. After the traditional butter-manufacturing process, the butter can be chilled further in an SSHE, formed, wrapped in foil or plastic, and subsequently stacked on the pallet without the cardboard box (Kirkeby 2001). The abovementioned hot topics should only be taken as examples from a long list of trends around the world.

32.1 INTRODUCTION

Cream is an oil-in-water (o/w) emulsion of milk fat containing fat globules coated with native milk fat globule membrane (MFGM) material. This protective layer reduces both the extent of lipolysis and oxidation of the fat (Chen and Nawar 1991), and the extent to which globules aggregate and rise to the surface to form a cream layer. Surrounding the fat globules in an aqueous serum phase are soluble components such as salts, organic acids, whey proteins, other nitrogenous compounds, and lactose, as well as dispersed casein micelles in suspension.

This chapter will describe physical and chemical changes that take place during processing of cream and how these impact upon functionality. For more detailed information on the chemistry and physics of the milk fat globule, the reader is directed to other literature (Mulder and Walstra 1974; Wong and others 1988), and particularly Walstra and others (1999), from which some of the discussion on the physico-chemical properties of cream in this chapter are derived.

32.2 COMPOSITION OF CREAM

32.2.1 Lipids

The fat component of cream consists of a lipid core containing approximately 98% triacylglycerides, as well as the lipid components of the MFGM. Other relatively minor components of the lipid phase include diacylglycerides, monoacylglycerides, free fatty acids, sterols, and phospholipids. The most common fatty acids at levels greater than 10% in milk fat are oleic acid (C18 : 1), stearic acid (C18 : 0), palmitic acid (C16 : 0), myristic acid (C14 : 0), and butyric acid (C4 : 0). Milk fat melts completely at around $+40^{\circ}$C and is completely solid at -40°C, with about 50% solid fat content at 0°C.

32.2.2 Proteins and Enzymes

The serum phase of cream contains casein micelles and whey proteins, which retain their original composition in the aqueous phase after cream separation. The presence of casein in the serum phase can be exploited by the addition of a small amount of rennet to increase the firmness of cream.

Plasmin is an alkaline milk protease found associated with the casein micelle and is important in cheese ripening. Pasteurization increases plasmin activity by activating the transformation of the plasminogen precursor into plasmin. Cream also contains an acid milk protease associated with the casein micelle. More detailed descriptions on enzymes in milk can be found in Fox and McSweeney (2003).

32.2.3 Milk Fat Globule Membrane

The MFGM layer is a complex multilayered arrangement of protein, lipids, and other components at the fat–water interface (Danthine and others 2000) with a thickness of between 10 and 50 nm (Freudenstein and others 1979). The amount of membrane material adsorbed to the surface is inversely proportional to the square of the globule radius. The major protein components of the MFGM layer are butyrophilin and xanthine oxidase along with at least 30 identified enzymes. Approximately 25–60% of the MFGM is protein-based, with the remaining being mostly neutral lipids or phospholipids. The large variation is a consequence of different methods of assay and the washing procedures used to isolate MFGM material. A review of the nomenclature of the main proteins found within the MFGM layer is provided by Mather (2000). Other lipid-based components of the MFGM layer include cerebrosides, free fatty acids, sterols, sterol esters, and glycerides. Copper and iron are also found in trace amounts.

32.3 STRUCTURE OF CREAM

32.3.1 Emulsion

Cream contains fat globules dispersed within an aqueous continuous phase, and, as such, can be considered a fat-in-water emulsion. The globules have an overall negative charge, as shown by the negative zeta potential, ranging from −12 to −16 mV as the calcium concentration varies (Dalgleish 1984).

32.3.2 Globule Size Distribution

The fat globules in cream are mostly within the size range 0.1–20 μm. Larger globules will rise faster than smaller ones during the process of creaming. One gram of fat contains around 10^{11}–10^{12} globules, one-quarter of which are greater than 1 μm in size (Walstra and others 1999). Although larger globules are fewer in number, these constitute most of the fat in cream on a volume or weight basis. The average surface area weighted diameter (d_{32}) of bovine fat globules is around 3 μm, although this will vary across breeds, and certainly will vary according to the species of mammal. Ayrshire and Holstein milk contains larger fat globules, on average, than Jersey or Guernsey milk (Jenness 1988).

32.4 CREAM PREPARATION

Full-fat bovine milk contains an average of 4% fat, ranging from around 3.8% for Holstein milk up to around 5% for Jersey. Increasing the fat content of milk to around 12–80% is the essence of cream manufacture. This is commonly achieved by centrifugal separation; however, membrane processing can be employed to a similar effect. Centrifugal cream separators consist of concentric 60° cones stacked one on top of another. The cream

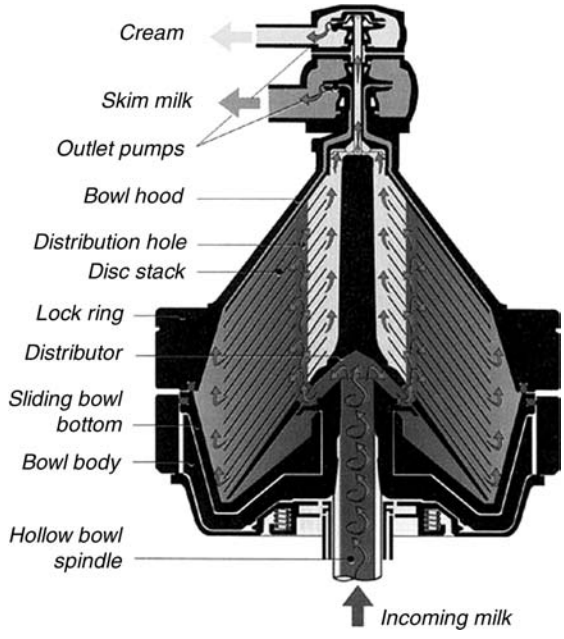

Figure 32.1 *Diagram of Tetra Centri hermetic separator (used with the kind permission of Tetra Pak).*

phase moves to the top of each cone under centrifugal force and exits the separator through a different outlet to the skim milk phase (see Fig. 32.1).

32.4.1 Separation

The basic steps involved in cream production are shown in the flow diagram in Fig. 32.2. With efficient separation, the fat content of skim can be as low as 0.05%. Factors that affect separation include temperature, centrifugation speed, cone configuration, and flow rate of milk. A review of the operation of a separator is given by Towler (1994). Stabilizing salts such as sodium citrate may be added at levels of around 0.15% prior to heat treatment to reduce the effect of heat instability during processing (see Section 32.4.2.2).

The temperature of milk separation affects the physical properties of the resultant cream. Cold separation (12°C) produces larger fat globules, higher viscosity, shorter whipping time, and higher free fat (perhaps due to more extensive shear damage) compared to separation at 50°C (Hillbrick and others 2000). There is also a greater concentration of phospholipids in the cream when separated at colder temperatures.

32.4.2 Heat Treatment

32.4.2.1 Pasteurization. Cream is usually heat-treated at 77–82°C for about 30–60 s. This is a higher temperature compared to that used in pasteurization of raw milk (72°C for 15 s). Heat treatments above 80°C for 20 s result in milk with a significant cooked flavor. High heat treatments will also denature α-lactalbumin and β-lactoglobulin, which will complex with the surfaces of casein micelles and fat globules (Corredig and Dalgleish 1996a,b). The time and temperature heating regime will also affect the functionality of buttermilk derived from the MFGM layer (Corredig and Dalgleish 1998).

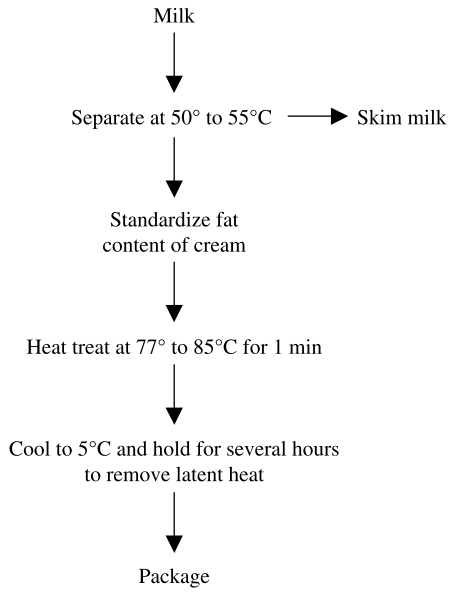

Figure 32.2 *Basic principles of cream separation (adapted from Walstra and others 1999).*

32.4.2.2 Heat Stability. Homogenization creates additional surface area that then must be coated with surface-active material to maintain stability against phase separation. Adsorption of casein micelles and micellar fragments effectively yields a fat globule that functions as a casein micelle with a lipid core. These casein-coated globules are capable of interacting with casein micelles in the surrounding aqueous phase. Higher protein content in the serum phase lowers heat stability by increasing the surface load of proteins on the fat globule after homogenization.

Heat stability decreases as both the amount of fat and the homogenization pressure increase. A larger number of fat globules and a higher homogenization pressure both result in statistically more collisions. Both of these effects will enhance heat-induced clustering.

The pH optimum of heat stability is near 6.7 (Walstra and others 1999). Processing conditions such as acidification, renneting, or high heat treatment of cream will result in decreased heat stability brought about by casein–casein surface interactions. This problem can be circumvented by addition of stabilizing salts such as sodium citrate or sodium hydrogen phosphate, which raise the pH and chelate calcium ions from the micelle, therefore reducing the propensity for interaction with homogenized fat globule surfaces.

Heat stability rises as temperature increases up to about 75°C, beyond which stability decreases (Mulder and Walstra 1974). As temperature increases to 75°C, the amount of adsorbed casein per unit surface area decreases due to spreading and breaking apart of micelles into smaller fragments. The lower surface concentration of caseins at the higher temperatures will promote a more stable fat globule. Above 75°C, whey proteins denature and adsorb to the fat globule surface, promoting fat globule interactions and thus reducing heat stability.

It is usually desirable for heat treatment to precede homogenization. The coating of fat globules with casein as a consequence of homogenization will decrease heat stability. The application of heat, particularly above 135°C, will promote casein-induced aggregation of

globule surfaces (van Boekel and Folkerts 1991). These aggregated fat globules will have a higher density than native globules due to the extra adsorbed casein and will sediment over time in UHT treated cream. To circumvent this problem, homogenization should preferably take place after UHT heat treatment.

Addition of sweet buttermilk, buttermilk powder, or monoacylglycerides enhances heat stability prior to homogenization. Both phospholipids and monoacylglycerides migrate to the interface and reduce the homogenization-induced adsorption of caseins responsible for heat instability. Lecithin improves the heat stability of recombined and conventional full-cream evaporated milk by interaction with the MFGM layer (McCrae 1999).

32.4.3 Homogenization

Homogenization of milk or cream is employed to break apart larger fat globules into smaller globules, largely to prevent creaming, or to incorporate newly adsorbed material to the fat–water interface. This is concomitant with an increase in the total fat–water interfacial surface area, which must be coated with additional surface-active material, primarily casein micelles and micellar fragments, to prevent large-scale coalescence and phase separation. Homogenization at a typical pressure of 20 MPa results in a thousand-fold increase in the number of globules, a ten-fold increase in the total surface area, and a ten-fold reduction in the average diameter.

Emulsions are thermodynamically unstable, but kinetically stable, meaning that globules remain as discrete entities for long periods of time. Aggregation is hindered by the presence of the surface-active membrane layer, whether it be native MFGM or an introduced emulsifier. The size of globules is dictated by many factors, not limited to the following:

1. Homogenization pressure;
2. Time between collisions of globules during homogenization;
3. Concentration of emulsifier;
4. Solubility of emulsifier;
5. The hydrophilic–lipophilic balance (HLB) number, or the amphipathicity of the emulsifier;
6. Conformation of the emulsifier;
7. Propensity for adsorption of the emulsifier at the surface;
8. Time for migration of the emulsifier to the interface;
9. Flexibility of the emulsifier on the surface after adsorption;
10. Solution conditions such as pH and ionic strength;
11. Temperature; and
12. Fat or oil content.

32.4.3.1 Types of Homogenizers. The process of homogenization introduces a kinetic barrier to phase separation in a bi- or multiphasic system. In dairy products, this usually means that fat is emulsified by coating with a surface-active component (such as proteins and phospholipids) and the resultant globules are dispersed in the aqueous serum phase. The surface coating serves to reduce surface tension, and also to provide a barrier against re-coalescence during homogenization where globules undergo rapid collisions.

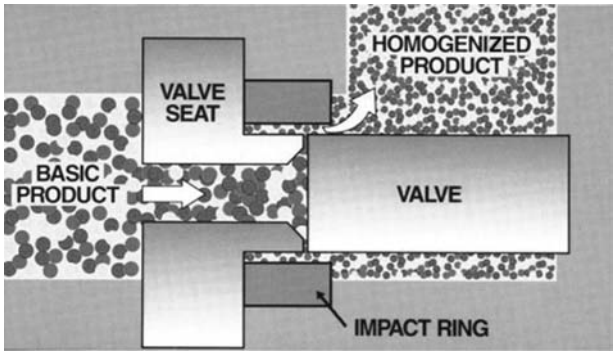

Figure 32.3 *Homogenizer valve (used with kind permission from Invensys APV).*

The energy to break apart large fat globules is introduced through turbulent flow and cavitation while the fluid product passes through a narrow orifice (homogenization valve) or into a high-speed blending device. Pressure can be adjusted by altering the distance of separation between the valve and the valve seat (see Fig. 32.3). An increase in the temperature of milk occurs during homogenization, approximately 1°C for every 4 MPa of pressure. Cavitation takes place where high-velocity fluid enters the homogenizer at a lower pressure, in accordance with the Bernoulli effect. This effect causes localized vaporization of the aqueous phase to form vapor bubbles that collapse in the homogenization valve under pressure, sending shock waves through the fluid and breaking apart fat globules.

Different types of homogenizers can be used to process fluid products such as cream or milk. High-speed blending does not create sufficient turbulence for this to be an effective process. High-pressure valve homogenizers are common in the dairy industry. These usually employ two stages of homogenization (Fig. 32.4) to create smaller globules at the higher pressure first stage, and to break apart fat globule clusters at the lower pressure second stage. Ultrasonic homogenizers utilize vibrating piezo-electric crystals or liquid jet generators. Fat globules can also be broken apart by membrane processing. Homogenization using a Microfluidizer™ involves a process of accelerating cream to a high velocity followed by separation into two streams with subsequent violent collision. Microfluidization can result in very high effective pressures in excess of 100 MPa, with fat globules sizes as low as 100 nm with a relatively narrow particle size distribution. Additional information on homogenizers and the homogenization process is provided by McClements (1999).

32.4.3.2 Effect on Physical Properties. Homogenization reduces the extent of creaming by several mechanisms. The first stage of a two-stage homogenization process increases the rate of fat globule collisions and promotes the formation of heat-stable clusters of globules. A typical first-stage homogenization pressure is around 15–20 MPa. A second homogenization stage at a lower pressure of less than around 5 MPa is sufficient to break apart clusters, but not to form new clusters. Homogenization also narrows the fat globule size distribution width, which minimizes creaming. Homogenization of milk with subsequent separation to a higher fat content will yield a narrow particle size distribution of globules with less creaming. Other effects of homogenization are to make cream whiter, enhance lipolysis in unpasteurized cream, slow down the rate of rennet reaction during cheese manufacture, increase the viscosity of yogurt, and inactivate agglutinin factors to prevent creaming. Viscosity of cream increases at a higher fat content, and also after first-stage homogenization

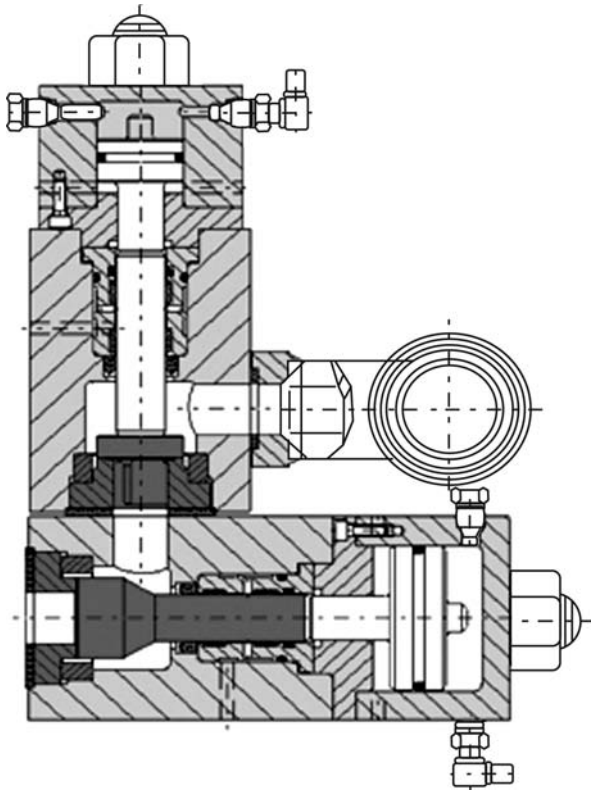

Figure 32.4 *Two-stage homogenizer* (*used with kind permission from Invensys APV*).

at higher pressures due to increased clustering of globules. The resultant cream will be more viscous, which may be a desirable outcome for particular types of cream products.

Higher homogenization pressure will increase the overall stability of fat globules as smaller fat globules are less likely to aggregate. The application of heat will have the opposite effect; higher pressure plus sufficient heat treatment will decrease stability (see Section 32.4.2.2). The different effects of heating and homogenization, and combinations of these two processes, must clearly be differentiated.

32.4.3.3 Lipolysis. Cream contains around 1–2 mg per liter of milk of a native milk lipase (Weihrauch 1988). The pH optimum of this enzyme is 8.5, and there is sufficient present in milk to cause rancidity within a few minutes. It is highly selective for hydrolysis of butyric acid, found primarily at the sn-3 position of triacylglycerides. The enzyme is inactivated by holding cream at 78°C for 10 s, whereas under pasteurization conditions at 72°C for 15 s, 10–15% of the original amount of lipase remains active. The native milk lipase is mainly associated with casein micelles, although there is an increasing proportion adsorbed onto fat globule surfaces at lower temperatures. This explains in part why lipolysis of raw milk is more rapid at a cooler temperature of 15°C. Lipolysis resulting in free fatty acids occurs at a faster rate in raw milk held at 4°C for 24 h compared to holding at 8°C (Wiking and others 2002).

Lipase from psychrotrophic bacteria is more heat stable than native milk lipase, and adsorbs onto the fat globule surface. Pseudomonas bacteria produce a phospholipase

that acts upon the MFGM, allowing lipase access to the inner triacylglyceride core. The phospholipase activity in skim milk is not eliminated completely by pasteurization (Koka and Weimer 2001). The affect of psychrotrophic bacteria on the quality of dairy products has been reviewed by Champagne and others (1994), and by Meer and others (1991).

The rate of lipolysis can be reduced by holding cream at a lower pH of around 6.7, compartmentalization of the lipase by association with the casein micelle, protection of the lipid phase by the MFGM layer, and possibly by proteose-peptone 3 inhibition. Lipolysis is more common in late lactation and at a higher frequency of milking. Spontaneous lipolysis occurs in raw milk with a high level of lipoprotein lipase associated with fat globules (Bachman and Wilcox 1990). Prevention of lipolysis, and the growth of psychrotrophic organisms can be achieved by addition of hydrogen peroxide (Ozer and others 2000) with subsequent addition of catalase to remove the hydrogen peroxide. This treatment has efficacy in parts of the world where refrigeration is not readily available. Hydrogen peroxide treatment of milk for cheddar and Swiss cheese manufacture is permitted in the United States; however, it should be noted that this type of treatment of milk may not be permitted in some countries.

The natural MFGM layer protects the lipid phase in cream from hydrolysis by the lipase. MFGM reduces surface tension to low values of less than 2 mN/m. The native lipase cannot displace the MFGM components and adsorb onto the surface because of this already low surface tension; therefore, lipolysis is hindered.

Homogenization creates extra fat globule surface area, which is coated primarily with serum proteins. These are mainly casein micelles and casein micellar fragments rather than whey proteins (Gelin and others 1994). The surface tension is raised to around 15 mN/m and this increases the propensity for the displacement of the newly formed membrane material by the lipase. Once the lipases have adsorbed to the surface, access to the lipid interior of the globule is enhanced. For this reason, milk is first pasteurized to inactivate the native milk lipase before homogenization. It has been noted, however, that homogenization of ultra high temperature (UHT) treated cream with added lipases has increased the susceptibility to lipolysis compared to raw cream or pasteurized cream (Iametti and others 1997).

32.5 STABILITY

Stability is often an ill-defined term used in the scientific and technological literature. When considering fat globules, stability may mean the propensity for

1. Rupture of the membrane coating to form pools of free fat;
2. Clustering of fat globules during homogenization to form an aggregate structure that traps the serum phase;
3. Heat-induced aggregation;
4. The feathering phenomenon found after cream is added to hot coffee;
5. Clumping of fat globules at the air–water interface, such as is required for ice-cream manufacture;
6. Gelation of proteins that settle to the bottom of UHT-treated products;
7. Displacement of the natural MFGM layer with surfactants to induce aggregation of globules;

8. Aggregation of globules to form a cream layer; or
9. Rupture of the MFGM of two adjoining globules that subsequently combine to form either a single larger globule or a partially joined dumb-bell-shaped structure.

Each of these mechanisms will impose different physical properties onto a cream product.

After some initial consideration, stability is intuitively a desirable outcome. However, in some instances, instability may be required to process milk into a particular dairy product. Two such products containing air cells are ice-cream and whipped cream, where fat globule clumping is necessary. An obvious example where instability is required is large-scale phase inversion of cream to form butter. The type of stability must be stated when discussing emulsions, such as dairy cream. To make this discussion clearer, different terms are used to indicate different types of instability.

32.5.1 Rupture

Rupture is the process where part of the MFGM layer is broken and removed from the globule surface. Breakage of the MFGM layer is unlikely to take place during laminar shearing of cream as the shear forces are not sufficiently high (see Section 32.6.1). Turbulent flow may, however, result in membrane rupture. Adsorption of globules to an air–water interface may allow fat crystals to pierce the air cells and spread liquid oil over the interface. Heating will promote coalescence and loss of membrane material into the serum phase. An example of heat-induced rupture is the formation of pools of fat in Mozzarella cheese (Rowney and others 2003). Cooling can also result in partial loss of MFGM material.

32.5.2 Clustering

Clustering is used to describe aggregation of fat globules induced by heat, homogenization, or both processes. Higher shear rates will increase the rate of globule collision and, as a consequence, the degree of clustering. A higher fat content and larger fat globules will result in more collisions and more clustering. Beating of air into cream will facilitate adsorption of globules at the air–water interface, and therefore the extent of clustering. Replacement of native MFGM by caseins as a consequence of homogenization will facilitate bridging and, therefore, clustering of adjacent fat globules by adsorbed casein micelles.

32.5.3 Clumping

Clumping occurs when globules aggregate following some change to the surface characteristics, such as addition of surfactants in the ice-cream manufacturing process. Clumping of native fat globules is hindered due to the net negative charge on the surface and the presence of a steric hindrance layer of glycoproteins. Addition of nonionic surfactants, such as those of the Tween series or monoacylglycerides, may displace caseins from the surface of homogenized fat globules and decrease stability to aggregation. This is not a heat-induced effect. It can be employed to partially destabilize fat globules in ice-cream manufacture (Goff 1997). Surfactants will decrease cluster formation during homogenization and increase clumping of fat globules that form during the whipping process.

32.5.4 Coalescence

Coalescence refers to the physical joining of two globules, either completely or partially, following rupture. In this instance fat crystals may be shared by two joined globules, a

mechanism that takes place in butter manufacture. Crystals of fat within the fat globules may pierce the MFGM layer if the crystals are correctly orientated, and join together two or more adjacent fat globules. This will most likely only happen under conditions where fat globules are under shear or turbulent conditions.

Coalescence requires some solid fat to be present. At lower temperatures where the fat is mostly solid, crystals may not be as free to orientate and pierce another fat globule. At higher temperatures there may not be sufficient crystals available to link globules, and coalescence under shear conditions will result in the formation of larger spherical globules. Some liquid fat is still required to allow the globules to initially bond together. This property can be exploited to increase the viscosity of cream by homogenization while the fat is partially solidified. Raising the temperature will melt the fat crystals and reduce partial coalescence, and therefore reduce viscosity. Temperature fluctuations from 5°C to 30°C followed by cooling may result in coalescence (see Section 32.6.3).

Coalescence of fat globules will not, of course, decrease the volume or the weight of fat in cream, but it will result in a decrease in total interfacial surface area due to an increase in average globule size. One consequence of this is the release of MFGM material, the main solid component of buttermilk, into the serum phase.

32.5.5 Creaming

Creaming refers to the rising of fat globules to the surface of milk or cream. This property is exploited to produce cream from milk by centrifugal action. The rate of creaming increases for larger fat globules, for higher fat content, and under conditions where the agglutinin reaction is facilitated (see Section 32.6.4). Creaming rate can potentially increase as a consequence of heat treatment or homogenization. Carrageenan can be added to increase viscosity, which slows down the rate of creaming during storage.

Fat globules rise at a velocity v, due to a density difference with the serum phase. This is given by the Stokes equation,

$$v = \frac{2g(\rho_s - \rho_g)r^2}{9\eta_s}, \tag{1}$$

where r is the radius of the globule, ρ_s is the density of the serum phase, ρ_g is the density of the fat globule, and η_s is the viscosity of the serum phase. The most temperature-dependent of these parameters is viscosity; at higher temperatures the viscosity is reduced and the rate of creaming increases. Homogenization of milk fat with polyoxyethylene-4-sorbitan monolaurate (Tween 21) with subsequent UHT treatment results in less creaming compared to treatment with other emulsifiers such as sorbitan tristearate (Span 65), sorbitan monopalmitate (Span 40), or 90% monoacylglyceride preparation from palm oil (Mayhill and Newstead 1992).

32.6 PHYSICAL PROPERTIES

32.6.1 Rheological Properties

Cream with a fat content more than about 40% exhibits a pseudoplastic (or shear thinning) flow profile with a yield stress. This type of flow profile is characterized by a decreasing apparent viscosity as the rate of shearing increases. Below this fat level the flow profile

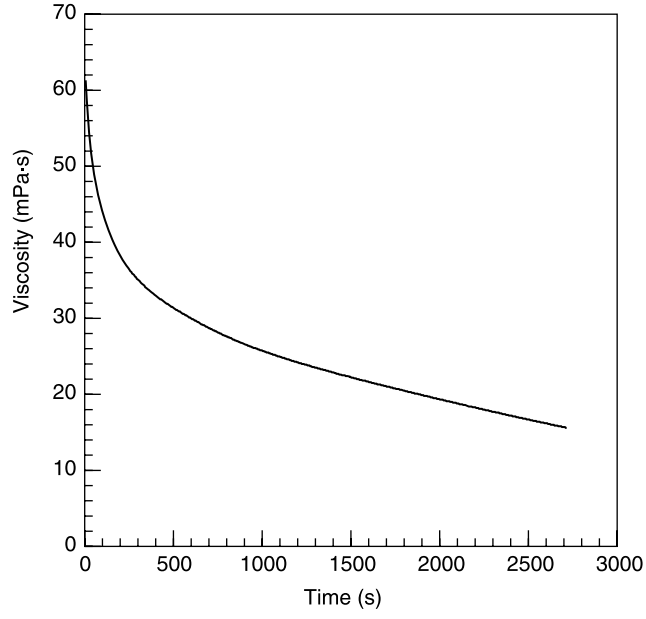

Figure 32.5 *Viscosity of homogenized 30% fat cream under shear conditions of 1465 s^{-1} over a period of 45 min at 31°C. Cream was homogenized in a one-stage homogenizer (Type 8.30H, APV – Rannie Inc., St. Paul, Minnesota) at pH 7, 50°C, and 20.0 MPa.*

tends to be Newtonian, where shear stress is proportional to shear rate. The presence of a yield stress means that no flow can occur until a stress has been applied that exceeds this characteristic stress. Cream also exhibits thixotropic time-dependent behavior where viscosity decreases slowly over time at a fixed shear rate (Figs 32.5 and 32.6). Both of these phenomena occur due to aggregation of fat globules to form flocs that trap the serum phase. At higher shear rates or over a period of constant shearing, these flocs break apart, concomitant with less serum phase trapped within the floc structure, and the viscosity is reduced. The re-bodying effect results in cream with a plastic flow behavior, characterized by a linear shear-stress–shear-rate profile with a relatively large Bingham yield stress, corresponding to the intersection of the linear flow profile with the stress axis. Bingham yield differs from yield stress in that the former is an extrapolation of a linear part of the flow profile to the stress axis, whereas the latter is an extension of any shaped flow curve to the stress axis by measuring stress at increasingly lower shear rates. The experimentally measured yield stress is a closer representation of actual yield stress than Bingham yield.

Flocs that trap serum behave essentially as large particles. This increases the effective volume fraction of particulate matter in the cream, and viscosity increases according to the Kreiger–Dougherty equation,

$$\eta = \eta_0 \left(1 - \frac{\phi}{p}\right)^{-[\eta]\phi} \tag{2}$$

where η is the viscosity of the cream, η_0 is the viscosity of the continuous aqueous phase, $[\eta]$ is the intrinsic viscosity (related to the shape and the concentration of fat globules),

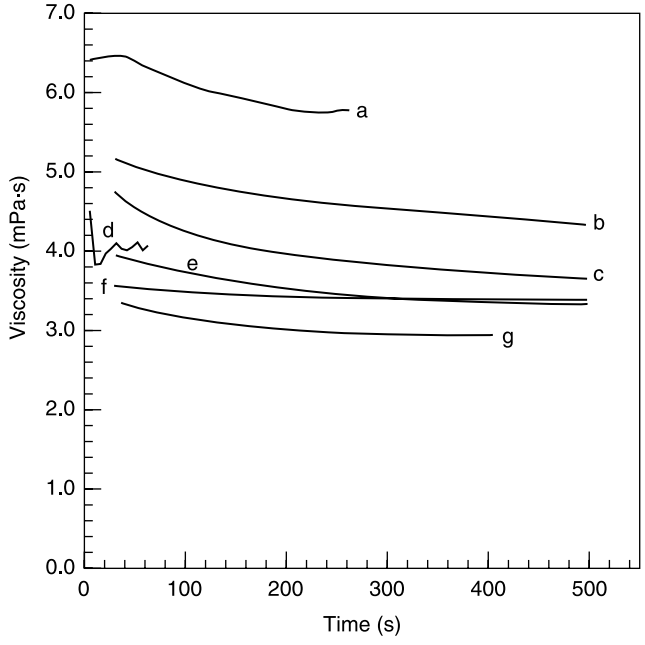

Figure 32.6 *Viscosity of 30% fat (unhomogenized) cream and recombined anhydrous milk fat emulsions prepared by homogenization under shear conditions of 1465 s^{-1} at 31°C. Recombined emulsions were prepared using a one-stage homogenizer (Type 8.30H, APV–Rannie Inc., St. Paul, Minnesota) at pH 7, 50°C, and 20.0 MPa. (a) Unhomogenized cream; Recombined creams containing globules coated with (b) β-casein, (c) α_{s2}-casein, (d) Tween 80, (e) κ-casein, (f) phosphatidylcholine, and (g) α_{s1}-casein.*

ϕ is the volume fraction (the fraction of the total volume occupied by fat globules), and p is the volume fraction at closest pack (approximately 0.72).

Addition of polysaccharide stabilizers to cream increases the viscosity of the aqueous continuous phase and slows down the rate of collisions between fat globules. The effect is to slow down the rate of creaming. Addition of stabilizers such as alginate or carrageenan can also be used to increase the viscosity of dessert creams.

Homogenized 30% fat cream has a viscosity of around 60 mPa·s at 31°C, which decreases slowly under shear conditions of 1465 s^{-1} to around 15 mPa·s after 45 min, and continues to decrease thereafter (Fig. 32.5). The viscosity of 30% fat unhomogenized cream is approximately 6.4 mPa·s at 31°C and this decreases to a much lesser extent to around 5.8 mPa·s after 5 min under the same shearing conditions (Fig. 32.6). Emulsions containing milk fat globules coated with a nonionic Tween 80 surfactant, phosphatidylcholine, or individual caseins show similar behavior to unhomogenized cream with about the same magnitude of viscosity. Cream and prepared emulsions thus exhibit time-dependent thixotropic behavior. The process of homogenization yields a cream with a higher viscosity and increases the time taken to break apart clusters of fat globules.

Unhomogenized cream has a very small yield stress of less than 0.2 Pa. Homogenization increases the yield stress to around 0.6 Pa. Coating fat globules with milk proteins such as whey or caseins, or surfactants such as Tween 80 or phosphatidylcholine reduces the yield stress to a value approaching zero. These recombined globules contain very thin (perhaps monolayer) coverage of membrane material. With recombined milk fat emulsions, viscosity is lowered to around 3–5 mPa·s and the extent of time-dependent

viscosity reduction is lessened, despite the use of homogenization to prepare the emulsions. This indicates that non-native fat globule membranes do not interact and form clusters to the extent of native globules or homogenized globules coated with casein micelles.

The pressure at the interface of an emulsion globule is given by the Laplace pressure P, where

$$P = \frac{2\gamma}{r}. \tag{3}$$

With a surface tension γ of 1.5 mN/m and a globule radius r of 10^{-6} m, the Laplace pressure is 3000 Pa. Under laminar shearing conditions, the shear stress τ, in units of Pascals, is given by

$$\tau = \eta \frac{\mathrm{d}\gamma}{\mathrm{d}t} \tag{4}$$

where η is the viscosity (about 6 mPa·s for 30% unhomogenized fat cream at 31°C) and $\mathrm{d}\gamma/\mathrm{d}t$ is the rate of shearing, in units of s^{-1}. For globules to be broken apart under laminar shearing conditions the shear stress must be higher than the Laplace pressure. For this to occur the shear rate will need to exceed $5 \times 10^5\ s^{-1}$ for globules of radius 10^{-6} m. This high shear rate is unlikely to be exceeded under most laminar shear processing conditions. Rapid shearing is therefore not likely to rupture fat globules, and this likelihood will only decrease if globules are made smaller by homogenization. Beating of air into cream will, however, disrupt fat globules by the forces associated with adsorption to the air–water interface.

Viscosity of cream rises during refrigerated storage. Cream separation at 30°C results in a higher viscosity compared to cream separated at 45°C. A possible explanation for these observations may be formation of triacylglyceride crystals (to a greater extent at the lower temperature), which pierce the MFGM layer and link adjacent fat globules through partial coalescence.

32.6.2 Effect of Cooling

Cooling of fat globules leads to a loss of MFGM material from the surface. This is an irreversible process, and is countered by reversible adsorption of a class of proteins called cryoglobulins. These proteins facilitate the agglutinin creaming reaction. At low temperatures triacylglycerides form a network structure of crystals within the globule, providing some rigidity.

Frozen cream results in large-scale phase separation upon thawing. This is not a desirable attribute for consumer cream, but it can still be used as a food ingredient to standardize homogenized consumer milk to a higher fat content, or in butter manufacture. If cream is to be frozen, it must be done quickly to ensure that large ice crystals do not form that pierce the native MFGM layer and induce fat globule coalescence. Rapid freezing can be achieved by immersion into liquid nitrogen, yielding smaller ice crystals. The integrity of the MFGM layer is critical for the maintenance of freeze–thaw stability. Cycling of temperature during frozen storage can have a detrimental effect on cream stability.

32.6.3 Re-Bodying Effect

In cream with more than 25% fat, temperature fluctuations can result in an increase in viscosity. This phenomenon is called the re-bodying effect (Walstra and others 1999).

Holding cream at 5°C for several hours, followed by warming to 30°C and holding for 30 min, then slow cooling again, produces clusters of fat globules. This may result in formation of a gel under some conditions. The slow cooling back to 5°C allows crystals of triacylglycerides to form that bridge adjacent globules. Re-bodying is eliminated by shearing, but this is a reversible process that occurs again once the cream is cooled.

Re-bodied cream exhibits more leakage of the serum phase from the fat globule network (syneresis). This phenomenon occurs with washed cream but not with recombined cream. The presence of phosphatidylcholine in the membrane layer may be a necessary criterion for re-bodying. The re-bodying process can be utilized to improve the whipping properties of UHT treated cream.

32.6.4 Agglutination

At cold temperatures cryoglobulins (lipoproteins and immunoglobulins) adsorb onto the surface of bovine fat globules. This facilitates the agglutinin reaction where fat globules aggregate, trapping serum phase in the globule network structure, and increasing the rate of creaming. The problem is not as great above 37°C, where cryoglobulins do not adsorb to the surface of globules. The agglutinin reaction does not occur significantly with goat or sheep milk, which may partly explain why cream, and hence butter, is less common from these two types of milk compared to bovine milk. The lower pressure second stage of homogenization is commonly used to break up agglutinin-induced clusters to prevent creaming.

Heat treatment of cream at 71°C for 20 s has no effect on minimizing the agglutinin reaction. Treatment at 65°C/30 min, 73°C/20 s, and 78°C/20 s reduces creaming by 10%, 25%, and 100% respectively (Walstra and others 1999), possibly due to immunoglobulin denaturation. If warm milk is separated, the agglutinin factors remain in the skim phase. Separation of cold milk results in the factors locating in the cream phase. Mixing the cold skim with the warm cream will reduce the agglutinin reaction and subsequent rate of creaming.

The agglutinin reaction is more pronounced in colostrum and less so in late lactation milk. Agitating milk at low temperatures reduces creaming, possibly by inducing aggregation of agglutinin factors.

32.7 TYPES OF CREAM

The fat content of cream can vary from values above that of milk (a requirement to distinguish it from milk) to the maximum amount that can be held in an emulsion, beyond which cream phase-inverts to become butter. The maximum fat content in cream is typically around 70–80%, and the propensity for possible subsequent phase inversion will depend upon the shearing conditions imposed during the concentration process. More turbulent conditions will produce butter more readily, thus lowering the maximum amount of fat that the cream can hold as a fat-in-water emulsion.

The extent of separation of milk to form cream dictates the cream classification. "Half and half" cream contains the lowest typical fat content of all types of creams, usually around 10–12%. It is commonly served as a whitener for hot tea and coffee. Light cream is usually around 20% fat, and heavy cream about 40% fat. Cream containing around 48% fat is referred to as double cream. Cream can be heated to form fat globule clusters and to also denature whey proteins. This type of cream with around 55% fat is called clotted cream, and is more common in Britain. Cream with the maximum amount of fat, whilst maintaining a fat-in-water emulsion, is termed plastic fat.

Cream with a fat content as high as 80% can be dried to a powder. This requires the addition of surface-active proteins such as sodium caseinate to maintain the encapsulation properties of the dried powder particle. The cream must first be heat treated to minimize lipolysis during storage. Antioxidants can be added to prevent oxidation of the milk fat.

32.7.1 Whipping Cream

The steps involved in whipping cream preparation are shown in the flow diagram in Figure 32.7, adapted from Walstra and others (1999). The amount of air incorporated into the whipped cream structure is given by the over-run. This is expressed as a percentage,

$$\frac{V_f - V_i}{V_i} \times 100, \tag{5}$$

where V_f is the final whip volume containing air and V_i is the initial volume of the unwhipped cream.

Whipping cream is available as a pasteurized product containing 35–40% fat, with a minimum of 30% fat required before successful whipping can occur. The process of pasteurization limits the growth of psychrotrophs, which produce heat-stable lipases. *Bacillus cereus*, which causes fat globules to become unstable, can be reduced by additional heat treatment at 85°C for 30 min. *Bacillus cereus* has also been implicated in curdling of sweet whipped cream (Buck and others 1992). Other types of heat treatment include

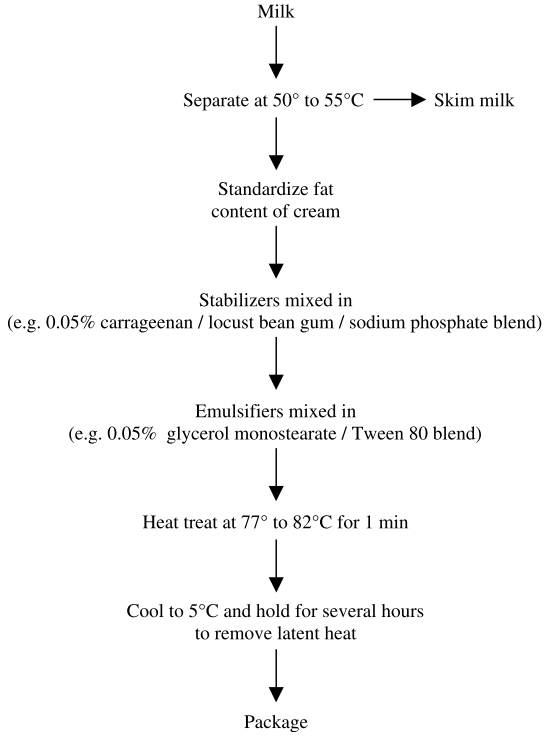

Figure 32.7 *Preparation of whipping cream.*

use of plate heat exchangers at greater than 100°C, or in-bottle treatment at 103°C for 20 min. Deodorization to remove off-aromas can take place in an open vessel with stirring.

Whip volume depends upon the fat content of the cream and the thickness of adsorbed fat globules at the air–water interface (van Aken 2001). Whipped cream contains air cells of 10–100 μm in size. Soluble surface-active proteins (β-casein and whey proteins) adsorb to the air–water interface during the initial stages of whipping and form an air cell network (Besner and Kessler 1998a). Fat globule aggregates adsorb to the interface and provide some stability and rigidity to the maintenance of the air cells. This is a two-step process of complete coalescence of smaller globules followed by partial coalescence of larger globules (Smith and others 2000). Harder milk fat leads to better whipping properties (Overbeck and others 1994), and for this reason, the best whip structure is obtained at 10°C. Whipping cream may require several hours of tempering at this low temperature to initiate sufficient fat crystallization to promote fat globule coalescence. The globules leak some liquid oil, which spreads across the interface, providing a sticky surface that catches fat globules at the interface. Excessive whipping causes the fat globule aggregates to become so large that they cannot stabilize the air cells. These large aggregates form butter granules, and ultimately butter if excessive whipping continues. Adsorption of an excessive amount of fat crystals at the air–water interface results in cream with long whipping time and low over-run (Brooker 1990). Higher amounts of fat will decrease the whipping time and the over-run, increase the firmness of the whipped cream, and decrease the amount of serum leakage from the network of air cells.

Homogenizing cream reduces the propensity for whipping (Besner and Kessler 1998b), possibly due to the fat globules being too small to form a cohesive aggregate structure at the air–water interface, or perhaps the newly created casein-coated globule surface prevents fat crystals from piercing through the membrane. In this case, whipping time will increase and the firmness of the whipped cream will be reduced. However, at low homogenization pressure, coalescence is promoted. This is because the globules are larger and do not contain as much casein at the globule surface, showing clearly that the surface characteristics are important in dictating whipping functionality.

Addition of emulsifiers such as Tweens or monoacylglycerides decreases whipping time, increases whip firmness, and decreases serum phase leakage from the air cells. This is further evidence for the importance of the fat globule surface layer in forming a whipped cream structure. Comparisons of the effect of different emulsifiers on whipping cream functionality is provided by Towler and Stevenson (1988).

Carrageenan can be added to minimize leakage of serum phase from the air cell network (Stanley and others 1996). Stabilizers can also increase whipping time and reduce over-run (Camacho and others 1998). Synergistically with emulsifiers, stabilizers also reduce the viscosity of UHT-treated processed whipping cream during storage (Towler 1988).

Whipping cream can be made available in a pressurized can that provides the necessary air to create a structure with sufficient over-run to provide for a firm product. Over time, the larger air cells grow by adsorbing smaller cells, a process called Ostwald ripening, which culminates in foam collapse. Whipped dairy topping is another product packaged in aerosol containers. A typical formulation consists of 30% milk fat, sucrose for flavoring, sodium caseinate, corn syrup solids, stabilizers, and emulsifiers.

Although fat globules stabilize a foam network, fat can also depress foam formation. The apparent contradiction is resolved by realizing that fatty acids produced by lipolysis of triacylglyceride fat reduce foam volume. Spreading of intact and unemulsified triacylglyceride fats will also depress foam formation.

Churning of cream to form butter is a form of flotation, where air cells pick up fat globules and form butter granules at the air–water interface. As smaller globules do not adsorb as well as the larger ones, churning has the effect of reducing the average fat globule size. Churning or beating at a low temperature (around 5°C), where liquid fat is not sufficient, produces whipped cream rather than butter as there is not sufficient liquid fat at the air–water interface to catch fat globules to subsequently form butter granules.

Cholesterol can be removed from cream by complexation with β-cyclodextrin. The functional properties of whipped cream after using this process are not significantly different from unprocessed whipped cream (Shim and others 2003).

32.7.2 Sterilized Cream

The steps involved in sterilized cream preparation are shown in the flow diagram in Figure 32.8, adapted from Walstra and others (1999). As the sterilization heat treatment comes after the homogenization step, the likelihood of heat-induced aggregation is increased.

The sterilization process minimizes fat lipolysis; however, the Maillard browning reaction can occur during storage. Sterilized cream should be homogenized to prevent oiling-off (phase separation). Sodium alginate can be added to increase viscosity and prevent precipitation of proteins. Sterilized cream can be sold as "half and half", or coffee cream containing around 25% fat.

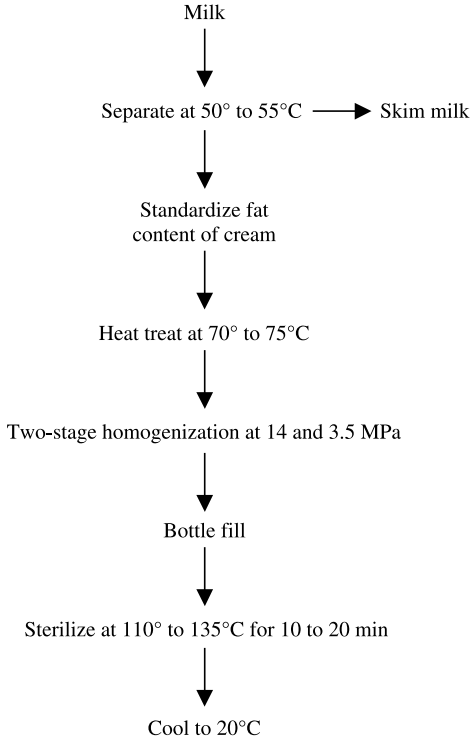

Figure 32.8 *Preparation of sterilized cream.*

32.7.3 UHT Processed Cream

UHT milk has a cooked flavor due to the high-temperature heat treatment. The steps involved in the preparation of UHT-treated cream are shown in the flow diagram in Figure 32.9, adapted from Walstra and others (1999). In some processes homogenization can take place before the UHT step, after the UHT step, or split such that the first homogenization stage is applied before, and the second stage after the UHT treatment step.

The UHT treatment process can result in feathering of cream when added to hot beverages such as coffee. The feathering process is caused by aggregation of fat globules coated with casein micelles from the homogenization process. The extent of feathering depends upon the pH, concentration of calcium ions, and the temperature of the beverage. A film comprised of milk constituents, primarily aggregated fat globules, can form on the surface of hot tea (Spiro and Chong 1997). This is exacerbated by higher calcium and lower concentration of tea polyphenols in solution, and is more pronounced for UHT treated milk. Sequestering of calcium will help in eliminating feathering.

UHT-treated cream is susceptible to age gelation, which is manifested as a thickening of the cream during storage. Homogenization takes place aseptically after UHT heat treatment to prevent heat-induced coagulation of proteins and clustering of fat globules. Creaming and clustering of fat globules can be reduced by addition of stabilizers. There is some suggestion that the cream microstructure of UHT-treated milk does not depend on homogenization being performed before or after heat treatment (Hillbrick and others

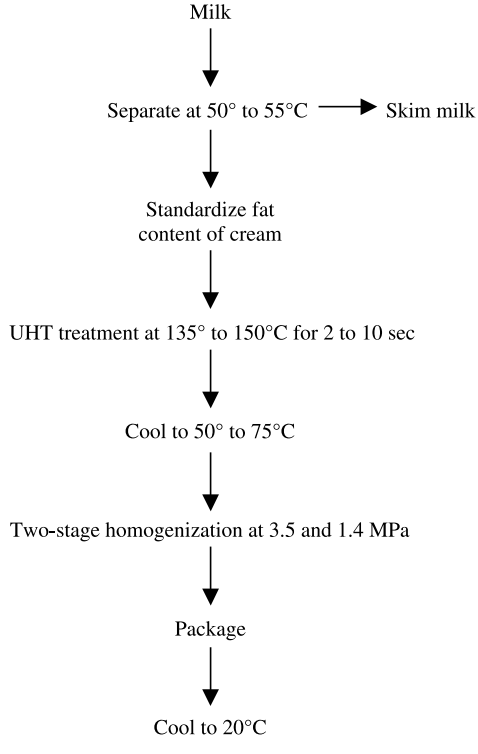

Figure 32.9 *Preparation of UHT-treated cream.*

1999). This may allow for homogenization to take place before heat treatment, with the elimination of aseptic homogenization during processing.

Inadequate homogenization can result in creaming during storage of UHT-treated milk, limiting the shelf-life of this product (Hillbrick and others 1998). High-pressure processing of UHT-treated cream at the very high pressure of 450 MPa can cause fat globule aggregation and increase viscosity through the formation of an extensive network of fat crystals (Dumay and others 1996).

UHT-treated cream has a shelf-life of months if stored at around 5°C. Storage at higher temperatures can exacerbate fat globule agglomeration and creaming.

32.7.4 Recombined Cream

Recombined cream is produced by emulsifying milk fat with surfactants such as milk proteins or buttermilk solids. Filled cream contains other nondairy sources of fat, and will not be discussed in this chapter.

The nature of the membrane layer on the surface of globules will have some impact upon crystal formation within the globule. Buttermilk, serum phase from anhydrous milk fat manufacture, or other similar emulsifiers are necessary to maintain good whipping properties of recombined cream. In these recombined creams, an interface containing adsorbed caseins will result in a lower temperature to induce crystallization and less fat globule coalescence in a whipped formulation compared to globules coated with whey proteins (Relkin and others 2003). Whey protein isolate and sodium caseinate produce a more stable butteroil emulsion compared to skim milk proteins (Segall and Goff 1999). Recombined cream formed by emulsifying a medium melting point (dropping point of 26°C) fraction of butteroil with buttermilk results in a cream with less cholesterol compared to natural cream (Scott and others 2003). UHT processing of recombined milk can promote creaming. A lower melting point milk fat fraction (dropping point of 23°C) results in more rapid creaming over a two-month period compared to a higher melting fraction (Mayhill and Newstead 1992).

32.7.5 Cream Liqueur

The basic principles involved in the manufacture of cream liqueurs are illustrated in the flow diagram in Figure 32.10, adapted from Banks and others (1982). The final composition of a cream liqueur is 14% ethanol and 40% solids. Ionic conditions, pH, and the type of caseinate will affect the structure of cream liqueurs. A reduction in pH below 6.4 results in increasing flocculation of fat globules (Dickinson and others 1989). Sodium chloride will increase the viscosity of sodium-caseinate-stabilized emulsions in cream liqueurs (Lynch and Mulvihill 1997). Addition of cream liqueur to coffee will mix into the beverage rather than form a cream layer above the coffee. By adding trisodium citrate to sequester calcium, and at a high fat content of 40%, a stable cream liqueur can be produced that floats on top of hot coffee (Muir 1988).

32.8 VOLATILE COMPONENTS
