Preface

This book is the result of three decades of endeavors in outpatient diabetes management, starting with the creation of a diabetes clinic in a public hospital in Mexico City. Shortly afterward, we had the privilege of meeting Donnell Etzwiler and his colleagues from the International Diabetes Center in Minneapolis. Don was one of the pioneering supporters of structured diabetes care, the importance of teamwork between health professionals and patients, with a patient-centered approach at the center. He was also aware of the need to improve the quality of diabetes care based on the principles established by Shewhart, Deming, Juran, and many other brilliant minds in the history and evolution of quality in industry, and he guided us to develop and implement a model of diabetes management based on these principles. Starting in 1991, we have presented a diabetes conference in which we have had the opportunity of meeting more than a hundred experts from multiple areas of diabetes from all over the world, from basic science to clinical management. Many of them are collaborators of this book or have supported its creation. We have also came to understand and respect the importance of the multidisciplinary approach to confront, in the words of Professor Paul Zimmet, "the largest epidemic in human history" [1] in a globalized world where social determinants of health are crucially linked to clinical outcomes.

The Diabetes Textbook was conceived to address and recognize the expertise and efforts of countless people, from multiple disciplines and from all over the world, devoted to improve the life of persons with diabetes. I am extremely grateful for the contributions and enthusiasm of more than a hundred experts from five continents. Their leadership and experience in the most diverse professional areas reflect the importance of diabetes and the multiple needs arisen for its management. All the coauthors of *The Diabetes Textbook* are kindly and forever recognized, but special thanks are for Barry Ginsberg, Maggie Powers, and Sanjay Kalra. Their guidance and support were essential to achieve the final work. Thank you so much to all.

We should never ignore the patients [2]. Above and beyond, this book is dedicated to persons with diabetes and their families. Our greatest challenge is to honor the compromise and the privilege to support them.

Mexico City, Mexico — Joel Rodriguez-Saldana

Preface: A New Disease?

1

Joel Rodriguez-Saldana

At the Scientific Sessions of the American Diabetes Association in 1992, Professor Gian Franco Bottazzo delivered the Banting Lecture, in which he announced that diabetes was "a new disease," based on criteria originally described by Mirko D. Grmek in his classical book about the history of AIDS:

Criteria to define a new disease [1, 2]:

1. Previously nonexistent
2. Previously existent but rare
3. Only occurring in regions
4. Only occurring in animals

In his book, Grmek explained that "a disease can appear to be new in at least five different settings: (1) it already existed but it was unrecognized as a clinical entity, (2) it already existed, but did not appear until changes occurred in its manifestations; (3) it did not exist in one region of the world; (4) it did not exist in humans; (5) it is absolutely new" [2, p108]. Diabetes was recognized as a clinical entity since early times, but its magnitude worldwide and its phenotype have remarkably changed during the last 50 years.

The ancient history of diabetes started in Egypt, Asia, and Arabia 3500 years ago [3–5]. The first recorded description appeared in 1552 BC in the Ebers Papyrus, the oldest and most complete medical record from ancient Egypt. In the second century AD, Aretaeus of Cappadocia in Greece coined the term "diabetes" to describe polyuria as the most common symptom of the disease "a melting down of the flesh and limbs into urine," and he also gave the most detailed account of diabetes ever published (Bliss, Galmer). In the fifth to sixth centuries AD, Sushruta and Charaka in India described the sweetness of urine, the use of ants to diagnose the urine of a person with diabetes, and the distinction of two types of diabetes, one affecting thin, young individuals and another in the obese elderly (Galmer).

Reports of persons with diabetes were scarce in the ancient period, but nevertheless, arising worldwide interest. Hippocrates made no mention of it, Galen regarded as a kidney disease ("diarrhea of the urine") associated with "dipsakos" (violent thirst) [5]. In those days, Galen admitted that it was a very rare disease, which he had only observed twice, but at the same time proposed tasting the urine as probably the first diagnostic method in the world (Tattersall). The contributions to diabetes of Avicenna in Arabia are multiple: he gave an accurate description of the clinical features of the disease; he listed some of its vascular and infectious complications (sexual dysfunction, gangrene, carbuncles, and tuberculosis); he noted that when the urine evaporated, it left a residue like honey; and he recommended treatments based on mixtures of seeds with mild hypoglycemic activity [3]. Advances in the diagnosis of diabetes started to appear centuries later in Europe, including the description of a powder-like deposition in the urine of diabetic persons by Paracelsus in the sixteenth century; the sweet taste of urine of persons with diabetes by Thomas Willis in the seventeenth century; the measurement of glucose in the urine by Dobson in the eighteenth century; the description of excess sugar in the blood and urine by Rollo, who first used the term "mellitus" as the Latin and Greek root for honey; and identification of glucose as the type of sugar in blood and urine in the nineteenth century by Chevreuil [3–6]. Diabetes was still a rare disease in this period, and like almost all other patients, persons with diabetes received more harm than good by doctors' orders, including bleeding, blistering, and doping with opium, which was still in use in the early twentieth century and was very difficult to discontinue (Bliss). Therapeutic interventions were mostly related to diet, exercise, and "behavior" including eating large quantities of sugar (Piorry), reducing food intake and exercising (Bouchardat), starvation dieting (Allen) or specific types of carbohydrates (von Noorden), and even isolating patients under lock and key to obtain "sugar freedom" (Cantoni and Naunyn)(Bliss, Galmer, Hurley, Tattersall). Despite all these efforts, life

J. Rodriguez-Saldana (✉)

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_1

expectancy for persons with diabetes, especially children, was very low.

The etiology of diabetes started to be pursued in the nineteenth century. Proposed factors were multiple and disparate, including "grief," "chills" and "excess of venery" (Elliotson), "exposure to cold," "rheumatism and gout," "mental anxiety and distress" (Prout), "sexual excess," and "hereditary predisposition." Based on his assumption that sugar was formed in the stomach from vegetables, Rollo made one of the first proposals of a diabetic diet in which greens were eliminated and consisted mostly of animal food, emetics, ammonia, and narcotics [4](Tattersall). A "thunderbolt" in the physiological world disclaiming these assumptions, occurred when Claude Bernard showed that blood glucose levels are regulated not just by the absorption of dietary carbohydrate but also by the liver, from glucose and non-glucose precursors, its storage as glycogen, and the involvement of the central nervous system in controlling blood glucose concentration [4]. In persons with diabetes, he stressed that the cause of the disease was disequilibrium between sugar formation and disintegration.

Early speculations about the source of diabetes located the disease in the stomach, frequently in the kidneys, and even as a derangement of the central or autonomic nervous system [3–5] (Farmer, Hurley, Tattersall).Traditionally considered a supportive cushion in which the surrounding visceral organs rested, anatomic dissection allowed identification of its ducts and its role in digestion [5]. Advances in "the experimental period in the history of diabetes" included the microscopic description of the pancreas by Langerhans and the endocrine function of the islets by Laguesse [3]. Cawley was the first to suggest a relationship between the pancreas and diabetes, and Minkowski and Mering confirmed the role of the pancreas in diabetes when they showed that pancreatectomized dogs developed "real permanent diabetes, which corresponded in every detail to the most severe form of the disease in man" and which could be reversed by subcutaneous implantation of pancreatic fragments [4, 5]. The race to isolate the hypothesized glucose-regulating hormone which in 1909 was named insulin by Jean de Meyer (Tattersall) was on. Between 1900 and 1921, at least five investigators came close to its discovery, including Nicholai Paulescu from Romania, who described a pancreatic extract that cured diabetes in pancreatectomized dogs in 1916, but for lack of resources, he could not produce in large quantities. The discovery and purification of insulin by Banting and Best from bovine pancreases with the support of MacLeod and Collip, and the first injection on a human being on January 111,922, "was (and still is) one of the most dramatic events in the history of the treatment of the disease (Bliss)," the crowning event of the race started by Mering and Minkowski in 1899 [5–6](Tattersall). Its therapeutic use quickly spread around the world and became a remarkable example of the rapid translation of basic science into a benefit for patients [6]. Beyond its landmark achievement, the discovery of insulin had not solved the problem of diabetes (Bliss).

Almost one century afterward, countless advances in the understanding of normal glucose metabolism, the pathogenesis of diabetes, and the discovery of many effective therapies to treat hyperglycemia and its complications have occurred [3, 6]. Controlled clinical trials have shown the benefits of glycemic control and traditional cardiovascular risk factors (blood pressure, lipoproteins) on reducing the risk of macrovascular and microvascular complications in type 1 and type 2 diabetes [7–10], but implementation "in the real world" is still a huge challenge after one century of efforts [11]. At the same time, the magnitude of diabetes as a worldwide health problem has increased to epidemic levels. The "diabesity" (obesity and type 2 diabetes) epidemic is likely to become the largest epidemic in human history [12]. The burden of suffering and death is unprecedented and in many countries surpasses the impact of scientific achievements.

The Ascent of Diabetes Mortality

The frequency of diabetes started to be measured through gathering of death certificates in Europe and America in 1850 when it was still a rare disease [13]. For example, in 1866, New York City's death rate from diabetes was 1.4 per 100,000 residents, and Charles B. Brigham found only 40 death reports from diabetes between 1854 and 1866 (Hurley). Diabetes became a worldwide health problem in the twentieth century: in the USA, it was the 27th cause of death in 1900, and 45 years later, it became the eight cause despite the fact that insulin was prolonging life for hundreds of thousands of patients [14, 15]. International standardization and the creation of the mortality data system by the World Health Organization raised the awareness about the importance of diabetes as a cause of death and the differences in mortality rates among countries and regions [13]. In 1943, the last year in which statistics for the USA were available before the World War II, the number of recorded deaths due to diabetes was 36,314, 35,000 on average per year [16]. One of the best sources of information on mortality in diabetes was assembled by E.P. Joslin and his colleagues through collaborations with the Metropolitan Insurance Company and the Massachusetts Department of Public Health[13]. In consecutive reports, they showed increases in the age of death because of improvements in survival, refinements in registration of causes of death, and rates of cardiovascular disease and glomerulosclerosis [13]. Starting in the 1960s, multiple studies about mortality and its causes in persons with diabetes appeared in the USA, Scandinavia, England, Asia, and Africa [13]. Estimating mortality due to diabetes continues

to be challenging for two reasons: more than one third of the countries of the world have no reliable data and routine statistics underestimate diabetes deaths resulting from cardiovascular disease and renal failure (or infection) [17]. Despite limitations in the availability of information, diabetes mortality continues to advance at alarming rates: for example, in Mexico, only 368 deaths attributed to diabetes were reported in 1922, representing one death per one thousand people dying [18]. These numbers have continued to increase in the second half of the twentieth century to 105,500 deaths in 2016 and no decrease in sight [19]. By comparison to people without diabetes, having diabetes increases almost twice the risk of mortality, even in developed countries, as documented by a recent report from the German National Health Interview [20]. Based on the WHO life tables for 2010 and 2015, the International Diabetes Federation (IDF) estimated that approximately five million deaths attributable to diabetes occurred among people aged 20–99 years in 2017, accounting for almost 10 percent of the global all-cause mortality in this age group [21].

Prevalence and Costs

Also in 1943, the estimated diabetes prevalence was 3.5 per 1000; prior to 1946, all available estimates were based on interview or testing of selected groups [13]. Pioneer surveys from the USA showed that diabetes was not uncommon [14]. Rates of glycosuria in men were above 2.0% among recipients of life insurance from New York in 1909, but mass screening started to be carried out after the World War II in the USA and Europe [13]. In 1947, Wilkerson and Krall published the results of the first series of mass screening and detection enterprises in Oxford Massachusetts, the birthplace of E.P. Joslin, a native-born resident of the town who supported and sponsored them [13, 22, 23]. Seventy years ago, the prevalence for diabetes in this region of the USA was 1.65 percent [14]. Surveys carried out in Europe reported similar prevalence rates in the range of 0.5%–2–4% [22, 23]. Even in those years, higher prevalence rates, above 30 percent, were reported among aboriginal subpopulations, like the Nauru, the Pima Indians, and other American Indian tribes [24]. In sharp contrast and beyond the challenges involved in collecting accurate data, the prevalence of diabetes has literally soared worldwide. The report of the Non-Communicable Disease Risk Factor Collaboration is eloquent: global age-standardized diabetes prevalence increased from 4.3% in 1980 to 9.0% in men and from 5.0% to 7.9% in women [25]. Accordingly, the number of adults with diabetes in the world increased from 108 million in 1980 to 422 million in 2014 [25]. Estimates from the IDF put the number of people with diabetes at 451 million in 2017, and the projection is that almost 21.3 million live births were affected by some form of hyperglycemia in pregnancy [25]. In conclusion, diabetes directly affects approximately half a billion people worldwide, probably twice as much relatives, inflicting a non-precedent personal and economic burden estimated at $1.31 trillion USD, or 1.8% of the global gross domestic product in 2015 [26]. Direct costs of illness are important drivers, but indirect costs account for 34.7%, ranging from one fifth to almost three fifths of the total economic burden [26].

Trends in diabetes prevalence are heterogeneous: they are lower in northwestern Europe and highest in Polynesia and Micronesia [21], but the sustained increase in the largest populated countries is of great concern. In China, for example, the prevalence of diabetes ascended from 0.67% in 1980 to 10.9% in 2013, and the prevalence of prediabetes increased from 2.09% in 1994 to 15.5% in 2008 [27, 28]. In the USA, the prevalence and incidence of diabetes increased by 90% in the first decade of the twentieth century and tripled in some states [29]. Between 2002 and 2012, the adjusted annual incidence of type 1 diabetes increased by 1.8% per year, and the incidence of type 2 diabetes increased 4.8% per year [30]. The prevalence doubled from 3.5% in 1990 to 7.9% in 2008, while the incidence increased from 3.2/1000 persons in 1990 to 8.3/1000 persons in 2008 [31]. Despite reaching a plateau in 2008–2012, national trends among African-American and Hispanic subpopulations continue to increase [31]. The most recent data from the National Health Interview Survey based on self-report estimated that 0.55% of US adults had diagnosed type 1 diabetes, representing 1.3 million adults, and 8.6% had diagnosed type 2 diabetes, representing 21 million adults [32]. Despite limitations resulting from self-report, validation, and overestimating type 2 diabetes, this first study provided information to track the prevalence by type of diabetes, to assess the burden of disease and the huge challenge of education and prevention programs [32]. In 2014, the estimated number of adults with diabetes in China, India, and the USA was 189.4 million, representing 45% of the total population with diabetes in the world [21].

To complicate the scenario, the incidence of type 1 and type 2 diabetes in children and adolescents is increasing worldwide, along with its consequences (Hurley) [33, 34]. For example, in the USA, the incidence of type 1 increased at a rate of 1.4% annually, from 19.5 cases/100,000 youths per year in 2002–2003 to 21.7 cases/100,000 youths per year in 2011–2012, but the incidence of type 2 diabetes more than doubled in the same period at 7.1% per year [33]. The resulting changes of type 2 incidence in persons younger than 20 ascended from 9.0/100,000 in 2002–2003 to 12.5/100,000 in 2011–2012 [33]. Having diabetes in youth elevates the risk of complications at earlier ages: the study by Amutha and colleagues in India shows that the frequency of hypertension and hypercholesterolemia and the incidence of retinopathy, nephropathy, neuropathy, and ischemic heart disease are 2.1

times higher in patients with type 2 diabetes [34]. The results of this study data are concerning and suggest that 60% of the participants would develop one or more complications of diabetes in one decade and therefore may lose 15 years of the remaining life expectancy [34]. Venkat-Narayan is accurate when he stated that some countries are gaining battles against diabetes [35], while others are losing the war and unable or unwilling to do anything about it [36].

The "Wrong" Lifestyle

The drivers of the diabetes epidemic have been described for decades and involve genetic and environmental risk factors which induce inflammation, autoimmunity, and metabolic stress [37]. Beyond the genetic background of every type of diabetes, the prevalence of type 1 and type 2 diabetes is increasing globally at rates that surpass genetic variation and revealing the key role of environmental factors in both types of diabetes [37]. The pioneering work of David J.P. Barker challenged the idea that chronic diseases like diabetes are explained by bad genes and unhealthy adult lifestyles and proposed that their roots lie in the early life environment [38]. Using old birth records, he showed that people of lower birth and infant weight had more cardiovascular disease, impaired glucose tolerance, beta-cell dysfunction, and diabetes in middle age and proposed a thrifty genotype hypothesis, in which type 2 diabetes is the outcome of the fetus and early infant having to the nutritionally thrifty as a result of impaired growth of beta cells [39, 40]. His statement was visionary: "as long as the individual persists in the undernourished state there is no need to produce much insulin." However, a sudden move to good or overnutrition exposes the reduced state of beta-cell function and diabetes results [40]. Recent research has refined Hales and Barker's hypothesis and demonstrated the role of environmental factors in the etiology of obesity, type 1 and type 2 diabetes, and current strong data supporting a genetic-epigenetic predisposition in type 2 diabetes [41–43].

Despite brilliant efforts showing stabilization and even decline in some countries, worldwide trends in overweight and obesity in children [41, 42], adolescents, and adults continue to rise [44–46]. From 1975 to 2016, the global age standardized prevalence of obesity increased from 0.7% to 5.6% in 2016 in girls and from 0.9% to 7.8% in boys. From 1975 to 2014, age-standardized prevalence of obesity increased from 3.2% in 1975 to 10.8% in men and from 6.4% to 14.9% in women, and the prevalence of morbid obesity continues to increase [47]. Rising trends in children's and adolescents' body mass index have stabilized in many high-income countries, especially at high socioeconomic levels, but have accelerated in East, South, and Southeast Asia [46]. If post-2000 trends continue, the bad news is that moderate and severe infant underweight will be surpassed by obesity in 2022 [46]. In addition to their established roles in type 2 diabetes, obesity and insulin resistance are environmental determinants of type 1 diabetes [37, 48]. Increased childhood growth and weight gain increases peripheral insulin demand, which could place greater stress on beta cells and make them more vulnerable to autoimmune attack; reduction in type 1 diabetes is a potential additional benefit of preventing childhood obesity [49].

Obesity, Syndemics, and Diabetes

Far fewer people globally are underweight than becoming obese; as economic inequalities have increased worldwide, so have inequalities in weight [50]. Beyond violence and substance abuse, social inequalities create syndemics: aggregations of two or more diseases or health conditions in populations with some level of deleterious biological or behavior interface that exacerbates the negative health effects of any or all of the diseases involved [51]. The syndemics framework was described by Merrill Singer in the mid-1990s and refers to the adverse interactions of all types of diseases (infectious, chronic noncommunicable, mental health, behavioral, from toxic exposure and malnutrition) which emerge under conditions of health inequality caused by poverty, stigmatization, stress, or structural violence [51]. Three elements interact in syndemics: disease concentration (genetic predisposition), disease interaction (e.g., obesity and insulin resistance), and the large-scale social forces that give rise to them [52]. Syndemics provides an innovative and important alternative to interpret the co-occurrence of noncommunicable diseases like obesity and diabetes, addressing the importance of social conditions in the emergence and medical outcomes [53]. The concept of syndemics departs from traditional medical approaches that treat diseases as distinct entities, detached from the social context of the people suffering from them (Mendenhall). It moves beyond the common medical conceptualization of comorbidity: concerns the consequences of disease interaction and the social, environmental, or economic factors that cluster with the diseases and shape their interaction [51]. The role of syndemics in persons with diabetes was brilliantly described by Emily Mendenhall in 2012 in a study about the social context of clustering of diabetes and depression among Mexican immigrant women in Chicago, in which she demonstrated the parallelism between syndemics and the embodiment construct that states that "we literally incorporate, biologically, the material and social world in which we live (Mendenhall, Krieger)."

Beyond the undeniable role of genetic traits in the pathogenesis of diabetes, environmental and social determinants have become preeminent in its ascent and the response at

every level, including people with diabetes, providers, and society. In a highly cited study, Christakis and colleagues analyzed the possible contribution of person-to-person spread of obesity in a densely connected social network of 12,067 people assessed as part of the Framingham Heart Study from 1971 to 2003 [54]. The results showed that clusters of obese persons were present in this network at all time points, albeit did not seemed to be solely attributable to the formation of social ties. Among the obese, a person's chances of becoming obese increased by 57% if he or she had a friend who became obese; by comparison, if one sibling became obese, the chance that other would become obese was 40%, 20 percent lower [54]. This study suggests that social networks are even more important than genes on a person's risk to become obese and became a milestone in the story of network medicine [55]. The revolutionary work of Albert Barabasi has shown the existence of networks pervading all aspects of human health [55]. Network-based systems may account not only for the genetic but also for the environmental and social influences of disease [55]. Recent trends of obesity and diabetes have led the WHO and the scientific community to describe them as epidemics [12, 56]. Traditionally, until today, diseases like obesity and diabetes have been described as "noncommunicable," but current evidence indicates that this formulation is inaccurate [57]. As the study of social networks has demonstrated, behavioral risk factors are acquired through social mechanisms and are thus communicable [57]. A recent report from the Israeli IDDM Registry Study Group shows that between 1997 and 2014, familial cases of type 1 diabetes increased 1.9% per year, while sporadic cases decreased 0.2% per year in the same period [58]. The authors conclude that the rapid rise in the proportion of familial cases of type 1 diabetes suggests that environmental factors impose higher diabetogenic pressures in patients with susceptible genetic background [58].

The Social Environment of Diabetes

The inverse care law states that availability of good medical care tends to vary inversely with the needs of the population served [59]. Social and geographical inequalities in morbidity and mortality persist worldwide, with direct effects in the lifestyle and the outcomes of persons with diabetes. The hardships of people with diabetes to achieve effective, multidisciplinary care have been repeatedly documented, even in developed countries, in every age group. For example, children with diabetes in Canada have worse levels of glycemic control if they live in areas of highest neighborhood index, defined by indicators evaluating economic, social, environmental, and lifestyle factors [60]. Food insecurity, defined as limited or uncertain availability of nutritionally adequate and safe foods owing to cost or distance, is associated with increased consumption of inexpensive food alternatives, frequently calorically dense and nutritionally deficient [61]. Food insecurity increases the risk of obesity and diabetes [61]. Compared to people living in food secure households, food insecurity increases the risk of poor glycemic control (A1c >9.0%), hospitalizations, and emergency department visits [59]. In the USA, two studies have estimated that one fifth of people with diabetes have to deal with food insecurity [62, 63]. Social determinants of health continue to prevail in the outcomes of people with diabetes from every age group [64]. Daneman and the realities of clinical practice show the most common cause of death in youth with type 1 diabetes worldwide continues to be lack of access to insulin and that in some countries, life expectancy of a child with type 1 diabetes is less than 1 year [64]. The five fundamental requirements for diabetes care (availability of food and clear water, availability of insulin and glucose or urine testing, prevention of hyper or hypoglycemia, and protection against harm) [64] are still and increasingly unavailable to a large number of people.

The Disease, the Illness, and the Predicament

As a result of its global burden, diabetes is perceived from multiple perspectives. The most important nevertheless is from persons and their families. In 1979, David C. Taylor brilliantly described three different ways of being sick: diseases, physical entities discernible through diagnostic tests; illnesses, or the experience of being sick; and predicaments, or the complex of psychosocial ramifications, contacts, meanings, and ascriptions which bear on the individual [65]. The predicament and the positive or negative way in which it is faced and solved by persons with diabetes and their families are crucially linked to the outcomes. Bob Anderson described it as "the personal meaning of diabetes" and the levels of personal responsibility, from absolute denial to total commitment that every individual has the option to assume [66]. Tinetti and Fried eloquently claimed that:

> Time has come to abandon disease as the focus of medical care. The changed spectrum of health, the complex interplay of biological and non-biological priorities render medical care centered on the diagnosis and treatment of individual diseases at best out of date and at worst, harmful…clinical decision making should (achieve to) attainment of individual goals and identification and treatment of all modifiable biological and non-biological factors, rather than solely on the diagnosis, treatment or prevention of individual diseases [67].

We hypothesize that although the conversation has shifted, paternalism in health care has not changed [68]. Health-care systems continue to focus on engaging patients in behaviors that are desirable from a biomedical perspective, with no space left for patient (concerns) goals, needs, desires,

abilities, and backgrounds that make humans so rich and diverse [68]. Health-care organizations and providers should consider the use of language more appropriate for their role in the user's care such as coach, guide, counselor, or advocate [68]. Reductionist approaches seek to build holistic constructs for disease etiology, pathophysiology, epidemiology, and therapeutics without including the multiple insertion points of the social world and reduce the "whole person" to pieces that can be coded into data and fed into network analysis [69]. In the twenty-first century, biomedical research and clinical practice have begun to shift from close examination of disease parts (beta cells, endothelium) toward a "personalized approach" that focuses on the whole person as a unit of analysis [69]. This task will be complex, time-consuming, and arduous but is essential to the advancement of medicine [69].

New Approaches to an "Old" Disease diabetes has changed in many ways, each representing a challenge. The "old disease" described in Egypt 35 centuries ago in a small number of patients has become a worldwide health problem affecting directly one sixth of the general population and indirectly at least another sixth of siblings and relatives [70]. The social distribution of the disease leads to large inequalities in management; most of even the "reasonably" expected benefits go to a small fraction of the patients, the ones who have access and can afford the progress [70]; a huge mismatch exists between countries and regions with the largest diabetes burdens and the sites of research and clinical excellence [35]. Even people with economic resources have to endure individualistic, vertical physician approaches and low quality of services. Improvements in quality of diabetes care [71] and reductions in complication rates among people with type 2 diabetes in the USA and high-income countries [72] are exemplary but contrast with the inability of countries like Mexico, where despite high levels of obesity and diabetes, glycemic control continues to be poor, diabetes is associated with a far worse prognosis than in high-income countries, and complications continue ascending [73]. Achievements in the science of diabetes are unprecedented, and the future looks even more promising [73–76]. The paradox is unprecedented: never before has there been so much knowledge and resources about diabetes, but never before has there been so much suffering.

The concept of a "cascade of care" proposed by Ali and colleagues is a powerful tool to visualize gaps and disparities across groups to improve engagement and the quality of diabetes care, including awareness, and effectiveness of prevention programs for people with prediabetes [77]. Years ago, Frank Vinicor summarized the challenges in the future of diabetes [78]. Besides new medicines, it is essential to (1) continue the improvements in diabetes care; (2) recognize and address the complexities of diabetes management; (3) improve the system of care; (4) broaden the definition of "office"; (5) address the dual impact of the diabetes epidemic, maintaining the efforts to improve the management of people with diabetes, and develop and implement primary prevention programs; (6) recognize and deal with "non-health forces" influential on diabetes prevention and control; (7) look for special opportunities for health professionals; (8) empower patients; (9) achieve a balance between individuals and communities; and (10) accept and embrace globalization [78]. The challenge is formidable, and the stakeholders are multiple.

Part I

Magnitude of the Problem from an Individual and Social Context

The Dynamics of Diabetes Prevalence, Morbidity, and Mortality

2

Edward W. Gregg and Paula Bracco

Introduction

Diabetes mellitus has caught the attention of the world as a major public health problem due to the explosive increases in prevalence that have occurred, affecting virtually all regions of the world, and within regions, affecting all age and demographic subgroups and across the full range of socioeconomic status [1–3]. The global prevalence is now estimated at around 420 million, affecting 9% of men and 8% of women, with lowest regional prevalence in Northeastern Europe (6%) and highest prevalence in Polynesia and Macronesia (25%) [1]. This growth has included both type 1 and type 2 diabetes, although between 90 and 95 percent of the cases and the predominant increase in prevalence has been driven by type 2 cases [4]. Dozens of individual-level genetic and environmental factors have been prospectively associated with type 2 diabetes, but the increases in prevalence in most societies have likely been driven by a smaller set of trends, including increasing prevalence of overweight and obesity, declining levels of physical activity, poor-quality carbohydrate in our diets, sugary drinks, increased fast food and portion sizes, aging and longer lifespan, and increasingly diverse socioeconomics [5, 6]. There is also increasing recognition of heterogeneity in diabetes types, even within the classic categories of type 2 and type 1 diabetes, that likely have different patterns of risk factors that may further vary by region and context [7].

The growth of diabetes prevalence has ominous implications for numerous health and economic-related reasons. Ultimately, diabetes places an enormous burden on individuals, families, health systems, and societies because of the treatment required, the acute and chronic complications, its demand for health services, the direct impact on quality of life, and the loss of years of life [8]. In addition to the effects of diabetes on traditionally recognized macrovascular and microvascular conditions, the complications of diabetes may be further diversifying due to the long-term reductions in cardiovascular mortality in many settings [9].

While the growth of diabetes is most apparent in prevalence trends, there are numerous dynamics in the epidemic underway, with important implications for the clinical and public health priorities that follow. We have synthesized primary findings from population studies of the burden and trends in prevalence, incidence, morbidity, and mortality, with a particular focus on the status in North America and Latin America.

Current Burden of Prevalence and Incidence

Prevalence

Countries of the Americas tend to be around the median of worldwide prevalence of adult diabetes, now estimated at 8.3% diagnosed [1]. The highest estimates from the Americas region come from the Caribbean Islands and Belize, where prevalence ranges from 10 to 15%, making it one of the higher diabetes prevalence regions of the world. Similarly, the Central America region contains countries of particularly high prevalence (Guatemala, Nicaragua, and Belize), of between 10.5 and 12.5% [10, 11]. Prevalence estimates modeled for subregions of the Americas from the Global Burden of Disease Study are generally highest in Mexico, the Caribbean, Central Latin America, and high-income North America and lowest in the Southern Latin America, Tropical

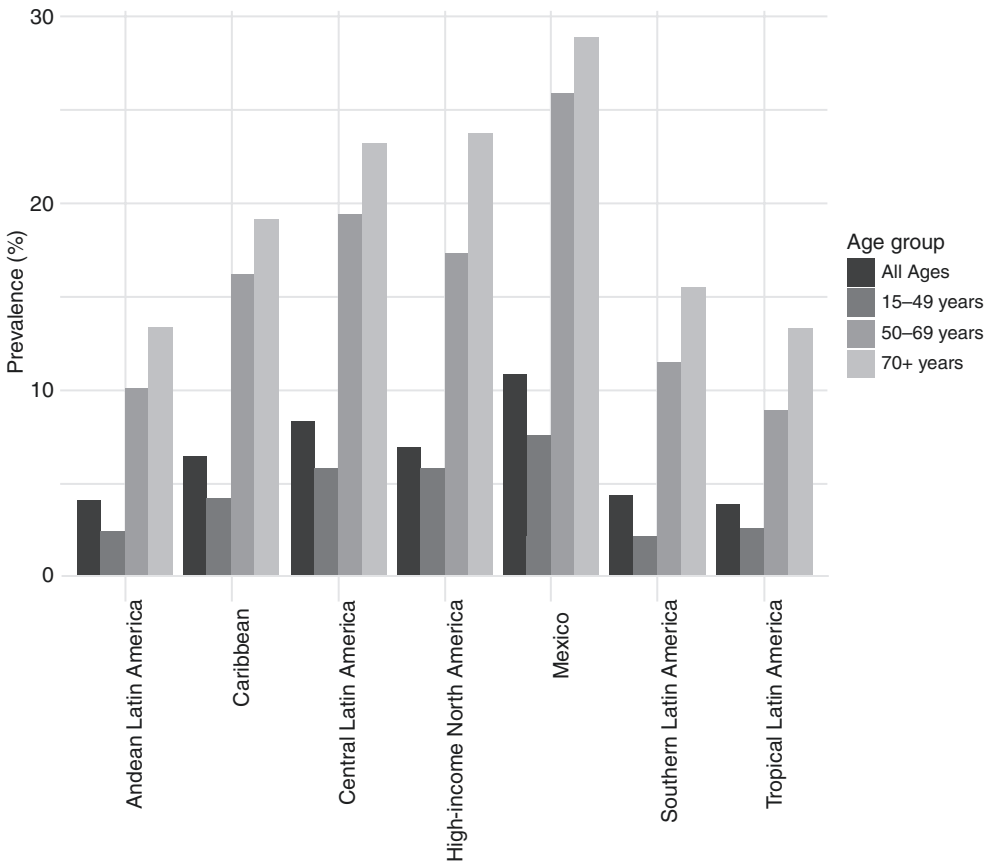

Fig. 2.1 Estimated prevalence of diabetes in subregions of the Americas, by age, 2016

Latin America, and Andean South America (Fig. 2.1). Other estimates within the past 10 years suggest that prevalence is similar for Canada (6.7% diagnosed diabetes in 2014 and an additional 3% undiagnosed in 2007–2009) and Brazil (6.2%) but higher for Mexico (8.9% diagnosed in 2012) and Colombia (12.3% diagnosed in 2016–2017) [12, 13]. Prevalence is strongly associated with age, ranging from 2 to 7% across subregions among young adults (age 15 to 49 years), from 8% to 25% in adults aged 50–69, and from 12% to almost 30% in those aged >70 years.

In the USA, 9.3% of adults have diagnosed diabetes and 2.9% have undiagnosed diabetes, for a total of 12.2% [14, 15]. The national prevalence in the USA conceals considerable geographic variation, ranging from less than 5% in low prevalence areas of the USA to greater than 16% in high prevalence areas, including areas of concentration in the Mississippi Valley and Deep South, the Appalachian Mountain chain, and selected areas of the West and Midwest corresponding to Native American lands [16–18]. Prevalence is also notably high in areas corresponding to areas of high concentration of Native Americans and in Canada, areas with large populations of First Nations residents.

In the USA, diabetes prevalence is similar across genders but increases steeply with age, such that young adults (age 18–44), middle-aged (45–64), older (≥65 years), and very old have prevalence of 2.6, 12.7, and 20.8, respectively (Fig. 2.2). Prevalence also has a strong association with race/ethnicity in the USA, as compared to whites women, American Indians and Alaska Natives and non-Hispanic blacks have prevalence that is about twice that of whites, while Hispanics and Asians have prevalence that is about 80% higher than whites [15]. Education level is also a key factor, as adults with less than a high school education have a prevalence (15.5%) that is about 60% higher than those with more than a high school education (9.65). Within Latin America, indigenous populations have historically low prevalence but now represent the populations with the greatest magnitude of recent increase, as evident in indigenous populations in Brazil and Chile [11].

Undiagnosed Diabetes

Because early stages of diabetes are usually without symptoms, many individuals have several years with diabetes before detection and diagnosis, and thus a large proportion of the population with diabetes is undiagnosed. In the USA, prevalence of undiagnosed diabetes is about 3%, representing about one-fourth of the population with diabetes [19]. Older adults, Mexican Americans, and persons with lower education are somewhat less likely to be diagnosed. Although it is commonly believed that awareness and detection of diabetes is increasing over time, changes in the proportion of the population with undiagnosed diabetes converting to the diagnosed

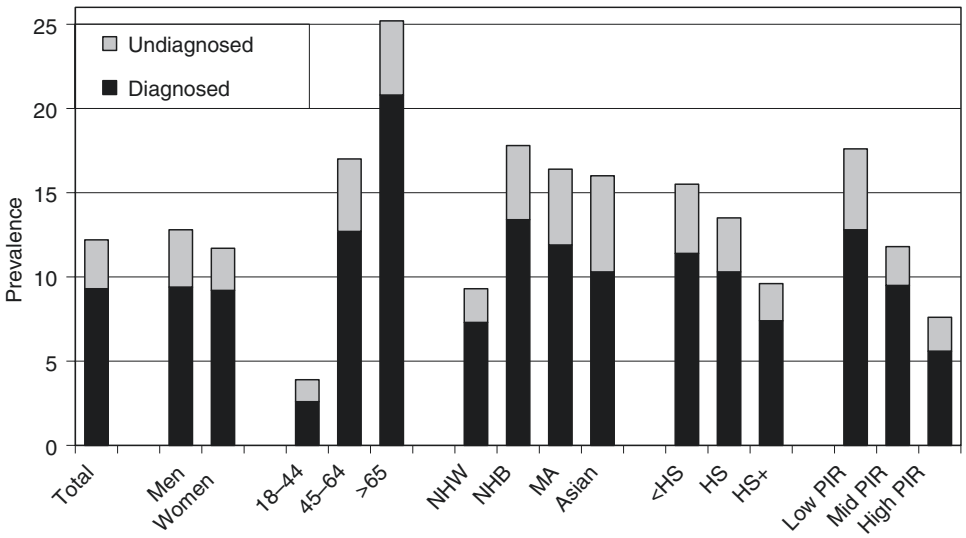

Fig. 2.2 Prevalence of total diabetes (diagnosed diabetes and undiagnosed diabetes) in the US adult population, age ≥ 20, 2011–2014. Legend: Reference; National NHW non-Hispanic whites, NHB non-Hispanic blacks, MA Mexican American, HS high school, PIR poverty-income ratio

state have been relatively unchanged over time, with exception of recent improvements in detection in older adults, non-Hispanic whites, and wealthy individuals and worsening detection in Mexican Americans [19]. Few other studies in the Americas have reported undiagnosed diabetes. Considerably higher proportions of cases remaining undiagnosed have been documented in many other regions of the world. Although diagnostic definitions and time periods vary across studies, the proportion of undiagnosed diabetes has been reported to range from 20% to 49% in the South and Central American regions [20]. However, national data from Mexico suggests that up to 50% of cases remain undiagnosed and in Canada 20 to 40% depending on the glycemic definition [21].

Incidence

Incidence, or the rate of new cases per population, is less directly affected by mortality rates than is prevalence and is thus a more sensitive indicator of the trajectory of the epidemic. Current adult incidence of diagnosed diabetes is about 7 per 1000 adults, with similar estimates for men and women and race/ethnic patterns that parallel the estimates for prevalence [14, 22]. Like prevalence, incidence increases steeply with age, from 3 per 1000 in young adults (age 18–44) to 11 per 1000 in middle age (45–64 years), but there is no further age-related increase thereafter, as incidence is 9 per 1000 among persons aged ≥65, reflecting the age-related incidence peak in the early 60s. Incidence estimates from population-based studies only include the detected cases and thus do not reflect true incidence. When undiagnosed cases are included, estimates in the USA approach 1 percent per year and can be used as a general benchmark of the risk of a population, as subpopulations with different designations of prediabetes, such as impaired fasting glucose and impaired glucose tolerance, have incidence estimates that range from 1 to 5 percent per year [23].

Prediabetes

Estimates of prediabetes vary considerably with the definition that is used, which remains an area of debate because of the high degree of discordance that exists across different glycemic markers, including fasting plasma glucose, post-challenge glucose response, and HbA1c. Using the American Diabetes Association-like prediabetes definition of fasting plasma glucose or elevated HbA1c, 33.9% of adult Americans have prediabetes, with estimates ranging from 23.7% among young adults (age 18 to 44) to 48.3% among adults age ≥ 65 years. It is noteworthy that only about 10 percent of persons with prediabetes are aware of their risk status. Since risk of progression from prediabetes to diabetes with the ADA definition is relatively low, the Centers for Medicare and Medicaid Services (CMS) has adopted a definition of FPG > 110 mg/dl or HbA1c > 5.7%.

Trends and Trajectories in the Epidemic

Prevalence and Incidence

Prevalence of diagnosed and total diabetes has been increasing in most regions for as long as population-based estimates have existed [1, 24, 25]. From 1980 to 2014, worldwide prevalence increased from 3.6% to 8.8% in men and from 4.7% to 8.2% in women, corresponding to an increase in total numbers from 108 to 422 million adults. Diabetes prevalence increased in virtually all regions of the world except for women in mainland Europe and men in northwestern Europe, while the greatest absolute increases have occurred in Polynesia, Micronesia, and the Middle East. Although the growth of mega-urban areas in the low- and middle-income countries are often regarded as an accel-

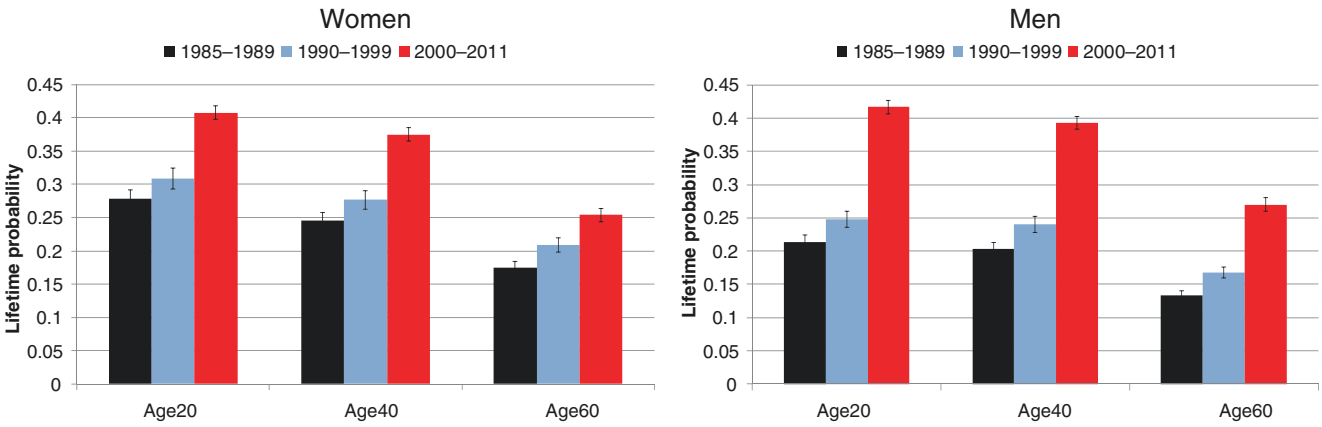

Fig. 2.3 Lifetime risk of developing diabetes, according to age in the USA, according to sex and cohort. (From Gregg et al. [33])

erator of the diabetes epidemic, large increases have also been observed in rural areas [26].

In the USA, national-level prevalence was first recorded in 1960 at less than 1% of the population and grew steadily in the 1960s through the 1980s to about 3.5% in 1980 (Diabetes in America, 1995) [27, 28]. However, in the 1990s prevalence and incidence increased more rapidly, with a dramatic 50% increase in prevalence from 1990 to 2010 and continued increase until a peak incidence of 9 per 1000 in 2008 [22]. These trends followed large increases in the prevalence of overweight and obesity occurring during the same period. The increases in prevalence of diagnosed diabetes were paralleled by increases in total diabetes, as small increases in undiagnosed diabetes paralleled the changes in known diabetes [28]. Throughout this period, the increases in prevalence were paralleled by increases in incidence from around 4 cases per 1000 per year in the 1980s and early 1990s to almost 10 cases per 1000 adults in 2009 [14, 22].

Prevalence increased in both men and women and all age groups; the greatest relative increases were observed in youth and young adults, and the greatest absolute increases occurred in older adults [29, 30]. However, the greatest increase in total numbers was observed among middle-aged adults, driven by the US baby boom generation, born between 1945 and 1965, reaching the ages of peak diabetes incidence. The increases in diagnosed diabetes increased in virtually all other demographic subgroups of the population but were particularly notable in those of low education and socioeconomic status, leading to a particular widening of prevalence by social class [22, 31]. This is also evident in the trends in geographic trends, wherein the poorest areas of the USA saw the greatest increase in diabetes prevalence [32].

Impact on Lifetime Risk and Years of Life

The enormous increases in incidence, combined with large decreases in mortality, described in more detail below, have had a large impact on the lifetime risk of diabetes, the number of years spent with and lost due to the disease [33]. Lifetime risk, or the probability of developing diabetes before death, increased from 27% in women and 21% in men in the late 1980s to 40% for both sexes in the 2000s. For persons who arrive at the age of 60 without diabetes, their remaining lifetime risk is lower than from birth but remains high, at 26% for men and 25% for women (Fig. 2.3). Lifetime risk in the USA is highest among Latinos (52% for both men and women) and non-Hispanic blacks (55% in women and 45 in men). The large decreases in mortality in the population with diabetes mean that there has also been a decrease in the number of years lost to the condition. For the average person diagnosed at age 40, the number of years lost to diabetes decreased from 8 to 6 for men and from 9 to 7 years for women. However, this also means that there has been an increase in the number of years spent with the disease, from an average of 13 to 18 years for men and from 19 to 21 years for women. When applied to an entire community, combining the number of years spent with the condition with the growth in prevalent cases, this translates to a more than doubling of the number of years of life in men and 70% increase in women. This metric of number of total years per community of 1000 adults is particularly ominous in light of the association of duration of diabetes with an erosion of quality of life and increased health service use. Although this changing burden is a function of both increasing incidence and declining mortality in the diabetic population, the increases and sustained incidence is the predominant factor, underscoring the continued need for effective prevention strategies at policy, community, clinical, and individual levels.

A Turn of the Tide?

Following the large increases in prevalence in the 1990s and 2000s, data from the US National Health Interview Survey (NHIS) described a peak at an incidence level of 8.5 per 1000 in 2008 followed by a 25% decline through 2015

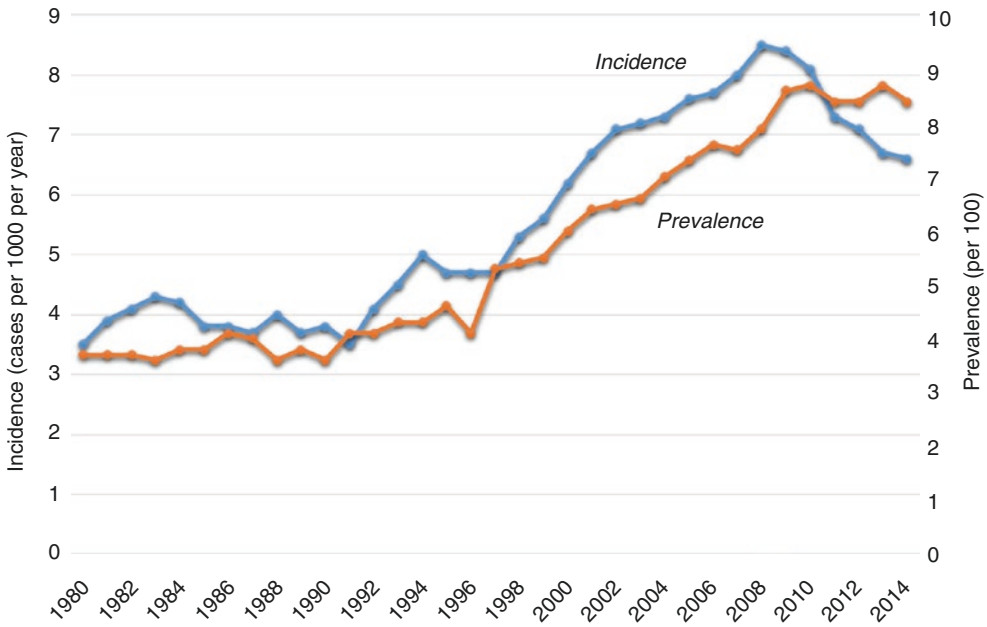

Fig. 2.4 Trends in incidence and prevalence of diagnosed diabetes among adults aged 20 to 79, USA, 1980–2014

to 6.5% [14] (Fig. 2.4). In contrast with incidence, prevalence of diagnosed diabetes did not decline, but reached a peak and plateau during the same period. Similar trends have been reported in state-level prevalence from a separate survey (the Behavior Risk Factor Surveillance System), confirming the encouraging reduction observed in the NHIS. The reductions appear to have generally affected all major subgroups of the population [29]. Youth and young adults stand out as a remaining area of concern, however, as prevalence and incidence continues to grow [34, 35]. The most recent findings from the SEARCH Study (SEARCH for Diabetes in Youth) revealed a 4.8% yearly increase in incidence of type 2 diabetes from 2003 to 2012. The increases in incidence were greatest for American Indians and Alaska Natives (8.9% increase), Asian or Pacific Islanders (8.5%), non-Hispanic Blacks (6.3%), and Hispanics (3.1%), as whites were the only group with no change (Fig. 2.5). The increases in type 2 diabetes incidence were also paralleled by increases in type 1 diabetes of about 2 percent per year, paralleling concerning trends observed in other areas of the world [35]. The continued increases in prevalence and incidence in youth is a discouraging harbinger for the future given the implications of such early diabetes diagnosis on long-term cumulative diabetes-related complications.

Several explanations for the reduction in incidence have been raised, ranging from true reductions in the rate of the disease due to declining underlying risk of the population to measurement biases stemming from changes in detection, diagnosis, or definitions of diabetes [22]. Midway through the past decade, surveillance reports also described peaks and decreases in total dietary intake, sugared beverage intake, and plateaus in prevalence of obesity and

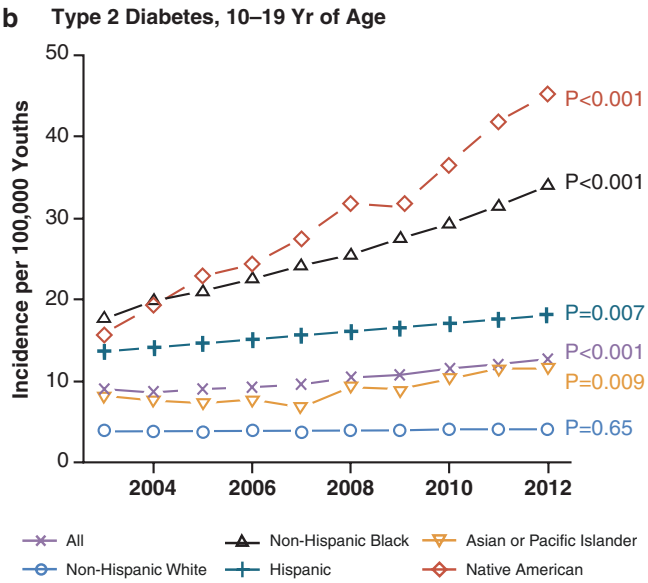

Fig. 2.5 Trends in type 2 diabetes incidence in youth in the USA. The SEARCH Study in Youth

physical inactivity. The year 2010 American Diabetes Association recommendation to use HbA1c for the diagnosis of diabetes is another potential factor, because the HbA1c threshold of 6.5% selects fewer people than the fasting glucose threshold of 126 mg/dl. Thus, a shift from FPG to HbA1c for diagnostic purposes would lower incidence and prevalence [36]. However, if healthcare providers use both tests, it could actually increase prevalence and incidence. As no surveillance systems measure the actual rates of diagnostic testing or the method of diagnosis, it is unclear how testing or changing awareness of diabetes is affecting incidence rates.

The Burden and Trends in Diabetes Complications

Prevalence and Incidence

Diabetes is notorious for its systemic effect on a diverse array of diabetes-related complications including macrovascular, microvascular, neuropathic conditions, and infections with coronary heart disease, stroke, foot ulcers, vision loss, kidney failure, amputations, and death regarded as many of the most feared outcomes [9, 37, 38]. Diabetes is also increasingly associated with nontraditional complications, including cancers, liver disease, dementia, disability, and other geriatric syndromes [9, 39]. The etiology of diabetes is believed to be multifactorial with genetic and environmental influences and a key influence of level of glycemic and blood pressure control on most complications.

Diabetic retinopathy is recognized as the signature complication of diabetes and, being the complication that is most specific to diabetes, has been used to guide diagnostic thresholds for diabetes. Prevalence of any diabetic retinopathy has been estimated at 28.5% of the US adult diabetic population, with 4.4% of them having vision-threatening retinopathy [40]. However, no nationally representative estimates of retinopathy exist within the past decade. While it is conceivable that the reductions in incidence of diabetes complications (described in detail below) have served to reduce prevalence of retinopathy, it is also possible that the concomitant reductions in mortality have resulted in a maintenance of similar or even higher levels of retinopathy.

Chronic kidney disease and coronary heart disease are prevalent at similarly concerning levels in the adult diabetic population, with 19% of adults having stage 3 or stage 4 chronic kidney disease and 18.3% of adults having coronary heart disease [41]. CKD is notably higher in African-Americans than in whites, and although coronary heart disease prevalence is similar across race/ethnic groups, a strong gradient with education level has been noted for coronary heart disease, wherein persons with less than a high school education have a prevalence that is 8 percentage points higher (26%) than those with more than a high school education (18%). Although recent estimates of CKD represent a reduction relative to the early 2000s, when prevalence was around one-fourth, there has been no significant reduction in prevalence between 2003–2004 and 2011–2012. Finally, estimates of prevalence of specific complications do not reveal the full burden of diabetes-related morbidity; when prevalence of the full range of vascular, musculoskeletal, neurologic conditions and cancers are considered, most persons with diabetes have multiple chronic conditions present, and the mean number of comorbid conditions is already 3 at the time of diagnosis [42].

Trends in Complications

Despite the high prevalence of morbidity among patients with diagnosed diabetes, there have been large reductions in the incidence rates of diabetes complications over recent decades [27]. In a report of nationally representative data from 1990 to 2010 in the USA, there were substantial declines in a diverse spectrum of diabetes complications, including myocardial infarction, stroke, lower extremity amputation, end-stage renal disease, and hyperglycemic death, resulting in an overall halving of rates of complications for the average US adult with diagnosed diabetes [27]. The magnitude of decline in was greatest for myocardial infarction, declining 68% to draw even with stroke, which also declined by 53%. Rates of amputation declined 51%, end-stage renal disease by 28% (Fig. 2.6).

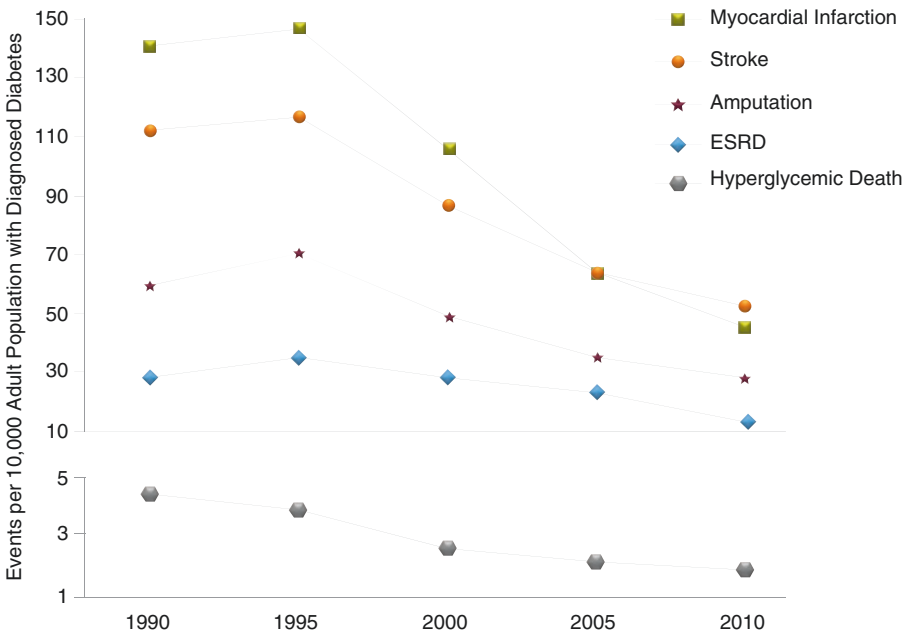

Fig. 2.6 Trends in age-standardized rates of diabetes-related complications from 1990 to 2010 among US adults with diagnosed diabetes. (Gregg et al. [27])

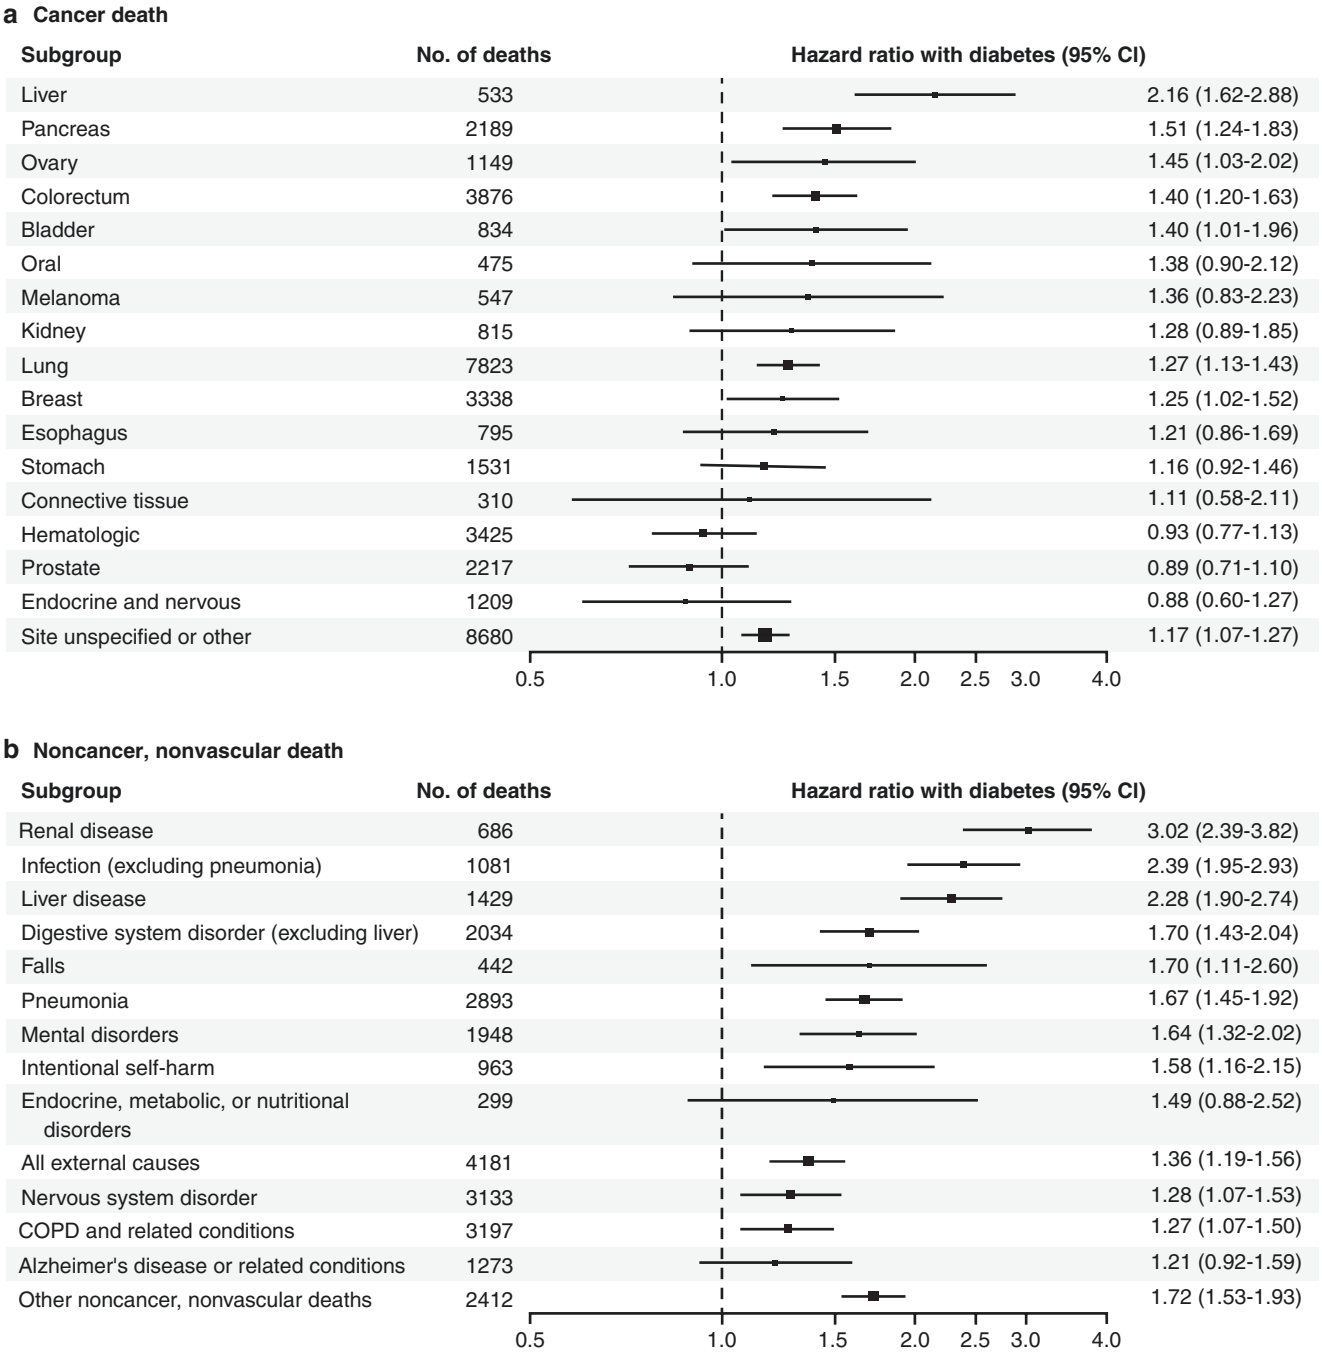

Fig. 2.7 Hazard ratios for deaths from cancer and non-cancer, nonvascular causes among participants with diabetes. The Emerging Risk Factors Collaboration (Seshasai et al. [46])

Rates of death due to hyperglycemia, which was less common in absolute terms, also declined substantially. These reductions in complications generally included men and women and both whites and nonwhites. However, the declines in complications were substantially greater in older adults (age > 65 years), moderate in middle-aged adults, and either modest or nonexistent in young adults. Although no national data exists on rates of diabetic retinopathy, the prevalence of vision impairment in the USA declined by 25%, from 24% to 18%, generally paralleling the other improvements in rates [14] (Fig. 2.7).

While the long-term perspective on trends in diabetes complications has clearly been positive, more recent reporting of results from the 2010 to 2015 period from the US National Diabetes Surveillance System suggests that the improvements in complications may have stalled or in some

populations even increased [14]. Rates of lower extremity amputations increased overall, particularly among men, the middle-aged population, and potentially driven by an increase in amputations of the toe, as trends in amputations above the foot have been stable. Similarly, trends in myocardial infarction, stroke, and end-stage kidney disease appear to have plateaued [43, 44]. No in-depth published reports have examined most recent shifts in trends in complications, and thus it remains unclear whether such apparent shifting trends are related to changing characteristics of the population with diagnosed diabetes, changes in self-care, risk factor management or treatment, health policy effects, or even broader secular trends in the health of the population.

The encouraging trends in incidence of diabetes-related complications described above take the perspective of the average risk for a person with diagnosed diabetes. When trends in diabetes-related events are expressed as the absolute number of events, wherein the increases in diabetes prevalence over time are permitted to influence rates, the trends have been less encouraging [27]. From this general population burden perspective, rates of diabetes-related MI declined by 32% and hyperglycemic death declined by 42%, perhaps reflecting the impressive gains that have been made in smoking and management of hypertension hyperlipidemia in recent decades. However, trends in amputation stroke have been flat, and ESRD increased when viewed from this population perspective, reflecting the continued wave of new diabetes cases and perhaps an indication that there has been less success in reducing microvascular disease risk than macrovascular disease risk in many countries.

Despite the large reductions in the incidence of diabetes complications, the excess rates of complications associated with diabetes remain substantial, and areas of important disparities remain. Relative risks for lower extremity amputation and ESRD were 10.5 and 6.1, respectively, and adults with diabetes still have 80% increased risk of myocardial infarction and 60% increased risk of stroke, respectively [27]. Considerable disparities still exist across subgroups, as non-Hispanic blacks still have twice the risk of amputation and ESRD and one-third higher rates of stroke, Hispanics have a 33% increased risk of ESRD, and Asians have an elevated risk of stroke [14]. In addition, compared to women men have 30% higher rates of MI and twice the rate of lower extremity amputation.

Limited population-based data on trends in other areas of the world exists to confirm whether the encouraging trends from the USA are also occurring elsewhere. Although reviews of international data have revealed reductions in rates of lower extremity amputations in numerous settings, these data generally come from Canada, Europe, and Australia. There is limited data on the trends in complications in the Americas or the remainder of middle- or lower-income countries around the world.

Diabetes and Mortality

Adults with diabetes in the USA, Canada, and several countries of Europe have been shown to have overall mortality rates that are approximately 60–80% higher than equivalent-aged adults without diabetes [45, 46]. However, recently published data from a Mexico City cohort finding considerably higher relative risk of death, ranging from 1.9 in persons aged 75–84 to 3.1 in those aged 60–74 and to 5.4 for adults aged 35–59 years, serves as a reminder that there may be considerable variation across populations in excess mortality associated with diabetes [47].

Cardiovascular disease is the leading cause of death among adults with diabetes in the USA, accounting for 34% of the total, followed by cancers (20%), diabetes itself, and renal disease (5% of total). In addition to the five most common causes of death described above, diabetes is associated with an increased risk of several other causes, including unintentional injuries, lower respiratory diseases, septicemia, influenza, and liver diseases. Comprehensive data from the Emerging Risk Factors Collaboration reveals several other specific causes of death that are notably increased in adults with diabetes including cancers of the liver, pancreas, ovary, and colorectum [46]. These differential rates likely reflect multiple factors, including the chronic hyperglycemia associated with diabetes, as well as the underlying risk factors, including hypertension, insulin resistance, and inflammation commonly recognized in persons with diabetes.

The association of diabetes with mortality varies considerably by demographic subgroup. For example, the relative risk of all-cause, CVD, and renal disease mortality decreases steeply with age. In the USA, among young adults (age 20–44) and middle-aged adults (age 45–64), diabetes is associated with about 3 times the death rate of those without diabetes. Among those aged 65–74, diabetes is associated with twice the death rate and about a 25% increased rate among adults aged >75 years. The lower relative risk among older age likely reflects several factors, including the possibility that type 2 diabetes onset in young adulthood is a more severe form that is more difficult to manage for physiological as well as environmental and behavioral reasons.

A Diversification of Long-term Diabetes Associated with Diabetes

Several dynamics in the diabetes epidemic may be leading to relative shifts and diversification in the character of diabetes-related complications [9]. First, the proportionately greater declines in diabetes complications among older adults mean that proportionately more diabetes-related complications now occur in middle age than in previous decades. This is particularly evident in the USA, where adults aged 45–64

accounted for only one-third of amputations in 1990 and now account for more than half. Second, this may be further compounded by the greater relative increase in diabetes incidence in youth and the earlier exposure to long-term hyperglycemia and development of diabetes-related complications [48, 49]. The large reductions in cardiovascular disease events and related mortality may be responsible for the relative persistence of end-stage renal disease, as people with diagnosed diabetes are living longer to develop renal disease. Similarly, the reduction in cardiovascular disease mortality observed in most populations with diagnosed diabetes is now accompanied by a proportional increase in deaths due to other causes. Among the US population with diabetes, the proportion of total deaths that were due to cardiovascular causes declined from almost 50% in the early 1990s to 33% in 2010. During the same period, deaths due to cancer in the population with diabetes stayed stable around 18, and deaths due to all non-CVD, non-cancer causes increased from 33% to 50% of the total. This latter group of "other causes" included several causes, including influenza, pneumonia, septicemia, renal disease, and chronic liver disease, that have an increased association with diabetes. For these latter causes, there has been no improvement in recent decades, and for x of them, there was actually an increase in the rates of diabetes-related complications.

Primary Conclusions and Implications

This synthesis of the epidemiology and trends of diabetes and its complications reveals the following general observations:

1. Changes in underlying risk of most societies has led to large increases in the incidence and prevalence of diabetes over recent decades, leading to an enormous burden for individuals, families, health systems, and societies.
2. Signs of a peak in the epidemic are apparent in the USA and selected other countries of the world, with recent decreases in incidence and a plateau in prevalence. However, the explanations for these trends are unclear, and the encouraging news is offset by continued increases in diabetes incidence in youth.
3. Diabetes leads to an extensive and diverse array of morbidity, including macrovascular, microvascular, and neuropathic complications, and health outcomes that results.
4. Rates of diabetes-related complications have declined in the USA and other selected countries, likely due to improved risk factor management and organization of care.
5. The disproportionate reduction in cardiovascular disease mortality and increasing lifespan among adults with diabetes, combined with the continued growth of diabetes prevalence in youth, may be fueling a diversification of diabetes-related complications and continued population-wide exposure to hyperglycemia that will drive high rates of diabetes-related morbidity into the figure.

Multiple-Choice Questions

1. The global prevalence of diabetes is currently estimated to be:
   (a) 100 million
   (b) 220 million
   (c) 310 million
   (d) 420 million
   (e) 500 million
2. The region with the lowest worldwide prevalence of diabetes:
   (a) Middle East
   (b) Northeastern Europe
   (c) North America
   (d) Africa
   (e) Australia
3. Increases in diabetes prevalence are likely been driven:
   (a) By autosomal dominant genetic traits
   (b) By Mendelian inheritance
   (c) By increasing prevalence of obesity and overweight
   (d) By aging and longer lifespan
   (e) By socioeconomic factors
4. Current estimated prevalence of adult diabetes in the Americas:
   (a) 2.0%
   (b) 4.5%
   (c) 6.0%
   (d) 8.3%
   (e) 10.0%
5. Regarding ethnicity, diabetes prevalence in the USA is higher among:
   (a) Native Americans
   (b) Afro-Americans
   (c) Caucasians
   (d) Mexican Americans
   (e) Asians
6. Estimated prevalence of persons with prediabetes aware of their risk status:
   (a) 100%
   (b) 75%
   (c) 50%
   (d) 20%
   (e) 10%
7. Greatest relative increases of diabetes have been observed:
   (a) In newborns

(b) In youth and young adults
(c) In pregnant females
(d) In middle-aged adults
(e) In the elderly

8. Largest absolute increases of diabetes in the USA have been observed:
   (a) In newborns
   (b) In youth and young adults
   (c) In pregnant females
   (d) In middle-aged adults
   (e) In the elderly
9. Lifetime risk of developing diabetes before death increased in women and men up to:
   (a) 100%
   (b) 80%
   (c) 60%
   (d) 40%
   (e) 20%
10. The signature, most specific complication of diabetes:
   (a) Coronary heart disease
   (b) Renal failure
   (c) Diabetic retinopathy
   (d) Diabetic foot
   (e) Stroke

Correct Answers

1. (d) 420 million
2. (b) Northeastern Europe
3. (c) By increasing prevalence of obesity and overweight
4. (d) 8.3%
5. (a) Native Americans
6. (e) 10%
7. (b) In youth and young adults
8. (d) In middle-aged adults
9. (d) 40%
10. (c) Diabetic retinopathy

3 Economic Costs, from Individuals to Health Systems: Evidence from a Middle-Income Country

Armando Arredondo, Emanuel Orozco, Maria Beatriz Duarte, Silvia Magali Cuadra, Ana Lucía Recamán, and Alejandra Azar

Introduction

In the current context of health system reforms, there is a need to generate and promote models for comprehensive analysis that will advance the generation of a critical mass that will direct and sustain the changes that, in terms of production and financing, are taking place in the different subsystems of health in Latin America. Indeed, it is not surprising that health system reform programs are central to health analysis and action, particularly when it is explicitly stated that the challenge of such reforms is to achieve a balance between supply and demand of health of the different population groups [1].

Health market imbalances are one of the major challenges to overcome in the rethinking of health systems, mainly due to the disparities that exist in contrasting the available health services versus the demands, required from the epidemiological changes. As health reform projects move forward, the cost of providing services only to the demand for hospital cases of chronic-degenerative diseases will be higher, relative to the cost of providing service to the demand for outpatient and hospital cases of infectious diseases, so to further progress of the epidemiological transition, it will have greater financial implications in the production of health-care services for the short-, medium-, and long-term demands [1, 2].

In this context, health economics is defined as the application of economics to the study, production, distribution, and consumption of health-care services. Its main task is to contribute to the improvement of health without subordinating the ethical values inherent to the health of populations [1].

In economic terms, the meaning of changes in the epidemiological and demographic profile represents an increase in the demand for care for costly diseases (treatment of chronic-degenerative diseases and accidents) that will compete with the budget allocated for the treatment of infectious diseases still unresolved.

Health economics contributes to the field of health its theoretical and methodological body to support decision-making in the allocation and use of resources. It is important to recognize the need to choose better alternatives for the allocation of resources for health care, since they are scarce to meet the new or changing needs of society. It is for this reason that cost analysis tends to be an increasingly important tool for decision of planners, managers, politicians, and providers, especially in setting priorities, funding, and regulation of services of health [1, 2].

The cost of care raises the need to develop broader perspectives for the study and resolution of priority health problems, particularly chronic-degenerative problems that require ongoing attention in the short, medium, and long term depending on the phase of the natural history of disease in patients who are at the time of diagnosis. Indeed, the economic burden in managing a health problem varies depending on the quality standards that make the economic valuation of attention to a specific health claim.

The usefulness of economic evaluation evidence in health care can sometimes increase uncertainty for decision-making. For example, it is not the same as saying that the management of chronic damage to health costs 100 US$ and that was controlled with minimum quality standards, than the same damage cost 120 US$ plus not controlled with minimum quality standards [3].

In the first case we have a comprehensive evidence, solid and very relevant to make decisions for the management of health damage to the high degree of certainty and confidence to make strategic decisions that enable more efficient and effective use of resources. In the second case, where the economic valuation does not control the quality of care, we have a situation with no conclusive evidence or relevant to make

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_3

correct decisions, so that decisions in this context does not guarantee high levels of efficiency and effectiveness interventions to meet the demand for health with a specific damage such as diabetes or hypertension, as a priority public health problems not only in Mexico but throughout the world.

Regarding the epidemiological history and cost of diabetes, we note that the diabetes is a health problem that requires an integral approach, since its tendency to increase has not been addressed with the developed efforts and assigned economic resources for its resolution. The high costs in health and the demographic behavior of Mexico, in which a change in the population pyramid is noticed, will add risks for the adult population that adding to the existing cases will increase the demand of health services in the near future [4, 5].

Mexico at the moment occupies the ninth worldwide place in the diabetes prevalence. This is a truly alarming site, but the projections of the international specialists refer that for year 2025, the country will occupy the seventh place. This disease has become a worldwide epidemic due to the high rates of deaths that have been registered in the last 10 years. For example, in Mexico one third of heart attacks and half of the chronic renal failures are direct consequences of diabetes [6, 7]. For this reason, the diverse institutions of health in the country have begun to reinforce their preventive campaigns to avoid even higher costs. Indeed, by the time the diagnosis of diabetes and its complications is made, the costs for the treatment are very high, and practically the patient is gradually losing his productive life years, with important repercussions in terms of indirect costs attributable to the diabetes [8, 9]. In addition, the costs in the quality of life of these patients are very high, and at the same time, the financial burden for the health sector to control the problems associated with diabetes is not known in the majority of the countries, making difficult an efficient allocation of resources and strategic planning to face the high demand of health services [10–12].

In addition to the epidemiological background of diabetes, it is also noteworthy the increase in health services demand and health-care costs of this type of patients. Indeed, it is quite evident that the increased costs of health services and, by consequence, the need to increase the health expenditures and changes in the methods of resource allocation for the diabetes have provoked multiple restlessness in decisions-makers. Accordingly, it becomes imperative to incorporate the economic perspective for the analysis of the health sector [13, 14]. In economic terms the meaning of the changes in the epidemiologic and demographic profile means an increase in the demand of health care of expensive diseases (treatment of chronic-degenerative diseases and accidents) that will still compete with the budget assigned for the treatment of infectious diseases. Thus, it is important to remember that there will be a need to reassess health priorities and to establish the strategic actions that will allow optimal use and organization of health resources for each health problem, in this case for diabetes mellitus [15, 16].

In summary, the observed and estimated changes in the morbidity and mortality for diabetes mellitus will generate constant increasing changes in the expected tendencies for the health services demand for diabetes. On the other hand, the constant increasing costs of the medical care and the unknown costs of handling ambulatory case management and handling of diabetes hospital cases, as well as the unknown economic resources needed to satisfy the future health services demand, justify in a pertinent and urgent way the development of research studies of applied investigation. It will allow the measurement, development, and determination of indicators of the increasing changes in the demand, of costs of case management controlling by quality of care, and of the financial amounts that will be required to be able to face the problem of diabetes mellitus in Mexico in the next years.

Methodology

The results that are presented here were generated from a study of annual monitoring on the costs and the financial consequences of the epidemiological changes in chronic-degenerative diseases in Mexico. For the case of the diabetes, we make the following methodological precisions:

- The changes in the health services demand for diabetes were determined by means of analysis of series of time from cases observed for period 1990–2013. The estimated models of prognosis of the demand are referred to the period of time 2014–2016. The estimation method was based on the methodology of Box–Jenkins for health prognosis [17]. The expected cases for diabetes were estimated for the health system as a whole and for each sector. For the estimation of expected direct and indirect costs for diabetes, we took the year 2015 as a cutoff year since it corresponds to half of the projection period of time.
- The quality of care was controlled from the definition of minimum quality standards of care for case management at each institution in accordance with the standards and protocols for health care for patients with chronic-degenerative diseases. The case management was determined by means of the technique of times and movements, and its validation was made by consensus with clinical experts in the management of diabetes mellitus in different institutions of the health sector. For this task we designed seven instruments to gather information according to the functions of production and inputs required to

satisfy the health sector demand (see Appendix 1 with a model format to determine costs of case management).
- The direct costs of the case management were determined from the functions of production, the combination of inputs, the standards of quality, and the costs of the inputs for each sector.
- The indirect costs were determined using the capital human model developed for Latin America, making the necessary adjustments for the case of Mexico. The model is based on indicators of premature mortality and temporary handicap and permanent handicap attributable to diabetes [18].
- The financial requirements for future years, like in similar studies, were considered from the expected cases, the costs of case management taking as period of reference the last year of observed cases and applying an adjustment econometric factor to control the expected inflationary process for health services in the short, medium, and long term [19].

Results

After making the estimation cases for period 2014–2016, it was decided to take as point of cutoff the year 2015 to determine the costs of diabetes mellitus care for each sector of the health system. The national annual average cost of case management was of 711 US$, and the base population estimate was 4,854,689 patients diagnosed with diabetes and treated in different institutions of the health system. The direct costs represent 46% vs 54% of indirect costs from the total costs of diabetes mellitus in Mexico. Figure 3.1 shows the distribution of the direct costs among the main items of economic impact in the management of the diabetes for different institutions of the health system.

In relation to the cost of the different functions of production, it is worth noting that the inputs with the greater impact refer to medications, followed by costs of outpatient services and in smaller degree the costs of hospitalization in the cases of acute complications due to diabetes mellitus, without considering the management of chronic complications (see Fig. 3.1).

For the relative weight of the cost in the overall management of the main complications of diabetes, in all the institutions, the greater impact is in the costs for managing diabetic nephropathy, followed from largest to smallest impact by retinopathy, cardiovascular disease, diabetic neuropathy, and finally peripheral vascular disease.

With respect to the relative weight of the economic impact per origin of the costs, of the total of direct costs, the greater economic impact corresponds to the pocket of the heath service users, that is to say for each 100 US$ that are spent in diabetes in Mexico, 55 come from the pocket of the users. It follows in order of importance by its relative weight: the IMSS (27 US$ for each 100), the SSA (12 US$), and finally the ISSSTE (6 US$). What is necessary to stand out on the economic impact of diabetes among the different health institutions of the public sector is that the economic impact for the IMSS is more than double than that of the SSA and four times more than that for the ISSSTE (see Figs. 3.1 and 3.2). The same tendencies were observed when determining the costs of diabetic complications for all institutions.

With regard to the indirect costs of diabetes mellitus health care, in this dimension of costs, we were only able to estimate the indirect costs for users that sought care in the three main institutions of the public sector. These costs rep-

(2016) Costos y consecuencias financieras del cambio en el perfil epidemiológico en México. INSP–Update of probabilistic models, January 2016). Exchange rate: January 2016, 1 US$ = 13.35 Mexican $. 95% CIs. Box–Pierce statistical test ($p < 0.05$). IMSS Mexican Institute for Social Security, ISSSTE Institute for Social Security and Services for State Workers, na not available, PHI private health insurance, SSA Ministry of Health

resent 56% of the total cost of diabetes mellitus in Mexico. They are distributed in three categories of estimation: costs by premature mortality (5%), costs by permanent handicap (95%), and costs by temporary handicap (1%) (see Figs. 3.3 and 3.4).

Discussion

With respect to the costs of case management in the three public health-care institutions of interest, the results show important differences among the institutions and the hospitalized case management and outpatient cases. Before discussing the details of the results about the economic evaluation, it is important to mention that all costs were expressed in American dollars for any international comparison. From these findings it is possible to establish minimum and maximum ranges by type of disease from the three main institutions of the health system in Mexico. Indeed, on the cost of case management of hospitalized patients, the results are in a range from $675.00 to $751.00 US$. The smallest cost corresponded for the SSA and the greatest cost for the IMSS. The same tendencies are observed for the cost of the case management as outpatient cases.

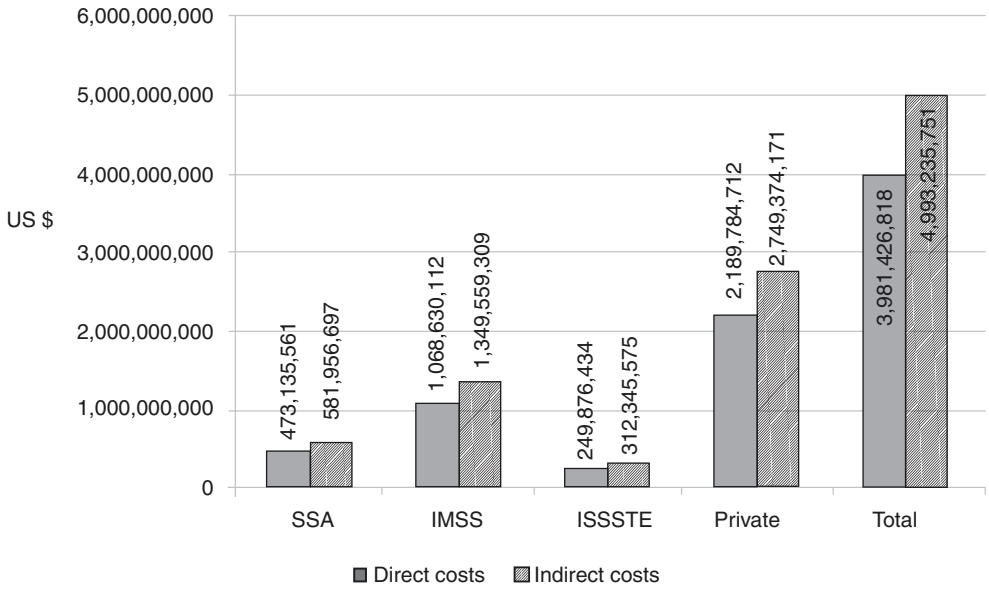

Fig. 3.4 Total costs attributable to diabetes mellitus in Mexico, 2014: SSA. IMSS, ISSSTE, private sector (DLS). (Source: Arredondo A. (2016) Costos y consecuencias financieras del cambio en el perfil epidemiológico en México. INSP–Update of probabilistic models, January 2016). Exchange rate: January 2016, 1 US$ = 13.35 Mexican $. 95% CIs. Box–Pierce statistical test ($p < 0.05$). IMSS Mexican Institute for Social Security, ISSSTE Institute for Social Security and Services for State Workers, na not available, PHI private health insurance, SSA Ministry of Health

The differences between costs of case management and total costs attributable to the diabetes in Mexico, observed among the different institutions of interest, are explained due to the significant differences in the specific populations that demand their services, in the cost of inputs, and in the way to combine these inputs at the time of producing the demanded service; but also the quality of the heath care whereupon each institution offers the services is an intervening and determining variable which relates to the actual cost of diabetes care for each of the main institutions of health care in Mexico. In relation to the effects of the observed epidemiological changes for the health demand of hospitalized and ambulatory services for period 2014–2016, it is expected a tendency toward an increase in the costs, although the increase is more relevant for the insured population in comparison with the uninsured population.

In the case of the insured population (IMSS and ISSSTE), they take the major amounts of financial resources. This increase responds not only due to the increase in the health demand from the changes in the epidemiological profile, but in addition to this factor, it is important to also consider the increase in the percentage rate of the projected inflationary index for period 2014–2016. It is also important to stand out that in the case of the uninsured population (SSA), it not only represents the smallest financial requirement, but also tendencies of the required financial resources are much more moderate than in the case of the insured population. From a quality of medical care perspective, social security institutions like IMSS used to provide access to their users to costly interventions, especially complications of acute diseases like those analyzed in this chapter.

When comparing the results of the direct costs for the different health-care models according to the type of institution, it is the IMSS health-care model the one that will pay the greatest cost, followed by SSA and finally ISSSTE with the smallest direct cost. The same type of tendency was observed for the case of the direct costs of the ambulatory health-care model. This pattern can be influenced by the amount of demand of medical care in each institution and by the type of utilized resources. For the uninsured, the current public insurance policy has not included yet in the medical interventions catalogue medical attention to acute kidney failure, for instance. If interventions like this were included, the costs tendency for the SSA could be modified.

With respect to the indirect costs by type of disease, it is important to stand out that the obtained cost is the minimum amount that would appear in each type of institution in agreement with the projected demand for the year 2015 as point of cutoff. On the average of the costs to the pocket of the users, it is noteworthy the high relative weight of the origin of the expenses for diabetes from the family income and its implications in the matter of equity and access to health care in Mexico. Indeed, from each 100 US$ that are spent in diabetes in Mexico, approximately 55 US$ come from the patients' household income. This situation represents a social burden of very high impact that evidently will have a considerable effect in the measurement of the catastrophic health expenditures in the country, more importantly because it is a very expensive and of a high-priority disease that has become a public health problem in Mexico.

In relation to health-care coverage in Mexico, this is distributed more or less in the following form: 48% of the population is taken care by social security institutions; 42% of the population is taken care by institutions that serve the uninsured; and 10% of the population utilizes private care institutions. According to our results, this means that, with respect to the direct costs, out of each 100 pesos that are spent in diabetes in Mexico, 52 are spent in 10% of the population,

33 in 48% (insured) of the population, and 15 pesos in the 42% rest of the population (uninsured). With these data it is evident that there's an equity problem and poor health-care access for the poorest population in Mexico.

Undoubtedly, it is quite evident that the problem of diabetes in Mexico not only represents a high economic and epidemiological impact. Public health-care organizations should improve their medical processes and resource allocation schemes in order to become more efficient according to their care demand and population characteristics. Under this perspective, medical services for diabetes in the social security should analyze costs reductions for high-cost interventions, while medical services for the uninsured should implement ambulatory and preventive care. For these organizations, quality improvement of medical care will be an important support to achieve efficiency and effectiveness. The economic evaluation of diabetes impacts rises in a pertinent way in terms of economic resource flow and allocation analysis. This approach could be helpful to reduce inequity and health-care accessibility for the patients with diabetes and to protect their family assets in case of economic need derived of out-of-pocket health expenditure.

With respect to the indirect costs, although they do not constitute a direct impact on the heath budget, in terms of cost and social impact, they do represent a high burden that society in general will have to assume, mainly in terms of lost productivity by premature death and handicap whether it is temporary or permanent.

The relevance to incorporate economic, epidemiological and quality of medical care aspects to the clinical perspective constitutes an integral proposal for the analysis and evaluation of the performance of the health system in the context of health system reforms. Indeed, the results of health systems research with an approach that combines economic, clinical, and epidemiological perspectives become relevant for identifying greater financial consequences in the production of health-care services for future health-care demands of chronic-degenerative diseases, particularly for the case of the diabetes mellitus.

The observed and expected changes in the epidemiological profile of diabetes, both in the public sector and in the pocket of health-care users, will lead to a financial competition in the use of resources. In such a way, the financial resource allocation for the demand or production of health services directed to diabetes will be affected by the production or demand of services for infectious diseases and other chronic diseases like hypertension. In this sense, the internal competition in the use and allocation of the economic resources requires data to estimate the approximated financial requirements to produce the services that will be demanded in short and medium terms. Therefore, the production and financing of health services for diabetes will require the incorporation of clinical, economic, and epidemiological indicators, integrated under diverse efficiency criteria.

If the risk factors and the different health-care models for ambulatory and hospitalized care remain as they are at the moment in the three institutions of analysis, the financial consequences of diabetes would be of greater impact for the IMSS, following in order of relevance the SSA and finally the ISSSTE. On the other hand, the financial requirements for the treatment of diabetes, both in the health-care demand of ambulatory and hospitalized services, would represent approximately 9% of the total budget assigned for the uninsured population and approximately the 16.5% of the assigned total budget for the insured population.

The generated analysis constitutes a tool for defining in which type of health interventions and levels of medical care to invest within the context of transformations, adjustments, or reforms of the health sector, as it is suggested in several studies. On the other hand, the estimated financial requirements constitute a base of fundamental information for strategic planning. Indeed, given the financial consequences of the expected epidemiological change, not only the need to invest greater financial resources is fundamental and justified for activities of health promotion and prevention, so that the damage to health can be diminished and controlled, avoiding the economic burden for the health systems. In summary, the economic gain in productivity and efficiency will be able to happen at the same time that the unitary costs by production functions are known for the different stages of health care. In this way it is possible to establish both the patterns of equipment needs and the patterns of productivity and efficiency of the used resources, justifying them in relation to the quality of medical care that they will generate.

With regard to equity, it is possible to affirm that every time resources are wasted, patients' health care is compromised, and a lack of quality has been observed. In this sense, the integral planning of the costs, as an indicator of efficiency, is intimately related with the principle of equity in access to health care. The relative weight of the different inputs required in the process of care by disease allows the selection of critical inputs in health-care services, in such a way that this set of inputs must be covered in the financial resource allocation for the problem of diabetes. In addition to this type of inputs, there should be implemented preventive and quality of medical care measurements so that the conditions for a better use of the budget occur. For example, knowing that some of the critical inputs are in the expenses of hotel or hospital daybed, human resources, drugs, and solutions, the preventive and control measurements must be directed to avoid that the patients with diabetes become ill so that they require hospitalized care.

It is necessary to indicate that for greater trustworthiness, validity, and relevance of these results, it is recommended to implement systems of monitoring costs that allow to update

annually or biennially the average cost of case management of diabetes to adjust in agreement with inflationary changes and changes in the costs of the inputs and more importantly changes in the tendencies of the health services demand for diabetes. Certainly to evaluate the changes in the health services demand from the expected epidemiological transition, it is also recommended that the probabilistic models are updated annually with the observed data. In this way, we will see a greater impact in the decision-making in the matter of efficient allocation and use of resources destined to the health sector. On the other hand, as regards the relative weight of diabetes costs, our direct versus indirect costs results are within similar cost ranges for other countries that have developed the economic burden of diabetes analysis [11, 20–23].

The evidence presented in this chapter constitutes a relevant input to decision-makers in order to define in which type of health interventions and levels of medical care to invest within the context of adjustments or reforms of the health sector. The estimated financial requirements constitute a base of fundamental information for strategic planning. Indeed, given the financial consequences of the epidemiological changes, not only the need to invest greater financial resources is fundamental; it also justify more activities and programs for health promotion and prevention.

In summary, the economic gain in productivity and efficiency will be able to happen at the same time that the unitary costs by production functions are known for the different stages of health care. In this way it is possible to establish both the patterns of equipment needs as well as the patterns of productivity and efficiency of the used resources, justifying them in relation to the quality of medical care that they will generate.

With regards to equity, it is possible to say that every time resources are wasted, patients' health care is compromised, and a lack of quality has been observed. In this sense, the integral planning of the costs and quality, as an indicator of efficiency, is intimately related with the equity in access to health care.

The relative weight of the different inputs required in the process of health care by disease allows the selection of critical inputs in health-care services, in such a way that this set of inputs must be covered in the financial resource allocation for disease. In addition to these critical inputs, there should be implemented preventive and quality of medical care measurements to generate the conditions for a better use of resources. For example, knowing that some of the critical inputs are in the expenses of hospital daybed, human resources, drugs, and solutions, the preventive and control measurements must be addressed to avoid that the patients with diabetes become with complications that require hospitalized care and more expensive services.

Finally, it is necessary to indicate that for greater trustworthiness, validity, and relevance of these results, it is recommended to implement systems of monitoring costs that allow to update annually or biennially the average cost of case management of diabetes to adjust in agreement with inflationary changes and changes in the costs of the inputs and, more importantly, in concordance with changes in the trends of the health services demand for diabetes. Certainly, to evaluate the changes in the health services demand from the epidemiological transition, it is also recommended that the probabilistic models are updated annually with the observed cases by institution. In this way, we will see a greater impact in the decision-making in the matter of efficient allocation and use of resources addressed to chronic diseases.

Conclusions

With regard to the implications and to the impact for the health system and to patients, we conclude and suggest the following:

1. The economic burden and financial consequences for diabetes health care constitute the fundamental basis of the information for strategic planning. Indeed, given the financial consequences of the expected epidemiological changes, not only is it essential to invest greater financial resources, but it also justifies the implementation of health prevention strategies.
2. The evidence on changes in costs and in the demand for health care in diabetes patients can be used as a reference for the allocation of resources directed toward diabetes by different types of public institution. With a knowledge of likely financial requirements, each institution could then target the necessary resources for promotion, prevention, healing, and rehabilitation effectively and efficiently.
3. A consequence of the implementation of cost-monitoring systems is the design and application of strategies for cost containment for weight-by-cost items. For example, knowing that the cost of medicines is high, it will be necessary for each institution to review its agreements with the pharmaceutical industry on the consolidated buying of medicines for diabetes.
4. As regards the equity and diabetes care, development of economic indicators would enable the design of patterns of resource allocation based on efficiency criteria with regard to clinical, epidemiological, economic, and administrative aspects. Each institution could develop models for the distribution of resources in accordance with the changes in costs and epidemiological factors expected in future years.
5. As a "Citizen Observatory of Diabetes," social organizations could suggest and develop follow-up programs for the costs of diabetes in different public and private health

institutions. The Observatory should function as a checking system that would monitor how much is being spent on managing diabetes and what the money is being spent on.
6. Knowledge of the relative weight of the management of diabetes based on the annual family income, as well as precise knowledge of the cost of complications to the users, should be made available through a bulletin sent to diabetic patients and their relatives and to the community as a whole. Knowledge of the high costs of diabetes per family could lead to a greater self-awareness, as well as to effort in avoiding complications caused by diabetes.
7. To avoid further impoverishment by health expenditures attributable to diabetes, a list of recommendations is needed to promote greater self-care, control of risk factors, and the benefits of carrying out these measures, and more importantly to avoid falling into a catastrophic cost situation because of diabetes (to avoid an impact >30% of the family income).

In the context of health system reforms and particularly as regards the universal coverage strategy, our results allow us to put a greater emphasis on the need to allocate more resources to health promotion and prevention, with important changes in the social aspects of diabetes as a high-priority public health problem. The treatment of diabetes should be approached from a transdisciplinary perspective: sociological (social determinants and governance indicators), clinical, economic, epidemiological, and organizational. In other words, an integrated approach to the problem of diabetes requires the development of indicators of clinical and economic efficiency, expected epidemiological changes, and social determinants associated with diabetes, as well as identifies the actors, roles, and rules for greater equity and equality of opportunity in solving the problem of diabetes. From this perspective is that it could advance to ensure effective universal coverage where patients and families would not have to pay so much for dealing with the problem of diabetes.

Concluding Remarks

- Comparing the economic impact in 2013 versus 2015 ($p < 0.05$), there is a 26% increase in financial requirements. The total amount for diabetes in 2015 (US dollars) was $ 8,974,662,570. It includes $ 3,981,426,810 in direct costs and $ 4993,235,752 in indirect costs.
- The total direct costs expected are $ 473,135,561 for the Ministry of Health (SSA), serving to uninsured population, $ 1318,506,546 for insured population (Mexican Institute for Social Security (IMSS) and Institute for Social Security and Services for State Workers (ISSSTE)), $ 2070,341,961 to users, and $ 119,442,750 to private health insurance (PHI).
- If the risk factors and the different health-care models remain as they are currently in the institutions analyzed, the financial consequences would be of major impact for the pockets of the users, following in order of importance, IMSS, SSA, and finally ISSSTE. We suggest rethinking the process of planning, organization and allocation of resources, in terms of demand for hospital and outpatients services for patients with diabetes.
  - The diabetes in Mexico in 2015 was on average 16% of total health expenditure.
  - The analysis of different findings shows that catastrophic expenditures attributable to diabetes have a greater impact in the pockets of patients and their families in relation to the expenditure for health systems. Of every 100 US$ spent on diabetes in Mexico, 55 are from users pocket and 47 from health institutions.
  - Comparing trends in 2014 vs 2016, we show evidence that there is an increase of 9–13% on number of new cases and an increase of 26% on the economic burden.
  - The societal diabetes-attributable costs of diabetes in Mexico 2015 were estimated to be 8.9 billion US$, corresponding to 721 US$ per patient year.
  - Nearly 35% of diabetes-attributable costs were to the patients with major complications.
  - By 2015, the amount of indirect costs of disability and premature death (4.9 billion) than the direct costs of care (3.9 billion).
  - Urgent call for a strategic alliance between government, health care, businessmen, civil society, and patients with diabetes.

Multiple-Choice Questions (Note That Some Questions May Have More Than One Answer)

1. What consequences can the late diagnosis of diabetes have?
   (a) Increases treatment costs
   (b) It improves the prognosis of the disease
   (c) It reduces the productive years of the person with diabetes
   (d) All of the above
   (e) Options 1 and 3

2. In what area is the largest out-of-pocket expense of patients with diabetes and their families in Mexico?
   (a) In drugs
   (b) In treatment of complications
   (c) In consultations and diagnosis
   (d) In hospitalization
   (e) By transport
3. Why is it important to invest in health promotion prevention of diabetes and its complications?
   (a) Because the damage to health is reduced and controlled
   (b) Because it avoids excessive economic burdens for health systems
   (c) To avoid the suffering of diabetes and its complications, for patients and families
   (d) All of the above
   (e) None of the above
4. For the integral approach to diabetes, which of the following perspectives should work together (can mark more than one)?
   (a) Sociological
   (b) Economic
   (c) Epidemiological
   (d) Organizational
   (e) Clinical
5. Which of the following actors are considered key to lower costs and the prevalence of diabetes and its complications?
   (a) The health system in its role of rectory
   (b) Organized civil society
   (c) Health-related industry (pharmaceuticals, equipment and technology)
   (d) All of the above
   (e) None of the above
6. Which are the major tendencies in resources expenditure for diabetes in the Mexican case?
   (a) Resources expenditure tends to be the same for public and private medical care providers.
   (b) Costs of medical care tend to be higher for insured populations, with a considerable burden of out-of-pocket expenditure for patients.
   (c) Costs of medical care tend to be higher for insured populations, without out-of-pocket expenditure for patients.
   (d) Costs for medical care remain constant in time for all providers.
   (e) Nevertheless costs for medical care of diabetes tend to be higher; there's no need to be concerned about.
7. Why is it urgently necessary to incorporate economic evidence to improve health systems' capacities in response to the described diabetes challenges?
   (a) Economics and management should not be related, because of theoretical and practical reasons.
   (b) Economic evidence is hard to translate for managerial purposes.
   (c) The medical care for diabetes is complex and hazardous; it is difficult to establish adequate resources planning.
   (d) Economic evidence is helpful for reducing uncertainty in the planning and decision-making processes.
   (e) Variations in direct and indirect costs are not relevant for an adequate planning
8. What reasons could explain that spending resources for diabetes care used to be higher in insured populations for the Mexican case?
   (a) Social security health providers have developed an economic platform that creates strong commitment of health-care provision.
   (b) The health financing has three different sources; availability of resources tends to be higher for these providers.
   (c) Infrastructure and human resources for social security tend to be wider and more aligned to health needs.
   (d) All previous.
   (e) None.
9. What is the rate of increase in the financial trends of the epidemiological changes for the period under study?
   (a) 9–13%
   (b) 10–12%
   (c) 13–16%
   (d) 14–17%
   (e) 8–13%
10. What is the rate of increase in epidemiological trends for the period under study?
    (a) 23%
    (b) 20%
    (c) 24%
    (d) 26%
    (e) 28%

Correct Answers

1. (e) Options 1 and 3
2. (a) In drugs
3. (d) All of the above
4. (a–e)
5. (d) All of the above
6. (c) Costs of medical care tend to be higher for insured populations, without out-of-pocket expenditure for patients.
7. (d) Economic evidence is helpful for reducing uncertainty in the planning and decision-making processes.
8. (e) None.
9. (a) 9–13%
10. (d) 26%

Appendix 1. Model Format to Determine Production Costs by Diabetes Case Management

Institution---------- Production function----------

Type of input	Measure unit	Unit cost	Quantity by case management	Average cost	Equation of depreciation	Total cost
Human resources						
Equipment and furniture

The Ecological Approach to Self-Management in Diabetes

4

Edwin B. Fisher, Paul Bloch, and William Sherlaw

Interaction and Multi- and Interdeterminacy at All Levels

Whether our lives are directed by events around us or events within us, "not in our stars, but in ourselves,"[1] is of concern in ethics, aesthetics, law, religion (the Old Testament of laws and the New Testament of "faith as a mustard seed"[2] within us), and, of course, behavioral science, biology, and health. The present paper emphasizes the importance of contexts – ecological, social, organizational, community, policy – in health and health behavior; describes peer or social, community, and policy approaches to addressing contexts; and considers all of these with reference to the challenges of diabetes prevention and management.

Epidemiology of Social and Ecological Determinants of Health

Contexts play a large role in health disparities. Examples abound. Since the middle of the twentieth century in many high-income countries, smoking has evolved from a privilege of the well-to-do to a problem among those who are poorly educated, poorly paid, and/or burdened by a variety of personal and psychological problems such as depression, schizophrenia, or divorce [1]. In the United States, African Americans, Latinos/Latinas, and American Indians are about twice as likely to have diabetes as the rest of the population. Internationally, infectious diseases, especially HIV/AIDS, are much more prevalent in poor nations and, within all nations, among poor people. Diabetes along with other noncommunicable diseases are also socially stratified. Socioeconomic factors along with the production, marketing, and drawing profit from the sale of food all contribute to the sharply increasing levels of obesity both within the United States and globally [2]. At the same time, health problems can have enormous impacts on the social and economic environment as shown by the impact of HIV/AIDS in many countries in Africa.

The social determinants of health – "the circumstances in which people are born, grow up, live, work and age" (WHO 2008, 2010a) – have received great attention in recent decades. Differences in health may be revealed and characterized through statistical analysis linking health and illness and disease and death to latent variables of social inequity such as income, education, and socioeconomic status. Typically a social gradient emerges. Increases in income, education, or socioeconomic status are associated with improved health status and decreases in mortality and morbidity across a range of diseases. Reduction in income, education, and socioeconomic status is associated with worse health and increases in mortality and morbidity across a range of diseases. Causality may occur in both directions, however, such that poor health may also lead to lower socioeconomic status, income, or education, so-called health selection. Nevertheless the overriding tendency and bulk of evidence tend to show that social position determines population health status, and for this reason we may speak of social determinants of health and health inequities.

Cross-national analyses support the view that disparities in health reflect variability in socioeconomic characteristics of countries [3]. Michael Marmot's analysis of this global variability in health extends, however, beyond socioeconomic contexts per se. For example, the populations of the United States, Greece, Costa Rica, and Cuba have life expectancies ranging from 76.5 years (Cuba) to 78.1 years

(Greece). However, their 2016 GNPs in US dollars range much more widely, from $7815 per person (Cuba) and $11,825 (Costa Rica) to $57,808 (United States) [4]. Marmot interprets such data as indicating that, along with income poverty and material conditions, social determinants must also play roles in the development of health risks and the paths of infectious disease transmission. Key social determinants include stress, early life circumstances, social exclusion, unemployment, poor education, lack of social support, and various addictions [5]. If obesity and other risks such as smoking and hypercholesterolemia and hypertension are the causes of noncommunicable diseases, then social determinants are among the "causes of the causes" [5], attention to which is likely to reduce population disease burden.

Articulating a Broad View of Experience and Environment: Ecological Perspectives

Several different models have been put forward to frame how social determinants in constant interaction are linked to health status and how they produce a social gradient of health. Certain approaches underline the importance of proximal factors (lifestyles and behaviors), while others place greater emphasis on distal fundamental or structural determinants such as socioeconomic conditions, "the causes of the causes" of health and disease [6]. Whitehead and Dahlgren, for instance, famously represent "the main determinants of health as a set of concentric arcs around the individual" [7]. Health is represented as "the outcome of a web of social influences" [8].

In ecological approaches [9–11], the behavior of the individual is viewed as guided by layers of influences including the family, proximal social influences such as social networks or neighborhoods, organizational influences such as worksite or community systems or healthcare systems, and larger social influences such as government, policy, or large economic structures.

Different models may specify different layers of influence and different components of each, but they share two important emphases: (1) that the behavior of the individual reflects the influence of all the layers and (2) that the layers interact in their influence so that, e.g., communities may influence families but families may also influence communities [12].

Habitually there has been a tendency to think of social determinants of health acting through different levels in a cascade, the distal impinging on intermediate factors and finally on individuals through proximal factors. But as Krieger (2008) has argued, it is important to understand that interventions at nonadjacent levels may have direct impacts. A new national law restricting or granting rights or cutting or attributing welfare taken at the macro-governmental level may have immediate implications for individuals subject to it. Furthermore different factors may operate at different levels simultaneously in consort. This is especially evident in the case of the accumulation of disadvantages within vulnerable or marginal groups and individuals. The same factors may differ in their impact at different moments in the life course, and unexpected effects may emerge. Such impacts on health and well-being do not occur in a vacuum but are mediated through the wielding of political and economic power. Discussing Pierre Bourdieu's rich but complex sociology, Ghassan Hage speaks of an "political economy of being" [13]. We may consider that different groups and individuals through social, economic, and cultural capital may have the possibility to deploy their social being to a lesser or greater extent. The real meaning of accessibility for disabled people lies here. When services and resources in the community are less easily accessible, it will be difficult for disabled people and indeed other marginal groups to fully deploy their social being, that is, to be able to exert choices which they have reason to value. Such capabilities [14] are dependent on political and economic power which both enables and obstructs choices of groups and individuals.

Relationships Among Influences: The Example of Genetic Expression and the Environment

Gene-environment interactions illustrate well how interactions among levels of ecological models are fundamental to health and well-being. Many think of genes as causes that obviate other influences on behavior. Old controversies as to whether one or another disease, e.g., schizophrenia, is *either* genetic *or* learned presumed that the one trumps the other. The reality is that genetic, other biological, behavioral, and environmental variables interact in complex ways to lead to behaviors and health states [15].

The importance of environment to whether or not a gene will have any effect is illustrated in the work of Michael Meaney and his colleagues with rat pups and their dams. It turns out that the frequency with which rat dams lick their pups and other maternal behaviors influence expression of genes related to stress response in adults. "Epimutations" (specific changes in methylation of cytosines on genes) mediate the relationship between rearing and adult stress response [16]. A large number of studies of Meaney and his colleagues and other groups show that this epigenetic structuring of gene expression is the result of a series of intracellular processes that can be set in motion by external contextual influences such as maternal nurturance [17]. The expression of a cell's genes is thereby dependent on the environment within the cell, an interdependence between gene and the intracellular environment that sets a model for gene X environment interactions at the levels of whole animals and populations.

The role of central nervous system serotonin in cardiovascular disease illustrates well the complexities surrounding gene X environment interaction. As contributed to and summarized by Williams and his colleagues [18–20], there is considerable evidence that long and short alleles of the serotonin transporter gene promoter polymorphism appear to affect CNS serotonin activity in ways that impact CVD risk. But this is not a simple relationship in which, for example, one or the other allele lowers serotonin and raises CVD risk. Among rhesus monkeys reared by their parents, for example, there is no difference between those with long and short alleles in CNS serotonin levels. However, among those reared among peers, the short allele is associated with reduced CNS serotonin and greater risk [21].

Socioeconomic and social factors surely may influence the pathways from the serotonin transporter gene to CVD risk. For example, overstressed parents or neighborhood crime may be analogous in humans to the levels of a rat dam's nurturance or to the peer vs parental rearing that moderates gene expression in monkeys. There are also several broad contextual factors that influence the pathway from genotype to CVD risk. The prevalence of the long allele genotypes varies by country of origin, from less than 30% in China and Japan to over 70% among populations originating in Africa [22].

But what is most interesting and most illustrative of the complexities of gene X environment interaction are perplexing inconsistencies regarding the serotonin transporter gene. It turns out that the same genotype can have both advantageous and disadvantageous effects. In some studies, the long alleles are the "bad actors" [18, 23]; those with one or two long alleles have significantly greater blood pressure responses to stress and greater CVD risk. However, in a longitudinal study of depression among young adults, the number of *short* alleles (either one or two) was related to greater likelihoods of depression and suicidality [24].

If we think of genes as conferring a simple advantage or vulnerability to some disease or condition, it is confusing that a particular genotype is associated with benefit in some studies and vulnerability in others. Williams and his colleagues have suggested another way of framing these influences, as conferring a greater or lesser *sensitivity* to environmental influences [25]. Thus, in a study of depression among young adults, those with two short alleles of the serotonin transporter gene reported greater depression than those with other genotypes *if* they had been exposed to early adversity in childhood or recent negative life events. Among those exposed to positive early environment or recent events, on the other hand, those with two short alleles reported least depression [26]. It seems that the two short alleles confer not advantage or disadvantage, per se, but greater responsiveness to the environment, for good or ill.

Others have noted a similar pattern of greater sensitivity to environment. In one study, observers' measures of poor home and neighborhood quality during adolescence predicted lower self-esteem in young adulthood among those with short alleles. In contrast, there were no effects of home and neighborhood quality among those with two long alleles [27]. In a study of those exposed to a series of hurricanes in Florida in 2004, county-level indices of joblessness and crime moderated the effects of the transporter gene in a remarkable interaction. In counties with high crime/high unemployment, the short allele was associated with higher levels of post-traumatic stress disorder, but in counties with low crime/low unemployment, the short allele was associated with lower risk of post-traumatic stress [28]. Putting these findings together, it seems that short alleles confer greater sensitivity to environmental influences, either positive or negative. That is, sensitivity to environment may be, itself, influenced by genetic variation. Thus, genotype is far from destiny, independent of context. Rather, sensitivity to context is itself embedded in some genotypes – no doubt further influenced by other contexts in the external, phenotypic, and intracellular environments.

What Meaney and Williams and their colleagues point out at the level of the cell is parallel to what others have called "reciprocal determinism" [29] in the relationships between human behavior and its environmental surround. Just as the cell phenotype acts as an environment that influences the expression of the cell's genetic material and the further emergence of the cell's phenotype, so our environment governs our actions which, in turn, influence the environment that will govern our next actions. Continuing up the ladder of complexity, one can see the same kind of reciprocity in the influence of:

- The group on the individual and the individual on the group
- The organization on the division and the division on the organization
- Policies on organizations and organizations on policies

This pattern of reciprocal influence of surround on agent and of agent on surround appears an important dynamic across living systems. It poses an important counterpoint to more primitive models such as those which get lost in debate over whether genes *or* environment is important, models that seek a single cause and in which a single thing can be only a cause or an effect but not both.

The Illusion of the Fundamental It is worth noting that we can see either party to such a reciprocal relationship as fundamental. We might say the work unit is the fundamental determinant of employee performance as moderated by the organization, or we might say that organization is the funda-

mental determinant, as moderated by the work unit. Both may be equally true. Both illustrate the illusion of "fundamental" amidst the reality of multiple, multi-level, interacting determinants. Diabetes provides a classic example. Pima Indians in the United States show "the highest prevalence of type 2 diabetes mellitus … of any population in the world" [30]. Yet, Pimas living in Mexico have relatively low levels of diabetes. Ample evidence links genetics to diabetes *within* the Pima population [30]. Thus, the relationships among genes, environment, and diabetes among the Pimas can be stated in either of two ways:

- Genetic factors associated with membership in the Pima population have a strong influence on prevalence of diabetes among a population exposed to the obesigenic environment of US diet and food distribution.
- The obesigenic environment of the United States has a strong influence on prevalence of diabetes among a population genetically predisposed to high rates of diabetes.

Genetics as Model for Analyzing Social and Ecological Influences

In genomics, causal relationships are inferred through cluster analysis and related statistical techniques that compare differences in probabilities of hundreds or even thousands [31] of genes among those with varied phenotypes. As an example, Fig. 4.1 shows gene arrays characterizing women with poor or good "signatures" for likelihood of subsequent metastases following incident breast cancer [32]. In such analyses, no one gene is the cause or indicator of the phenotype. Instead, the relationship between phenotype and all the genetic markers in the analysis is probabilistic, not all or none.

This approach to characterizing genetic influences is descriptive but persuasive as to the likely causal relationship between profiles and outcomes. To what extent does it provide a model for making judgments about causal influences in a multilevel approach to complex behavior, such as might be arrayed by genetic, personal, social, organizational, and geographic influences?

From the perspective of the individual, we can envision complex webs of influence including genetic and other individual characteristics as well as, outside the individual, the ecologic layering of family, neighborhood, community, worksite, government, and policy, all arrayed in a spatial analysis. These multilevel complexes could be examined as they explain, for example, likelihood of smoking and its relationship with rates of cardiovascular disease and cancer or BMI and its relationship with diabetes, obesity, and other related diseases.

Ecological Analysis and Diabetes

Consider adults with diabetes. Even if they spend 6 hours a year in a professional's office – certainly more than average – that still leaves over 8760 hours a year they are "on your own." The ecological perspective provided a basis for program planning of the Diabetes Initiative of The Robert Wood Johnson Foundation that demonstrated successful implementation of diabetes self-management programs in "real world," ethnically and economically diverse primary care, and community settings around the United States [33, 34]. To guide program development across 14 different project sites, an ecological perspective was used to identify the resources and supports for self-management that people with diabetes need to manage their disease in their daily lives.

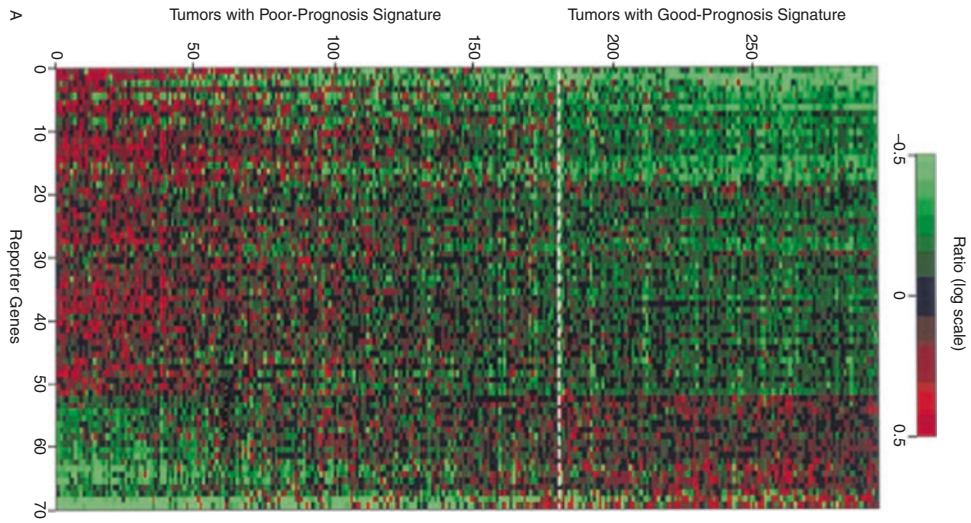

Fig. 4.1 Gene arrays among women with poor or good prognosis signatures for subsequent metastasis following incident breast cancer (from van de Vijver et al. [32])

These include (i) continuity of quality clinical care; (ii) individualized assessment; (iii) collaborative goal-setting; (iv) opportunities to learn skills both specific to diabetes (e.g., measuring blood sugar) and for addressing challenges, including negative emotions, that may interfere with management; (v) ongoing follow-up and support; and (vi) community resources such as for regular physical activity and healthy diet [33–35]. The last two, ongoing follow-up and support and community resources, especially illustrate the contributions of an ecological perspective to diabetes management.

Sustaining Health Behaviors: Follow-Up and Support

Sustaining diabetes self-management is of key importance. We all have great respect for intervention studies that include follow-up of 1, 2, or 3 years. Consider now that the average individual with type 2 diabetes will live 20, 30, or 40+ years with the disease. How do we make the extension from studying maintenance of change over a year or two to developing systematic ways of supporting individuals needing to maintain changes for decades?

Major guidelines [36] of the American Diabetes Association, the American Association of Diabetes Educators, and the American Dietetic Association distinguish between diabetes self-management education, the results of which often deteriorate by 6-month follow-up, and diabetes self-management support to "assist the individual … to implement and sustain the ongoing behaviors needed to manage their illness." This reflects reviews in diabetes self-management that showed that length of time over which intervention is maintained is the best predictor of changes in blood sugar control [37].

The importance of sustained contact is not limited to diabetes. It was recognized in early meta-analytic reviews of research on smoking, for example. In their 1988 review, Kottke and colleagues noted that "Success was … the product of personalized smoking cessation advice and assistance, repeated in different forms by several sources over the longest feasible period" [38]. More recent reviews have continued to document the importance of duration of interventions in smoking cessation [39]. In research on weight loss and weight management as well, duration of interventions emerges as a key predictor of success [40–42].

The *Diabetes Initiative* of the Robert Wood Johnson Foundation came to recognize that the most important characteristic of type 2 diabetes and self-management of it is that it is "for the rest of your life." [43] It sounds simple, but it is striking how this consideration reframes thinking about self-management programs. As an example consider the goals in working with a 45-year-old adult whose diabetes is in poor control. Is the goal getting that control improved in the next 3 months? Or is the goal establishing an approach to living with diabetes that will help the individual attain the best possible control over the next three or four decades? Does the choice of goal have implications for the approach to helping the individual? Clearly, the life-span is an important context of behavioral medicine and one we are just beginning to grasp [44].

In 1968, early leaders in the field of behavior modification, Donald Baer, Montrose Wolf, and Todd Risley, noted that maintenance of behavior changes needed to be arranged or planned, as they put it, to be "programmed rather than wished for or lamented" [45]. An April 2018 search of PubMed for papers with "diabetes" (or "diabetic") and self-management in their titles or abstracts yielded 4287 responses. A subsequent search with these terms and cognates of "sustain" or "maintenance" yielded only 504, 8.51%[3]. A parallel search just of "self-management" yielded 14,506, while that with "self-management" as well as cognates of "sustain" or "maintenance" yielded 1730, again 8.38%. Clearly our research has focused on and indeed made progress in developing approaches to initiating change in health behaviors. A major challenge now entails sustaining them.

From the perspective of "programming" maintenance of behavior, contexts take a central role. Behavior will be sustained to the extent that daily lives of individuals provide opportunities for the behavior, facilitate it, and reinforce it. It is the contexts of neighborhoods, workplaces, communities, families, and friends that must sustain the healthy behaviors that prevent or manage disease and enrich lives.

The content of follow-up may include continued assistance in refining problem-solving plans and skills, encouragement in the face of challenges, and assistance in responding to new problems that may emerge, assistance that may entail linking patients back to primary care providers or other parts of the disease management team. The Diabetes Initiative grantees identified a number of strategies for providing follow-up and support [43], including nurse follow-up by telephone [46–51] as well as through community health workers, lay health workers, *promotoras*, or health coaches [52–55].

The structure of clinical care may also contribute to ongoing support through group medical visits [56, 57]. In these, all patients in a particular category (e.g., those with diabetes, cancer survivors, or, perhaps, those with any of several chronic diseases) are scheduled for a group visit in a 2- or 3-hour block of time. Physicians and other staff carry out individual medical visits within this group visit that also includes educational and supportive discussions or other activities.

[3]Search syntax: ((diabetes [tiab] OR diabetic [tiab]) AND self-management [tiab]) AND (sustain* [tiab] OR maintain* [tiab] OR maintenance [tiab]). Date of search: 26 April, 2018

In spite of the importance of sustaining key behaviors, *ongoing* follow-up and support for *good self-management* are not recognized as an important service. For example, Medicare and, in most states, Medicaid provide 10 hours of DSME but only with physician certification and only for 1 year after diagnosis [58]. After that year, services are limited to 2 hours of DSME unless further worsening triggers eligibility for another 10 hours of DSME. Additionally, education by a dietitian, "medical nutrition therapy," is also covered but also only with a physician's order. In a variety of programs, health "coaches" are often made available for those whose HbA1c measures exceed some criterion (e.g., 8%) but not to help those who are below that criterion to maintain their good management. Our systems of providing healthcare are still slow to recognize what Baer, Wolf, and Risley noted in 1968, which maintenance of changes in behavior "… needs to be programmed rather than wished for or lamented" [45].

Community Resource Access to Healthy Food

An early study examined the distribution of supermarkets and fast-food restaurants in St. Louis in the United States [59]. Supermarkets were audited and sorted into tertiles according to their offering fresh fruits and vegetables and lean, low-fat, and fat-free meat, poultry and dairy products. Of 21 supermarkets in census tracts with greater than 75% African American population, none were in the highest tertile. In contrast, 17 of 30 (57%) of census tracts with less than 10% population below the poverty level and more than 75% white population were in the top tertile.

Do neighborhood resources make a difference? Obesity rates vary between neighborhoods within cities such as New York. A range of factors would seem to be involved including the presence of supermarkets and food stores and the area income [60]. Earlier research examined the relationships among obesity and supermarkets and convenience stores in neighborhoods [61]. After adjusting for gender, race, age, income, education, and physical activity, it turns out the presence of supermarkets in a census tract is associated with a lower prevalence of obesity (prevalence ratio = 0.83 relative to census tracts with no supermarkets), while the prevalence of convenience stores was associated with a higher prevalence of obesity (prevalence ratio = 1.16 relative to neighborhoods with no convenience stores). Those in census tracts with only convenience stores were 1.45 times as likely to be obese as those in tracts with only supermarkets.

This is an area in which the view of self-management as the individual's own responsibility can be especially damaging. The benefits of teaching about physical activity and healthy diet are compromised if people live in neighborhoods in which it is dangerous to walk alone, in which food sellers offer little healthy food, and with little public transportation to access better resources. Studies indicate that such deprivation of community resources is more common in low-income and minority neighborhoods [59].

The Ecology of Professionals

A critical feature of application of the ecological model is to recognize that it applies as much to providers as to recipients of care. For example, the network analyses of influences of social networks and ties on obesity [62], cigarette smoking [63], depression [64], and other features of health and quality of life have been extended to physicians' prescription of medications [65]. This leads to recognition of the importance of systems that facilitate good clinical care and professional services, not just the training and commitment of individual providers.

Wagner's Chronic Care Model articulates the organizational and system features that support integration of Resources and Supports for Self- Management with key components of clinical care [66]. One health system instituted a comprehensive approach to improving a range of diabetes care services, including handouts and manuals, outpatient programs, web-based programs, telephone/nurse case management, financial incentives for physicians' meeting testing guidelines, and patient incentives for annual eye exams. These were followed by improvements in a variety of outcomes [67]. But the emphasis on such integration of comprehensive clinical and self-management services is not widely shared in healthcare. Audits of health plans utilized by major companies [68] show little support for such elements of care, and 60% to 70% of patients with diabetes report not having received self-management interventions [69].

Another ecological approach to systems of care is the Patient- Centered Medical Home (PCMH). A recent review of evaluated demonstration projects showed encouraging evidence for the benefits of PCMH in diabetes care [70]. At the organizational level, the PCMH includes resources such as electronic medical records, evidence-based algorithms and care plans, and ties to referral sources and other community-based resources for patients. In many presentations of the Patient- Centered Medical Home, the interdisciplinary, collaborative team – i.e., the social or organizational level of the ecological model – is emphasized as its central characteristics.

A Social Strategy: Peer Support

The chapter now turns to three areas of application corresponding to three key levels of the ecological model, the social, community, and policy levels. At the social level, peer

support programs – as known by varied terms, e.g., "community health workers," "*promotores de salud*," "lay health advisors," and "health coaches" – are widespread and supported by a diverse literature [71–77]. There are many ways in which peer supporters can encourage health. Among these are helping individuals sustain important health behaviors.

Peer support may be an especially promising approach to providing ongoing support for disease management and sustained changes in health behaviors, such as in smoking cessation and weight management. To begin, peers have time, a critical ingredient in all of healthcare [78]. Whether volunteer or paid staff, nonprofessionals trained to assist and encourage ongoing efforts at disease management and prevention can be readily available to those they help and spend time with them to get to know them and their circumstances, thus increasing the credibility of their assistance. Additionally, peers gain the advantage of being "like me." Research shows that individuals rely on experts to understand what is important and set priorities but to peers and "peer coping models" [79] to gain confidence that they, themselves, can implement a plan of action. Adding to their credibility, peer supporters have the advantage oftentimes of having the health problem with which they are assisting. Also, they often come from similar neighborhoods and so share the perspectives and experience of those they are seeking to help.

Extending the advantages of time and similarity, peer supporters can work with individuals on the details of implementing important health behaviors. For example, it is one thing to set as an objective physical activity for 150 minutes a week. It is another thing to work out exactly what activity, how often, and where and to organize how that activity will fit in with other responsibilities and daily routines. In a report of qualitative analyses aptly titled "*Teaching How, Not What*," [55] a participant noted that her peer supporter "taught me a lot about how to control my diabetes, how to eat healthy, and how to do my exercise."

A 2014 review in the *Annual Review of Public Health* [80] identified contributions of community health workers to basic health needs (e.g., reducing childhood undernutrition), to primary care and health promotion, and to disease management. Another review [81] included peer support interventions from around the world that addressed a wide variety of prevention and health objectives entailing sustained behavior change (in contrast to relatively isolated acts such as cancer screening). It identified papers from the United States (34 papers); Canada (7); Bangladesh, England, Pakistan, and Scotland (4 each); and Australia, Brazil, Denmark, Ireland, Mozambique, New Zealand, South Africa, and Uganda (1 each). The health issues papers addressed included pre- and postnatal care (17 papers), cardiovascular disease (10), diabetes (9), asthma (6), HIV (6), mental health (8), cancer (4), substance use (3), and chronic fatigue syndrome and chronic obstructive pulmonary disease (1 each). Across all 65 papers, 54 (83%) reported significant between-group or pre-post changes showing benefits of peer support. Among the 48 papers reporting RCTs, 39 (81%) reported significant between-group or pre-post changes. The review also included summary of 19 reviews of peer support interventions. Across these 19 reviews, a median of 64.5% of papers reviewed reported significant effects of peer support.

Nineteen papers reviewed provided pre- and post-intervention measures of hemoglobin A1c (HbA1c) as a measure of glucose control [82–95]. Using the individual publication as the unit of analysis, the average HbA1c declined by 0.76 points (e.g., from 8.76% to 8.00%; $p = 0.001$). In diabetes circles, a reduction of HbA1c by half a percentage point, e.g., from 8.5% to 8.0%, is generally considered clinically meaningful. The average reduction across these 19 studies of 0.76 points is thus very striking and adds considerably to the evidence for the benefits of peer support in diabetes management [81].

Peers for Progress (peersforporgress.org) is a program at the University of North Carolina, Chapel Hill (led by coauthor EF), that is dedicated to promoting peer support in health, healthcare, and prevention [96]. In addition to effectiveness, projects sponsored by Peers for Progress have shown real-world applicability. Among 14 funded in 9 countries – Argentina, Australia, Cameroon (2 projects), China, England, South Africa, Thailand, Uganda, and the United States (5 projects) – all 14 were able to be implemented, often in under-resourced settings and/or with disadvantaged populations. Based on data provided in progress reports, average baseline HbA1c in these 14 was 8.71%; clearly the projects were not "cherry picking." Across peer support interventions, projects retained 81.9% of their participants, again quite impressive especially considering the underserved settings and disadvantaged populations of many of the projects. The average decline in HbA1c was 1.18 points, well above the 0.5 point reduction generally considered clinically meaningful. Other indicators of benefits included reduced hospitalizations. Two years after the end of funding from Peers for Progress, group programs in Uganda and South Africa had continued and reported *increased* participation and attendance. Similarly, a private, not-for-profit healthcare company adopted the program as routine care for diabetes in all of its clinical sites [97].

Strategic Advantages of Peer Support

Peer support is especially beneficial for PWD with high needs and those that are hardly reached by conventional healthcare services. Two meta-analyses have shown an association between higher baseline HbA1c and larger effect size [98, 99]. Compared to usual care, peer support is an effective strategy for improving glycemic control for underserved, low-income, minority populations [100–102]. For example, a program for ethnic minority patients of safety-net clinics in

San Francisco reported significantly greater reductions in HbA1c with peer support in addition to usual care, compared to usual care alone [103]. These benefits of peer support were significantly greater for patients categorized as *low* on medication adherence and self-management at baseline [104]. Similarly, in support exchanged within dyads of US veterans with diabetes, improvements in blood glucose relative to controls were greatest among those with initially low levels of diabetes support or health literacy [87]. In an underserved Chicago population, a low-intensity, home-based community health worker intervention was more effective at decreasing HbA1c among participants that had lower levels of diabetes self-care at baseline [105]. These are important observations: intervention worked across all individuals but worked especially well relative to controls for individuals whose diabetes management was in most need of improvement (as suggested by various indicators). This pattern of peer support reaching and benefitting those whom we would expect are most difficult to reach and benefit was sustained in a systematic review of peer support programs across a variety of health conditions [106]. Therefore, peer support is a viable strategy to address one of the major challenges in population health management: benefitting high-need groups that experience disproportionate burdens and costs of care.

Peer support has also demonstrated strong potential to address diabetes and comorbidities [100, 107]. The co-occurrence of diabetes and depression is quite common; PWD are twice as likely to be depressed as those without diabetes, and symptoms of depression are present among almost one third of PWD [108]. Psychological problems, from heightened distress to serious psychopathology, compromise self-management behaviors and exacerbate disease. Among PWD, depression is associated with poor glycemic control and decreased adherence to medical treatments [107]. Peer support directly mitigates depressive symptoms by providing social and emotional support through regular, affirming contacts. Even if recipients of peer support do not change their behaviors, they still experience emotional benefits from having someone to talk to [109]. Additionally, peer support addresses diabetes and depression together by helping PWD overcome socioeconomic barriers and teaching common skills to cope with both conditions. Peer supporters can help identify safe places to exercise and ways of buying affordable food, as well as coach PWD to develop healthy coping skills when facing stressful situations and setbacks. For example, a CHW stress management intervention for US Latinos with type 2 diabetes found a dose-response relationship between attendance at stress management sessions and improvements in HbA1c and diabetes distress [110].

In some cases, psychological improvements have been observed as a by-product of peer support programs designed principally for diabetes. With support from *Peers for Progress*, the PEARL project in Hong Kong examined the impacts of peer support on diabetes-related distress [111]. The study found that peer support reduced distress and lowered hospitalization rates to normal among patients with high levels of depression, anxiety, and/or stress at baseline. In the control condition, these patients accounted for a disproportionate amount of hospital care. PEARL was designed to assist diabetes management, not to reduce emotional distress. Nevertheless, the peer support model was able to achieve substantial effects on distress and associated hospitalizations. Another example is the REACH program, a CHW diabetes lifestyle intervention for African Americans and Latinos with type 2 diabetes in Detroit [112]. Although the intervention was not intended to reduce symptoms of mental health problems, it was able to reduce diabetes-related distress by encouraging positive lifestyle changes and coping skills that could be applied to both diabetes and mental health.

A Community Strategy: Community Action

Recognition of the diverse types and levels of influence on behavior and health can leave one discouraged as to the possibility of changing such influences as the built environment, culture, or social networks. Surely interventions in such arenas are challenging. Nevertheless, promising approaches have been developed. Here, we focus on broad community campaigns to combat cardiovascular disease (CVD), smoking cessation, and diabetes prevention. These provide models for community approaches to diabetes management but ones that have been too little pursued.

North Karelia: CVD Risk Reduction in Finland

The North Karelia project [113] sets a strong example for incorporation of multiple channels and intervention approaches, from mass media to cooperation with agricultural, dairy, and food merchandising groups to improve the availability of healthy foods such as low-fat milk [113]. The program was developed through the Department of Epidemiology of the National Public Health Institute within the Finnish region of North Karelia with field offices at the level of county departments of health and local advisory boards. Community organization in North Karelia included collaboration with existing official agencies and voluntary health organizations so that "the new health service activities initiated by the Project became part of formal public health activities in the area." [113], p. 166. Mass media interventions interacted with local newspapers and community organizations and campaigns as well as including the production of health education materials. Training activities included doctors and nurses but also social workers, representatives of voluntary health organizations, and informal opinion leaders. Training was organized through county-level or other

local organizations. Training and development of treatment guidelines in the health system included reorganizing treatment for hypertension and care following myocardial infarction. Cooperation with other local organizations included not only the voluntary health agencies but also the critical food industry (e.g., including dairies and sausage factories) and grocery stores [113], pp. 166–167.

In comparison to other parts of Finland, the North Karelia campaign led to significant reductions in cardiovascular risk factors [114] and mortality [115] as well as reductions of cancer risk factors [116]. Two characteristics appear critical in the North Karelia community organization: (1) the variety of activities and channels included and (2) the attention in all areas to implementation through and in collaboration with local organizations.

Since the days of the North Karelia project, numerous population and community-based interventions on health promotion and diabetes prevention have been carried out around the world, and important learnings and recommendations for optimizing intervention and evaluation processes have been published [117].

A Danish research group (coauthor PB and colleagues) has developed a conceptual framework, the supersetting approach, to integrate the breadth of community resources, including citizens and professional stakeholders, for social action and health promotion. It involves the coordinated engagement of multiple stakeholders in multiple community settings to implement multiple actions at multiple levels [118]. The supersetting approach includes five principles:

1. *Context* to ensure that everyday life challenges of citizens and professionals are respected and considered in planning activities
2. *Participation* to ensure that people are motivated to take ownership of processes of developing and implementing interventions
3. *Action competence* to ensure that people acquire skills and competences to express and act on their visions and aspirations
4. *Integration* to ensure that activities are implemented across the boundaries of specific settings
5. *Knowledge* to ensure that scientific knowledge is used to inform action and produced from action.

Moreover, the supersetting approach includes three highly participatory, structured, and research-based phases of (1) describing the context, (2) developing and implementing the intervention, and (3) conducting the evaluation. These phases have been optimized methodologically through iterative processes of co-creation with citizens, social workers, health professionals, and researchers. Although generally acknowledged that complex interventions are difficult to evaluate [119], there is now sufficient evidence from meta-analyses of intervention studies on community engagement to conclude that they may positively impact on a range of health outcomes [120].

An important extension of community approaches is their integration with life course perspectives. Type 2 diabetes provides a case in point, as conventional approaches targeting high-risk adults will not efficiently ameliorate this growing disease burden. It is therefore essential robustly to identify determinants across the entire life course and, subsequently, appropriate interventions at every stage to reduce an individual's disease risk [121]. A life course approach has the potential to prevent noncommunicable diseases, from before conception through fetal life, infancy, childhood, adolescence, adulthood, and into older age. Epidemiological research in cardiovascular disease has shown health benefits resulting from the cumulative effects of health behavior over an individual's lifetime, not from a change in lifestyle [122]. On this basis it is important also to involve children and youth in decisions pertaining to the shaping of the social and built environments of their everyday lives. This was done within the framework of a large community-based intervention project in Denmark by addressing school children's perceptions and visions for a socially and physically improved school environment [123]. Guided by an everyday life perspective and applying participatory action research methods including social imagination and visual techniques, the study observed that children were very capable of articulating their thoughts, ideas, and visions for a better and healthier school environment. Identified challenges and solutions differed widely and represented a broad perspective of health including social, physical, environmental, and emotional aspects. The paper concluded that children can be visionary and creative stakeholders and important agents of change in community development efforts if methods to include them are interactive, participatory, and carefully adapted to the age of the target group.

Cigarette Smoking

Although apparently a simple behavior, cigarette smoking illustrates well the broad range of contexts emphasized in this chapter. As detailed in an integrative review in 2004 [1], influences on smoking range from the brain physiology of nicotine addiction to broad economic factors. At the individual level, addiction to nicotine and genetic factors contribute to long-term smoking [124, 125]. Psychological conditioning is also important. The average smoker of a pack a day for 20 years has inhaled over a million times, establishing diverse conditioned associations of smoking with work, relaxation, drinking coffee, and other routines and various moods like anxiety and depression [1].

Research from Scotland and France [126] shows that people at the lower end of the social gradient are more likely to smoke and smoke longer than those from higher

up on the social gradient. However it is not only social position that will determine whether one becomes a smoker and one's smoking habits. These will also depend on which neighborhood one lives in. It has been shown that the practice of smoking is favored by the proximity and density of points of sale for tobacco (Henriksen et al., 2008, McCarthy et al., 2009, Cantrell et al., 2015). These have often found to be concentrated in deprived areas. Van Lenthe and Mackenbach (2006) have also found that people from deprived communities are more likely to smoke but even more so if they live in stressful neighborhoods. Stressors included "physical quality (decay), required police attention, noise pollution from traffic, and population density in neighborhoods." Similarly, objective and perceived measure of neighborhood crime have also been correlated with smoking.

Smoking also illustrates well the reciprocal and complex relationships among influences. As lower socioeconomic status may incline people to smoking, better economic and social prospects and associated better health, increased life expectancy, and security that go with them provide incentives for quitting smoking or not taking it up in the first place [126].

Other determinants among the broad range of social and environmental influences on smoking include:

- Parents' and peers' smoking are major predictors of youth smoking [127].
- Marketing and advertising – cigarettes are one of the most heavily marketed consumer products in the United States: tobacco companies spent $12.49 billion in 2006, even with restrictions on electronic, print, and billboard ads (American Lung Association) [128]. Youth with greatest exposure to tobacco marketing are more likely to start smoking and to become frequent smokers [129].
- Influence on government regulations through contributions to candidate campaigns for office [130] and influence on media coverage of risks of smoking through advertising in major media [131], all driven by the profitability of cigarettes.

The many determinants of smoking across multiple levels of influence illustrate well the concept that influences at different ecological levels interact with each other. For example, the genetics of nicotine metabolism and the addictive nature of nicotine create strong markets for cigarettes. Profitability of selling cigarettes drives both (a) enormous advertising and marketing campaigns that promote the anxiety-reducing and mood-elevating benefits of nicotine as well as (b) political contributions to control restrictions on harmful tobacco products. The cycle continues as the success in addicting large numbers of smokers and keeping them addicted ensures the profitability of the cigarette business.

Comprehensive Intervention Programs to Reduce Tobacco Use Smoking rates among adults in the United States have declined from 42% in 1965 to 15.5% in 2016 [132]. This reduction in smoking rate has been achieved through the best example of a multi-level population-based health behavior interventions to date. Highlights at the several ecological levels include individualized smoking cessation programs, nicotine replacement therapy, and counseling by health professionals (intrapersonal level); workplace and community-based programs as well as programs tailored to reach different groups (social and cultural level); clean indoor air restrictions (physical environments), news coverage, government reports, and anti-smoking campaigns of various health agencies (population-level mass communication); and restricting access to cigarettes and raising taxes on their sale (policy level) [1]. Clearly, interactions among these levels are numerous. For example, clean indoor air policies have driven changes in the physical environment of smoking as well as workplace programs. As another example, creation of desire to quit through mass communication and social marketing has created markets for the development of improved individual cessation interventions.

There has been considerable development of organizational- and community-level interventions to promote nonsmoking. At the organizational level, reductions in smoking have been reported through programs restricting smoking at the workplace [133]. Community-based studies that emphasized community participation in program development have been successful in low-income city neighborhoods and at the county level [134, 135]. COMMIT was a large trial of community organization designed to improve access to numerous options for smoking cessation throughout the entire cities. It achieved appreciable impacts among light and moderate smokers but failed to show benefits among heavy smokers [136, 137]. Commentaries that accompanied publication of these results noted the importance of broad, public health approaches to reducing population prevalence of smoking [138] as well as ways in which intervention planning might have more broadly and effectively engaged communities, their organizations, and leaders [139].

Extending beyond the organization or community, comprehensive statewide programs have created substantial reductions in smoking. These programs embody broad campaigns of public education, including "counter-marketing" TV advertisements and billboards, increased taxes on cigarettes, support services for cessation, smoking prevention programs for youth, and multicultural approaches, all coordinated through community coalitions [140]. The scope of tobacco policy has expanded to include international initiatives such as the World Health Organization's Tobacco Free Initiative and Framework Convention on Tobacco Control (www.who.org).

Amidst the many contributors to reductions in population smoking, Livingood, Allegrante, and Green have also suggested that mass communication on the harms of cigarettes has had a role to play in this irrefutable normative "culture change of accommodation to intolerance of smoking" seen in the United States [141]. This is seen to operate through indirect effects through secondary transmission within groups of people rather than being attributed directly to the influence of mass campaigns. This reinforces the message from North Karelia that multi-level and diversity of interventions contribute to bringing about such a change in norms and indeed behavior change.

Finally, the broad ecological approach to smoking cessation is underscored by the recognition that no one type of smoking cessation intervention is reliably effective for 50% or more of those to whom it is delivered [1], and only a small proportion of smokers ever participated in a formal program. Tobacco use is a social and public health problem, not just an individual behavior. Smoking reductions *require* an ecological perspective; population-level changes reflect the aggregate of the many influences promoting nonsmoking, not a single "magic bullet."

Community Organization for Diabetes Prevention in India

The Kerala Diabetes Prevention Program (K-DPP) was a cluster RCT conducted in 60 polling areas (clusters) of Neyyattinkara sub-district in in Trivandrum district, Kerala state in India [142]. Polling areas are well-defined and identifiable locations demarcated with landmarks such as hills, roads, etc. Participants included those at risk according to age, family history, low level of physical activity, and waist circumference as included in the Indian Diabetes Risk Score. The intervention extended over a year and included group sessions held on weekends in community settings. After an introductory meeting, two half-day sessions led by local experts covered key information about prediabetes, diabetes, and ways to prevent it. Trained peer leaders were chosen in conjunction with group members. They then led meetings to discuss how to apply the information about diabetes prevention in their daily lives. These discussions were held twice in the first month and then monthly for the remainder of the 12-month intervention. Sessions lasted 60–90 minutes and included 10–23 participants with family members also encouraged to attend.

In addition to the structured sequence of educational and discussion sessions, participants were encouraged to participate in a variety of group activities to support healthy lifestyles and diabetes prevention. These included yoga and walking groups, kitchen gardens, etc. Additionally, the organization of the program at the local, community level of polling places facilitated casual contact of peer leaders with group members. Through these contacts, peer leaders provided encouragement of individuals' prevention plans, information about missed sessions, reinforcement of progress, and the opportunity to share and discuss other questions or concerns of participants.

At 24-month follow-up, incidence of diabetes was 17.1% among participants from control polling places who received an educational booklet and advice for lifestyle change and 14.9% in the intervention polling places (RR = 0.88, $p = 0.36$). The two groups differed significantly, however, in several important areas. Those from the intervention polling places achieved greater reductions on the Indian Diabetes Risk Score ($p = 0.022$). Most notably, among those with impaired glucose tolerance, the relative risk of diabetes in the program relative to control polling places was 0.66 ($p = 0.03$). It should be noted that incidence among those with impaired glucose tolerance was the primary outcome of the major efficacy studies of diabetes prevention in China [143], Finland [144], and the United States [145]. That is, the K-DPP, developed with substantial community input and implemented in rural polling places in a low-/middle-income country, replicated the results of major international efficacy trials, reduction of incidence of diabetes among those with impaired glucose tolerance.

A Policy Strategy: Health in All Policies

If you wish to markedly improve population health in an equitable way, it will be necessary to orient policy toward the non-health sector such as housing and to take into account the environment, and especially the built environment, in which people live, work, and play. Social, economic, and cultural conditions should be considered as a significant part of our environments. The bulk of evidence from social determinant research and informed practice suggests that in order to improve health and reduce health inequities, it is necessary to act on areas of life and activity lying beyond the health sector [146, 147].

The idea of Health in All Policies (HIAP) is not new. The first article of the Alma Ata declaration proclaims that "… the attainment of the highest possible level of health is a most important world-wide social goal whose realization requires the action of many other social and economic sectors in addition to the health sector." More recently, the Adelaide Statement [148] has argued strongly for Intersectoral Action for Health (IAH). This stressed how cross-sector collaboration and joined-up government were not only a key to better health and equity but may also be linked to sustainable development, citizen participation, and more efficient economies. The Adelaide Statement singled out the following non-health sector areas and issues: economy and employment, security and justice, education and early life, agriculture and food, infrastructure, planning and transport, environments and sus-

Table 4.1 Sectors in which actions can be taken to reduce key risk factors for NDCs

Adapted from Figure 6 in Meiro-Lorenzo et al. [149]

tainability, housing and community services, and land and culture. As can be easily appreciated, all these areas are related to social determinants of health and tackling inequities. The logical policy follow-up to such initiatives, "Health in All Policies," highlights the necessity for intersectoral initiatives including the health sector.

Table 4.1, adapted from a World Bank report [149], indicates how different sectors such as education, finance, urban planning, agriculture, industry and transport, and health itself may have a significant role to play in reducing risk factors for chronic and noncommunicable diseases.

Healthy Cities

Perhaps the best examples of health in all policies and a "beacon of hope" may be seen in the WHO Healthy Cities movement [150]. Its evolving agenda and philosophy initiated in 1986 incorporate health into urban policy and planning to create healthy sustainable and economically prosperous environments and just communities. The Working Cities movement is epitomized by the WHO European Healthy Cities Network involving some 100 flagship cities and 31 national networks across the WHO European region. [151] This comprises some 1500 cities (some 90 in France alone). Twenty networks have been accredited formally by the WHO. These represent 1137 local governments and a population of 156 million people Healthy Cities endeavor to foster health in all policies through highlighting the importance of improving leadership for health, participatory governance, intersectoral collaboration, and upstream action at the local level to improve population health and tackle health inequities [152]. Different cities and their municipal councils fix priorities and initiate projects in a wide range of environmental and health domains. In France these include projects on Radon and indoor air pollution, physical and sporting activities to tackle obesity, school transport schemes encouraging walking to school or environmentally friendly vehicles, healthy nutrition, and carrying out a Health Impact Assessment in order to inform decisions about such initiatives. Healthy Cities teaches us that such initiatives need long-term vision and planning. It may take 30 years to reverse the taken-for-granted dependency on cars. Planning may involve thinking, participation, and implementation of policy changes in successive phases to reach long-term goals [150, 153].

A study of the members of the French Healthy Cities Network investigated how health was taken into account by city authorities through different non-health sectors such as transport, green spaces, social action, youth, education, culture, sport, and housing. Although it was featured less strongly within some sectors, e.g., housing policy, health was featured prominently in connection with green space policy, urban design and transport, and active travel or mobility policy. There is now good evidence that such urban policies prevent disease and impairment, and, important for sustainability, save energy, money, and lives.

City of Well-being: A radical guide to planning [150] provides a wide range of evidence suggesting that "spatial arrangement of towns can influence active travel and recreational activity to a significant extent – and in certain situations it can influence diet" [150]. Walkable, safe environments, and in particular distance from stores and services are key factors in fostering walking and cycling. The fact that this varies substantially from country to country and city to city and neighborhood to neighborhood indicates that urban design taking into account spatial factors and distance can influence norms and reduce dependency on cars. Thus a joint Canadian and American study [154] cited by Heritage [152] suggests that people living in neighborhoods adapted to walking and in proximity to stores move four times more than those living in areas adapted to cars. However living in a walkable district or a car-friendly area may not always be a matter of individual choice.

Evidence cited from the United States, China, and India suggests that cycling rather than driving can reduce obesity, diabetes, and hypertension significantly [150]. It is estimated that increasing cycling in the Paris area to 4% of all travel will produce benefits in terms of mortality 20 times greater than the risks due to accidents or accidents caused by cyclists or the effects of air or noise pollution and stress [155].

The WHO recently championed a system for assessing the economic impact of changing urban mobility patterns. The Health Economic Assessment Tool (HEAT) which may

contribute to broader assessments of health impact allows municipalities to make estimates of the amount of money and lives saved that could be gained through switching from driving to cycling and walking. The value of a statistical life is fixed at 4 million Euros for France, but it is also possible to simply reflect on benefits in terms of number of lives saved [156]. As an example of such estimates, the French city of Nantes hopes that 12% of all journeys in 2030 will be by bike. If this is achieved, the HEAT calculation shows that 67 lives will be saved each year or 670 over 10 years. In monetary terms the estimate is made that 2,682,000,000 € will be saved over the next 10-year period if the 12% target is reached. Currently this stands at 4.5% in the Nantes metropolitan area. This in itself represents a saving of some 1,005,000,000 € and 260 lives over 10 years.

In addition to walking and cycling, urban planning may consider distances needed to walk to stores and services. Other effective policies include car sharing/pooling promoted through strategically placed carpooling parks, transport zoning with 20 km and 30 km zones coupled to the designation of cycle lanes, bike parks with credit card renting of both regular and electric bicycles (especially important in hilly cities), chaperoned walking of children to their local school by volunteer parents, signage indicating not distance but time necessary to walk from one point to another, and general interchangeability in public transport so that transfers from bike to rail to bus are cost-free. Coupled to encouraging active mobility, there are also parallel efforts made to render all public places and spaces accessible to physically disabled people using wheelchairs or parents pushing baby carriages, tactile paving guidelines and studs in foot pavement for blind people, traffic signals equipped to give oral cues, and even instructions to blind people guided by personal GPS controllers. If well-planned, cities will not just favor more walking but also chance encounters with people from the neighborhood thus fostering social support and community ties and impacting on mental health.

Behavior change is not just about education and providing information to individuals but is also about creating new physical, sociocultural, and attitudinal environments which favor healthy behaviors and habits. The Healthy Cities movement embodies this idea well and illustrates how a holistic view of health and health promotion such as in the following statement of the International Union of Health Promotion and Education's may reap great benefits if applied with intelligence:

> Health is a basic human need. It is fundamental to the successful functioning of individuals and of societies…./… The main determinants of health are people's cultural, social, economic and environmental living conditions, and the social and personal behaviours that are strongly influenced by those conditions. [157]

As much as research may guide and show the value of HiAP and related approaches, evaluation such as through Health Impact Assessment can never be a substitute for political decisions. It will never replace the necessity for politicians to take difficult decisions and have the vision and political will necessary to tackle sources of disease in our environment to develop opportunities for health and well-being especially where these would seem to run counter to short-term institutional prerogatives or market opportunities [158]. Barton and his co-workers have put forward a Settlement Health Map [150, 159] to explain and analyze the interplay of different factors impacting on health and well-being in the built environment. As Barton suggests this offers a useful tool for generating discussion and debate, thus situating different stakeholders' responsibility within the urban environment, and for shaping intersectoral and multi-stakeholder involvement in creating healthier conditions for urban living [150]. Health Impact Assessment and other evaluation approaches may provide data for consideration in such processes, but they cannot replace them.

Globalization

Globalization and the trends associated with it provide an important context for HiAP. Globalization typically describes changes in production and its organization associated with neoliberalism, the free circulation of information, capital, and goods and the primacy of financial markets over other aspects of the economy [160]. However as Scholte argues [161], it should not be conflated with liberalization as such since other economic policy agendas could be pursued which would highlight positive benefits of globalization and supra-territorial relations. These are according to Scholte "social connections that substantially transcend territorial geography": [161] a new way of configuring and handling social space. In recent years, such supraterritoriality is epitomized by the Internet and by the fact that local events may become instantly global and have global consequences. This may be seen in communication campaigns such as the response to terrorism "Je suis Charlie" or the current "Me Too" campaign in denouncing sexual violence toward women. Trans-world travel and migration and how business, financial operations, and markets are organized globally working as a network also highlight that we are living in a supraterritorial world. Territorial space can also be bridged, for example, in telemedicine or online trans-world training such as MOOCs.

Arguably, globalization is not new. There has always been movement of goods and labor, but distances are being shrunk, and travelling times across the world have grown progressively shorter. Current global connections are characterized by transplanetary flows with simultaneity and instantaneity. The premier property of successful modern commerce is its capacity to create universally transferable objects which circulate through frontiers and borders with utmost ease. This

aligns well with a neoliberal agenda which espouses the free movement of information, goods, and financial capital, together with the nonintervention of states in the economy, private and business affairs. This agenda after some resistance from non-aligned developing countries has been taken up by an overwhelming majority of countries in both the developed and developing worlds who now organize or have to organize their economies in conformity with such neoliberal principles [160]. It is associated with changes in management, work organization, and practices. It has led to the delocalization of industry, reduced wages, and wage costs for multinational companies within a globalized economy.

Geertz [162] has noted that, along with globalization, people living in different communities are also subject to an opposing movement emphasizing the uniqueness of nations, and nationalistic ideologies, and regions, local products, customs, and beliefs perhaps as a bulwark against threats to local identities. Thus people from different countries may not only find similar globalized goods, modes, and beliefs in their countries but also be united by a sense that they must respect their local traditions and ways of doing things. Again people may strive to be as connected to the contemporary as much as possible while at the same time falling back on and upholding tradition. Recent political changes may confirm this dialectic and the current move toward political isolationism and a backlash against free trade and political cooperation, e.g., Brexit in the United Kingdom or the recent emphasis in the United States on "America First." Such apparently contradictory movements (which may be harnessed politically) uphold the idea, nevertheless, that ultimately we live in both globalized and localized worlds.

Locality and local cultures should not be opposed to globality and universalism, since both are intermeshed and interact with each other to produce new forms of social organization, space, and sociocultural being. Thus it is more fruitful in line with the overall socio-ecological model of this chapter to avoid dichotomies and to conceptualize social space as not being made up of discrete entities but incorporating both the global and the local and similarly characterizing the people living in them as having plural identities influenced through both their global and local cultures. Furthermore it is also wise not to demonize globalization since it also allows the transfer of knowledge and experience quickly to enable and emancipate people.

We live in a global world on one planet, and ultimately we are all affected by planetary phenomenon such as global climatic change, migration, widening inequities, emergence of infectious disease, and noncommunicable disease epidemics. The latter, for instance, are associated with the spread of tobacco and obesity. These however are driven not by globalization as such, but rather by the neoliberal harnessing of this phenomenon for private profit.

Globalization and Health

Bearing such complexities in mind with respect to different contexts, globalization has been argued to produce both positive and negative impacts on health [163, 164]. In 2001 Feacham claimed that "Globalisation is good for your health, mostly." [165] Dollar maintained that "the higher growth that accompanies globalization in developing countries generally benefits poor people … globalization has indirect positive effects on nutrition, infant mortality and other health issues related to income" [163]. Among negative aspects cited were the spread of disease (AIDS) due to increased migration and travel as well as the impact of tobacco through free trade [163]. Huynen, Martens, and Hilderink [166] citing Fidler [167]suggest that the World Trade Organization has more influence on the governance of global health than the WHO and that it is unclear whether World Trade Organization agreements may protect health.

Globalization appears to have affected some countries, such as Asian countries, more positively than others (African, Latin American, and Eastern European countries). On one hand slow and uneven growth was associated with stagnation in health indicators, and on the other, economic crises in middle-income countries such as the former Soviet Union produced economic instability, sharp rises in unemployment, and dramatic effects on health and life expectancy. Additional negative claims have included that globalization has had deleterious impacts on health and health inequities, especially in poor developing countries and among poor households [168–170]. Of particular interest with respect to health and inequity is the observation that "high income inequity reduces the pace of growth and of poverty reduction." [164]

Income Distribution and Other Effects of Globalization

Recent work on austerity shows that recessions can impact on people's health negatively, as one would intuitively suspect, but also positively [171]. This may largely depend on whether support from social protection systems is maintained or cut. Ironically however recession in itself may have less effect than the austerity measures taken to combat it, measures that arguably are bad for health and kill massively [172].

"Population health tends to be better in societies where income is more equally distributed. Recent evidence suggests that many other social problems, including mental illness, violence, imprisonment, lack of trust, teenage births, obesity, drug abuse, and poor educational performance of schoolchildren, are also more common in more unequal societies." [173] The measure of inequity taken is how much richer the top 20 percent than the bottom 20 percent are in each country. Significantly in richer countries what counts is not absolute wealth but whether the wealth is distributed more or less equally. As Wilkinson has stressed [173], it

makes little difference how a degree of equality is achieved. Countries such as Sweden and Japan are vastly different in many respects and have different social protection and fiscal systems, but their relatively low degree of income inequity correlates well with health and may be contrasted with the situation in less equal societies. The situation with respect to inequity and health and other social indicators seen between countries is also mirrored among states in the United States. States with the highest degree of inequity also have high levels of poor social outcomes including health.

Of particular importance is the labor market. Bambra [174] reminds us that "work (paid wage labor) and worklessness (lack of paid work) are not the discreet activities of individuals, but are essential parts of the way in which the totality of society is politically, socially and economically organized." Being in work is an important condition for health, having an income and for social inclusion, but can also lead to bad health through the impact of an adverse physical or indeed psychosocial working environment. These risks follow a social gradient, lower-paid workers being more vulnerable to workplace hazards and accidents as well as having less control over their work and related stress in the workplace.

Supranational Policy

One example of the influence of European policy on national policy is the regulatory context on urban planning and environmental health of the European Union (EU). The Green Paper and the Leipzig Charter put forward an integrated sustainable urban development to overcome demographic, social, and environmental problems in European cities. Two EU Directives have been implemented to address the issues related to ambient air quality (2008/50/EC) and environmental noise (2002/49/EC). The Parma Declaration (5th Ministerial Conference on Environment and Health in 2010) [175] described the way forward in the work of environment and health in Europe. It set out concrete targets to tackle key urban environmental risk factors, paying special attention to children's health, inequities, and emerging environmental health challenges.

The influence of supranational policy agendas sets the scene for national legislation and implementation and can have both positive and negative effects on health. This can easily be seen in another important non-health field within Europe, namely, agriculture and food policy. The Common Agricultural Policy provides a strict regulatory framework and subsidies for farmers in Europe. This has important impacts on land use, the form of agriculture practiced, its impact on employment and the environment, and the type and price of food available favoring either health or disease [176]. Thus on one hand, subsidizing beef and dairy production favors high saturated fat intake, and on the other hand, the lack of support for fruit and vegetables favors comparatively high prices and lower consumption, all with obvious implications for health. Consequently recommendations have been made for public health policy and agricultural policy goals to be aligned to favor higher and more equitable consumption of fruit and vegetables and less sugar, dairy produce, and meat [176, 177].

Interactions Among Determinants and Sectors

A central point of most writing in these areas is that different environmental or contextual determinants often interact in their influences on health. Good examples include the relationships between air pollution and poverty. Irrespective of the levels of exposure, there is a correlation between being poor and the resultant harmful effects of pollution. This would seem to be related to the second mechanism of differential susceptibility. Through having been exposed to repeated insults of their environment during certain periods of their life (windows of exposure) [178], poorer populations have developed a greater susceptibility to resultant health effects. As Deguen and Zmirou conclude, in the case of ambient air quality, long-term multipolar urban planning and diversity-sensitive housing policy may be the best way to tackle environmental and social inequities and to mitigate differential health impacts [179].

Examples: Housing and Urban Life

To further the discussion of HIAP, we will now take a more detailed look at two of the most important non-health sector areas: housing and urban planning and development and how these impact on people's lives.

National and local government policy with respect to issues such as mortgages, local housing taxes (rates), and rent fixing will largely determine whether the supply of social housing is high or low. As this is written, the US federal government is considering raising rentals on low-income housing. Access to social housing (housing owned and rented out by local authorities to people with low incomes or specific needs) will for the most part be determined by residence in the community and recognized need such as being a lone woman with children. In France, a country with a tradition of strong social policies, it is estimated that more than 500,000 people do not have a home. Among those, 133,000 are actually homeless, others are living on sofas of friends, hostels, squats, etc. [180] If the number of people living in very "difficult housing" (chronic overpopulation, dangerous buildings, lack of basic amenities) is added, the number rises to 3.6 million, more than 5% of the French population. Another 5 million people are considered to have a very fragile housing

situation (lack of house maintenance, large unpaid rents, etc.), and nearly 3.5 million face fuel poverty [180].

Even if appropriate and affordable housing has been heralded as a fundamental human right, it remains one which is far from being upheld in many developing and developed countries alike. The WHO "Closing the gap in a generation" report warns that "One of the biggest challenges facing cities is access to adequate shelter for all. … This crisis (of housing) will worsen social inequities in general, and in health in particular." [181] The US Surgeon General's 2009 Call to Action asserted that "To improve the nation's overall health, we must improve the health of the nation's homes and ensure that safe, healthy, affordable, accessible and environmentally friendly homes are available to everyone." [182]

Closely related to housing, indoor air pollution can be caused by both chemical and biological sources. Interventions directed to these can be effective, however. Lead hazard control in the United States has shown to be a very effective intervention, decreasing dust lead levels by 78% over a 3-year period (Sandel et al., 2010). In France, exposure to radon is the second leading cause of lung cancer after tobacco causing up to 2900 deaths per year [183]. Radon mitigation is effective in reducing individuals' risk of lung cancer and is cost-effective compared to other healthcare and environmental interventions [184].

Examples: Urban Environmental Impacts, Planning, and Development

More than half of the human population worldwide now lives in towns and cities. This is likely to increase to 60% by the year 2030. In Europe and the United States, 75% and 80% of people, respectively, live in urban areas [185, 186]. In the developing world, this is likely to lead to megacities in Asia and other large cities in Africa and 2 billion people living in slum conditions worldwide. Thus it is important to draw lessons from the Healthy Cities movement to prepare for an increasingly urban world [187].

From a physical perspective, the urban environment has also assumed considerable importance due to its high population density, the size of buildings, and the existence of a considerable technical infrastructure coupled to diverse industries having high potential for different kinds of environmental pollution impacting on human health. These may aggregate or intensify the chemical and biological hazards associated with housing described above. Additionally, the health impact of noise is strongly related to the proximity of the population concerned and the source of noise emission. Thus an increase of 10 dB of sound intensity corresponds to an increase in prescribed sleeping pills and cardiovascular disease medications [188].

The Chicago, 1996, and French, 2003, heatwaves illustrate how the urban environment may also exacerbate risks to health. Built-up environments lacking trees, hedges, bushes, and other plants tend to conserve heat (or cold). The impact of such events on mortality and morbidity is exacerbated, vulnerable isolated members of the population being trapped in veritable islands of heat within the urban environment [189].

The design of the neighborhood and the provision of urban green spaces have an impact on health risks, influencing aesthetic perceptions and physical constraints and determining the degree of social mixing. Poorly maintained and deteriorated urban environments lacking of green areas are associated with lower levels of physical activity and increased rates of overweight, partly explained through people's perception as a reaction to the aesthetic impression, which also affects mental health and social isolation. The presence of accessible municipal services, public gathering places, and green areas can counteract some of these effects. In addition, environments mimicking natural conditions (green corridors, parks, etc.) help by reducing ambient air pollution, cooling urban areas, and providing a barrier against noise and may even have an influence on preventing the development of some forms of cancer [190].

Capabilities go beyond achieving a set goal to encompass the idea that what matters is possessing the freedom to envisage and choose from a range of possibilities in relation to the projects and life plans that people have reason to value. Neighborhoods structure the health practices that people engage in, notably through the unequal distribution of resources. The idea of resources may be widened to include not just physical resources but also intangible resources which may be seen as relational processes. Neighborhoods are not just passive geographical spaces, but living dialectics of structure and agency in which people adapt to constraints and embrace freedoms in different domains over time, places where individuals and communities engage in practices producing health on a daily basis [191].

Given that low-income populations are disproportionately found in environments with worse urban features (less green spaces, poor urban design, etc.), many different approaches have been developed in the last decades to address health inequities by changing the neighborhood characteristics of low-income people. One approach to changing neighborhood characteristics is to move people from high- to low-poverty neighborhoods. Moving neighborhood can improve mental health, reduce obesity, and impact positively on some wider determinants of health [192]. Several studies have examined the effects of giving people housing vouchers to change home and neighborhood. "Moving to Opportunity" permitted families to move from public housing in high-poverty neighborhoods to private housing in lower-poverty or nonpoor New York neighborhoods. Moving out of the

public housing/high-poverty neighborhoods was associated with lower distress among parents and lower anxious/depressive and dependency problems among their sons [193]. Similarly a randomized environmental experimental intervention carried out in Chicago [194] has shown that obesity and diabetes risk may be reduced by moving to different neighborhoods. Three groups were constituted. One group was offered housing vouchers provided they changed address and moved to another neighborhood. Another group was offered the equivalent sum but was given no instructions or advice on moving, and a third, control group, was offered neither advice nor money. Over a 7-year period, there was no significant difference between the latter two groups, but the objectively measured risks of developing obesity and diabetes were reduced in the group who moved home. Positive effects were seen 10 to 15 years later in prevalence of obesity and diabetes [194].

Evaluation of the effects of moving inhabitants out of unhealthy neighborhoods shows benefits that might be achieved but not a feasible approach for general application. Urban regeneration programs, aiming at the whole neighborhood level, are argued to be more cost-effective than the movement of individuals to better areas, including because they benefit the community as a whole [195]. Yet the evidence supporting this idea is still weak. A systematic review in the United Kingdom [192] found small positive impacts on socioeconomic determinants of health but potential negative impacts as well. Mixed tenure has also been promoted in many European countries as a means to tackle social exclusion and create sustainable communities. However the evidence is inconclusive on whether it actually promotes social cohesion and residential sustainability or improves people's perceptions of the neighborhood. Nor has it been found to provide better job opportunities or changes in income mix [195].

Other interventions that have the potential to improve health and health inequities include the demolition of distressed housing and relocation of residents; universal design standards to favor the elderly and people with disabilities; crime prevention through environmental design; smart growth and connectivity designs; zoning (regulating how land or a site may be or not used for certain purposes, e.g., prohibiting alcohol outlets near schools); and interventions concerning green space around housing [196].

Urban environments are already home to two-thirds of people with diabetes. This makes cities the front line in the fight against type 2 diabetes. In 2014, three global partners, Steno Diabetes Center Copenhagen, University College London, and Novo Nordisk, launched the Cities Changing Diabetes (CCD) program to accelerate the global fight against urban diabetes. Today, the program has established partnerships with key stakeholders in ten cities around the world to address the social factors and cultural determinants that increase type 2 diabetes vulnerability among those cities residents [197]. The CCD partners have modelled what it will take to hold the rise of diabetes prevalence at 10.0% globally. A 25% reduction in obesity from 2017 levels is required by 2045. This is the long-term global target for CCD.

Neighborhood Design and Social Isolation

A rapidly emerging area of research that epitomizes the ecological perspective is that regarding the impact of our physical and built environment on our social relationships and behavior. As background, there is ample evidence about the association among mortality, health, and social isolation.

A meta-analysis of 148 studies involving 300.000 persons documented that individuals with strong social relationships had a 50% increased likelihood of survival over an average study period of 7.5 years compared to individuals with weak social relationships [198]. Moroever, associations between social isolation and type 2 diabetes have been documented in several studies [199, 200].

Research suggests that architectural design impacts social isolation and integration. Among older adults in Chicago, Illinois, in the United States, social isolation was more common in dilapidated, run-down areas [201]. In addition, elderly people who lived in high-rise public housing buildings were less likely to venture into neighborhoods than those who lived in low-rise public housing buildings (after controlling for other environmental aspects and personal characteristics) [201].

The influence of neighborhood design on perceived social isolation can also be understood on a population-level basis. Wu and Chan conducted a cross-sectional study among approximately 4500 Singaporeans over the age of 60 to determine how public housing influenced older urban residents' social interactions [202]. In Singapore, almost 90% of residents reside in Housing Development Board (HDB) public housing, which function as a neighborhood block in which residents are able to access social support services for the elderly and children and public spaces such as playgrounds, markets, and cafes [202]. The remaining 10% with higher household incomes reside in private housing. In their study, Wu and Chan found that the strongest predictors for decreasing the likelihood of isolation were residence in the HDB public housing and daily social participation in HDB neighborhood events. Accordingly, they hypothesized that the HDB built environment functioned as a community and encouraged social care, social support, and social interaction among residents. In contrast, those who resided in private condominiums or gated communities were at greater risk of social isolation because of less frequent social interaction and proximity to others [202].

As the built environment may discourage social interaction, several features have also been linked to increased social interaction. In particular, indoor and outdoor common spaces have been shown to support social ties among older individuals [203]. By offering opportunities for informal face-to-face contact, common spaces allow individuals to foster and maintain casual social relationships that have been found associated with health, including among older adults [204]. In a study of older individuals aged 60–90 in Chicago Public Housing buildings [203], those who lived in the closest proximity to trees and vegetation experienced higher levels of social support and integration than those with little nearby vegetation. Moreover, in a study of 273 Hispanic elders living in East Little Havana in Miami, Florida [205], researchers found that architectural features such as porches and stoops encouraged greater person-to-person contact and were positively associated with perceived social support and negatively associated with psychological distress. On the other hand, architectural features, such as windows, allowed for broader observation of the surrounding area but removed individuals from close person-to-person contact and resulted in lower levels of perceived social support. This suggests that common spaces that actually allow individuals to engage with others are more beneficial in increasing support than those that simply increase observation of surroundings [205].

In addition to common spaces and architectural design, social interaction may also be influenced by perceived accessibility of resources. Richard and colleagues [206] conducted a study to assess neighborhood correlates of social participation among older adults living in an urban environment in Montreal, Quebec. They found that a significant predictor for social participation was perceived accessibility to key resources, in that greater access to key resources within a 5-minute walk was associated with increased social participation. This has been confirmed by several other studies, which have found that higher levels of participation occur in places where people hold a positive image of their environment [201, 207]. For instance, Bowling and Stafford [207] conducted a cross-sectional study of perceptions of neighborhood infrastructure and social engagement among older adults. They found that perceptions of poor local facilities in the area, particularly poor facilities for people aged 65 an older, were associated with greater likelihood of low social activities. This suggests that the accessibility of social resources, services, and facilities is an important determinant of social participation and interaction. This emerging field of evidence thus points to an association between the built environment and social support, whereby neighborhood design, architectural features, and perceived accessibility of resources influence individuals' levels of social support and participation. However, research is still needed to document how these components can be manipulated in existing settings to reduce social isolation.

HiAP and Community Organization

It has been argued that HiAP approaches are distinguishable from other intersectoral initiatives to advance health equity in two important ways [208]. First, because they emphasize health in all *policies*, HiAP approaches are coordinated primarily by formal structures and mechanisms of governments that are responsible for policies. Second, initiatives adopted under HiAP approaches are explicitly linked to structural or long-term governmental policies or agendas, rather than focusing on specific problems. While recognizing the importance of applying the HiAP approach at governmental level, it has also been argued that intersectoral collaboration and action should also be nurtured at more local levels. The Sundsvall Statement on Supportive Environments for Health that emerged from the 3rd International Conference on Health Promotion in Sundsvall, Sweden, in 1991 thus recommended the building of alliances and strengthening cooperation between health and environment campaigns and strategies to advance supportive environments at the community level [209]. Health in All *local* Policies is thus a meaningful concept in the context of local community development when referring to the polices and strategies of all stakeholder organizations involved in decision-making and agenda setting and not just local government institutions [210]. The meta-message of this chapter clearly applies here. Because of the multiple layers and sectors of multiple determinants of health behaviors and health, the broadest possible range and diversity of sectors and influences should be brought into campaigns to address important health problems and challenges. We should reject analyses or rhetorics that incline to privileging one or another approach.

A Key Change in Perspective

Increasing emphasis on non-health policy flies in the face of representations of health that are taken for granted in the general population. Health is often reduced to healthcare, and this is how governments and citizens traditionally represent health, dividing up the world into health and non-health. Similarly, health is often viewed as determined by individual characteristics – e.g., "good genes" – and individual choices. This may lead to viewing the individual as responsible for her/his own health [211]. In contrast, the ecological perspective casts such views as imposing an unreasonable attribution of responsibility to the individual – a sort of victim blaming – by ignoring the diversity of forces that shape each individual's behavior. Some may see such "robbing" the individual of responsibility as a reduction of individual and human dignity. This concern about dignity may represent a Western view that individual dig-

nity and recognition of external influence are somehow opposed. In other cultures, influence of the surround is assumed and not seen as detracting from the dignity of the individual [212].

A 2015 French study [213] suggests that local stakeholders involved in a community project may perceive health more broadly than might have been anticipated. They were described as seeing health "as a global resource for life, determined by a large number of factors (behaviors, social life, work conditions, education, transportation, etc.) and for which every local actor has a responsibility." Similarly, the success of a Healthy Cities initiative in Portland in the US state of Oregon shows that such policies can be acceptable and effective outside Europe's strong tradition of social and health protection.

The example of Penwerris, in Falmouth, Cornwall in the United Kingdom provides a model for changing perspectives and achieving intersectoral collaboration at the community level. In 1995, this socially deprived area had the highest number of poor households, the highest proportion of children in households with no wage earners, and the second highest number of lone parents. More than 50% of homes lacked central heating and the illness rate was 18% "above the national average" [214]. Community health nurses, known as "health visitors," pinpointed 20 residents who they felt could work constructively on the estate's problems with the authorities. Five agreed to participate. The health visitors went on to initiate intersectoral action inviting the representatives of health, social services, education, local government, and the police to a series of meetings. Most importantly, in parallel with an injection of funds following a successful application for an energy improvement grant for the area, a shift in power was granted by the authorities to allow the community partnership to fix priorities and take decisions about their own community and lives. Problems were discussed and "discovered" between the actors, and different solutions are being explored. This was not based on classical needs analysis carried out from above but emerged and relied on local knowledge, ideas, and initiative. Regeneration was not planned from outside but emerged from within [214].

Five years on, the situation had undergone a spectacular radical transformation. Improvements of a whole series of community indicators had occurred including a 50% drop in crimes, a 42% fall in child protection registrations, and a drop of 70% in postnatal depression. Furthermore there were no unwanted teenage pregnancies, educational achievement had hugely improved, and the unemployment rate had fallen by 71% in both men and women [214]. Interviews and two focus groups to understand the process of change suggested that, in line with complexity theory, the downward spiral of social deprivation and urban decline was reversed through acting at a critical point, developing trust and self-confidence, favoring self-organization within the community, and leading to a reconfiguring of social relationships among residents, different statutory agencies, and new actors. This success has led to similar initiatives with other deprived communities based on similar principles of trust and self-organization being set up in other urban areas in the United Kingdoms [215].

Implicit in the emphases on ecological determinants and, especially, Health in All Policies is a focus on general health and well-being, not one or a particular disease. As agricultural policy, for example, will affect diet and all the diseases that nutrition influences, the breadth of impacts on health will be necessary to justify proposals to alter policies not directly related to health. Surely a proposal for major changes in national agricultural policy to benefit a small number of people with a specific disease would have much less likelihood of adoption than one that may be justified as benefitting all children and adults in a society. So too and consistent with considering the many determinants of health, it is important also to consider health beyond the prevention of disease and incorporate salutogenesis and resources for health and well-being favoring a sense of coherence and quality of life [216–218]. Again, the broader focus makes excellent conceptual and policy sense and also recruits additional reasons in support of policy proposals that may emerge from it.

Extension to Diabetes

We have presented a range of ways non-health sector factors and policies may impact on human health. We have also sketched a number of different policies that may reduce or mitigate deleterious health impacts. We have also stressed that health should be seen positively and that physical and sociocultural environment have the potential to promote and improve health. Increasingly non-health policy is taking up the gauntlet and addressing a number of these issues at the macro and micro level. At the macro level, this has been tackled notably through adapting recommendations from Health in All Policies within national and supranational government policy agendas. At the micro or local level, numerous initiatives tackle proximal lifestyle issues. At the local level, the practice of carrying out systematic health impact assessments on new infrastructure development projects has become increasingly frequent. Also at the community and city level, collaborative community organization such as in the supersetting approach has been shown effective.

As a way of summarizing the many topics the chapter has addressed, Table 4.2 sets out advantages or contributions each of the approaches can make toward diabetes prevention and management.

Table 4.2 Examples of application to diabetes prevention and management of multilevel, multi-sectoral interventions

Peer support	A major approach to dissemination of the Diabetes Prevention Program in the United States is group-based, implemented by trained nonprofessionals [221] Substantial evidence for benefits of group, individual, and dyad-based peer support in diabetes management [81]
Community organization	Kerala Diabetes Prevention Program [142] in rural communities in India utilized community engagement in program development and implementation and replicated results of major diabetes prevention programs [143–145] while reducing CVD risk
Health in All Policies	Urban, agricultural, housing, economic, transportation, and business policies of local, regional, national, and international governments all influence activity levels, diet, stress and emotional well-being, as well as access to care and adherence to preventive and treatment regimens for diabetes and other chronic diseases
Multi-sector, multilevel engagement	The global prevalence and burdens of diabetes in terms of health impacts, complications, quality of life, and costs of care of the disease and its many complications all justify engagement of all sectors of society and government in prevention and improving its treatment

Concluding Thoughts

In contrast to old oppositions of nature versus nurture, genetics versus environment, or biology versus psychology, twenty-first century science is clear that causes of health, illness, and well-being are complex, multidimensional, and interactive. Those with serious diseases need good medical care, but it is also clear that economics, policies, environments, organizational and social factors, personality, and a host of other contextual features play major roles in the etiology of health problems, their prevention, and their management. Moreover, despite frequent pessimism as to population trends in health, a broad range of community, health education, and health promotion approaches addressing community, policy, economic, social, and personal factors can be successful in reducing populations' health problems, such as with cigarette smoking in the United States [1, 138] or cardiovascular disease in Finland [113–115].

At least since Villermé's writings of the nineteenth century, e.g. [219], we have known that the places we live in are not equal as regards health, well-being, and indeed death. Here we have emphasized social, community, and non-health policy over clinical care. In line with Health in All Policies, it will become more and more necessary for government, policymakers, and indeed stakeholders to accept that all these segments have important parts to play in making the world a healthier and safer place. Such a realization however is also linked to our values and views on the sources of inequity and health. It is clear that inequity is a major source of poor health and disease. It is also abundantly clear from the evidence we have at our disposal that the social, community, and non-health sectors could have a substantial role in righting such inequities. In the field of environmental health, a sea change has occurred through the recognition that we all live in the same world with finite resources, and this has opened the way for greater sustainable development and more friendly environmental policy. We believe it will be necessary for a comparable change of representations to occur accepting that the health and welfare of individuals are deeply tied to the circumstances and environments in which they work, live, and play.

The time has perhaps come when it will become habitual to think of people being embedded in sociocultural and economic contexts with habitual practices rather than as decontextualized individuals within statistical populations with free choice of behaviors and free choice of dwelling and neighborhood [220]. Once this way of thinking has become normative, then the determining role of the social, community, and non-health sectors and the necessity for different sectors and the health sector itself to work together will be very apparent. Furthermore the idea that insalubrious, rundown, unhealthy, unsafe, non-accessible, or segregated environments are acceptable will become unthinkable, a thing from the past.

Multiple-Choice Questions

1. Reduction in income, education, and socioeconomic status is associated with:
   (a) Improved health and decreases in mortality and morbidity
   (b) No changes in health, mortality, and morbidity
   (c) Better health and increases in mortality and morbidity
   (d) Worse health and increases in mortality and morbidity
   (e) Worse health and decreases in mortality and morbidity
2. Social determinants of health:
   (a) Are irrelevant in the development of health risks
   (b) Play key roles in the development of health risks
   (c) Can be corrected with the use of new medications
   (d) Are important, but only secondary to genetic traits
   (e) Are irrelevant in the paths of infectious disease transmission
3. Epimutations refer to:
   (a) The relationship between rearing and the adult stress response
   (b) Abnormalities resulting from environmental factors
   (c) Acute changes in DNA methylation

(d) Prenatal disorders of genetic development
(e) Major causes of stillbirth

4. Socioeconomic and social factors:
   (a) Are irrelevant to CVD risk
   (b) Probably are related to CVD risk, but it has not been documented
   (c) Influence the pathways from the serotonin transporter gene to CVD risk
   (d) Are the leading contributors of CVD risk
   (e) Are not influential for health status at all
5. Resources and supports for self-management that people with diabetes need to manage their disease in daily life include all of the following except:
   (a) Continuity of quality clinical care
   (b) Individualized assessment
   (c) Collaborative goal-setting
   (d) Community resources
   (e) Access to the latest, most-expensive medications
6. Sustaining diabetes self-management:
   (a) Is secondary to the level of professional expertise of health providers
   (b) Is a component of key importance in the ecological approach
   (c) Is not important because intervention studies include follow-up of 1–3 years
   (d) Is based on a 1-week admission to a specialized diabetes center
   (e) Has negative consequences in physician-patient relationship
7. Diabetes self-management support:
   (a) Is exactly the same as self-management education
   (b) Is exclusively provided by specialists in the medical office
   (c) Is provided by other patients with expertise
   (d) Is the ability to assist the individual to implement and sustain ongoing behaviors needed to manage their illness
   (e) Is unnecessary in diabetes management
8. The best predictor of changes in blood glucose control:
   (a) Medical expertise
   (b) Number and cost of medications
   (c) Absolute compliance with doctor's orders
   (d) Length of time over which interventions are maintained by patients
   (e) Self-monitoring of blood glucose
9. The most important characteristic of type 2 diabetes and self-management:
   (a) It is "for the rest of your life."
   (b) It is impossible to achieve.
   (c) It has to comply with protocols of randomized controlled trials.
   (d) It is feasible for all patients.
   (e) It is totally dependent on new technologies.
10. Patients rely on peers:
    (a) To understand the pathophysiology of diabetes
    (b) To learn how to best comply with doctor's orders
    (c) To gain confidence to implement a plan of action
    (d) To understand what is important and set priorities
    (e) To endure the increasing burden of suffering

Correct Answers

1. (d) Worse health and increases in mortality and morbidity
2. (b) Play key roles in the development of health risks
3. (a) The relationship between rearing and the adult stress response
4. (c) Influence the pathways from the serotonin transporter gene to CVD risk
5. (e) Access to the latest, most-expensive medications
6. (b) Is a component of key importance in the ecological approach
7. (d) Is the ability to assist the individual to implement and sustain ongoing behaviors needed to manage their illness
8. (d) Length of time over which interventions are maintained by patients
9. (a) It is "for the rest of your life."
10. (d) To understand what is important and set priorities

Acknowledgments We wish to thank especially our colleagues with whom we have previously written on these subjects and who have greatly influenced our thinking regarding them Timothy Daaleman, D.O.; Cyrille Harpet, Ph.D.; Zoe Heritage, Ph.D.; Sarah Kowitt, Ph.D.; Hairong Nan, M.D.; Yao Patrick Tang, M.P.H.; and Xuefeng Zhong, M.D., Dr.P.H.

Preparation of this chapter has been supported by the Michigan-UNC Peer Support Research Core of the Michigan Center for Diabetes Translational Research (P30DK092926 from the National Institute of Diabetes and Digestive and Kidney Diseases, PI: William Herman) and by funding from the Healthcare Foundation of New Jersey, the Merck Foundation, Novo Nordisk, and Sanofi China.

Social Determinants of Health and Diabetes Outcomes

5

Hideki Hashimoto

Introduction

Throughout this textbook, the disease burden of diabetes is taken as a major threat to global health [1, 2]. Understanding of the biomedical mechanisms of diabetes, such as insulin resistance and beta cell dysfunction, has dramatically deepened in the past few decades [3], and new pharmaceutical strategies (e.g., DPP-4 inhibitors) have been developed to better counter the disease. Despite all of the advancements in technology and science, however, diabetes remains a social challenge because the process and consequence of the disease's development are rooted in the very context of human behavior and life experiences. Indeed, accumulated evidence has confirmed that the burden of the disease is distributed unequally across populations and countries [4], as this chapter will review. This chapter aims to introduce readers to the concept of the "social determinants of diabetes" and to articulate the significance of this concept for policy discussions about confronting the social challenge of diabetes.

The following section presents a short review of the existing evidence regarding the societal distribution of diabetes morbidity and mortality. In the third section, theoretical frames relevant to explaining the societal distribution of the disease, including the concept of the "social determinants of health," are introduced. This section also articulates the negative impact caused by social stigma to the patients with diabetes that may interfere with effective self-care and treatment of diabetes. The fourth section discusses how the social determinants of diabetes could be translated into policy interventions to address the disparity in the burden of diabetes across populations, and the chapter concludes with some policy and research implications of the social determinants of diabetes.

This chapter focuses mainly on type 2 diabetes mellitus (T2DM), although different effects for type 1 diabetes have also been observed in terms of mortality, morbidity, and access/adherence to high-quality diabetes care among people with different socioeconomic conditions reflected in occupational class, educational attainment, and income levels [5]. The mechanism through which type 1 diabetes affects people with lower socioeconomic positions more seriously remains open to academic and clinical debate, and whether the mechanism of the disparity is distinct from that of T2DM is unclear. Although access to quality health care is suspected to contribute, some have argued that the "opportunity costs" of properly conducting self-care management, in terms of psychological, economic (including time), and social costs, may be higher for those with lower socioeconomic positions, and this likely prohibits them from effectively protecting their own health. We return to this point later in the chapter.

Social Disparity in the Diabetes Burden

A large body of evidence has been accumulated on the unequal distribution of the incidence, comorbidity, and mortality of T2DM among people, depending on income level, occupational class, educational attainment, gender, race/ethnicity, and the economic development stage of the country where they live [4]. Of these factors, socioeconomic position, measured as household income, occupational class, educational attainment, or the combination of these attributes, has been the most widely studied in terms of its association with diabetes outcomes. In general, diabetes incidence, or the population rate of new development of diabetes, is consistently reported to be higher among those with lower socioeconomic positions in developed countries, and limited empirical findings indicate that this is possibly also the case in middle-low-income countries [6].

However, the association may vary by gender. A study using data from a European cross-country panel survey of the aged population showed no consistent association between diabetes incidence and education among men, whereas a significant and negative association between these variables among women remained even after adjusting

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_5

for body mass index and lifestyle-related behaviors such as physical activity [7]. Another cross-country study of existing cohorts in European countries found a consistently higher diabetes incidence rate in subgroups with lower education for both genders; this effect remained significant but was substantially attenuated by including body mass index in the model [8]. A study using data from the Canadian Community Health Survey also found an education gradient in diabetes incidence that was clearer among women than among men and was partially explained by body mass index [9]. A nationally representative study using the US National Health and Nutrition Examination Survey also showed a stronger relationship between diabetes incidence and education among women than among men [10]. An exceptional result was reported for a recent Chinese population-based survey: This study revealed a negative relationship between diabetes incidence and education among men, but not among women [11].

As for diabetes mortality, a US study showed that lower income and lower education were related to higher diabetes-related mortality [12]. In a similar vein, a number of studies in developed countries have shown that lower socioeconomic position was related to a higher chance of diabetes-related comorbidities (e.g., retinopathy and nephropathy), even among patients with diabetes [13–15].

Turning to diabetes prevalence or the proportion of current patients with diabetes among the general population, several studies in middle-low-income countries have demonstrated that subpopulations with higher socioeconomic positions have a higher prevalence of diabetes [16, 17], whereas reports from high-income countries consistently show that diabetes prevalence is higher among those with lower socioeconomic status [7, 18, 19]. In Ghana, the associations of diabetes prevalence with socioeconomic positions have been found to differ between urban and rural regions [20, 21].

Mixed results for diabetes prevalence by socioeconomic position could be explained by the associations of socioeconomic position with diabetes incidence and mortality varying across regions and countries by level of economic development. Where the higher incidence of diabetes among those in lower socioeconomic positions has been overwhelmed by the higher mortality of diabetes in that stratum, it may lead to a lower diabetes prevalence among those in lower socioeconomic positions. If the disparity in mortality by socioeconomic position is compensated for by access to diabetes care and the survivorship of patients in lower socioeconomic positions is relatively improved, it may result in a higher prevalence of diabetes among those in lower socioeconomic positions, simply reflecting the higher incidence of the disease among that subpopulation.

A series of recent studies has focused on socioeconomic conditions in early life. A review of ten existing studies indicated that experiencing low socioeconomic conditions during early childhood was related to current diabetes morbidity, though the association varied by gender and conditional adult risk factors (e.g., obesity) [21]. Very few studies have shown a protective effect of low childhood socioeconomic position on adult diabetes status (ibd).

More recently, a US-based cohort study reported that early socioeconomic position predicted current diabetes (measured as blood glucose and HbA1c), and the association was significantly mediated by current waist circumference, physical activity, and depressive symptoms [22]. Along the same lines, a population-based study in the Netherlands found self-reported economic difficulties during childhood and parental educational attainment to be significantly associated with current diabetes status, although these associations were attenuated after adjustment for current socioeconomic conditions [23]. Taken together, these results imply that early socioeconomic hardship may increase the risk of diabetes-related risk factors in adulthood, indicating the significance of life-course trajectories and critical windows during childhood for the later onset of diabetes in adulthood.

Some studies have even explored the association of child abuse experience with diabetes outcomes in adulthood. A study using data from the Canadian Community Health Survey showed that the experience of childhood abuse was related to self-reported diabetes status and the association was substantially mediated by diabetes risk factors such as obesity and smoking [24]. Similar findings were obtained in the US Nurses' Health Study, in which the participants were registered nurses and were therefore relatively homogenous in their current socioeconomic position. Despite the relatively higher and homogenous educational attainment of the study participants, adverse experience during childhood showed a significant impact on diabetes incidence [25].

These observational studies indicate that development, disease control, and subsequent prognosis of diabetes are highly dependent on the social context in which people are situated throughout their lives.

Supposed Mechanism of Social Disparity in Diabetes

Individual risk factors for diabetes are related to lifestyle behaviors (e.g., obesity and physical activity), and the control of diabetes requires the healthy modification of these behaviors. Indeed, observed socioeconomic disparities in diabetes incidence, morbidity, and mortality were substantially explained by socioeconomic differences in lifestyle behaviors—especially obesity [6, 26]. However, this does not yet explain why such differences in lifestyle behaviors by

socioeconomic position and gender occur at all or how they are translated into disparities in the burden of diabetes.

Brown et al. proposed a model to help us comprehend the complex mechanism of diabetes development within a social context. In this model, lifestyle behaviors, access to care, and the process of care are set as proximal causes that link socioeconomic conditions and diabetes outcomes [27]. Brown et al. further advocated the inclusion of individual's health literacy, psychological stress, demands competing with self-care activities (e.g., time constraints), and availability of social support as mediating factors linking socioeconomic conditions to lifestyle behavioral choices and effective negotiation with health-care professionals for diabetes care. In addition, environmental factors such as the local availability of healthy food, walkability, and safety may also influence whether people make healthier behavioral choices. However, the most recent review on T2DM and environmental risk factors [28] and other related review articles on obesity [29] and nutrition [30] have concluded that, although the built environment (e.g., food access, walkability, and crime) is potentially associated with the chance of diabetes and related risk factors, the strength of the evidence for these associations is currently limited because of heterogeneity in measurement and study design, precluding comparison across studies.

Another conceptual model and literature review criticized the existing literature on socioeconomic conditions and diabetes outcomes for focusing too much on individual-level factors, such as behaviors and literacy, and emphasized the significance of the larger social context, such as family, health-care system, and society as a whole, which shapes an individual's likelihood of engaging in diabetes-related risk behaviors [31].

As seen earlier in this chapter, several studies have indicated that socioeconomic conditions affect the access to and the process quality of diabetes care [13–15]. Notably, the majority of these reports have been from countries with universal public health insurance coverage, suggesting that universal health insurance coverage may not be enough to close the socioeconomic gap in diabetes outcomes. Indeed, a study using the UK-based cohort of the Whitehall II study found that universal health insurance coverage may not be enough [26]. Among civil servants in the United Kingdom, this study found that the socioeconomic gradients in diabetes-related morbidity and mortality were substantially mediated by cardiovascular risk factors such as blood pressure and smoking. Most striking was the finding that such socioeconomic gradients in diabetes outcomes were found even among civil servants, who had relatively good job security, and even in the United Kingdom, where public health care is widely available without copayment.

Social relationships in the family and community are powerful structures that influence the distribution of obesity in society [32]. Social networks are supposed to provide a norm about obesity, psychological support, conflict-influencing behaviors, and/or social selection processes where "birds of a feather flock together" [33].

Recent studies have focused on the social influence of the stigma faced by patients with diabetes [33–37]. Patients with diabetes are often stereotyped as lazy and undisciplined, and they are blamed as responsible for their own diabetes condition. Prevailing social stigma, even among health-care professionals, causes psychological and social isolation and excludes patients with diabetes from social participation and effective self-care management.

Culture is another aspect of the social context that hinders effective communication and shared decisionmaking between patients with diabetes and health-care professionals. Although studies focusing specifically on cultural aspects of patients with diabetes are scarce, the existing literature suggests that cultural norms about the body, food, and physical activity influence people's lifestyle-related choices [27].

In addition to macro-social mechanisms, biological mechanisms also need to be understood to see the whole picture of how social context gets "under the skin." The most influential biological mechanism is the intrauterine programming and thrifty phenotype hypothesis (also known as the Barker hypothesis) [38]. This hypothesis views exposure to low nutrient intake during the fetal stage as causing adaptation for survival, which, in turn, causes diabetes in adulthood when the nutritional environment becomes richer. Several epidemiological studies support the idea in that those who experienced poor nutrition during early life have higher risks of obesity, insulin resistance, and diabetes [39–41]. Recent epigenetic research has further investigated how the early environment becomes inscribed on the epigenome as "metabolic memory" that reveals itself later in life as metabolic dysfunction [42].

Another series of studies has suggested a possible role of chronic inflammation. A UK-based longitudinal survey revealed that about 50% of the excess risk of T2DM incidence associated with low socioeconomic position was explained by lifestyle behaviors, whereas a quarter of this excess risk was explained by chronic inflammation markers such as C-reactive protein and interleukin-6 [43, 44]. The role of chronic inflammation may indicate a biological mechanism that translates social stress related to low socioeconomic position into a pathological path leading to insulin resistance and beta cell dysfunction.

As we have reviewed so far, no single theory can tell the whole story about how social context gets "under the skin" and results in differential diabetes outcomes. This is why two larger frameworks are needed to comprehend diabetes as a social challenge—namely, the ecological perspective and the life-course perspective.

The ecological perspective regards individuals as nested within families, which are further nested within communities, which are further nested within larger social contexts, such as states. All of these levels (individual–family–community–society) interact with each other. For example, an individual's behavioral choices may be enhanced if he/she has a supportive relationship with his/her family and community. A supportive relationship is more likely to be available if the community environment is safe and has relatively less deprivation—factors that will be further determined by a nation's economy and social policies.

The life-course perspective examines the sequence of life stages from the fetal period to childhood, adolescence, young adulthood, midlife, and later stages of life. Each stage exhibits a unique window, with specific vulnerabilities to biological, behavioral, and psychosocial risk factors for chronic disease, and the impact in a certain stage will echo in the later stages [45]. For example, life difficulties in early stages affect an individual's chances of getting diabetes in later life through biological programming, reduced opportunities to nurture health literacy, and smaller changes of obtaining a secure job and income, which will further impede access to necessary health-care resources.

Bridging the ecological and life-course perspectives is the concept of the "social determinants of health." This concept sees health as determined not only by medical systems but also by daily life conditions where people are born, live, learn, and work [46]. The concept of the social determinants of health can be applied to diabetes. As the above review shows, to achieve equity in diabetes outcomes, it is important—but not sufficient—to provide equal access to quality health care. The social determinants of health concept indicates that changes should be made in the root cause of the biological, behavioral, psychosocial, and socioeconomic causes of health gaps (ibid; Figures A and B). For this purpose, the social determinants of health concept require interventions that are multilevel, multi-domain, and longitudinal.

Health-care sectors are important, but it is not only institutes that enable a reduction in the health gap. For example, a study from Scotland based on a nationwide clinical database reported that diabetes incidence declined from 2004 to 2013 in all socioeconomic strata except the lowest decile—the most deprived group. This group showed a resurgence in diabetes incidence beginning in 2010, after the global economic shock, resulting in widening socioeconomic disparity in diabetes incidence, especially among women [47]. Apparently, macroeconomic policy is a strong social structural determinant of health. Attention to the social determinants of health calls for inter-sectorial collaboration across health, finance, labor and industry, education, civil engineering, and other sectors in government and global institutes [46].

Social Determinants of Diabetes Interventions to Close the Social Gap in Diabetes Outcomes

What can be done to close the social gap in diabetes outcomes? Good quality of diabetes care should be available to all, regardless of socioeconomic status, ethnicity/race, or gender. The introduction of universal health coverage is a high priority policy for closing the gap [1, 2]. However, this is not sufficient; quality care availability may help to close the gap in diabetes mortality, but it will do little to prevent a gap in diabetes morbidity and, especially, incidence.

Lifestyle and related behaviors are strong risk factors for diabetes outcomes, and the provision of information through community education to support people in making healthier choices is promising. Indeed, a large randomized clinical trial showed intensive health education will have a significant preventive impact on diabetes incidence, if the intervention is properly prepared [48]. However, a longer follow-up of the same randomized clinical trial revealed that the difference originally observed between the treatment and control groups gradually declined over time [49]. This decline was not simply because the program effectiveness attenuated over time after the intervention ended; rather, it was because behavioral change among the control group caught up with that of the treatment group patients over time, suggesting that factors other than the educational program influenced behaviors among patients with prediabetes afterward. Social changes in the norms about healthy diet and habitual exercise, improvements in access to supportive information, and environments facilitating the maintenance of behavioral modifications are the suspected explanation. This supports the idea that behavioral choices are not completely volitional; instead, behaviors are influenced by social, economic, cultural, and other structures. Creating supportive environments for behavioral modification toward healthier lifestyles is promising. However, existing reviews on the effectiveness of policy interventions such as the development of walkable cities and improving access to heathier food in the community concluded that the current evidence is mixed and further research on the effectiveness of environmental architecture and other interventions on the social determinants of diabetes is required [28, 29, 31].

Among the possible policy interventions, accumulating evidence has begun to show that sugar taxes, or the taxation of sugar-sweetened beverages, are a promising policy on obesity prevention [50]. The sugar tax and the subsequent price increase of sugar-sweetened beverages are expected to provide disincentives for consumers' purchasing decisions. By nature, this intervention is regressive: The disincentives have a stronger influence on the poor, who have lower income, suggesting that the impact of the sugar tax on obesity prevention should be largest among the poor, who are also at higher

risk of obesity. Currently, the policy has already been introduced in several countries, including Mexico, where the consumption of sugar-sweetened beverages has been considered a major target for reducing caloric intake for obesity prevention, especially among children and poor adults. In April 2014, the Mexican government enacted a policy to incur a 1 peso-per-liter excise tax on all sugar-sweetened beverages. This has resulted in a reduction in the consumption of sugar-sweetened beverages, and, as expected, the impact was observed to be larger among low-income households than among high-income households [51, 52]. More recent studies using simulation models have suggested that the impact of this policy on reducing consumption will result in a considerable reduction in obesity and related diabetes incidence [53]. Although the Mexican case seems to have been highly successful, the introduction of taxes for health promotion is not always effective or politically feasible [54, 55]. Additionally, because of the regressive nature of this type of policy, such a "sin tax" for health promotion should be accompanied by alternative, healthy choices at affordable prices for the poor.

Despite its challenges, the sugar tax provides a good example of the "proportional universalism" approach or the universal inclusion of people in health promotion, with resource allocation proportional to needs or risks [56]. As we argued earlier, patients with diabetes are vulnerable to social stigma, and high-risk approaches that target people with high diabetes risks (e.g., targeted educational interventions for patients with prediabetes) often induce discrimination and subsequent social exclusion among targeted vulnerable people. Instead, universalism approach will provide a wider range of community people with the opportunity for self-management of their own health without selection. In addition to offering community campaigns to reduce social stigma by providing precise information on the etiology and control of diabetes, health-care professionals should be aware of the significance of structural interventions for changing the social environment to help people achieve healthier lifestyles in a socially inclusive manner (Figs. 5.1, 5.2, and 5.3).

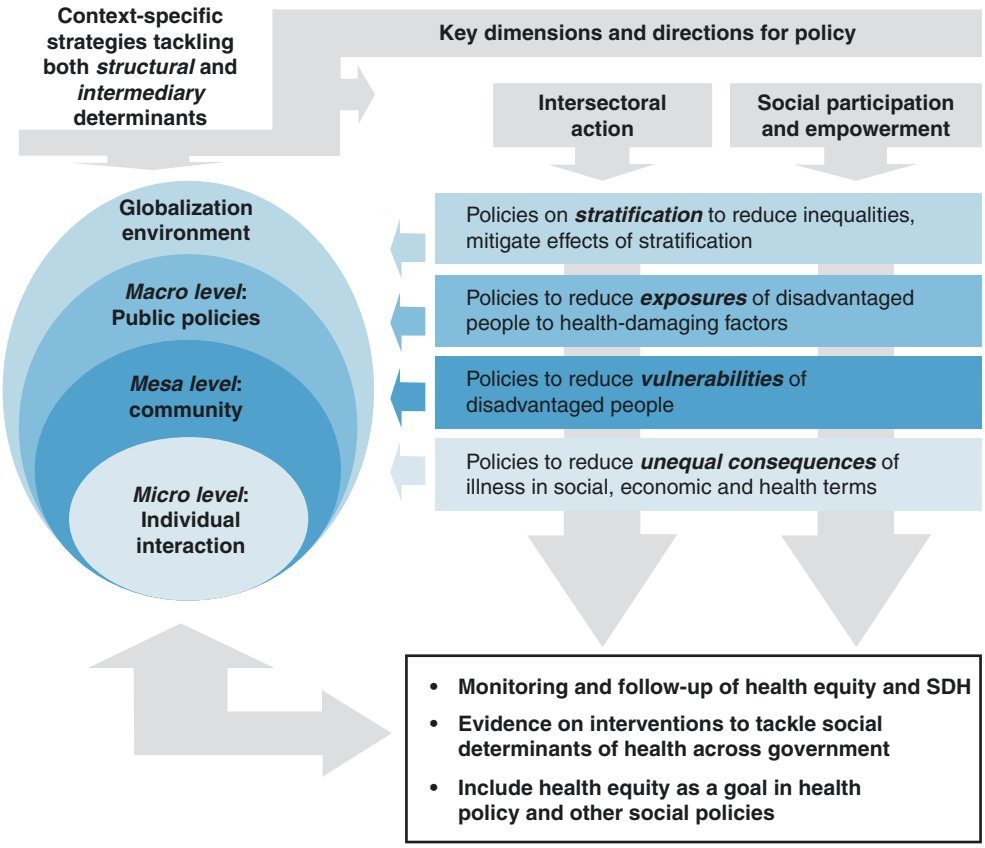

Fig. 5.3 Levels of policy to address social determinants of health. (Source: World Health Organization (2010a), Conceptual Framework of Social Determinants of Health, Paper 2, Figure B, p. 8)

Conclusion

Epidemiological and clinical studies have convincingly demonstrated that the disease burden of diabetes is disproportionally distributed across society because the incidence, mortality, and morbidity of diabetes are influenced by the socioeconomic and environmental determinants of diabetes. Lifestyle behaviors such as diet and exercise are significant factors in diabetes control, and they are shaped not only by individual capacity but also by the social environment surrounding individuals. Interventions to improve diabetes control among selective high-risk groups through lifestyle modification have been shown to be effective. However, this selective approach may run the risk of inducing social stigma toward people with high diabetes risk, which may seriously hinder effective self-care. As an alternative, the proportionate universalism approach, putting forward structural interventions to change the social environmental determinants of diabetes, is promising, although it will require further research and policy evaluation to effectively translate the concept into action, helping people to overcome the social challenges of diabetes.

Multiple-Choice Questions

1. Which of the following statements best fits the concept of the social determinants of diabetes? (Choose one that fits best.)
   (a) Patients' rights to quality of diabetes care should be addressed.
   (b) Patients are responsible for modifying their lifestyles to improve diabetes control.
   (c) The government health sector should provide community education to improve knowledge about diabetes risks.
   (d) All social, economic, and health policies related to people's life-course experiences should be considered in terms of their potential leverage to close the gap among people in the diabetes burden.
   (e) None of the above.
2. What determines the prevalence of diabetes? (Choose one.)
   (a) Genomic predisposition
   (b) Local availability of healthy food
   (c) Education
   (d) Motorization (transportation by car driving)
   (e) All of the above

3. Which subpopulation is more vulnerable to diabetes incidence? (Choose one.)
   (a) Richer men
   (b) Poorer men
   (c) Richer women
   (d) Poorer women
   (e) This depends on the local stage of economic and social development.
4. Which of the following options describes a policy intervention that is in the frame of the social determinants of diabetes? (Choose all correct responses.)
   (a) Research and development of genetic treatments for diabetes
   (b) Patient education to improve adherence to diabetes care regimens
   (c) Introduction of a sugar tax
   (d) Improvement of health literacy among community dwellers
   (e) Civil engineering to design a walkable city
5. Why is the incidence of diabetes higher among people with lower socioeconomic status in low-middle-income countries as well as in high-income countries? (Choose all correct responses.)
   (a) Limited availability of healthy food
   (b) Limited affordability of resources to sustain healthy lifestyles
   (c) Lower health literacy to support heathy lifestyles
   (d) Early life experience with deprivation and the related physical manifestations
   (e) Social influence of close peers with poor diets and prevalent smoking
6. Which of the following statements fits the ecological model of health and diabetes? (Choose one.)
   (a) An individual's dietary habits are influenced by family and close friends.
   (b) Walking habits are facilitated if the community is safe and walkable.
   (c) Healthy diets are discouraged if the availability of fresh vegetables is limited in the community.
   (d) The national economy affects an individual's chances of having suitable resources to protect their own health.
   (e) All of the above.
7. How does the social stigma of patients with diabetes affect their self-management of the disease? (Choose one.)
   (a) Social stigma blames patients with diabetes, considering them responsible for their own disease.
   (b) Social stigma socially excludes patients with diabetes from necessary social support.
   (c) Social stigma discourages self-esteem and self-efficacy related to self-management among patients with diabetes.
   (d) Patients with diabetes are forced to conceal their diabetes status in public because of fear of stigmatization.
   (e) All of the above.
8. Which of the following options best fits the concept of the "proportionate universalism" approach to tackling social disparity in the diabetes burden?
   (a) Screening for obesity to provide publicly subsidized education programs for behavioral modification
   (b) Targeting people with low incomes or low educational attainment to provide free vouchers for fresh and healthy food
   (c) The introduction of a sugar tax on sweetened beverages to reduce the sugar intake in the general population
   (d) Free provision of diabetes care for people living in targeted communities, with means testing
   (e) All of the above
9. What are the strengths and weaknesses of the population approach compared with the high-risk approach? (Discuss.)

Correct Answers

1. (d) All social, economic, and health policies related to people's life-course experiences should be considered in terms of their potential leverage to close the gap among people in the diabetes burden.
2. (e) All of the above
3. (e) This depends on the local stage of economic and social development.
4. (c, d, and e)
5. Correct answers were all (a, b, c, d, and e)
6. (e) All of the above.
7. (e) All of the above
8. (c)

Objectives of the Chapter

- The aim of this chapter is to delineate the definition of diabetes mellitus and its diagnostic criteria. Following a brief discussion on evolution of the current diagnostic criteria, the recent ADA criteria and recommendations for screening will be discussed.
- The section on the diagnostic criteria for gestational diabetes compares and contrasts the various criteria recommended by different professional bodies and their merits. This section will also discuss the utility and fallacies of HbA1C as a measure of glycemic status.
- The section on classification of diabetes lists the various aetiologies of diabetes mellitus based on the pathophysiology or common mechanisms for better understanding. Few subsections like "endocrinopathies" and "drugs causing diabetes" are discussed in brief.

Definition

The word diabetes is derived from its Greek root which means "to pass through," referring to polyuria – the hallmark symptom of diabetes mellitus (DM). The word mellitus means "from honey," denoting glycosuria, differentiating it from its close mimic, diabetes insipidus [1].

DM is defined by the World Health Organization (WHO) as a metabolic syndrome characterized by chronic hyperglycemia resulting from any of the several conditions that cause defective insulin secretion and/or action. Prediabetes is a state characterized by metabolic abnormalities that increases the risk of developing DM and its complications.

Diagnostic Criteria

The diagnostic criterion for DM has undergone a sea change over the last several decades with improved understanding of its pathophysiology and complications. Though the association between chronic hyperglycemia and its complications is well established, the specific cutoff points for diagnosing DM still remain a matter of intense debate.

The WHO, in the year 1965, published the first guidelines for diagnosing DM [2]. The National Diabetes Data Group (NDDG) proposed a criterion based on the observation of bimodal distribution of plasma glucose (PG) in Pima Indians and Nauruan populations and the risk of progression to DM and development of complications. The NDDG also recognized an intermediate group of individuals with raised PG above normal, but not satisfying the criterion for diagnosing DM. This group faced a risk of progression to DM at the rate of 1–5% annually and also had higher prevalence of atherosclerotic disease. The terminology "impaired glucose tolerance (IGT)" was introduced to identify this important group of persons in whom early intervention could avert DM and its complications [3].

The subsequent modifications of the diagnostic criteria by WHO saw revision of the fasting and 2-h post glucose load venous PG thresholds to 7.8 mmol/L and 11.1 mmol/L, respectively, based on the observations that complications of DM rarely occurred below these PG levels.

In 2003, the American Diabetes Association (ADA) made a controversial change to its existing guideline by reducing the cutoff point for defining the upper limit fasting plasma glucose (FPG). This modification was based on data from four population-based epidemiological studies which showed that the ideal FPG cutoff point fell between 5.22 and 5.72 mmol/L and the cutoff of 5.55 mmol/L was arbitrarily chosen [4].

Glycated hemoglobin (HbA1c) was included as a modality to diagnose DM by the ADA in 2010 and the WHO in 2011.

The latest ADA criteria for diagnosing DM are given below: in asymptomatic individuals, these tests need to be repeated on another day for confirmation of diagnosis [5].

- FPG ≥ 7.0 mmol/L. Fasting is defined as no caloric intake for at least 8 h.
  or
- 2-hour PG ≥ 11.1 mmol/L during an oral glucose tolerance test (OGTT). The test should be performed as described by the WHO, using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.
  or
- HbA1c ≥6.5% (48 mmol/mol). The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP) certified and standardized to the Diabetes Control and Complications Trial (DCCT) assay.
  or
- In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random PG ≥ 11.1 mmol/L.

ADA Criteria for Diagnosis of Prediabetes

In addition to fasting and post glucose load PG levels, HbA1c is also recommended as a screening test for prediabetes.

The cutoff points recommended for the diagnosis of prediabetes are given below:

(a) FPG – 5.6 to 6.9 mmol/L [impaired fasting glucose (IFG)]
(b) 2-hour PG in the 75-g OGTT – (7.8 to 11.0 mmol/L) (IGT)
(c) HbA1c 5.7% (39 mmol/mol)

Criteria for Screening for Diabetes or Prediabetes in Asymptomatic Adults

The ADA 2017 guidelines have laid down certain risk factors for screening for diabetes and prediabetes. These include:

1. Overweight or obese (BMI ≥ 25 kg/m^2 or ≥23 kg/m^2 in Asian Americans) adults who have one or more of the following risk factors:
   - HbA1c > 5.7% (39 mmol/mol), IGT, or IFG on previous testing
   - First-degree relative with diabetes
   - High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
   - Women who were diagnosed with gestational diabetes mellitus (GDM)
   - History of cardiovascular disease
   - Hypertension (≥140/90 mmHg or on therapy for hypertension)
   - High-density lipoprotein cholesterol level ˂0.90 mmol/L and/or a triglyceride level ≥ 2.82 mmol/L
   - Women with polycystic ovary syndrome
   - Physical inactivity
   - Other clinical conditions associated with insulin resistance, e.g., severe obesity and acanthosis nigricans
2. For all patients, testing should begin at age 45 years.
3. If results are normal, testing should be repeated at a minimum of 3-year intervals, with consideration of more frequent testing depending on initial results (e.g., those with prediabetes should be tested yearly) and risk status.

Screening for Prediabetes and Diabetes

Prediabetes is an intermediate state of hyperglycemia characterized by elevated PG levels above normal though not qualifying for the diagnosis of DM. Its significance lies in the fact that 5–10% of patients can progress to develop DM annually without intervention [6, 7]. The dreaded complications of DM are also observed in this group of patients, stressing the need for early recognition and reversal of this state.

According to the WHO, prediabetes constitutes two distinct entities, namely, IFG and IGT. Different pathogenic mechanisms are believed to underlie these two distinct entities, and persons with a combination of both the abnormalities have more advanced metabolic abnormalities than those with either of the two. Similar to the increasing prevalence of DM globally, the prevalence of prediabetes is also expected to rise with an estimated 472 million people to be affected by this condition by the year 2030 [8]. Although a significant proportion of people progress to develop DM, several remain static and many go on to revert to normal state, although the rate of conversion has been reported to be different in various studies [7, 9].

It is well recognized that beta cell dysfunction and insulin resistance are already present in patients at the time of detection of prediabetes [10, 11]. It thus represents a phase in the continuum of worsening beta cell dysfunction and insulin resistance. Insulin resistance is a feature of both IFG and IGT, though the site of resistance varies. IFG is characterized by hepatic insulin resistance, while in IGT, resistance is mainly at the level of skeletal muscles. The beta cell dysfunction is however seen in both [10, 12]. This difference in the pathophysiology is reflected in the PG changes following a glucose load with persons with IFG demonstrating impaired early response in contrast to those with IGT who show impairment of both early and late phases of insulin secretion [12–14].

The ADA recommends screening for DM and prediabetes in asymptomatic people in those who are obese or overweight and have one or more additional risk factors as listed above. For all others, testing should begin at 45 years of age, and repeat testing in those with normal results is to be done at a minimum interval of 3–5 years [5].

Diagnostic Methods

Glycated Hemoglobin

With sustained exposure to hyperglycemia, proteins undergo nonenzymatic glycation. Hemoglobin A (HbA), the predominant fraction of hemoglobin in normal adults, also undergoes a similar modification. Three minor fractions of glycosylated hemoglobin are known to occur, namely, HbA1a, HbA1b, and HbA1c, based on their elution properties during electrophoresis. The HbA1c fraction that has been widely employed as a diagnostic test has a hexose moiety attached covalently to the NH2-terminal valine residue of the β-chain of HbA [15]. Several methods have been used to separate this fraction from the nonglycated hemoglobin. These techniques exploit the differences in structure (affinity chromatography and immunoassay), charge (ion-exchange chromatography, high-performance liquid chromatography [HPLC] electrophoresis, and isoelectric focusing), or chemical nature (photometry and spectrophotometry) of the various fractions. HbA1c is a measure of average plasma glucose levels over preceding 3 months [16]. There are several advantages of HbA1c over the measurement of plasma glucose. HbA1c estimation can be done regardless of the time of day or fasting status. It also shows less day-to-day variability and analytical stability [17]. HbA1c also predicts the development of micro- and macrovascular complications of DM as observed in clinical trials like the DCCT and United Kingdom Prospective Diabetes Study (UKPDS). However, it is not free from limitations and can be influenced by other non-glycemic factors (Table 6.1). Diseases affecting red blood cell turnover rate can result in imprecise values.

Table 6.1 Factors affecting HbA1c estimation

Physiological characters	Change expected
Age	HbA_{1c} increases by approximately 0.1% with every 10 years of age – not relevant clinically
Race	Variably reported
Hematological conditions	
Iron deficiency anemia [18, 19]	Falsely elevated in most studies Mechanism – not clear
Hemolytic anemia	Falsely low due to shortened life span of RBCs
Hemoglobin variants (HbF, HbS, HbD, HbE) [20]	Variable based on assay methodology
Analytical interference	
Hyperbilirubinemia	Variably reported interference [20, 21]
Hypertriglyceridemia [20]	Falsely low
Others	
Malaria	Falsely low [22]
Transfusions [23]	Falsely low
Splenectomy	Increases life span of RBC in conditions like hereditary spherocytosis resulting in elevated HbA1c after splenectomy [24]
Renal failure	Falsely low due to shortened erythrocyte life span, frequent blood transfusions, erythropoietin-promoted erythrocytosis, and drug-induced anemia [25]
Alcohol abuse	Falsely low [26]
Aspirin [27]	Modest increase – not clinically relevant

Standardization of HbA1c

The clinical utility of HbA1c largely hinges on the quality of the analytical method used. A plethora of tests are available today for estimating HbA1c. In order to establish uniformity in testing, reporting, and interpreting the HbA1c results, the American Association of Clinical Chemistry (AACC) and the NGSP (National Glycohemoglobin Standardization Program) developed a protocol to standardize the HbA1c test results to those of the DCCT [28].

In 1995, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) sought to establish a true reference method for HbA1c estimation instead of standardizing to a comparison method like the NGSP. Here, hemoglobin is digested using enzymes that cleaves a hexapeptide off the amino terminal of the β-chain. The glycated and nonglycated hexapeptide components are then separated and quantified. HbA1c was calculated as the ratio of two fractions and was reported as a percentage [29]. This method is expensive and laborious making it unsuitable for routine analysis of samples.

Classification of Diabetes Mellitus

It is prudent to try and classify the type of DM in order to identify the best management plan, screen for associated complications and comorbidities, and also screen other members of the family. However, this may not be straightforward in all scenarios. DM can be classified based on the underlying pathogenic mechanisms into the following categories: type 1 DM, type 2 DM, GDM, and secondary DM (Table 6.2) [5, 30].

Table 6.2 Secondary causes of diabetes mellitus

A. Genetic defects of β-cell function
Maturity-onset diabetes of the young (MODY) 3 (HNF-1α)
MODY 1 (HNF-4α)
MODY 2 (glucokinase)
Other rarer forms of MODY
Transient neonatal diabetes
Permanent neonatal diabetes
Mitochondrial DNA
B. Genetic defects in insulin action
Type A insulin resistance
Leprechaunism
Rabson-Mendenhall syndrome
Lipoatrophic diabetes
C. Diseases of the exocrine pancreas
Pancreatitis
Pancreatectomy
Neoplasia
Cystic fibrosis
Hemochromatosis
Fibrocalculous pancreatopathy
D. Endocrinopathies
Acromegaly
Cushing's syndrome
Glucagonoma
Pheochromocytoma
Hyperthyroidism
Somatostatinoma
Aldosteronoma
E. Drug or chemical induced
Glucocorticoids
Thiazides
Statins
Antipsychotic medication
Antiretroviral therapy
Phenytoin
Thyroid hormone
F. Infections
Congenital rubella
Cytomegalovirus
G. Other genetic syndromes
Down syndrome
Klinefelter syndrome
Turner syndrome
Wolfram syndrome
Friedreich ataxia
Huntington chorea

Type 1 Diabetes Mellitus

Type 1 DM is characterized by complete cellular-mediated destruction of the β-cells resulting in insulinopenia and insulin replacement therapy for survival. Majority of patients present with the constitutional symptoms of DM, namely, polyuria, polydipsia, and polyphagia. One third of the patients can present with diabetic ketoacidosis as the first manifestation [31]. The disease is believed to be precipitated by an environmental insult in a genetically predisposed individual. Type 1 DM is known to be strongly associated with human leukocyte antigen (HLA)-DR3-DQ2 and HLA-DR4-DQ8 haplotypes, alone or in combination [32, 33]. Some HLA haplotypes can offer protection from type 1 DM [34]. In addition, several other putative genes like cytotoxic T-lymphocyte-associated antigen 4, protein tyrosine phosphatase, non-receptor type 22, and insulin variable number tandem repeat affecting disease susceptibility have been identified [35]. Autoantibody against islet antigens like glutamic acid decarboxylase 65, insulin, insulinoma-associated antigen 2, and zinc transporter 8 are seen in majority of patients [36, 37]. The number of antibody positivity correlates with the rate of progression of β-cell failure with 70% of children with two or more antibodies progressing to develop DM [38]. In addition to islet cell autoimmunity, these patients are also predisposed to the development of other autoimmune disorders like Hashimoto thyroiditis, Graves' disease, Addison disease, celiac disease, vitiligo, autoimmune hepatitis, myasthenia gravis, and pernicious anemia [5].

A number of environmental triggers have been studied including cow's milk, certain viruses and gut microbiota, although none have been conclusively identified to influence the pathogenesis of type 1 diabetes mellitus [39–43]. A minority of patients with clinical picture consistent with type 1 DM do not have evidence of autoimmunity. This is particularly common in patients of Asian and African ancestry and is not HLA associated [44].

Type 2 Diabetes Mellitus

In contrast to type 1 diabetes, type 2 DM is characterized by relative insulin deficiency due to β-cell dysfunction and resistance to the action of insulin in target tissues. Unlike patients with type 1 DM, patients with type 2 DM at least initially are amenable with oral hypoglycemic agents. Beta-cell loss occurs progressively and can result treatment failure with oral hypoglycemic agents and requirement of insulin for control of hyperglycemia, especially in younger individuals [45]. The global epidemic of type 2 diabetes mellitus parallels that of its prime risk factors - obesity, physical inactivity, and lifestyle modifications. Excessive abdominal adiposity, prior history of GDM, and certain ethnicity (like Asian, African American, Hispanic) are other strong risk factors for developing type 2 DM [5].

Gestational Diabetes Mellitus

GDM has traditionally been defined as any degree of glucose intolerance that is first detected during pregnancy regardless of whether the condition may have predated the pregnancy or persisted after the pregnancy [46]. This definition of GDM, which is based on PG level alone, does not distinguish the underlying pathological process. Hence, this heterogeneous group comprises women with pre-existing insulin resistance and insulin deficiency worsened by deteriorating glucose homeostasis in pregnancy and women with short-term alterations in glucose homeostasis resulting from pregnancy-related physiological changes. Irrespective of the aetiology, the management of these patients remains more or less the same, though women with pregestational diabetes need screening for long-term complications of dysglycemia, which can worsen further as pregnancy progresses [47].

The very first diagnostic criterion for GDM was proposed by O'Sullivan and Mahan in 1964. The authors had suggested a 50 g, 1-h glucose challenge test (GCT) for screening and follow-up of women with a 1-h post glucose load exceeding 140 mg/dl with a confirmatory test. A 100 gram, 3-h OGTT was suggested to confirm the diagnosis. The cutoff levels were validated for the risk of the mother developing diabetes in the future and not for the pregnancy outcomes [48].

This criterion was subsequently modified by the NDDG in the United States and later by Carpenter and Coustan to account for the changes in the methodology of glucose estimation and for using plasma samples instead of whole blood [3]. This modified criterion was widely accepted and endorsed by professional bodies like the ADA and WHO, until the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criterion was proposed, following the results of the pathbreaking hyperglycemia and pregnancy outcomes (HAPO) study. The American College of Obstetricians and Gynecologists (ACOG) still recommends the Carpenter and Coustan criterion [49].

HAPO was a large multinational, multicenter study which included over 23,000 pregnant women of diverse ethnicity. OGTT was administered between 24 and 32 weeks of gestation using 75 g of glucose. A linear relationship was noted between PG levels following OGTT and several primary (umbilical cord-blood C peptide level, birth weight, neonatal hypoglycemia, and rate of cesarean delivery) and secondary outcomes (delivery before 37 weeks of gestation, shoulder dystocia or birth injury, need for intensive neonatal care, hyperbilirubinemia, and preeclampsia). The outcomes were directly related to FPG level and independently to 1-h and 2-h PG values [50].

Based on the results of the HAPO trial, IADPSG suggested a single-step, 75 g OGTT to be performed in all pregnant women at 24–28 weeks of gestation. The defined diagnostic cut points for diagnosing GDM were those levels at which odds for adverse outcomes reached 1.75 times the estimated odds of these outcomes at the mean fasting, 1-h, and 2-h PG levels of the study population. A single value above the suggested cutoff was enough to make a diagnosis of GDM unlike the two-abnormality criteria earlier followed [51].

Universal implementation of the stringent IADPSG criteria is likely to increase the prevalence of GDM as many women with mild GDM are likely to be included. The cost-effectiveness of this approach and its impact on improving maternal and fetal outcome has been questioned. A few studies have however shown that the additional patients diagnosed using the IADPSG criterion when compared to other criteria are at risk for GDM-related complications [52–54]. The IADPSG also recommends diagnostic cutoff values to diagnose GDM in the first trimester. This recommendation was not based on any hard data and was an extrapolation of the results of HAPO study. In 2011, the ADA also adopted the IADPSG criteria.

The NICE in 2015 published its guidelines for diagnosing GDM and had suggested higher FPG cutoff values when compared to that of the IADPSG. The prime reason quoted for choosing higher FPG levels was to reduce the economic burden imposed by the application of lower FPG cutoff on the health-care system. Though this criterion strives to strike

a middle ground, it has not been tested clinically, and its impact on maternal and fetal health will be seen in coming years [55]. The cutoff values for diagnosing GDM using the one-step and two-step strategies according to the ADA are given below [5].

One-Step Strategy

75-g OGTT is recommended with PG measurement when patient is fasting and, at 1 h and 2 h, at 24–28 weeks of gestation in women not previously diagnosed with overt diabetes. The OGTT should be performed in the morning after an overnight fast of at least 8 h. The diagnosis of GDM is made when any of the following plasma glucose values are met or exceeded:

- FPG: 92 mg/dL (5.1 mmol/L)
- 1-hour PG: 180 mg/dL (10.0 mmol/L)
- 2-hour PG: 153 mg/dL (8.5 mmol/L)

Two-Step Strategy

Step 1: Perform a 50-g GCT (non-fasting), with PG measurement at 1 h, at 24–28 weeks of gestation in women not previously diagnosed with overt diabetes. If the PG level measured 1 h after the load is ≥130 mg/dL, ≥135 mg/dL, or ≥140 mg/dL (7.2 mmol/L, 7.5 mmol/L, or 7.8 mmol/L), proceed to a 100-g OGTT. The ACOG recommends either 135 mg/dL (7.5 mmol/L) or 140 mg/dL (7.8 mmol/L).

Step 2: The 100-g OGTT should be performed when the patient is fasting. The diagnosis of GDM is made if at least two of the following four plasma glucose levels (measured at fasting and 1 h, 2 h, 3 h after the OGTT) are met or exceeded:

- FPG: 95 mg/dL (5.3 mmol/L)
- 1-hour PG: 180 mg/dL (10.0 mmol/L)
- 2-hour PG: 155 mg/dL (8.6 mmol/L)
- 3-hour PG: 140 mg/dL (7.8 mmol/L)

Screening for GDM

Recommendations for choosing the target population for GDM screening are shrouded by controversies and lack of uniformity among the existing guidelines. The WHO and ADA recommend universal screening of all pregnant women, while the NICE guidelines recommend a selective screening strategy [55, 56]. The selective screening approach is likely to miss a significant proportion of women who develop GDM in the absence of traditional risk factors [57, 58]. The ADA recommends screening for diabetes in women with risk factors for diabetes at the first prenatal visit using its standard diagnostic criteria. Those who are not known to have diabetes are to be screened at 24–28 weeks of gestation using a one-step or a two-step approach [5].

Screening for Persistent Diabetes After Pregnancy

The majority of women diagnosed with GDM will revert to normalcy in the immediate postpartum period leaving a small proportion with continuing hyperglycemia. The lifetime risk of developing type 2 DM is as high as 50–70% [59]. The immediate postnatal period provides a window of opportunity to identify this precarious cohort of at-risk women. The ADA recommends screening at 4–12 weeks postpartum using the OGTT and advises lifelong follow-up and screening at least every 3 years [5]. The NICE guidelines recommend using FPG or HBA1c after 13 weeks, and an annual testing with HbA1c is recommended if the first test is normal [55].

Specific Types of Diabetes Due to Other Causes

This heterogeneous group includes monogenic forms of diabetes and others with an underlying genetic defect affecting insulin secretion and action, diseases affecting the pancreas, diabetes associated with endocrine disorders, drug-induced diabetes, and post-transplantation diabetes.

Monogenic Diabetes Syndromes

Single gene defects causing β-cell dysfunction constitute around 1–2% of all cases of DM [60]. MODY is characterized by defective insulin secretion with intact insulin action. Thirteen different genetic loci have been identified so far and are inherited in an autosomal dominant fashion [5]. The most commonly reported types include MODY 2, MODY 3, and MODY 1. There is wide variation in severity and clinical course of the disease among the various types. Some forms show excellent response to sulfonylurea, and certain subtypes require insulin therapy for management. Identification of additional malformations or multisystem involvement helps in arriving at a diagnosis and also necessitates a multipronged approach to the management of these patients.

Neonatal Diabetes

Infants developing DM within the first 6 months of life should undergo genetic testing for identifying potential genetic defects. Neonatal diabetes can be transient or permanent and in patients who have an initial transient presentation can develop DM later in life. Making the correct diagnosis in these patients cannot be overemphasized as switching to oral hypoglycemic agents is possible in a subset of them with potassium inwardly rectifying channel, subfamily J, member 11 (KCNJ11) and ATP-binding cassette, subfamily C, and member 8 (ABCC8) mutations, thus greatly reducing the burden of management on the afflicted family [61, 62].

Diabetes Mellitus Secondary to Pancreatic Disorders

Acute and Chronic Pancreatitis

Acute pancreatitis often results in defective glucose metabolism at presentation. In many patients this defect is transient. However, the risk of developing DM is increased during follow-up of these patients. Chronic inflammation and destruction of pancreatic tissue can occur due to several aetiologies. Although the islets are more resistant to the destructive process in the earlier stages, significant β-cell loss eventually ensues resulting in varying degree of dysglycemia.

Fibrocalculous Pancreatitis

Tropical chronic pancreatitis or fibrocalculous pancreatic diabetes (FCPD) is a specific form of chronic pancreatitis which is encountered in several tropical countries as the name suggests. The aetiology of this condition is elusive, and a number of hypotheses exist to explain its occurrence. The earlier popular theories linking consumption of cassava with FCPD have been challenged [63]. Familial clustering of cases makes genetic predisposition a plausible risk factor. Several candidate genes have been explored in this context with the most prominent ones being serum protease inhibitor Kazal type 1 (SPINK1), cationic trypsinogen (PRSS1), anionic trypsinogen (PRSS2), and chymotrypsinogen C [64, 65]. Increased oxidative stress has also been reported in patients with FCPD [66].

Almost 90% of patients develop diabetes eventually due to β-cell destruction [67]. Although defective insulin secretion is the cardinal defect, development of insulin resistance is also known [68]. Defects in shifting of glucose transporter 2 (GLUT2) into the hepatocyte membranes during the postabsorptive phase have been shown in animal models of chronic pancreatitis. This can result in postprandial glucose excursions [69]. Also, pancreatic polypeptide secreted by the islet cells plays a role in the expression of insulin receptor gene in the liver. Deficiency of pancreatic polypeptide along with insulin deficiency could contribute to the development of diabetes [70]. Glucagon levels on the other hand have been postulated to be relatively unaffected or even elevated in a few studies indicating a selective destruction of the islet cells [71, 72]. However, not all studies corroborate this theory and it needs further analysis.

In patients presenting with symptoms of chronic pancreatitis, typical large ductal calcifications and dilatation of the pancreatic ducts visualized on imaging point to a diagnosis of FCPD. Diabetes in this scenario is generally ketosis resistant with most patients requiring insulin therapy [68, 72]. Most patients also have evidence of exocrine pancreatic insufficiency at the time of diagnosis, and enzyme replacement therapy can worsen glycemic control by improving malabsorption.

Pancreatic Ductal Adenocarcinoma

The relationship between pancreatic ductal adenocarcinoma (PDAC) and DM is complex. DM is believed to be a risk factor for developing PDAC, while the malignancy per se has been postulated to affect glucose homeostasis. Around 85% of patients with PDAC have IGT or DM [73]. A meta-analysis of 36 studies indicated that risk of developing PDAC is two-fold higher in patients with DM [74]. Also, studies show that 25–50% of patients with PDAC develop diabetes in the preceding 1–3 years of their diagnosis [75]. Pancreatitis related to the tumor, destruction of islets, and development of insulin resistance are the postulated mechanisms to explain the development of diabetes. Animal studies suggest that secretory products of the tumor cells can impair glucose metabolism [76]. New-onset DM in these patients is known to improve with resection of the tumor, further strengthening the link between the two [73].

Endocrinopathies

Acromegaly

Majority of patients with acromegaly are diagnosed to have either prediabetes or diabetes at presentation. The reported prevalence of prediabetes varies between 16% and 46% [77–79] and that of DM is between 15% and 38% [80]. The risk of developing diabetes is strongly associated with higher growth hormone (GH) levels, family history of diabetes, hypertension, increasing age and disease duration [79, 80]. Identification and appropriate management of diabetes is essential to prevent the increased cardiovascular morbidity and mortality associated with it.

GH plays an important role in regulating intermediary metabolism. It stimulates lipolysis, suppresses lipogenesis and also antagonizes the insulin-induced suppression of gluconeogenesis, resulting in increased hepatic glucose output [81, 82]. Increased levels of free fatty acids induce a state of insulin resistance at the liver and peripheral tissues [83]. Inability of the β-cells to compensate this state of insulin resistance results in the development of diabetes. Direct inhibition of insulin signaling by interfering with the downstream signaling molecules like insulin receptor substrate-1 (IRS-1) and phosphatidylinositol 3 (Pi-3) kinase also contributes to the development of diabetes [84]. Most patients with acromegaly undergo surgical resection and radiotherapy. Some in addition require medical management for ameliorating disease activity. The treatment modality chosen can also influence glycemic status. Surgical removal of the tumor and subsequent reduction of GH and insulin-like growth factor-1 levels are associated with improvement of glycemic status [85, 86]. Dopamine agonists have a modest effect on reducing PG levels, and the effect of somatostatin agonists

(SSA) on glucose metabolism is conflicting [87]. SSA can inhibit insulin and incretin secretion and worsen glucose levels, especially in those with an underlying insulin secretion defect, though this is often offset by the reduction in GH level and improvement of disease status [87]. Among the SSA, pasireotide seems to have a greater propensity to alter glycemic control and its effect is dose dependent. This tendency can be explained by its greater affinity for somatostatin receptor subtype 5 expressed in the islet cells when compared to other SSA [88]. Pegvisomant is another agent which can improve glycemic control by containing disease activity. There is a reduction in FPG levels and improved insulin sensitivity has been noted in most studies [87].

Cushing's Syndrome

Glucocorticoids exert a multitude of effects on the various organs involved in carbohydrate metabolism. It stimulates lipoprotein lipase activity and lipolysis [89]. At the liver, increased glucose output results from increased rate of gluconeogenesis. These actions, in addition to reduced glucose uptake by muscles and increased proteolysis, result in a state of insulin resistance [90, 91]. Reduced expression of glucokinase and GLUT2 in the pancreatic β-cells results in reduced insulin secretion, which compounds the diabetogenic action of glucocorticoids [92]. Glucocorticoids can interfere with the action of insulin directly by inhibiting downstream signaling molecules like IRS-1 and Pi-3 kinase [93, 94]. Disordered glucose metabolism is seen in 50% of patients with endogenous Cushing's syndrome with two third of them developing diabetes [95, 96]. Increased prevalence of diabetes and prediabetes is also observed in cases of adrenal incidentaloma associated with subclinical Cushing's syndrome [97]. Glucose metabolism generally improves with cure, though these patients seem to have a continuing greater risk of cardiovascular morbidity. Most drugs used in the management of Cushing's syndrome like ketoconazole, dopamine agonists, and metyrapone have a favorable effect on glycemic control. Pasireotide on the other hand is known to worsen hyperglycemia [87]. The frequency of hyperglycemia-related adverse effects is lower in patients with acromegaly who are treated with pasireotide long-acting release (57.3–67%) than those with Cushing's syndrome who are treated with the subcutaneous formulation (68.4–73%) [98].

Treatment with metformin is recommended as first-line therapy for patients on pasireotide with persistent hyperglycemia. Dipeptidyl peptidase-4 inhibitor can be added on in patients failing monotherapy with metformin. Glucagon-like peptide-1 receptor agonist should be added in place of the dipeptidyl peptidase-4 inhibitor if HbA1C continues to remain above 7.0%. Insulin is started as a final resort if adequate glycemic control is not achieved with above measures [98].

Other Endocrine Disorders

Glucagonoma

Islet cell tumors secreting glucagon are rare with a reported incidence of 0.04–0.12 per million per year [99]. They are exclusively seen in the pancreas with the tail being the most common location [100]. In two third of the cases, the tumor is malignant and half of them have evidence of metastasis at the time of diagnosis [101]. DM is known to occur in 40–95% of patients, along with other symptoms like weight loss, gastrointestinal manifestations, and neurological symptoms like ataxia, dementia, optic atrophy, and proximal muscle weakness [102, 103]. The characteristic dermatological lesion called necrolytic migratory erythema is seen in 90% of patients. Glucagon increases hepatic gluconeogenesis and also increases lipolysis and fatty acid oxidation [104]. Diabetes mellitus is generally mild and nonketotic.

Somatostatinoma

Somatostatinomas are rarer than glucagonomas and occur in less than 1 in 40 million people [105]. They produce excess somatostatin which directly suppresses insulin and glucagon secretion causing diabetes. The most common clinical manifestation is related to mass effects, and metabolic manifestations occur in a minority [103, 106].

Drug-Induced Diabetes Mellitus

Thiazide Diuretics

Studies reporting the incidence of diabetes with thiazide diuretics have been conflicting. A recent meta-analysis of 22 studies showed an increased risk of diabetes with thiazides and beta blockers when compared to other antihypertensive agents like angiotensin converting enzyme inhibitors and angiotensin receptor blockers [107]. Hypokalemia caused by thiazides has been linked to impaired insulin secretion in addition to other mechanisms like decreased insulin sensitivity, increased hepatic glucose production, alteration in body fat composition, and stimulation of glucagon [108, 109].

Statins

Statins are widely used as the first choice for their potent low-density lipoprotein-lowering effect. Evidence for their diabetogenic potential was first demonstrated in the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER) trial in which 32% increased risk of new-onset diabetes was noted in the statin arm [110]. Subsequently, similar risk for diabetes has been reported for other statins, prompting the Food and Drug Administration (FDA) in 2012 to add a warning of the increased risk of diabetes with statin use. A meta-analysis of 113,394 subjects showed a 15%

added risk of new-onset diabetes with 80 mg of atorvastatin and 25% with rosuvastatin at a dose of 20 mg [111]. Statins are also known to worsen glycemic control in patients with DM. The risk for DM with statins is more pronounced in those who already have the traditional risk factors. Mechanisms by which statins induce and aggravate diabetes include impaired pancreatic secretion of insulin (by blocking calcium channels), reduced expression of glucose transporter 4 (GLUT4) interfering with glucose uptake and disposal by skeletal muscle, and exacerbation of insulin resistance in liver and peripheral tissues [112]. Lipophilic statins like simvastatin and atorvastatin are transported across cellular membranes with ease, explaining their greater propensity to cause diabetes [113].

Beta Blockers

β-Blockers impair insulin secretion, increase hepatic glucose production, and impair lipoprotein clearance. The risk of diabetes is higher with nonselective beta blockers [108, 114].

Antipsychotic Medications

Weight gain is a common adverse effect of almost all antipsychotic medications. The magnitude of weight gain varies with the different drugs, and the greatest risk is associated with clozapine and olanzapine [115]. Aripiprazole has minimal effect on weight gain [116]. Maximum weight gain occurs in the first year of therapy and is related to the duration of exposure. Increased appetite and consequent food intake, reduced satiety, and effects on adipose tissue like increased lipogenesis contribute to weight gain [117, 118].

The risk for diabetes is also greater, especially with second-generation antipsychotics. It is estimated to be 32% higher in this group. Drugs causing increased weight gain are associated with greater risk for diabetes. In some patients, this effect seems to be independent of the change in body weight. Blockage of muscarinic receptor 3 by the antipsychotic medication is known and this can hamper insulin secretion [119]. Impaired insulin sensitivity at the peripheral tissues is also known to occur, possibly by interfering with functioning of glucose transporters [118].

Antiretroviral Therapy

Risk of new-onset diabetes is a well-known complication of antiretroviral therapy, particularly with stavudine, indinavir, and didanosine. The drugs per se and lipodystrophy associated with their use contribute to metabolic derangements. PG abnormalities are seen in 25% of patients following initiation of protease inhibitors. Redistribution of adipose tissue is the key factor contributing to increased insulin resistance. Age, body mass index, and waist circumference are additional risk factors [120–122].

Post-transplantation Diabetes Mellitus

New-onset diabetes after transplantation (NODAT) refers to the occurrence of diabetes in previously nondiabetic persons after organ transplantation. Twenty to fifty percent of patients following kidney transplant, 9–21% after liver transplants, and approximately 20% after lung transplants are diagnosed to have NODAT at 12 months post-transplant [123]. NODAT increases the risk of allograft loss, infections, and mortality in post-renal transplant recipients [124–127]. Patients with NODAT also develop microvascular complications associated with diabetes at an accelerated rate and are at an increased risk for cardiovascular morbidity and mortality [128]. In addition to the traditional risk factors for DM, exposure to immunosuppressive agents, CMV and hepatitis C infection, and acute rejection post-transplantation augment the risk of developing NODAT [129–132].

The ADA recommends screening for hyperglycemia in all patients post-transplantation using OGTT. A diagnosis of NODAT can be made using the standard criteria if the patient is on a stable immunosuppressive regimen and is free from infections [5].

Concluding Remarks

- Diabetes mellitus is a global epidemic and is associated with multiple morbidities and mortality. The importance of adequate glycemic control in order to circumvent these complications is proven beyond doubt. However, there still exists a controversy over the appropriate diagnostic criteria for diabetes mellitus and prediabetes, which is constantly evolving.
- Diabetes mellitus is the final common outcome of disrupted insulin secretion and/or action. An array of aetiologies is known to cause this disruption, ranging from monogenic and polygenic predisposition to endocrinopathies and drug therapy.
- Prediabetes is an intermediate state of hyperglycemia and includes the states of impaired fasting glucose and impaired glucose tolerance. The rise in the incidence of prediabetes globally, mirrors that of diabetes mellitus. Screening for and detection of prediabetes is an opportunity to intervene and prevent the progression to diabetes mellitus and its complications.
- Gestational diabetes mellitus is defined as any degree of hyperglycemia that is first detected during pregnancy and encompasses true gestational mellitus and pre-existing diabetes mellitus. There is no one universal criteria for diagnosing GDM. Several countries have adopted differing criteria that best meet the needs of their population.

Glossary

Diabetes mellitus Diabetes is derived from its Greek root which means "to pass through," and the word mellitus means "from honey." Diabetes mellitus is defined by the World Health Organization as a metabolic syndrome characterized by chronic hyperglycemia resulting from any of the several conditions that cause defective insulin secretion and/or action.

Prediabetes It is a state characterized by metabolic abnormalities that increase the risk of developing diabetes mellitus and its complications.

Impaired glucose tolerance Defined as an intermediate state where blood glucose levels are above normal but do not satisfy the criteria for diagnosing diabetes mellitus.

Gestational diabetes mellitus Defined as any degree of glucose intolerance that was first detected during pregnancy regardless of whether the condition may have predated the pregnancy or persisted after the pregnancy.

Neonatal diabetes Development of diabetes in the first 6 months of life.

NODAT (new-onset diabetes after transplantation) Defined as occurrence of diabetes in previously nondiabetic persons after organ transplantation.

Multiple-Choice Questions

1. Falsely low HBA1c levels can be seen in all of the following conditions except:
   (a) Hemolytic anemia
   (b) Hypertriglyceridemia
   (c) Postsplenectomy
   (d) Renal failure
   (e) Malaria
2. Maturity-onset diabetes of the young is inherited in _____ fashion.
   (a) Autosomal recessive
   (b) Autosomal dominant
   (c) X-linked dominant
   (d) X-linked recessive
   (e) Mitochondrial
3. Which of the following treatment modalities for acromegaly can worsen glycemic control:
   (a) Surgery
   (b) Radiotherapy
   (c) Dopamine agonists
   (d) Pasireotide
   (e) Pegvisomant
4. Glucocorticoid excess results in diabetes mellitus through which of the following mechanisms?
   (a) Stimulating lipolysis
   (b) Increasing rate of gluconeogenesis
   (c) Inducing a state of insulin resistance
   (d) Interfering with action of insulin by affecting downstream signaling molecules
   (e) All of the above
5. Which of the following drugs are known to cause or worsen diabetes mellitus?
   (a) Dopamine agonists
   (b) Thiazides
   (c) Loop diuretics
   (d) Alpha adrenergic blockers
   (e) All of the above
6. Genetic syndrome associated with diabetes mellitus is
   (a) Turner syndrome
   (b) Edward syndrome
   (c) Patau syndrome
   (d) Cri du chat syndrome
   (e) Down syndrome
7. Endocrinopathy associated with secondary diabetes is
   (a) Adrenal insufficiency
   (b) Somatostatinoma
   (c) Hyperthyroidism
   (d) Hypoparathyroidism
   (e) Insulinoma
8. ADA recommendations to begin screening for diabetes mellitus for all patients at _____ years of age.
   (a) 40 years
   (b) 45 years
   (c) 50 years
   (d) 35 years
   (e) 55 years
9. The rate of progression of prediabetes to diabetes mellitus in the absence of intervention is
   (a) 1–2% per year
   (b) 5–10% per year
   (c) 20% per year
   (d) 40% per year
   (e) 60% per year
10. The HbA1c cutoff recommended by the ADA for diagnosing diabetes mellitus is
    (a) ≥5.7%
    (b) ≥6.7%
    (c) ≥7%
    (d) ≥7.5%
    (e) ≥6.5%

Correct Answers

1. (c) Postsplenectomy
2. (b) Autosomal dominant
3. (d) Pasireotide
4. (e) All of the above

5. (b) Thiazides
6. (a) and (e)
7. (b) and (c)
8. (b) 45 years
9. (b) 5–10% per year
10. (e) ≥6.5%

Part II

Diagnosis, Classification and Mechanisms of Disease

Pathophysiology of Type 1 Diabetes

7

Rita A. Gómez-Díaz

Introduction

Type 1 diabetes (T1D) is a chronic disease measured by immunity with a silent period that lasts for a varied time before clinically manifesting, characterized by selective loss of insulin-producing cells in the pancreatic islets of genetically susceptible individuals.

It is known that the pathogenesis of this disease occurs in stages, with variations among individuals, who have different genetic susceptibilities. The environmental factors may come into play as early as during gestation and would continue through early childhood. Immune dysregulation leads to beta-cell destruction long before the classical autoantibodies are detected. C-peptide response is diminished at least 2 years before disease diagnosis [1].

In the last 10 years, new knowledge has been added in both pathogenesis and treatment of this disease. The search is ongoing for new tools that can identify the earliest stages of autoimmune activation in type 1 diabetes. A better understanding of the physiopathology of this disease can change the approach to treatment and prevention.

Etiopathogenesis of Type 1 Diabetes

There is evidence that type 1 diabetes is considered an organ-specific autoimmune disease in which genetic (such as a strong association with HLA haplotypes, genetic linkage with immune system genes), immunological (such as specificity for beta cells and the presence of antigen-specific T cells), environmental factors (such as age at onset) and gut microbiota participate.

It is also known that type 1 diabetes onset is triggered by an inappropriate activation of both the innate and adaptive immune systems, which causes a cascade that results in pancreatic islet destruction. Invariant natural killer T (NKT) cells interact with both systems and serve as a junction between them. Since they function through the production of cytokines, it has been suggested that they would be intrinsically involved in the disease. Figure 7.1 shows the pathogenesis of type 1 diabetes. The upper portion shows the various stages, as described by Eisenbarth [1]. Stage 1 involves genetic susceptibility. In stage II, an environmental factor triggers the immune process. During stage III, beta-cell antibodies and active self-autoimmunity are present. In stage IV, metabolic abnormalities appear, leading to the symptoms manifested in stage V. Finally, in stage VI, insulin dependency results. The lower portion of the figure shows the participation of $CD4^+$, $CD8^+$, and NKT cells in the onset of T1D.

The role of NKT cells in the physiopathology of type 1 diabetes will be discussed below.

Genetic Factors

The family histories observed in epidemiological studies have sustained the search for genetic causes of T1D. The major histocompatibility complex (MHC) holds a unique position as the link that unites clinical, immunological, and genetic medicine; many diseases, including T1D, have been associated with genes located in the MHC. The most important genes are coded to the group of leukocyte antigens (HLA), a family of surface proteins essential for immunological function. HLA genes present a great variety that has given rise to the diversity in immune response and susceptibility to various diseases. Overexpression of HLA molecules is considered a principal characteristic of type 1 diabetes pathogenesis and earmarks a chronic inflammatory state.

The HLA molecules associated with T1D are class II and are coded in the short arm of chromosome 6p21 (IDDM1) [2, 3]; they are responsible for the selection in the thymus of the repertory of T cells and participate directly in the presentation of antigens in the T CD4+ cells. The genetic region of

class II HLA contains alleles DP, DQ, and DR, which in turn are divided into subregions.

The genes of the HLA system are the most important in conferring protection or susceptibility for type 1 diabetes, and it is believed they contribute to between 30 and 50% of risk in the development of the disease. There are two combinations of HLA genes (or haplotypes): HLADR3-DQ2/DR4-DQ8 have a 20 times greater risk of developing type 1 diabetes compared with general population and are present in 90% of the children with type 1 diabetes. A third protector haplotype, DR15-DQ6, is found in less than 1% of children with T1D and 20% of the general population. The genotype that combines the two susceptibility haplotypes (DR4-DQ8/DR3-DQ2) increases the risk of contracting the disease and is most frequent in children that present at an early age [4]. It has been suggested that, in the presence of these haplotypes, the first signs of beta-cell autoimmunity might appear as early as during the first year of life [5]. Likewise, protection alleles have been reported in Caucasian population as being DRB1-DQB1 DRB1*1602-DQB1*0602, DRB1*07-DQB1*0303, DRB1*13-DQB1*0603, and DRB1*14-DQB1*0503 [6]. First-degree relatives with positive antibodies but protector alleles delay or nullify its debut, which might indicate that the protector effect exerted by these genes occurs after the immunological process has begun.

On the other hand, the DIAMOND Project of the World Health Organization (WHO) tested the hypothesis that the variation in the expression of some risk genes for type 1 diabetes influenced the incidence of the disease according to the participating country (mainly alleles DQA1 and DQB1 with sequence codes for arginine in position 52 of the alpha chain for DQ and another amino acid apart from aspartic acid in position 57 in the beta chain of DQ, respectively). Mexico was included among the countries reporting a low incidence at the time of the study, being that DQA1*0301 was the only allele consistently associated with type 1 diabetes [7].

In Mexican-American population, DRB1*0302 is a risk allele, while the protector is DRB1*1402. In contrast, in Mexican Mestizos the protection haplotype is DR5/DQ6 (DRB1*0501, DQA1*0102, DQB1*0602), and for risk it is

DR4/DQ8 (DRB1*0405, DQA1*0301, DQB1*0302) [8–10]. However, the fact that 38% of the population has DR3 or DR4 indicates that there must be other factors. Effectively, it has been observed that 95% of the DR4 that have allele DQB1*0302 have diabetes, while the DR4/DQB1*0301 do not. These data suggest that HLA DQ molecules are more important in susceptibility to diabetes and the association with DR is due to the linkage disequilibrium (association between alleles) that exists between HLA DR and HLA DQ genes [11, 12].

In addition, evidence of the participation of class II HLA in physiopathology has been observed in the murine model, since these molecules participate in the trimolecular complex that involves a peptide and the T cell receptor of autoreactive cells that escape from the thymus. One of the peptides recognized is the I-Ag-7 molecule (part of the insulin B chain) [13].

Nevertheless, even when the association of HLA alleles and haplotypes is strong, these loci represent less than 50% of the genetic contribution to susceptibility to the disease; this is due to the fact that the alleles are not totally penetrating, implying that not all who have inherited them develop the disease. This has pushed T1D research to new immunological and genetic horizons.

The other 50% of susceptibility for developing type 1 diabetes is given by non-HLA genes. Genomic association studies have identified around 40 non-HLA polymorphisms and other candidate loci in population studies. One of the most important is a polymorphism in the region of the insulin promotor gene, in chromosome 11p15.5 (locus IDDM2, polymorphism that consists in the number of tandem repetitions: VNTR) [14–17]. The insulin gene is transcribed and translated in the thymus and regulates glucose metabolism through insulin tolerance.

Many other susceptibility loci have been proposed after genome scanning (IDDM3-15). Another of the non-HLA genes that has been associated with T1D is the gene located in chromosome 1p13: protein tyrosine phosphatase, non-receptor type 22 (PTPN22). PTPN22 codes a specific lymphocyte phosphatase that inhibits T cell activity; the variant that changes arginine for a tryptophan in position 620 alters the B and T cell response, which is accompanied by a reduction in T cell inhibition, promoting multi-organic autoimmunity; but the specific genes responsible have not yet been identified [18–20].

The genetic evidence for the participation of peripheral B cell compartment and production of cytokines (IL-10) was measured by flow cytometry by Thompson et al., who did not find evidence of changes in IL-10 production through in vitro stimulation with IL-21, suggesting that the pathogenetic role of the B cells is limited to the early stages of the disease in the isles of Langerhans and in the draining pancreatic lymph nodes [21].

IDDM12, located on chromosome 2q33, is one of the confirmed susceptibility loci for T1D [22]. This 300-kilobase region contains at least three genes: CD28, cytotoxic T-lymphocyte antigen (CTLA-4: cytotoxic T-lymphocyte-associated protein A), and the inducible gene costimulatory molecule (ICOS). CTLA-4 codifies a molecule that is expressed on the surface of activated T cells, so polymorphism A49G has been associated with a reduction in the activation and proliferation of T cells. Genetic mapping has suggested that CTLA-4 or a closely related gene may be implicated in susceptibility for type 1 diabetes [23]. Other non-HLA risk genes include the interleukin 2 receptor alpha chain (IL2RA) as well as induced interferon with dominion 1 helicase C (IFIH1) [24, 25]. However, it was recently found that there was a significant association between the non-HLA risk genes and positivity for autoimmune antibodies. For example, PTPN22 associates with anti-GAD autoantibody, while ERBB3 associates with anti-IA-2 antibody (p = 0.042). By the same token, IL2RA and INS-VNTR associate with anti-insulin antibodies [26].

Other non-HLA genes not yet linked with specific antibody positivity include TFPR3, which mediates the release of intracellular calcium; BACH2, which coordinates the activation and repression of MAFK; and UBASH3A, which promotes the accumulation of target receptors, including T cell receptors [27].

Immunological Factors

Very little has been definitively proven concerning the immunological factors involved in T1D. But, as noted by Mannering et al., "an absence of evidence should not be confused with evidence of absence" [28]. To date, the known participation of the autoimmune component comes from various kinds of evidence. Insulitis is defined as an inflammation of the islets of Langerhans that results in the destruction of insulin-producing beta cells. Primary damage is due to an immune response mediated by cells, where Th1 cells (CD4+) collaborate during activation of specific in situ Tc cells (CD8+, associated with Th2) and are directed against the beta cell.

Thus, chronic autoimmune response is manifested clinically with the destruction of 60 to 80% of pancreatic β insulin-producing cells [29]. The insulitis observed in the islets, as well as their surroundings, is constituted mainly of macrophages, B and T lymphocytes [30], and dendritic cells. Various studies have shown that inflammation appears from stages prior to the manifestation of tissue damage and the destruction of beta cells activates the dendritic cells, which trigger the T cells in the pancreas [31].

Insulitis is diagnosed with the presence of at least 15 CD45+ cells per islet, in at least three islets. Long consid-

ered the pathologic characteristic of type 1 diabetes, it is usually, but not always, detected together with insulin-positive beta cells [32].

Although normally associated with younger patients, it has been suggested that this association is overestimated. Nevertheless, the presence of insulitis has been found in a majority of recent-onset type 1 diabetes patients [33]. However, the presence of insulitis has been shown to have an inverse correlation with time with diabetes, but not with age at onset [32]. Insulitis is probably the main cause of destruction of T γδ lymphocytes even after 1 year of insulin treatment, which might explain part of the evolution of the disease [34].

It was recently found that islet-invading T cells differ from allogeneic T cells. There are even differences between type 1 diabetes patients and patients with allograft rejection. Those with diabetes show very low levels of cytokines and chemokines [33].

Interferon-stimulated genes (ISGs) are upregulated by interferon to put cells into an antiviral state. These include GBP1, TLR3, OAS1, EIF2AK2, HLA-E, IFI6, and STAT1. In type 1 diabetes and/or insulitis, the levels of these genes are increased. The presence of insulitis in the peri-islet area has been found to increase the levels of ISGs up to fivefold. However, the actual role of this overexpression in the progression of type 1 diabetes remains to be clarified [35].

Nevertheless, there are differences in youth and adult onset of T1D. In youth, there is a rapid loss of beta cells (75–85%), offset by a high potential for beta-cell regeneration. The autoantibodies presented are mainly anti-insulin. In contrast, in adult-onset T1D, the loss of beta cells is more gradual (60–75%) but with a lower possibility for regeneration. There are more anti-GAD antibodies. The loss of C-peptide production varies greatly, and the reasons are not yet understood [36].

There is a direct correlation with the presence of T lymphocytes producing interferon gamma (IFN-δ) in the infiltrates located in the islets [37–41]. In fact, Gomez-Tourino et al. indicate that CD4 T cells can be considered as characterized by the secretion of either IFN-δ or IL-17, as opposed to the secretion of IL-10 in healthy subjects. They support the important role that T1 (IFN-δ) and T17 (IL-17) play in the development of type 1 diabetes [42]. On the other hand, Mannering et al. not only showed that $CD4^+$ T cells are associated with HLA risk genotypes for T1D; they also noted that clones of these T cells could recognize epitopes from the proinsulin C-peptide [28, 43].

A secondary effect is that specific autoantibodies are produced against autoantigens of the pancreatic islets. The quantification of antibodies against autoantigens has been useful in knowing the activity of the disease, determining its degree of progression, and contributing to the classification and prediction of the clinical status of the patients. From 60 to 80% of patients recently diagnosed present antibodies against glutamic acid decarboxylase (anti-GAD); a similar percentage (60 to 70%) show anti-tyrosine (anti-IA2) of zinc cation transporter (ZnT8) and only 30% to 50% have anti-insulin antibodies [44–46]. Nevertheless, the sensitivity and specificity of these autoantibodies varies with ethnicity and with follow-up time. However, as shown by Velluzzi et al., while positivity for one of these antibodies has a hazard ratio of 55.3, this drops to 14.5 with two positive antibodies and 3.0 for three [47].

In this regard, $CD8^+$ T cells have been suggested as the final cause of beta-cell death. This has been supported by the presence of antigen-specific (GAD65) and HLA-restricted forms. $CD8^+$ T cells can be specific for various epitopes, including insulin, insulinoma antigen 2 (IA 2), and GAD-65, and are pathogenic to beta cells [43]. Another study has suggested that $CD8^+$ T cells are autoreactive against such autoantigens as GAD65, ZnT8, and IA-2 [28, 34].

Environmental Factors

The rapid increase in the prevalence of type 1 diabetes, both in our country and worldwide, cannot be explained solely by the genetic component (in subjects with risk HLA haplotypes), epigenetic modifications being those that may be key regarding environmental risk factors and which are probably in line with the hygiene hypothesis, which proposes that environmental exposure to microbes and other pathogens and their sub-products early in life induce immunological tolerance and a reduction in atopy and autoimmune diseases.

One link between the genetic and environmental factors may lie in IFIH1, also known as MDA5, or the gene associated with differentiation of melanoma 5, detection of intracellular RNA of the picornavirus, virus family that includes enterovirus. Detection of intracellular RNA leads to activation of IFIH1 and the interferon route. It has been hypothesized that enterovirus leads to the activation of IFIH1 in the β cells of the pancreas, elevated interferon levels, and an increase in expression of MHC class I expression, activating CD8 T cells and the death of pancreatic β cells. The variants that result from less function of IFIH1 are protectors from type 1 diabetes [28].

Some other viruses [48] (*Coxsackie B*, *parotitis* [49], and rubella [50]) have been implicated as possible initiators, accelerators, or precipitators of the disease. The virus with the most demonstrated role is congenital rubella syndrome (children that acquire the infection in utero), where there is a 30% risk of presenting type 1 diabetes between 5 and 30 years later; however, this only explains a small proportion of the cases.

Many of the viruses use different mechanisms to ultimately lead to beta-cell death. In the case of rubella virus, it

causes two-way reactions between the antigens and GAD, stimulating T lymphocyte activity and leading to beta-cell infection. Cytomegalovirus also causes infection of beta cells, but using clonal activation of T cells to induce the recruitment of macrophages to the pancreas. However, in the case of mumps, there is increased expression of class I and II HLA in the beta cells, while rotavirus uses molecular imitation to infect the cells. In contrast, parvovirus does not infect beta cells, but rather uses macrophages to activate a Th1 immune response while at the same time increasing Th2 responses [51].

It has been suggested that the inability to quickly cure viral infections could be part of the reason that beta cells, but not alpha cells, suffer apoptosis during the development and progression of type 1 diabetes [52]. The "bystander hypothesis" infers that the infection of pancreatic cells leads to the release of pro-inflammatory cytokines, which may explain the aforementioned cell death [53, 54]. However, the "molecular mimicry" mechanism attributed to rotavirus, among others, remains controversial, due to conflicting experimental results [53, 55].

In fact, infection may delay or avoid the development of type 1 diabetes through various mechanisms. Over time, there is a mutual adaptation. Infections which trigger immunoregulatory cytokines, such as IL-10, help control inflammation and also reinforce regulatory T cell activity while sparking NKT cell activity. On the other hand, activated macrophages and "tolerogenic" dendritic cells inhibit Th1 responses through a variety of mechanisms, such as rerouting the response to Th2, prompting T cells, and producing amino acid-catabolizing enzymes. This activity limits tissue pathology [56].

Nevertheless, the *Enterovirus* genus has been given special attention in regard to type 1 diabetes, thanks to advances in techniques to identify it. Enteroviruses are the most common viruses causing disease in humans, including foot-and-mouth disease and poliomyelitis. Most are extremely resistant to antibiotics, as well as to the chlorine usually added to treated water, meaning they can be transmitted by water, food, or soil. This genus includes the *Coxsackie* family, most notoriously *Coxsackie B*. One study found enteroviral genomes in the islets in pancreatic biopsies of patients with type 1 diabetes [57]. In the Diabetes Virus Detection Study (DiViD), enterovirus was found in all of the insulin-containing islets of pancreas samples of patients with recent-onset (<10 weeks) type 1 diabetes [58]. This supports the idea that the viral infection precedes the appearance of diabetes. Several other studies in children have reached the same conclusions, such as VirDiab [59] and the study conducted by Laitinen et al. [60], both of which were carried out in children with type 1 diabetes against apparently healthy controls. With the growing body of evidence, it has been suggested that the enterovirus infection, and possibly other virus infections as well, may be the last straw and push an already unbalanced metabolism into a critical loss of beta cells [61].

On the other hand, among the environmental risk factors studied is diet, especially during the lactation period, which can modulate intestinal microbiota and is among the mechanisms that influence type 1 diabetes. Various studies have considered early exposure to cow's milk and highly hydrolyzed casein formula as the trigger for autoimmunity in some genetically susceptible individuals [62–65]. However, studies of the association between vitamin D, another suspected factor, and the development of type 1 diabetes remain controversial [66, 67]. Nevertheless, a recent study has found a significant inverse relationship between vitamin D and C-reactive protein, as well as with various cytokines, including IFN-γ, TNF-α, IL-6, IL-1β, IL-4, and IL-10 [68].

Microbiota

The development of intestinal microbiota is influenced by many factors, including diet, lifestyle, use of antibiotics, type of birth (natural or cesarian), and breast-feeding. It is known that a balance in intestinal microbiota is fundamental for a wide variety of physiological mechanisms, including the function of the immune system. It has been suggested that an imbalance in intestinal microbiome, called dysbiosis, is related with the pathogenesis of type 1 diabetes. The development of gut microbiota is influenced by changes in diet, as evidenced by the close association between T1D and celiac disease. These facts may help explain the fact that T1D is increasing worldwide, as diets change and become "westernized" [69].

In light of these facts, several recent studies have examined the microbiome profile of healthy individuals compared with those with T1D. One such study, conducted in Spain, found significant differences in *Bifidobacterium, Lactobacillus* and *Clostridium.* Patients had higher levels of *Clostridium* and lower levels of *Bifidobacterium* than controls, suggesting a relationship with glycemic level. In addition, they found that the quality of the bacteria was lower in T1D children than in healthy controls [70]. Another study in Mexican children in Sonora found that newly diagnosed cases of T1D showed high levels of *Bacteroides*, while healthy children had high levels of *Prevotella*. However, after 2 years of treatment, the levels of both bacteria had returned to those of the healthy children, suggesting not only the involvement of dietary changes but also the possibility of using therapies with microbiota to reduce the possibility of developing diabetes [71].

Nevertheless, whereas children with T1D have high levels of *Bacteroidetes*, children with obesity have reduced levels, but increased *Lactobacillus*, which indicates an important difference in the two conditions [71, 72]. However, this dif-

ference may depend on other factors, such as genetic risk, in addition to the gut microbiotic profile. In a portion of the TEDDY study, which included American and European children, it was found that probiotic supplementation associated with a decreased probability of islet autoimmunity but only in those with the high-risk genotype (DR3/4). The absence of any benefit in other genotypes may indicate a therapeutic strategy for high-risk individuals [73]. However, more research will be needed before implementing this kind of treatment, including genetics, the effect of infections, and the influence of the many other factors that affect microbiota profiles.

The Role of NKT Cells in the Physiopathology of Type 1 Diabetes

Finally, the participation of the autoimmune response in type 1 diabetes is due to an alteration in the regulatory mechanisms of acquired autoimmunity, which corresponds to the expansion and/or function of populations of regulatory T lymphocytes.

The interaction of the innate and adaptive immune systems is definitive in the genesis of the disease. Immune system responses are complex and have evolved to protect multicellular organisms from aggressors; evolutionary pressure has specialized the effecting functions that may also damage the organism's tissue. The immune system specialized in two arms: one innate capable of mounting nonspecific responses quickly and the adaptive, capable of promoting longer-lasting, specific responses. Evolution has given rise to specialized cells to carry out these functions. There are some cells that have mixed abilities, that is, both innate and adaptive. This cellular group may be key to understanding the physiopathology of various autoimmune diseases, including T1D. They have recently been linked to type 2 diabetes as well [74]. They share functions and cellular surface markers of both arms. In addition, their evolutionary permanence among species makes them an important link in the homeostatic regulation of the immune system.

To date, the regulatory cell population has not been accurately identified, but there are various candidates, including T lymphocytes CD4+CD25+ and natural killer lymphocyte-type (NKT) cells. NKT were identified in 1987 in mice [75] and later their counterpart was described in humans [76]. They are a population of lymphocytes that express the receptor for T lymphocyte antigen (TCR), as well as the common marker of NK cells (NK 1.1 for mice and CD161 in humans). The said heterogeneous population can be $CD4^+$, or $CD4^-CD8^-$ (double negatives), or even $CD8^+$; these express a repertoire of conserved TCR [77], in humans made up of variable regions Vα24 and Vβ11. Unlike most T cells, NKT recognize lipids in the presence of CD1d molecules. They respond to antigens presented in the context of CD1d molecules, and their important regulatory function is mediated by the secretion of cytokines: INF-δ or IL-4 [78]. NKT cells are found in significant numbers at the site of inflammation and may be a marker of diabetes risk. The frequency of NKT cells is associated with the relative frequency of specific tolerogenic dendritic cell subsets. It appears that NKT cells regulate diabetes, then, by influencing the frequency and possibly the function of dendritic cell subsets, as suggested by Naumov et al. in their work with non-obese diabetic mouse models (NOD) [79]. In addition to a key role against bacteria, viruses, and parasites, they are involved in the body's defense against tumors, as well as immune regulation.

In terms of autoimmunity and inflammation, the main results come from the prevention of diabetes in NOD mice [80]. Various studies show a defect in the number and function of NKT cells in these mice, so the disease may be reduced through the adoptive transfer of populations rich in NKT cells [81–84].

The numerical and functional deficiency of NKT cells (detected in the thymus and spleen of NOD mice at 3 weeks of age) mediates the pathogenesis of type 1 diabetes, but the phase of development of T cells in which this deficiency occurs is still unknown. Wagner et al. propose that conventional T cells and doubly negative NKT have a common lineage and that this lineage in the development of the thymus of NOD mice is defective [85]. Some evidence suggests that a deficiency in NKT cells may be coded by risk genes IDD9 and IDD6 (locus Idd9.1, Idd6, Nkt1, and NKt2) for the disease [86–88].

In the last 10 years, studies in humans have documented a decrease in the number and production capability of IL-4 [89] of NKT cells in patients with T1D, while others have described an increase in the frequency of these cells [90–92].

On the other hand, both the frequency of NKT and the production of IL-4 are maintained during the course of type 1 diabetes. Recently, in Colombian patients, upon comparing a healthy control group with type 1 and type 2 diabetes and autoimmune thyroid alterations, no differences were found between the group with type 1 diabetes and healthy controls, but the levels of NKT cells were found to be elevated in type 2 diabetes [93].

The discrepancy in the data seems to come from the type of population selected for the study, as well as the status of the patient in relation to the natural history of the disease, or the subpopulation of NKT cells quantified in those studies, since it has recently been suggested that the subset of CD4+ NKT cells may be activated in the prevention of autoimmunity, while the subset of double negative NKT (CD4- CD8-) may be pathogenic; to prove this hypothesis, a new, monoclonal antibody (6B11) was used to identify the subpopula-

tions of NKT and thus evaluate the individuals at risk and with type 1 diabetes. The results showed an increase and expansion of double negative NKT cells ($CD4^{-}CD8^{-}$) in patients at risk [94].

In working with children with type 1 diabetes and their first-degree relatives, our work group found a reduction in NKT cells, in addition to identifying in these cells two populations, a majority one that expressed an elevated quantity of invariant TCR (Vα24/Vβ11) and another minority population that expressed low density of invariant TCR [95–97]. In this subpopulation we found that they expressed activation marker CRTAM (class I-restricted T cell-associated molecule) [95]. CRTAM is also expressed on $CD4^{+}$ and $CD8^{+}$ T cells and is associated with the inflammatory process. Both CRTAM and CD69 are expressed in the NKT cells with low invariant TCR, suggesting a state of activation [96]. In addition, a clear association has been observed between the expression of CRTAM and the production of IFN-γ in NKT cells in both healthy individuals and those with type 1 diabetes, which suggests that CRTAM can be used as a marker to identify the NKT cells [98].

On the other hand, in class II MHC molecules, cathepsin-L lysosomal protease (CTSL) exercises broad influence on the immune system and has an important role in the expression of antigen-presenting cells. In CTSL nkt/nkt mice, it has been shown that the activity of the CTSL gene impacts the positive selection of CD4+ thymocytes and regulates the level of expression of various components of the extracellular matrix in lymphoid organs, influencing the number and composition of central and peripheral T lymphoids [99]. However, to date the role of NKT cells and CTSL gene expression has not been clearly established in humans as a biomarker in the physiopathology of type 1 diabetes. In the belief that CTSL is involved in the promotion of the survival of cytotoxic T lymphocytes, it was recently shown that the percentage and absolute numbers of NKT cells correlate with low levels of expression of the CTSL gene in T1D in humans [100].

To date, the complete pathogenesis of type 1 diabetes remains unknown. What is known that the process of developing this disease involves a myriad of factors.

Genetically, 50% of susceptibility to T1D can be associated with HLA genes, and the other 50% to non-HLA genes, such as PTPN22, CTLA-4, and IFIH1. Research continues to identify new candidates of the latter. The alleles that indicate risk or protection from the development of T1D vary with country and ethnicity. In addition, the presence of two or more autoantigen antibodies is an important indicator of risk.

It is possible that the drastic increase in the prevalence of T1D is largely due to the implicated environmental factors. Technological advances have helped identify genetic overexpression in reaction insulitis. Dysbiosis is involved in alterations in the immune system and has been linked to the pathogenesis of T1D. Current studies are focusing on this important aspect of the epigenetics of the disease.

Finally, NKT cells are found in significant numbers at the site of inflammation and may be a marker of diabetes risk. Their participation in both innate and adaptive autoimmunity has made them a target of interest. The clinical value of this tool remains under investigation.

Multiple Choice Questions

1. Type 1 diabetes
   (a) Is diagnosed only in children
   (b) Has a silent period before manifestation and diagnosis
   (c) Is diagnosed during pregnancy
   (d) Is often confused with type 2 diabetes
2. Which of the following is *not* a factor in the development of T1D?
   (a) Microbiota
   (b) Environmental factors
   (c) Immunological factors
   (d) Alterations in insulin secretion
3. The genotype that combines the two susceptibility haplotypes (DR4-DQ8/DR3-DQ2)
   (a) Increases the risk of T1D
   (b) Has no effect on the disease
   (c) Never appears in relatives
   (d) Always appears in relatives
4. HLA genes
   (a) Are responsible for all of T1D genetic susceptibility
   (b) Are not responsible for T1D genetic susceptibility
   (c) Are partially responsible for T1D genetic susceptibility
   (d) Have no connection with T1D susceptibility
5. Which of the following non-HLA genes is associated with T1D?
   (a) PTPN22
   (b) TCF7L2
   (c) SCL16A11
   (d) DRB1-DQB1
6. Insulitis has been associated with
   (a) Age at disease onset
   (b) Elderly patients
   (c) Time with diabetes
   (d) Patient siblings
7. All of the following has/have been associated with T1D except
   (a) Rubella
   (b) Coxsackie B
   (c) Enterovirus
   (d) Parvovirus

8. In children with type 1 diabetes, NKT cell populations usually
   (a) Are increased
   (b) Are not present
   (c) Are reduced
   (d) Are hyperactive
9. CRTAM is associated with
   (a) The production of IFN-γ in NKT cells
   (b) Cell apoptosis
   (c) Patients with type 2 diabetes
   (d) Age at onset of T1D
10. Quantification of antibodies against autoantigens in T1D helps us know all of the following *except*
   (a) The activity of the disease
   (b) Time since the onset of the disease
   (c) The degree of progression of the disease
   (d) Prediction of the clinical status of disease

Correct Answers

1. (b) Has a silent period before manifestation and diagnosis
   It has a silent period before manifestation and diagnosis.
2. (d) Alterations in insulin secretion
   Alterations in insulin secretion are a factor for type 2 diabetes.
3. (a) Increases the risk of T1D
   The genotype that combines the two susceptibility haplotypes (DR4-DQ8/DR3-DQ2) increases the risk of contracting the disease.
4. (c) Are partially responsible for T1D genetic susceptibility
   T1D is a multi-factorial disease, where HLA genes have around 50% of the genetic responsibility for T1D susceptibility. The other 50% comes from non-HLA genes.
5. (a) PTPN22
   PTPN22 associates with T1D.
6. (c) Time with diabetes
   Insulitis has an inverse correlation with time with diabetes.
7. (d) Parvovirus
   Parvovirus has not been shown to have an association with human T1D.
8. (c) Are reduced
   NKT cells are usually reduced in frequency in children with T1D.
9. (a) The production of IFN-γ in NKT cells
   A clear association has been observed between the expression of CRTAM and the production of IFN-γ in NKT.
10. (b) Time since the onset of the disease
   Quantification of antibodies against autoantigens has been useful to establish the activity of the disease, determining its degree of progression and contributing to the classification and prediction of the clinical status of the patients.

Glossary

Anti-GAD	Antibodies against glutamic acid decarboxylase
Anti-IA2	Anti-tyrosine
CRTAM	Class I-restricted T cell-associated molecule
CTLA-4	Cytotoxic T-lymphocyte antigen
CTSL	Cathepsin-L lysosomal protease
IA2	Insulinoma antigen 2
ICOS	Inducible gene costimulatory molecule
IFIH1	Induced interferon with dominion 1 helicase C
IFN-δ	Interferon gamma
IL2RA	Interleukin-2 receptor alpha chain
ISGs	Interferon-stimulated genes
MHC	Major histocompatibility complex
NKT	Natural killer lymphocyte-type
NOD	Non-obese diabetic mouse models
PTPN22	Protein tyrosine phosphatase, non-receptor type 22
T1D	Type 1 diabetes
TCR	Receptor for T lymphocyte antigen
WHO	World Health Organization
ZnT8	Zinc cation transporter

Pathophysiology of Type 2 Diabetes

8

Jothydev Kesavadev, Fatema Jawad, Asma Deeb, Ankia Coetzee, M. A. Jalil Ansari, Dina Shrestha, Noel Somasundaram, and Sanjay Kalra

Introduction

While in the earlier times type 2 diabetes (T2D) was only considered as a disease related to a disturbance in the functioning of the pancreas, lots of evidences accumulated during the past few decades revealed a plethora of additional factors that contribute to this devastating disease. The understanding of T2D has evolved from recognizing the duo of pancreatic β-cell failure with defective insulin secretion and insulin resistance (IR), to the triumvirate with the addition of hepatic gluconeogenesis. Recently, the ominous octet (addition of deranged adipocyte metabolism, incretin defect, increased glucagon secretion, increased renal glucose reabsorption, and neurotransmitter dysfunction and central appetite dysregulation) and of later the dirty dozen (addition of dopamine, vitamin D, testosterone and renin-angiotensin system) elaborated on the prior simplistic disease models. Furthermore, with the addition of the gut, the unlucky thirteen, suggests that the contributing factors toward T2D pathogenesis are still in the process of being identified [1–9]. In this chapter, we will explore the various factors that have been identified or are being proposed as the underlying contributors to the pathogenesis and pathophysiology of T2D.

Glucose Homeostasis

In healthy individuals, a normal glucose homeostasis in the basal or postabsorptive state is maintained, despite wide fluctuations in supply and demand, by means of a highly regulated and dynamic interaction between tissue sensitivity to insulin and insulin secretion. While maintenance of plasma and tissue glucose levels are required for vital functions of the brain, elevated glucose levels are deleterious or toxic to vascular endothelium and a myriad of other vital tissues. Normally in the postabsorptive state, most of the glucose utilization occurs in the insulin-independent tissues like the brain (50%) and splanchnic areas (25%) while the rest in the insulin-dependent tissues like muscles and adipose tissue. The insulin secretion during the next 2 hours depends on the glucose disposal rate and the degree of suppression of hepatic glucose production (HGP). Additionally, insulin stimulates lipoprotein lipase in the vascular endothelium and promotes lipolysis and removal of chylomicrons and VLDL from the circulation. A derangement in the appropriate β-cell insulin secretion or insulin action at the level of the muscle, liver, and adipose tissue foregoes the hyperglycemic states of prediabetic and diabetic states [10, 11].

Pathophysiology of Type 2 Diabetes

Individuals at risk of T2D are thought to inherit a genetic predisposition to insulin resistance [2, 12]. Chronic fuel excess is the chief pathogenic event that triggers the T2D development in these genetically and/or epigenetically

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_8

susceptible individuals [9]. In states of normal insulin sensitivity, HGP is suppressed by insulin. However, in the event of hepatic IR, gluconeogenesis continues during the basal state even when the fasting insulin level is high and leads to hyperglycemia [13]. During the fed state, suppression of HGP in response to insulin is impaired as well [14]. With peripheral tissue IR, post-meal glucose uptake ensues and postprandial hyperglycemia sets in [14]. The current epidemic of obesity and physical inactivity [15] are IR states [16] that unmask the pancreatic β-cell defect when they fail to augment insulin secretion to offset the effects of IR [2, 3]. As long as the β-cells are able to enhance their insulin secretion to compensate for the impact of IR, glucose tolerance/euglycemia is maintained [17]. However, with time β-cells become unable to compensate for the IR and initially the postprandial plasma glucose (PPG) levels and later the fasting plasma glucose (FPG) levels begin to rise, leading to overt diabetes. Individuals in the upper tertile of impaired glucose tolerance (IGT) are highly insulin-resistant and would have lost 80% of their β-cell function [3, 18].

In 1987 DeFronzo put forward the concept that T2D resulted from deficits in the pancreatic β-cell, the muscle, and the liver, which were collectively referred to as the "triumvirate" (see Fig. 8.1) [1, 18].

In addition to the triumvirate, numerous other factors have been demonstrated to contribute to T2D pathophysiology. In his Banting Lecture, Defronzo revealed some of the other players, viz., adipocytes (accelerated lipolysis), incretin defect, α-cells (hyperglucagonemia), kidney (increased glucose reabsorption), and brain (neurotransmitter dysfunction and central appetite dysregulation), that play important roles in development of glucose intolerance in T2D individuals [3]. Collectively, these eight players were named as the "ominous octet" [18].

The cast list in T2D pathophysiology is still being unraveled. In 2013, Kalra et. al. suggested another four factors responsible for T2D to be added to the list of ominous octet, viz., dopamine, vitamin D, testosterone, and the renin-angiotensin system (RAS), and labeled all the 12 factors as the "dirty dozen" [6]. In 2016, Somasundaram and Wijesinghe proposed a thirteenth mechanism—the role of gut and gut microbiota in T2D [7]. Other factors such as iron overload and gut-derived serotonin have also been proposed to have a role in T2D development [5].

The "Ominous Octet"

β-Cell Dysfunction

β-Cell dysfunction plays a major role in T2D development, across the spectrum of hyperglycemia, from prediabetes to overt diabetes. These cells are in a constant state of dynamic change, with continued regeneration of islets and simultaneous apoptosis. This delicate balance can be disrupted by multiple abnormalities. As the β-cell failure progresses, insulin secretion becomes inadequate to avert the rising blood glucose levels [10]. Although the plasma insulin response to IR is usually increased during the natural history of T2D, this does not imply that the β-cell is functioning normally. In fact, the onset of β-cell failure is found to occur much earlier, and the contribution to hyperglycemia is, in fact, more severe than previously appreciated [3]. For as long as the β-cells are able to augment insulin secretion

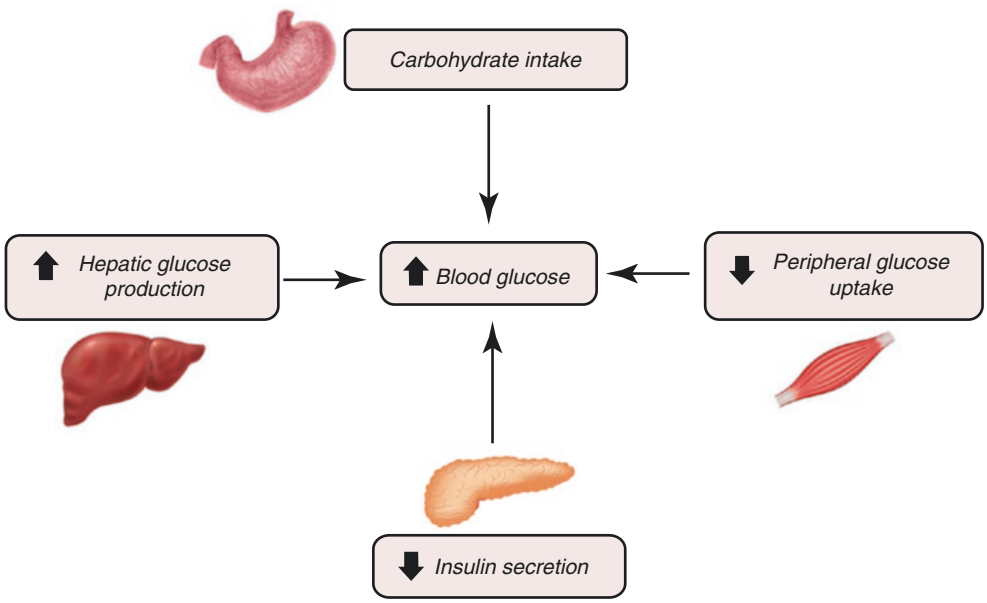

Fig. 8.1 The triumvirate: the core physiological defects that were earlier proposed to be involved in type 2 diabetes pathogenesis [3]. (Adapted from: Chawla [11])

sufficiently to overcome IR, glucose tolerance remains within limits. β-Cell responds to an increment in glucose (ΔG) with an increment in insulin (ΔI), and ΔI/ΔG was initially considered as the measure of β-cell function. The β-cell also takes into account the severity of IR and accordingly adjusts insulin secretion. Thus the gold standard to measure β-cell function is the insulin secretion/IR, i.e., ΔI/ΔG ÷ IR, known as the glucose disposition, index [19]. In individuals susceptible to T2D, there is a limitation to this hypersecretion of insulin. The insulin secretion/IR index seen in normal glucose-tolerant (NGT), IGT, and T2D individuals as a function of the 2-hour PPG during an oral glucose tolerance test (OGTT) is shown in Fig. 8.2. The onset of T2D is not associated with a further deterioration in insulin sensitivity but rather insulin secretion that wanes and fails to compensate for the prevailing IR [20]. Individuals in the upper tertile of "normal" glucose tolerance (2-h PG = 120–139 mg/dL, i.e., 6.7–7.7 mmol/l) would have lost two-thirds of their β-cell function (see first arrow in Fig. 8.2), while subjects in the upper tertile of IGT (2-h PG = 180–199 mg/dL, i.e., 10.0–11.1 mmol/l) would have lost 80–85% of their β-cell function (see second arrow in Fig. 8.2) [3, 21–23]. Concisely, although IR in the liver/muscle is well established early in the natural history of T2D, overt diabetes will not develop in the absence of progressive β-cell failure [18]. Also, with acquisition of recent knowledge, it appears that β-cells may become dedifferentiated in people with T2DM and that these dedifferentiated cells may convert to other cell types such as glucagon-secreting α-cells [24].

Age and genes are two well-known non-modifiable factors which influence the state of β-cell health. A progressive age-related decline occurs in the β-cell function [25], and the incidence of diabetes is found to increase with advancing age. β-Cell failure clusters in families and a number of genes have been associated with T2D in people from multiple ethnic backgrounds. Most common are the transcription factors associated with β-cell dysfunction (e.g., the T-allele of single-nucleotide polymorphism rs7903146 of the TCF7L2 gene) [12, 26, 27]. However, the modifiable contributors to insulin secretion and IR, e.g., lipotoxicity, glucotoxicity, and incretin defects, can improve β-cell function and should be sought [3, 28]. Hypersecretion of islet amyloid polypeptide (co-secreted with insulin) gives way to subsequent amyloid deposition within the pancreas, and it is speculated to be involved with disease progression rather than initiation [29, 30] (see Fig. 8.3).

Insulin Resistance

Insulin resistance is the diminished ability of insulin to exert its biological action across a broad range of concentrations [31]. Relatively high insulin levels observed during fasting and in response to insulin secretagogues are indicative of IR. Insulin resistance is a consistent finding in T2D, and it may appear many years before the disease onset. It is also a well-known associate of obesity, and many obese individuals develop T2D. Interestingly, some patients, despite being obese, never develop T2D highlighting the significant contribution of the β-cell deficit in the individuals who develop T2D. Important to note, physical activity has a significant positive effect on insulin sensitivity, even when correcting for confounding factors such as being overweight. What's more, during the latter half of pregnancy, even in women with normal glucose homeostasis, IR increases due to the production of placentally derived hormones like human placental lactogen. Gestational diabetes mellitus (GDM) ensues if the maternal β-cells are unable to produce sufficient insulin to overcome the IR. Insulin resistance is mediated at three organ levels—the liver, muscle, and adipose tissue. Much more than the mere IR, the triad of factors contributes to the biochemical potpourri of diabetes [5, 10].

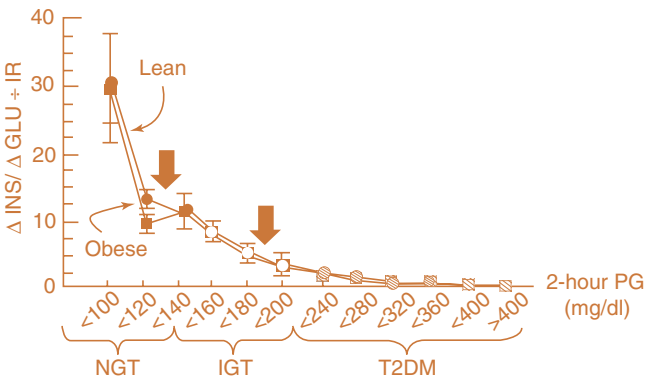

Fig. 8.2 Insulin secretion/insulin resistance (disposition) index in subjects with normal glucose tolerance (NGT), impaired glucose tolerance (IGT), and type 2 diabetes (T2D) as a function of 2-hour PPG in lean (closed circle) and obese (open circle) individuals [3]. (Adapted from: DeFronzo [3])

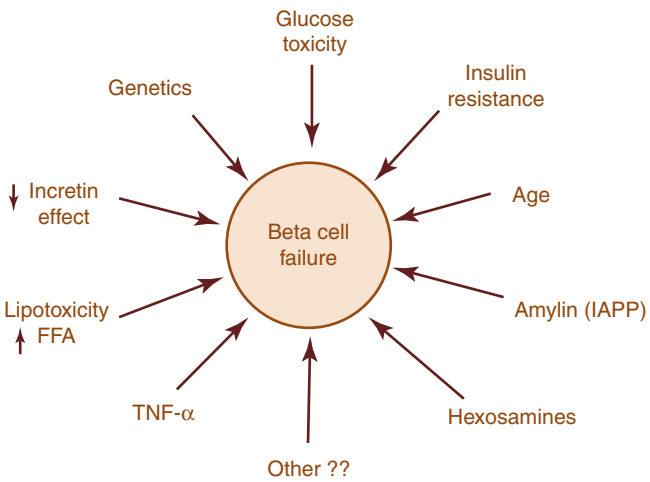

Fig. 8.3 Pathogenic factors implicated in progressive β-cell failure [28]. (Adapted from: DeFronzo et al. [28])

Hepatic Insulin Resistance

Insulin resistance in the liver is manifested by glucose overproduction during the basal state despite fasting hyperinsulinemia [13] and impaired suppression of HGP by insulin [32], following a meal [14]. Due to its obligate need for glucose, brain uses up more than half of the glucose produced. This glucose demand is met primarily by the liver and to a lesser extent by the kidneys [33]. Normally, the liver produces 2 mg/kg per min of glucose, whereas in diabetes-affected individuals, this basal rate of HGP is increased to 2.5 mg/kg per min. This increased HGP occurs even when the fasting plasma insulin levels are increased 2.5 to 3-fold, indicating severe resistance to the suppressive effect of insulin on HGP.

In the early stages of T2D, postprandial hyperglycemia is attributed to reduced glucose uptake by the muscles, and during the postabsorptive period, the fasting levels are maintained by HGP. Both sources of HGP, glycogenolysis and gluconeogenesis are under insulin control. But in IR state, the latter accounts for nearly the entire increase in hepatic glucose output. Around one-fourth of the glucose derived from a meal is extracted by the liver during recycling of portal and systemic blood, and insulin is suggested to facilitate the storage of this glucose as glycogen. Gluconeogenesis accounts for even greater amounts of glycogen. Moreover, during active gluconeogenesis, glycogenolysis is inhibited and results in excess hepatic glycogen [34] in uncontrolled diabetes. The accelerated gluconeogenesis in T2D can be due to elevated circulating levels of precursor molecules like lactate and alanine from the muscles and glycerol from the adipose tissue. Simultaneous upsurge in free fatty acids (FFA) and concomitant hyperglucagonemia facilitate gluconeogenesis. Insulin resistance also stimulates VLDL and apo-B synthesis in the liver, while HDL is lowered due to greater exchange of cholesterol ester transport protein. An increase in small dense low-density lipoprotein particles is also noted during the process [1].

Muscle Insulin Resistance

In the muscle, IR is manifested by impaired glucose uptake after carbohydrate ingestion, resulting in postprandial hyperglycemia [32, 35, 36]. In the insulin-stimulated postprandial state, the skeletal muscle accounts for more than 75% of the excess glucose uptake [37], and in diabetes patients, it accounts for the largest part of impairment of glucose disposal. Adipose tissue mass being smaller in size accounts for the rest, whereas there may not be any change in the case of brain and splanchnic tissues [10]. In T2D the muscle IR accounts for more than 85–90% of the impairment in total body glucose disposal [1, 2, 35, 36].

Adipose Tissue Insulin Resistance

Though deranged adipocyte metabolism was initially not considered to play a significant role in T2D pathogenesis, later on, evidences supported the adipose tissue to be considered as the "fourth musketeer" along with the triumvirate [3, 38, 39]. In healthy individuals, insulin exerts an anti-lipolytic effect on fat cells, whereas in T2D individuals, IR prevents insulin from exerting its anti-lipolytic effect. The result is sustained lipolysis with day-long elevation in plasma free fatty acid (FFA) levels. This, in turn, stimulates gluconeogenesis, induce hepatic and muscle IR, and impair β-cell function (lipotoxicity). FFAs also enhance the activity of glucose-6-phosphatase that ultimately controls the release of glucose by the liver [40]. Dysfunctional adipocytes produce proinflammatory adipocytokines in excess (IL-6, TNF-α, leptin, visfatin, etc.) which induce IR and atherosclerosis. This also induces a feed-forward process in which activation of transcription factors leads to further proinflammatory cytokine production [8, 41]. Deranged adipocytes also tend to secrete subnormal amounts of insulin-sensitizing adipocytokines (e.g., adiponectin). Enlarged fat cells are insulin-resistant and have lesser capacity to store fat. When the storage capacity of adipocyte is exceeded, lipid "overflows" into the muscle, liver, β-cells, and arterial vascular smooth muscle cells leading to muscle and hepatic IR, impaired insulin secretion, and acceleration of atherosclerosis [42].

Meanwhile, the discovery of functional brown adipose tissue raised the possibility for its involvement in human energy homeostasis and in preventing T2D. The detectability of this tissue lessens with age, high BMI and high FPG [9, 43]. A healthy obese state has been entertained, and the theory is based on the existence of differences in IR between adipose deposition sites. In other words, adipose site-specific IR by intra-abdominal adipose tissue seemingly more insulin resistant and harmful than subcutaneous adipose tissue (SAP). The former has particularities related to higher lipolysis, higher release of adipokines, etc. which are longitudinally associated with an increased risk of incident metabolic syndrome (MetS) [44]. In individuals who remain resistant to T2D, excess calories are safely partitioned to SAP rather than to the muscle, liver, heart, and β-cells, thus avoiding damages to the key organs. Major mechanisms for such protective effects include β-cell compensation, maintenance of near-normal blood nutrient levels, development of minimal IR, increased expansion of SAT relative to visceral adipose tissue, and limited increase in liver fat [9].

Alpha Cells (Increased Glucagon Secretion)

In as early as 1970s, it has been established that T2D individuals have elevated plasma glucagon levels [45–47]. While a reduction in β-cell mass is seen in diabetes patients as compared to normal individuals, there occurs no reduction in the α-cell mass. It is also proposed that β-cells dedifferentiate in T2D individuals and get converted to other cell types like glucagon-secreting α-cells [24]. Substantiating these, even when insulin levels progressively decline over the course of T2D, basal glucagon levels tend to remain elevated [48, 49].

The role of hyperglucagonemia in the maintenance of increased rates of HGP in T2D was demonstrated by Baron et al. [50]. In T2D, fasting glucagon levels are elevated, and the postprandial glucagon levels are not suppressed but paradoxically elevated. This raised blood glucagon levels increase the HGP leading to an elevation in FPG and PPG levels resulting in worsening of diabetes [49, 51].

Upon somatostatin infusion, there were declines in plasma glucagon levels by 44% and in basal HGP by 58%. When somatostatin was administered to alloxan-diabetic dogs [52] or to insulin-deprived T2D subjects [53], hyperglucagonemia was suppressed and hyperglycemia was reduced, even though insulin had been reduced or discontinued. Many other studies also support the prime role played by glucagon in T2D pathogenesis [45, 54, 55]. The drugs capable of inhibiting glucagon secretion or blocking the glucagon receptor are now proven effective in treating T2D [56–58].

Incretin Defect

Glucose ingestion can elicit a higher insulin response than an intravenous infusion which is explained by the incretin effect. The incretin hormones, Glucagon-like peptide-1 (GLP-1) secreted by the L-cells of the distal small intestine and Glucose-dependent insulinotropic peptide (GIP) by the K-cells of the more proximal small intestine, collectively act on the pancreatic islet [3, 8, 59, 60]. Of these, the GLP-1 acts on the β-cells to increase insulin and on the α-cells to suppress glucagon secretion [59]. GLP-1 thus imparts an indirect benefit on β-cell workload, since a reduction in glucagon levels leads to a reduced postprandial HGP. Gut hormones, including GLP-1, also have roles in central nervous system (CNS) regulation of energy balance and appetite [9, 61]. GLP-1 delays the rate of gastric emptying, results in a feeling of fullness and satiety, and is therefore associated with control of weight gain [3, 62, 63]. In T2D, the incretin effect is substantially impaired possibly due to impaired GLP-1 production and reduced sensitivity of β-cells to GIP [9, 64, 65]. Dysfunction in the glucagon secretion due to impaired incretin action is also suggested [66]. In subjects with NGT, IGT, or T2D, plasma GLP-1 levels do not seem to differ much [66] which suggests that the β-cell response to GLP-1 following meal ingestion is deficient, as seen during intravenous administration of GLP-1 under controlled conditions [67]. Elevations in GLP-1 levels are reported after bariatric surgery, which might partially explain the multiple beneficial effects of this intervention, especially among T2D individuals [8]. Numerous pharmacologic approaches are available nowadays that effectively harness the potential of incretins to treat diabetes, which include GLP-1 agonists and DPP4 inhibitors [68].

Kidneys (Increased Glucose Reabsorption)

The kidney's adaptive response to conserve glucose, which enables to meet the energy demands of the body, especially the brain and other neural issues, which have an obligate need for glucose, becomes maladaptive in diabetes. Rather than draining out the glucose into urine to correct the hyperglycemia, the kidney retains the glucose. Normally the kidney filters around 162 g of glucose daily, and the high-capacity SGLT2 transporter in the convoluted segment of the proximal tubule reabsorbs almost 90% of the filtered glucose, and the remaining 10% is reabsorbed by the SGLT1 transporter in the straight segment of the descending proximal tubule [69]. In both T1D and T2D, the maximum renal tubular reabsorptive capacity (Tm) for glucose is higher [70–73]. Therefore, in normal individuals, no glucose appears in the urine until the plasma glucose level is >180 mg/dL [74], whereas in T2D this threshold is much higher [72]. Medications to inhibit renal proximal tubular glucose reabsorption were thus thought out to treat T2D [69]. SGLT 2 inhibitors impart multiple benefits like better glycemic control by improving β-cell function and insulin sensitivity, reductions in body weight and blood pressure, etc. [75]. Currently, therapies aimed at inhibiting the SGLT1 receptors in the gut and downstream from SGLT2 receptors in the kidney are also underway [4, 76, 77].

Brain (Neurotransmitter Dysfunction and Central Appetite Dysregulation)

The nervous system also plays a key role in T2D pathogenesis. Sympathetic and parasympathetic nervous systems control glucose metabolism directly through the neuronal input and indirectly via the circulation to regulate insulin and glucagon release and HGP [8, 78]. Severing the vagus nerve impaired the insulin secretion revealing its important role in regulating the islet [79]. Ablation of the hypothalamus leads to β-cell dysregulation and subsequent hyperinsulinemia [80]. Insulin has a powerful appetite suppressing effect [81]. However, in obese individuals with or without diabetes, even though IR results in compensatory hyperinsulinemia, food intake seems to be higher indicating that the appetite centers are also IR. In a functional magnetic resonance imaging study where the cerebral response to ingested glucose was examined [82], consistent inhibition was noted in the lower posterior (which contains the ventromedial nuclei) and upper posterior (which contains the paraventricular nuclei) hypothalamus upon glucose ingestion. Both these areas are key appetite regulation centers, and the extent of inhibitory response upon glucose ingestion was decreased in these areas in obese, insulin-resistant, subjects even when euglycemic. A delay was also observed in the time taken to reach the maximum inhibitory response in these individuals even in the presence of a high plasma insulin response. Further studies have also indicated that cerebral IR leads to increased HGP and reduced muscle glucose uptake [83, 84]. High-fat diet-fed rodents are prone to inflammation-induced neuronal injury, and in humans, structural changes in the hypothalamus

have been observed in keeping with gliosis in obese compared to lean individuals [85]. Reduced dopamine levels in the hypothalamus and increased catecholamine levels in the CNS also contribute to the appetite dysregulation and are suggested to directly cause IR in liver and peripheral tissues [84, 86]. The neuroendocrine hormone amylin is also deficient in T1D and T2D [7], and its effect on appetite dysregulation is suggested to be chiefly mediated via central pathways that include high-affinity binding sites in the area postrema in the hindbrain [87]. It also has direct gut effects through a decrease in the rate of gastric emptying [88]. Clock genes located in the brain which are major determinants of circadian rhythmicity, together with sleep, are now being investigated due to their role in metabolic processes [89, 90].

The "Dirty Dozen," the "Unlucky Thirteen" and Much More

Dopamine

Dopamine the most abundant catecholamine in the brain has been nicknamed as the "forgotten felon" of diabetes [5], and along with the other catecholamines of the autonomic nervous system, this neurotransmitter modulates glycemia. It was Kalra et al. who proposed the specific addition of dopaminergic system as a ninth contributor to the T2D development [91]. Mammalian species have an inherent capacity to alter their metabolism from the insulin-sensitive/glucose-tolerant state to the insulin-resistant/glucose-intolerant state at exactly the right time of the year to meet the varying energy demands. Such seasonal metabolic changes are governed by the changes in monoaminergic concentrations/activity in the suprachiasmatic nuclei (SCN) of the hypothalamus—the mammalian circadian pacemaker—and in the ventromedial hypothalamus (VMH). Development of an IR state during such seasonal changes exactly mimics the T2D state: muscle and hepatic IR, increased HGP/gluconeogenesis, hyperglycemia, adipocyte IR and enhanced lipolysis, increased plasma FFA and triglyceride levels, and obesity. Evidences implicate endogenous dopaminergic and serotonergic rhythms in SCN and VMH in the transition from the insulin-sensitive to insulin-resistant state. In the animals that undergo seasonal changes in metabolism, within the VMH, during the insulin-resistant state, both serotonin and noradrenergic levels and activity are enhanced and decrease to normal levels upon returning to the insulin-sensitive state. On the contrary, dopamine levels are decreased during the IR state and increase to normal following return of the insulin-sensitive state. A selective destruction of dopaminergic neurons in SCN of the hypothalamus resulted in severe IR [86, 92, 93].

Both systemic [94, 95] and intracerebral [96] bromocriptine (a sympatholytic D2-dopamine agonist) administration to insulin-resistant animals decreased the elevated VMH noradrenergic and serotonergic levels with a resultant decline in HGP, reduced adipose tissue lipolysis, and improved insulin sensitivity. In T2D and obese nondiabetic individuals, systemic bromocriptine administration improved glycemic control and dyslipidemia without changes in body weight [97]. It was postulated that in T2D patients hypothalamic dopamine reduces in the early morning leading to elevated HGP and lipolysis resulting in glucose intolerance, IR, and dyslipidemia. Timed bromocriptine (quick release formulation) administration within 2h of awakening augmented low hypothalamic dopamine levels and decreased the sympathetic tone within the CNS, leading to an increase in insulin sensitivity, suppression of HGP, and thereby a reduction in PPG levels [86].

Vitamin D

Vitamin D subserves a range of biological functions like cell differentiation, inhibition of cell growth, and immunomodulation. Both direct and indirect effects of vitamin D on various mechanisms related to the T1D and T2D pathophysiology have been postulated including pancreatic β-cell dysfunction, impaired insulin action, systemic inflammation, and apoptosis. Vitamin D receptors occur in all tissues and organs that are involved in these diseases, and the machinery for producing vitamin D locally is also present in islets, immune cells, and other tissues involved [6, 98–100]. Children receiving recommended dose of vitamin D during the first year of life had an 80% reduced T1D risk [101]. Lower vitamin D levels might result in impaired β-cell function with lowered insulin secretion and sensitivity and with higher IR [102] and might also pose a risk for developing macrovascular and microvascular complications [103]. Among Caucasian children and adolescents, low vitamin D levels were associated with total adiposity, MetS, and hypertension [104]. Vitamin D supplementation to T2D and nondiabetic subjects impart beneficial effects on glucose homeostasis and other markers of MetS like improving β-cell function and insulin secretion and reducing IR [105, 106].

Renin-Angiotensin System

Evidences suggest a role for the RAS in the development of IR and T2D [107, 108]. Detrimental effects that RAS has on insulin secretion is mediated by a decrease in pancreatic blood flow and induction of islet fibrosis, oxidative stress, and inflammation, whereas both impaired skeletal muscle function (disturbances in skeletal muscle blood flow, insulin signaling, and mitochondrial function) and adipose tissue

(AT) dysfunction (adipocyte hypertrophy, inflammation, and impairments in AT blood flow and lipid metabolism) may contribute to RAS-induced IR [108]. Frequent association of T2D with hypertension, retinopathy, nephropathy, and cardiovascular disease (CVD) has also implicated RAS in the initiation and progression of these disorders.

RAS blockade significantly improves insulin sensitivity [109–111] and significantly reduces the incidence of vascular complications in T2D [112–114]. Such improvements are postulated to be due to the improvement of blood flow and microcirculation in skeletal muscles, decrease in adipocyte size, protective actions on pancreatic islets, etc., thereby facilitating insulin signaling at the cellular level and improvement of insulin secretion by pancreatic β-cells [7, 115–118]. Among high-risk populations, RAS blockade using either angiotensin II receptor blockers (ARB) or angiotensin-converting enzyme inhibitors (ACEI) led to a 22% reduction in the incidence of new-onset T2D [119]. The DREAM study in individuals without CVD but with impaired fasting glucose levels or IGT showed that the ACEI ramipril did not significantly reduce the diabetes incidence or death but significantly increased the regression to normoglycemia [120]. The NAVIGATOR study among individuals with IGT and CVD or risk factors showed that ARB (valsartan) use, along with lifestyle modification, caused a relative 14% reduction in the diabetes incidence but did not reduce the rate of CVD events [121]. Despite the lack of consistency in the findings between many of these trials, sub-analyses of some of them have shown that RAS inhibitors improve glucose levels and reduce the risk for diabetes in higher-risk populations [107, 122, 123].

Testosterone

An association between low testosterone and T2DM risk in men is well-proven [124–126]. Morbid obesity imposes negative effects on the hypothalamic-pituitary-gonadal axis in men [127]. A bidirectional relationship between visceral fat and testosterone is suggested, which sets up a self-perpetuating cycle promoting IR and diabetes. High visceral fat increases secretion of proinflammatory cytokines, estradiol, insulin, and leptin, all of which may inhibit the hypothalamo-pituitary gonadal axis activity at multiple levels [128, 129]. Decreased testosterone levels also build up IR via mechanisms involving the muscle [130], liver [131], and bone [132]. Testosterone decreases IR by regulating mature adipocytes and myocytes. Testosterone also increased catecholamine-induced lipolysis in vitro [133] and decreased lipoprotein lipase activity and triglyceride uptake in abdominal adipose tissue in humans [134]. A positive correlation exists between testosterone levels and insulin sensitivity, and the individuals with hypogonadal testosterone levels had higher BMI and higher prevalence of the MetS than their eugonadal counterparts [130]. Other studies, including the landmark studies like Massachusetts Male Aging Study (MMAS) and Multiple Risk Factor Intervention Trial (MRFIT), have all demonstrated an inverse association between low testosterone levels and risk for MetS and diabetes [126, 135–137]. Further, low sex hormone-binding globulin (SHBG) may lead to IR and to lower total testosterone [138]. Among prostate cancer patients subjected to androgen deprivation therapy (ADT), lower testosterone levels were associated with increased IR [139, 140] and an increased diabetes risk [141]. Testosterone substitution in hypogonadal men improved insulin sensitivity and glycemic control [142, 143]. In men with newly diagnosed diabetes, the addition of testosterone to a regimen of diet and exercise significantly improved the outcomes on glycemic control and reversal of the MetS [143, 144].

Interestingly, the effect of testosterone on IR and T2D is opposite between males and females. Its low concentrations in males but high concentrations in females favor IR and T2D [145–147]. In a systematic review and meta-analysis by Ding et.al, endogenous levels of testosterone and SHBG were found to exhibit sex-dependent relations with the risk of T2D. Elevated testosterone levels were linked to greater T2D risk in females but lower risk in males. Meanwhile, SHBG was more protective in females than in males [147]. Polycystic ovary syndrome (PCOS), characterized by chronic anovulation and hyperandrogenism, was also suggested to have partly contributed to this observed positive testosterone association in females. Insulin resistance with compensatory hyperinsulinemia is the key pathogenic factor in PCOS and can lead to the onset of hyperandrogenism by stimulating ovarian androgen production and by decreasing the SHBG levels. Females of reproductive age with PCOS are thus prone to metabolic disorders and T2D [147, 148].

Gut and Gut Microbiota

Gut

Centuries back, the ancient Greek physician Hippocrates had said: “All Disease Begins in the Gut.” Mounting evidence strongly supports the above-quoted hypothesis, and in 2016 Somasundaram et.al. proposed the role played by gut as the thirteenth mechanism in diabetes pathogenesis [7]. Even though the contribution of gastrointestinal (GI) carbohydrate absorption toward T2D pathogenesis had long been known, its contribution was rather underutilized as a target for therapy. Alpha-glucosidase inhibitor (AGI) is the only class of drug that effectively utilizes this mechanism for the treatment

of diabetes and has clear beneficial effects on glycemic control and post-load insulin levels [149]. SGLT1 plays a distinct and complementing role to SGLT2 in glucose homeostasis. Within the GI tract, SGLT1 is responsible for glucose absorption and is also involved in 10% of renal glucose reabsorption. Inhibition of SGLT1 and combined inhibition of SGLT1/SGLT2 is thus a new anti-hyperglycemic concept [4, 76, 77], which further implies the contribution of GI carbohydrate absorption in T2D pathogenesis.

Bile acids also play a significant role in modulating glucose homeostasis, and bile acid homeostasis is altered in T2D. Bile acids act as signaling molecules through receptor-dependent and receptor-independent pathways [150]. They act as endogenous ligands of the farnesoid X receptor (FXR), and their activation of FXR leads to the release of fibroblast growth factor (FGF) [151]. Through FXR, bile acids suppress the in vitro expression of fructose-1, 6-biphosphatase-1, gluconeogenic phosphoenolpyruvate carboxykinase and glucose-6-phosphatase [152]. G-protein-coupled receptors TGR5 (also termed GPR131) located on intestinal L-cells are activated by bile acids, resulting in GLP-1 secretion [153]. Intraduodenal bile acid infusion dose-dependently enhanced the plasma FGF19 concentrations, with smaller effects on GLP-1 and CCK [154, 155]. FGF19 possess insulin-like effects inducing glycogen and protein synthesis while suppressing glucose production [8]. A second-generation bile acid sequestrant colesevelam modestly reduces glucose in T2DM when used as an adjunct to other agents. Suggested mechanisms include its effect on bile acid receptors in the intestine as well as in the liver to reduce endogenous glucose production [7, 156].

Gut Microbiota

Besides the gut, the gut microbiome is also involved in the T2D pathogenesis [7, 8, 157, 158]. Gut dysbiosis, intestinal barrier dysfunction, and subsequent metabolic endotoxemia are all closely related to the inflammation, IR, and finally CVD events in T2D [159, 160]. Individuals with prediabetes or T2D have a moderate degree of gut microbial dysbiosis in terms of a reduction in the abundance of certain universal butyrate-producing bacteria (*Faecalibacterium prausnitzii*, *Roseburia intestinalis*, etc.) and an increase in various opportunistic pathogens (like *Lactobacillus* sp.) [160, 161]. In individuals with MetS, vancomycin treatment decreased the abundance of butyrate-producing gram-positive bacteria, which correlated well with impaired insulin sensitivity [162]. Decreased levels of butyrate-producing gut microbes in T2D individuals were thus suggested to lead to disease pathogenesis. Among the short-chain fatty acids, butyrate acts as a prominent energy source for intestinal epithelial cells and influences a variety of colonic mucosal functions, reinforcing the colonic defense barrier and attenuating oxidative stress [163]. Butyrate also enhances the intestinal barrier by modulating the assembly of tight junctions (TJs) via AMP-activated protein kinase (AMPK) activation [164]. Feces of T2D subjects were relatively enriched with endotoxin-producing gram-negative bacteria (phyla *Bacteroidetes* and *Proteobacteria*) which suggested the role played by these phyla in T2D pathogenesis through an endotoxin-induced inflammatory response pathway [161]. In the liver, cholic acid and chenodeoxycholic acid constitute primary bile acids produced from cholesterol, and the gut microbiota transforms these primary bile acids into secondary bile acids [165]. In line with these facts, 6 weeks after the infusion of intestinal microbiota from lean subjects, an improvement in insulin sensitivity was noted in subjects with MetS [166].

Iron Overload

There is no active mechanism for iron excretion in humans, and the amount of iron absorbed into the body is balanced by the iron lost by means of sloughing of the intestinal mucosa and skin and also lesser amounts that are excreted in the urine and bile [167]. Iron overload is thus a risk factor for T2D [168], whereas its depletion has a protective effect against T2D.

The foremost evidences for this were obtained from studies related to pathologic iron overload disease conditions like hereditary hemochromatosis (HH) [169] and transfusional iron overload [170]. Both insulin deficiency and IR can contribute to the T2D pathophysiology associated with HH [171, 172]. Individuals with HH have an inherent insulin secretory defect, making them highly prone to develop diabetes especially when IR from an independent mechanism such as obesity intervenes [173]. HH individuals have extremely high ferritin levels (1,000–10,000 ng/ml), and around 25–60% of them develop "secondary" T2D [174, 175]. Transfusional iron overload is usually seen in transfusion-dependent chronic hemolytic anemia such as β-thalassemia. Due to the numerous transfusions that are required to maintain adequate erythrocyte levels and the resultant increased iron absorption, these patients become iron overloaded [176]. Individuals with β-thalassemia mostly develop IGT during the second decade of life, and a diabetes prevalence is reported among 6–14% of the patients [177, 178]. T2D is also prevalent among survivors of pediatric bone marrow transplantation [179] and allogeneic hematopoietic cell transplantation [180]. Some rare inherited diseases that cause diabetes such as Friedreich ataxia are associated with iron imbalance and with mutations in the proteins involved in iron metabolism [181].

Positive associations between elevated body iron stores (measured as circulating ferritin), and the risk of T2D and of other IR states such as the MetS, GDM, PCOS, and possibly CVD, have been demonstrated [174, 182, 183]. Moderate increases in iron stores (lower than the levels found in HH subjects) were associated with increases in blood glucose and insulin levels. Furthermore, moderately increased body iron stores at baseline were associated with an elevated risk of developing T2D in the future [175]. In a National Health and Nutrition Education Survey (NHANES), the odds ratios for newly diagnosed diabetes in individuals with higher serum ferritin levels were 4.94 for males and 3.61 for females [184]. A link has also been established between increased dietary iron intake (particularly heme iron) and the risk for T2D and GDM [185–188]. No significant association of dietary intakes of total iron, non-heme, and supplemental iron intake was found with the risk of T2DM, whereas heme iron intake showed a positive association, after adjustment for potential confounders. Individuals who consume meat (a major source of heme iron) are thus reported to be more IR compared to the vegetarians [174, 175].

Iron overload is also implicated in the pathogenesis of many diabetes-associated vascular complications including diabetic nephropathy (DNP) and CVD [185]. In individuals with DNP, an increased proximal tubular lysosomal iron concentration has been observed. In iron-loaded subjects with thalassemia, an early development and accelerated course of DNP is reported. Similarly, mutations for HH appeared to predict the development of DNP [189]. Iron has an adverse effect on endothelium and accelerates the development of atherosclerosis. Elevations have been observed in ferritin gene expression during the course of atherosclerotic plaque formation [189, 190].

Multiple mechanisms have been proposed toward the association between iron and abnormal glucose metabolism, like β-cell dysfunction and IR, possibly mediated through oxidative stress [185, 191]. Being a redox-active transitional metal, excess iron is potentially hazardous. It catalyzes several cellular reactions that lead to the production of reactive oxygen species and thereby to an elevated oxidative stress, which is proposed to contribute to an increased risk of T2D. Pancreatic β-cells, due to their weak antioxidant defense system, are highly susceptible to oxidative damage, and thus iron deposition in these cells can result in impaired insulin secretion. In the muscle, iron overload may diminish glucose utilization, thereby leading to a shift from glucose to fatty acid oxidation, resulting in an increased IR. Increased substrate recycling to the liver may contribute to an elevated HGP. Iron may also impair the action of insulin and interfere with glucose uptake in adipocytes. Elevations in systemic inflammation may also modify iron metabolism. Inflammatory cytokines are found to induce the synthesis of ferritin [174, 175]. As iron influences the action of insulin, insulin also is in turn known to influence iron metabolism. Insulin plays a role in redistributing transferrin receptor (TfR) to the cell surface and thereby increasing the cellular uptake of iron in adipose tissue and the liver. Thus in the IR states, inherent hyperinsulinemia leads to elevations in levels of circulating soluble form of TfR (sTfR), a marker of iron status [174].

The potential benefit of iron depletion on insulin sensitivity and/or T2D has been evaluated by many. Phlebotomy enhanced insulin sensitivity and glycemia, in normal as well as T2D subjects with elevated ferritin levels [174, 192]. In HH patients, phlebotomy and/or iron chelation therapy (to decrease body iron stores) improved their glycemic control, and 30–40% of them achieved either elimination of oral diabetes therapy or a substantial decrease in dosage [193]. Blood donations reduce the circulating ferritin levels and frequent blood donors seem to have a better insulin sensitivity than the non-donors. Increased number of lifetime blood donations was found to be associated with decreased prevalence of T2D [194]. Among T2D individuals who were negative for common HH but had increased serum ferritin concentration, bloodletting improved their insulin sensitivity and reduced their C-peptide levels [189].

Conclusion

With the ever-increasing epidemic of obesity, physical inactivity, and an aging population, the prevalence of T2D is reaching pandemic proportions. This demands rigorous efforts to improve our understanding of this devastating disease. Valiant research endeavors have led to an improved understanding of the causality and pathophysiological aspects of T2D. From humble beginnings, with the recognition of only two factors, defective insulin secretion and IR, we are now able to appreciate the complexity and heterogeneity of the role-players in the pathogenesis of T2D (see Fig. 8.4). It is likely that many more factors are yet to be unveiled. While addressing the modifiable risk factors to prevent T2D, this knowledge empowers us to utilize the existing therapies efficiently and inspires us to explore and develop newer effective therapies. The complexity of T2D demands, a multifaceted therapeutic approach, which combines pharmacological and non-pharmacological interventions in an individualized way.

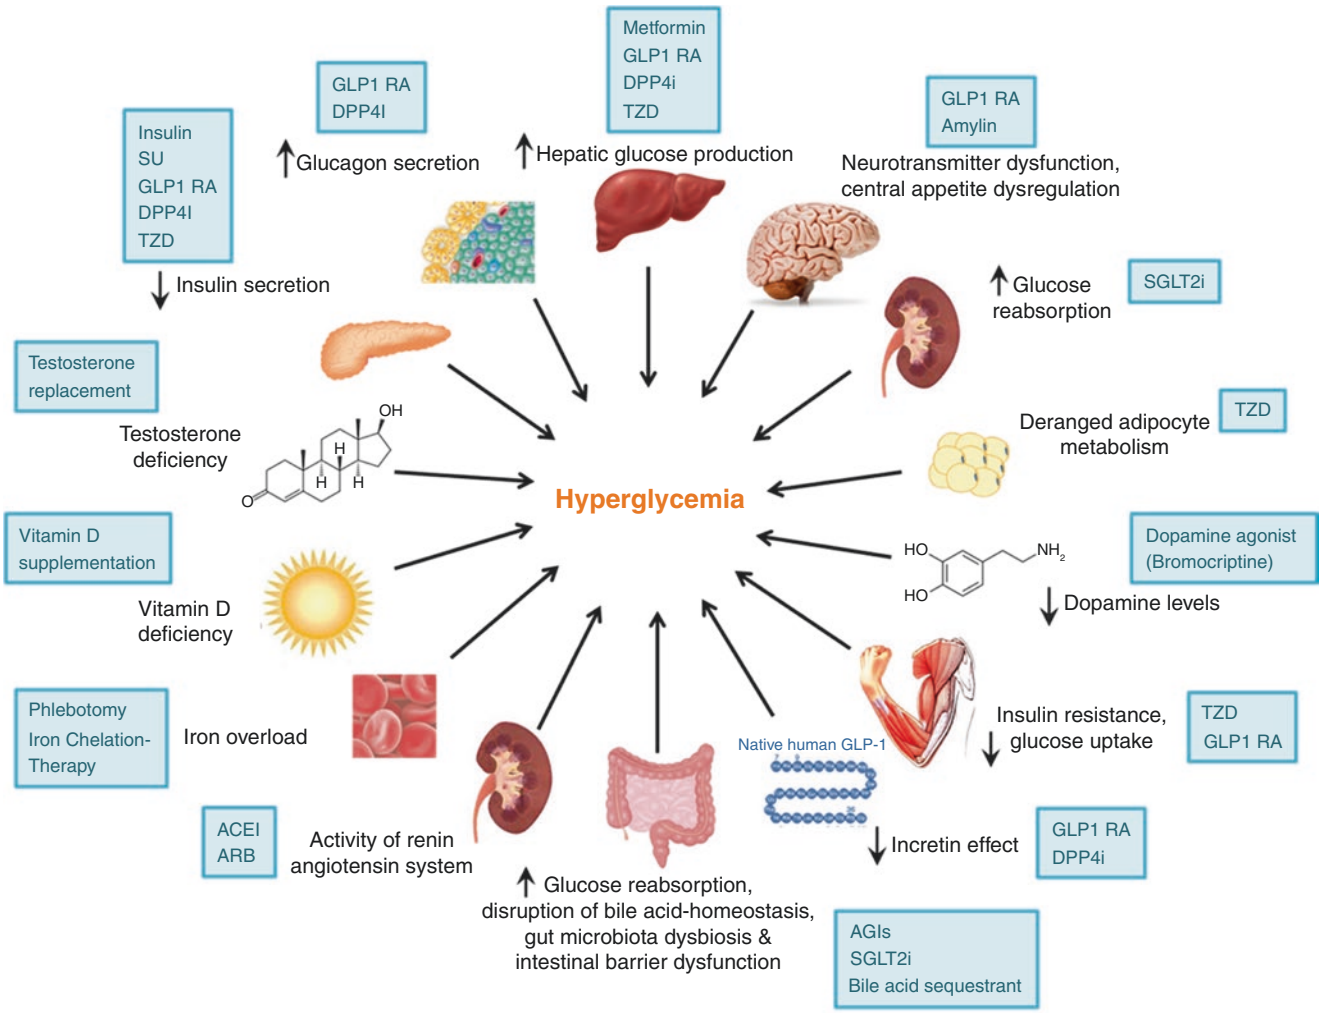

Fig. 8.4 Players in the pathophysiology of T2D

Multiple Choice Questions

1. In the postabsorptive state, most of the glucose utilization occurs:
   (a) In the muscle
   (b) In the brain
   (c) In adipose tissue
   (d) In beta cells
   (e) In red cells
2. Regarding lipoprotein metabolism:
   (a) Insulin has not demonstrated effects.
   (b) Insulin increases circulating VLDL levels.
   (c) Insulin stimulates lipoprotein lipase in adipocytes, promotes lipolysis and removal of chylomicrons.
   (d) Insulin stimulates lipoprotein lipase in vascular endothelium, promotes lipolysis and removal of chylomicrons.
   (e) Insulin increases triglyceride levels.
3. In the event of hepatic insulin resistance:
   (a) Hepatic glucose production is suppressed by low fasting insulin levels.
   (b) Hepatic glucose production initially continues but is suppressed as insulin levels increase.
   (c) Hepatic glucose production is stable.
   (d) Hepatic glucose production continues even when fasting insulin levels are high.
   (e) Hepatic glucose production is suppressed.
4. Postprandial hyperglycemia results:
   (a) From hepatic insulin resistance
   (b) From peripheral tissue insulin resistance
   (c) From beta-cell insulin resistance
   (d) From increased hepatic glucose production
   (e) From decreased transport of glucose in the central nervous system

5. The core physiological defects proposed in the triumvirate concept include the following except:
   (a) The central nervous system
   (b) Pancreatic alpha-cells
   (c) Pancreatic beta-cells
   (d) The liver
   (e) Skeletal muscle
6. Individuals in the upper tertile of "normal" glucose tolerance:
   (a) Maintain 100 percent of beta-cell function
   (b) Have lost 20 percent of beta-cell function
   (c) Have lost 50 percent of beta-cell function
   (d) Have lost 70 percent of beta cell-function
   (e) Have lost 100 percent of beta-cell function
7. Amyloid deposits within the pancreas:
   (a) Have a protective effect on beta-cell function
   (b) Are crucial to initiate type 2 diabetes
   (c) Are involved with disease progression
   (d) Are associated with disease remission
   (e) Indicate glucose toxicity
8. Insulin resistance
   (a) Appears year before the onset of type 2 diabetes
   (b) Is an unusual manifestation of type 2 diabetes
   (c) Is a late manifestation of type 2 diabetes
   (d) Occurs at the same time as beta-cell failure
   (e) Always evolve to type 2 diabetes
9. Hepatic gluconeogenesis is facilitated by:
   (a) The incretin effect
   (b) By overactivity of the beta-cells
   (c) By basal insulin secretion
   (d) By high levels of VLDL lipoproteins
   (e) By high levels of free fatty acids
10. In persons with type 2 diabetes, the largest impairment of glucose disposal occurs:
   (a) In the central nervous system
   (b) In adipose tissue
   (c) In the kidney
   (d) In skeletal muscle
   (e) In erythrocytes

Correct Answers

1. (a) In the muscle
2. (d) Insulin stimulates lipoprotein lipase in vascular endothelium, reduces lipolysis and removal of chylomicrons
3. (d) Hepatic glucose production continues even when fasting insulin levels are high
4. (b) From peripheral tissue insulin resistance
5. (a) The central nervous system
6. (c) Have lost 50 percent of beta-cell function
7. (c) Are involved with disease progression
8. (a) Appears years before the onset of type 2 diabetes
9. (e) By high levels of free fatty acids
10. (d) In skeletal muscle

Genetic Determinants of Type 2 Diabetes

9

Miguel Cruz, Adán Valladares-Salgado,
Eugenia Flores-Alfaro, and José de Jesús Peralta Romero

Definition of Genetic Polymorphisms

The genetic information of modern man, or *Homo sapiens*, is kept along 23 pairs of chromosomes located in the nucleus of every diploid cell. Diploid is understood as the cells that have in their nucleus a double number of chromosomes, that is, two complete copies of the genomes inherited from the parents, which correspond to maternal and paternal alleles.

Sequencing studies have described that the human haploid genome is made up of approximately 3300 million pairs of bases (3300 Mb), of which approximately 25,000 genes have a coding function and, of these, only 8% (8000) have a known function and/or action mechanism [1].

Genes are considered the unit of genetic information that codes a functional product and as a unit of inheritance, which are distributed throughout the chromatids of the chromosomes, is a specific position of DNA, known as the locus. During the process of transcription, a copy is made of the DNA, which is known as the heterogeneous nuclear RNA, which proceeds to form mRNA, which codes for structural and functional proteins.

Approximately a 99.9% of the DNA sequence is identical in humans, and the remaining 0.01% represents genetic or allelic variations, also called SNPs. The presence of SNPs varies in different populations and can explain evolution theories, migrations, and even the ethnic origin of different populations. In addition, it offers information about the phenotypical diversity within the same species, which describes a proportion of relative susceptibility to certain diseases among individuals.

The Importance of Studying Genetic-Environmental Variant Interaction and Its Perspective in Clinical Application

There are various kinds of polymorphisms which are characterized by their presence or absence and their shape or size, the largest being insertions and deletions. In addition there are other genetic variants known as repetitions of the copy number (CNV, copy number variation) and SNPs. Unlike mutations, SNPs are changes with a frequency greater than 1% of the population. If SNPs are characterized by a simple exchange of nucleotides of adenine, cytosine, thymine, or guanine in the alleles, they are extremely important due to the fact that they are responsible for almost 90% of human phenotypical diversity. In 2008, for the first time, "1000 Genomes Project" initiative was proposed, to analyze the genetic material of 1000 people around the world and to study genetic variability. Finally, in 2015, the number of subjects analyzed reached 2500; the data suggested that in every healthy individual, there are around 150 variants that cause premature ending of proteins and another 30 implicated in the appearance of rare diseases. In addition to the presence of more than 84 million SNPs in the human genome, they located between 100 and 300 pairs of bases throughout the genome [2, 3], generated by the genetic recombination or missense. (http://www.internationalgenome.org/data#download).

It has been reported that approximately 88% of the SNPs associated with disease are located in intronic and intergenic noncoding regions, which are found in areas not related with sequences that contain essential information for the expression of a gene [4]. The remaining 12% of the SNPs are called "coding," integrated in exonic areas, giving way, in the majority of cases, to proteins that can differ in their composition and biological functions. Also, exonic SNPs may be synonymous and not produce a change in amino acid or not synonymous and change the sequence of amino acids that would alter the

structure, conformation, and shape of the protein. Due to the fact that SNPs are genetically stable, they are maintained for various generations and can act as true biological signals. Currently SNPs are considered ancestral risk or protector markers for diseases, from the clinical point of view. Nevertheless, their analysis is complex due to the fact that clinical phenotypes are the result of the interaction between the genotype and the exome that involves personal pathological background and unhealthy lifestyle, which contribute to the metabolic alteration present in T2D. Therefore, the evaluation of the gene-environment correlation in cohorts will allow a better understanding and interpretation of the physiopathology of the genic behavior of complex metabolic diseases, which hold first place in global morbi-mortality. In addition they will create useful tools in early detection, prevention, and more effective treatment in order to reach adequate therapeutic goals [5].

Genome-Wide Association Study (GWAS)

Identifying the genetic determinants associated with T2D has been a complex task, due to the role that is also played by the environment in the development of the disease. Nevertheless, currently there are various genetic markers, distributed throughout the genome. Analysis of previously reported candidate genes has allowed confirmation of the association of the genes with the disease in various populations; however, replication is not always successful due to phenotypical variation and ancestry. GWAS is a method that bases its analysis on statistical and biological associations among various SNPs and phenotypes of the diseases.

The rapid development of genotyping techniques and the reduction in costs has allowed a greater number of GWAS. These studies use microarrays with more than 1,000,000 SNPs and have transformed research into the genetics of complex diseases, diabetes being outstanding. GWAS are characterized by possession of a greater power to discover variants with a modest effect, whose association is not previously known. The first studies confirmed the associations between T2D and various genetic variants located on *PPARG* genes, adding six new loci (*CDKAL1*, *HHEX*, *SLC30A8*, *IGF2BP2*, *CDKNA2A*, and *FTO*). Typically, each copy of these susceptibility alleles increases the risk of suffering diabetes by 10–15% [6].

Initially, GWAS was performed on European population and later in other populations from the African and American continents with different ethnic groups, which has contributed to identification of a greater number of genes associated with T2D. Table 9.1 shows the association of various SNPs with susceptibility to developing T2D in a trans-ethnic meta-analysis that included 1000 of cases and controls with European, East Asian, South Asian, Mexican, and Mexican American ancestry groups [7]. To date, there are more than 80 SNPs, among which variants in genes *WFS1*, *HNF1A*, *HNF1B*, *IRS1*, and *MTNR1B*. The importance of the genetic

Taken from Mahajan et al. [7]

component of T2D is clear when a concordance of 70–90% of the disease is observed between identical twins.

GWAS has allowed us to understand with greater precision the physiopathology of T2D, in order to establish better opportunities for treatment, diagnosis, and patient monitoring. From the genetic viewpoint, T2D is a multifactorial disease where the phenotype of a group of genes is modulated by environmental factors. The action mechanisms involved in the majority of signs associated with T2D offered by GWAS are involved in reduction in the secretion of insulin (be it due to dysfunction of the pancreatic beta cells or through reduction of cellular mass) or insulin resistance (associated with obesity). In conclusion, GWAS has offered important knowledge of the genetic variants most associated with T2D in the world [8]. Another focus for complex diseases is whole-exome sequencing. This has been successful in the study of low frequency variants.

The Importance of Ancestry in Association Studies

It is known that in populations native to the American continent, there was a process of miscegenation that took place when the Amerindians and Europeans met in the New World five centuries ago. The latest studies show that the genetic composition is different in each country, and within the same country, there are regional differences. For example, in Mexico it has been shown that Mexico City has the following percentages: 65% native American, 30% European, and 5% African, while Monterrey City, N.L. the percentage was 56% native American, 38% European, and 6% African [9, 10]. Even, in Mexico City there are variations in the proportions of ancestry when we compare the IMSS vs INMEGEN studies [11]. Recently, a high prevalence of Amerindian ancestry was reported in the Montaña region of the State of Guerrero, reaching 80% of Amerindian [12].

In Mexico there is a very high degree of stratification, where the differences in allele frequencies between groups and controls can lead to false associations [9]. The admixture mapping method avoids these false associations and requires markers that may be informative concerning ancestry, that is, those for which allele frequencies differ between mixed populations. With this method data is combined from all the markers to obtain information about ancestral alleles of each marker locus and then for the association of the disease with ancestral background. We can combine the information from multiple markers in a multivariate analysis to obtain information about the ancestral alleles of each locus of each individual in the admixture.

The importance of this chapter is to describe the most important genetic variants associated with T2D (Table 9.1), for more information about frequencies, haplotypes, etc. can be consulted in http://www.internationalgenome.org/ and variants associated with diseases like T2D in the link with the ENCODE Project, https://www.genome.gov/10005107/.

Genes Associated with T2D

Variants of the *TCF7L2* gene

The *TCF7L2* gene has a clinical relevance because it is implicated in a wide variety of signals, insulin resistance, and T2D, specifically the variant rs7903146 in European populations, later also in Latin peoples. In 2006, the first gene implicated in susceptibility to T2D was identified through microsatellite markers, being identified without previous biological knowledge and with an important power of association, which was named *transcription factor 7-like 2 gene* (*TCF7L2*; *TCF4*). It is known that *TCF7L2* is a transcription factor that influences the transcription of various genes, thus exercising a great variety of functions within the cell. This transcription factor is a member of the signaling pathways of Wingless Int (WNT), located on chromosome 10q25. Stimulation of the WNT pathway goes along with the association of β-catenine with BCL9 and its translocation to the nucleus associated with *TCF7L2*, which results in the activation of WNT target genes, specifically in the repression of synthesis of proglucagon in enteroendocrine cells. The noncoding area contains cis-regulatory elements that lead to expression of *TCF7L2* in various tissues involved in the

homeostasis of glucose, which suggests that the variants are probably regulating the expression of this gene. The T risk allele of *rs7903146* presents greater expression in the pancreas than the C protector allele [13]. Markers located on intron 3, *DG10S478*, and SNPs *rs12255372* (allele G > T) and *rs7903146* (allele C > T) were the first markers associated with T2D in individuals in Iceland [14]. Later, this association was replicated in various populations of the world, so that this gene susceptible to T2D has become the most important worldwide. In European population, each copy of the susceptibility allele increases the risk of developing T2D 1.4–1.5 times. In Mexican population, the risk is 1.78 for each copy of the T allele for rs12255372, after adjusting with ancestral markers [15].

Lyssenko et al. showed that the risk given by the T allele of *rs7903146* associates with a lack of insulin secretion, with the effect of incretin and increase in the production of hepatic glucose. In addition, a cohort in Bosnia and another in Malmö showed how diabetes-free survival is greater in individuals with genotype CC than in individuals with CT/TT del *rs7903146* [12].

Variants of Genes *ABCC8* and *KCNJ11*

Genes of the family *ABCC8* (union cassette ATP, subfamily C, member 8; SUR1) and *KCNJ11* (inwardly rectifying potassium channel, subfamily J, member 11; KIR 6.2) are located on chromosome 11p15.1; it has been observed that both are expressed in beta cells, and it has been reported that various polymorphism versions on these genes associate with insulin secretion disorders [16].

It has been noted that carriers of the variant *p.Arg1420His* of gene *ABCC8* have twice the risk of developing T2D, mainly among Pima Indians, although this also applies to subjects with mostly Native American ancestry [17].

In Europeans the association has been reported with variant *KCNJ11 E23K* (OR 1.23), but not with *ABCC8* (15). Nevertheless, between these two genes, there is a high degree of linkage disequilibrium (LD), which makes it harder to identify the variant causing the risk of the disease [18].

Variants of the *CAPN10* Gene

Calpain is a cysteine protease, which participates in various functions such as apoptosis, exocytosis, mitochondrial metabolism, and remodeling of the cytoskeleton and insulin secretion. Its expression is very high in metabolically important organs such as the heart, liver, pancreas islets, and muscle. Known as the common gene in diabetes, it is located on chromosome 2q37.3, formed by 15 exons and showing 8 isoforms [19]. The most recent meta-analysis showed that the C allele of *rs2975760* of *CAPN10* was the best associated with increased risk of T2D [20]. However, an analysis by haplotypes showed that individuals with haplotype 1121/1121 for SNP-44, SNP-43, SNP-19, or SNP-63 presented twice the risk of T2D than only SNP-*43* [21]. This haplotype is not associated in other populations, which means that the genetic structure of each population is important and should be considered, as in other SNPs.

Variants of the *PPARγ* Gene (*Peroxisome Proliferator-Activated Receptor Gamma*)

PPAR is a protein, member of a superfamily of nuclear receptors, which has a weight of approximately 56 kD. PPAR affects mechanisms present in the control of steroid hormones, of glucocorticoids, or thyroxine, of retinoic acid and of vitamin D, but mainly acts in the regulation of the expression of specific genes through a mechanism that is common to members of the nuclear receptor superfamily. It has been reported that the PPAR family is comprised of various subtypes, known as PPARα, PPARβ/δ, and PPARγ. This latter is coded by three different genes: *PPARγ1*, *PPARγ2*, and *PPARγ3*. The main function is the regulation of genes that participate in lipid and glucose metabolism. Variant of *PPARγ2* in 3p25 only is expressed in adipose tissue and regulates the differentiation, storage of lipids, and control of the transcription of various genes implicated in the metabolism, and it also participates in insulin sensitivity [22]. Various studies have shown that PPAR antagonists improve hyperlipidemia and glucose levels.

Pro12Ala (*rs1801282*) has been associated with T2D in different populations. *Pro12Ala* has a prevalence of 12% in Caucasian population, 10% in Native Americans, and 1% in Chinese. This change in amino acid near the extreme amino terminal (NH2-terminus) modulates the transcriptional activity. Alanine favors the formation of alpha-helix, which does not occur with proline, which forms alanine isoforms and stimulates deficiency in the target genes of the gene, carrying to the individual carriers a lesser accumulation of adipose tissue. In the latest meta-analysis, an OR of 0.86 was calculated, but unfortunately, the majority of the population at the global level carries the allele Pro12, which generates a high risk of T2D [23].

On the other hand, it has been noted that *PPARγ* has been highly studied, due to the fact that its ligands interact with thiazolidinediones, drugs used in the treatment of T2D. The effects of ligands of *PPARγ* are diverse, but the total effect is improvement in insulin sensitivity, in addition to regulation of other genes that have functions in glucose homeostasis and adipocyte differentiation.

Variants of the *CDKN2A/B* Gene

CDKN2A/B gene is located in region 9p21 and codifies for a protein p16, which has the function of inhibiting cyclin-dependent kinase p16 (INK4A) and p15 (INK4B), coded by the gene *CDKN2A* and a long noncoding RNA known as *ANRIL* (*CDKN2B-AS*) [24]. It participates in the cellular cycle and helps maintain pancreas beta cell mass, but the mechanism by which *CDKN2A/B* influences diabetes risk is not yet clear. The risk allele of marker *rs10811661* has been associated with reduced insulin secretion in European population [25], while genes *MTNR1B*, *TCF7L2*, and *KCNJ11* associate with the dysfunction of β cells; both pathways are related with reduction of insulin secretion [16].

Variants of the *FTO* Gene

Association of the fat mass and obesity-associated (*FTO)* gene with obesity was first reported in a European GWAS performed in individuals with T2D [26]. The power of association of the variant of the *FTO* gene with T2D was lost when correcting for body mass index (BMI), which suggested that susceptibility was being measured through obesity. Other studies have reported that the association between the variant and risk of T2D is maintained after adjusting for BMI. It appears that the main cause for the variability of results is related to the time when BMI was measured. The association has been demonstrated, before the development of T2D, when BMI is more elevated, and is reduced or lost with greater time of evolution of the disease.

Studies confirm the association between the variant *rs9939609 (T/A)* of *FTO* and obesity as the main risk factor for developing T2D. In other populations, such as the Mexican, the association is not as evident, particularly in children [27]. European homozygote populations for the risk allele (AA) of *rs9939609* have 1.7 times the risk of developing obesity and on average have 3 Kg more weight than the average population. Some studies have tried to identify the mechanism by which this association exists. In a metabolomic focus, metabolites have been identified, such as valine amino acid, a hexose, and other metabolites relevant to the phosphatidylcholine pathway. The alteration of valine metabolism leads to the accumulation of branched-chain amino acid in relation with the risk allele of *FTO*. The branched-chain amino acids and their derivatives seem to be an early manifestation of insulin resistance, probably via *mTOR/S6K1* kinase, which results in the phosphorylation of various residues of serine in the substrate of the insulin receptor (IRS-1). Metabolites of phosphatidylcholine are associated with apolipoprotein B, and it has been demonstrated that the risk allele of *FTO* is associated with the particles that form part apolipoprotein B.

Variants of the *IRS-1* Gene

The molecules of IRS are important mediators in the signaling of insulin, in addition to playing an important role in metabolism, growth, and survival of the cell. The IRS family is formed by four members, IRS-1 to IRS-4, presenting a different tissue distribution and therefore different expression. IRS-1 and IRS-2 are key for insulin action and glucose homeostasis. IRS-1 is coded in chromosome 2q36.3. Polymorphism *Gly972Arg* of *IRS-1* has been the most associated with the development of T2D. The union of insulin to its active phosphorylated receptor to *IRS-1*, phosphorylating tyrosine residue, serine threonine) (Ser/Thr), which join and activate PI3K, which contains the subunit p85, and p110 phosphorylates PI, and this allows it to join with akt and PDK1. The phosphorylation of tyrosine residue accompanies the mobilization of glucose transporters (GLUT 4) that mediate the internalization of the same. However, when the serines or threonines are phosphorylated, it leads to an accelerated degradation of the IRS protein, which generates an alteration in insulin signaling and insulin resistance and a decrease in the translocation of GLUT4.

As mentioned earlier, the polymorphism *Gly972Arg* has been the most reported in studies of association with T2D, in combination with environmental factors such as diet, age, and physical activity. Like other genes and depending on the population, important associations have also been reported (such as in Europeans), weak ones as with the Japanese, or absence of, as with the Pimas [28]. In Mexican population, variant *Arg* has been observed in 2.6% in controls and 7.9% in cases [29].

Variants of the Hepatocyte Nuclear Factor 1-Alpha (*HNF1A)* Gene

HNF1A is coded on chromosome 12q24.31. The protein joins inverted palindrome 5′-GTTAATNATTAAC-3′ for the activation and regulation of gene expression, mainly in the cells of the pancreatic islets and the liver. Some variants of the gene have been found to be associated with maturity-onset diabetes of the young 3 (MODY3). Through the study of exome sequencing, the variant pE508K has been identified and associated with T2D. This variant generates a reduction in the function of the protein, unlike MODY3 diabetes, where function is almost lost. The mechanism related with the affinity of the protein for joining DNA sequence does not appear to be altered. It seems the reduction in activity occurs mainly through a reduction in expression and the protein shows altered localization in the nucleus.

The effect of the variant on European populations is very high, with results similar to two studies in Latin population.

Carriers of the variant have up to fivefold increased prevalence of T2D. Interesting from a clinical viewpoint, carriers of the variant respond better to treatment with sulfonylureas than with metformin, a drug of choice in the treatment of T2D [30].

Variants of the *Solute Carrier Family 30 Member 8 (SLC30A8)* Gene

This transporter, coded on chromosome 8q24.11 and expressed importantly in the islets of Langerhans in the pancreas, participates in the packaging of proinsulin in secretory granules and liberation. These processes require the presence of ions Zn^{2+} and Ca^{2+}, which form complexes with proinsulin. The ions of Zn^{2+} are transported by transporter 8, which is found in abundance in the pancreas beta cells, also located in alpha cells, and participates in the liberation of glucagon. GWAS have associated the gene with susceptibility to developing T2D. A recent study showed that the marker associated with greatest frequency in European, Asian, and African population is rs13266634 [31]. However, other authors have not found this gene to be associated with T2D [32].

Other Variants Associated with Insulin Resistance and Dyslipidemias

Variant *R230C* of gene *ABCA1* of the HDL receptor participates in the reverse transport of cholesterol, associated with early-onset diabetes and obesity, particularly in Mexican population, with values of $p = 10^{-6}$ [11]. Also, in Japanese population, the presence of a haplotype with an OR of 2.59 has been reported associated with T2D [33].

In a meta-analysis of Mexican and Mexican-American samples to characterize genes associated with T2D in Hispanics, the following genes were identified, with values of $<10^{-5}$: gene *ATP2B2*, located on chromosome 3, *UNC5C* on chromosome 4, and *PIWIL4* on chromosome 11, in addition to three independent intergenic regions located on chromosome 10 and an *EST* (expressed sequence tag) located near the area of gene *RXRA* on chromosome 9. Upon adjusting for BMI, two additional groups of markers were observed, one in the intergenic area of chromosome 20 and the other within genes *C22orf30/DEPDC5*, located on chromosome 22. This meta-analysis showed SNPs with a high level of significance in ten genomic areas. In addition, two additional regions were identified when BMI was incorporated, in particular an intronic variant of *ANK2* gene and two intronic variants of *MCPH* gene [34, 35]. Other population studies have identified genes such as *HNF1A*, *KCNQ1*, and *PTPRD*. Also, two other genes identified, *CSMD1* and *ANK2*, were relevant due to their functionality in metabolic regulation. Other regions associated with T2D showed statistical significance, with *CDKN2A/CDKN2B* and *IGF2BP2* genes.

Biological Validation Studies

After the identification of the genes associated with a disease, what is sought is to know their biological function, so that the genes mentioned above have been studied for their expression in adipose tissue, skeletal muscle, and lymphoblast cell lines. One of the most significant signals of SNP *rs202983*, located within *CIT* gene (chromosome 12), showed an important effect on the regulation of gene *WFS1*. It has been documented that mutations of *WFS1* gene cause monogenic diabetes and common variants of this gene have associated with T2D. Lineal regression analysis of these genetic markers with five parameters (BMI, total cholesterol, HDL-C, LDL-C, and triglycerides) showed values of association at the genomic level in polymorphisms near *APOA5* gene, which is located on chromosome 11. The variant *rs964184* showed the lowest value at $p = 2.3 \times 10^{-9}$. Other variants of interest are those of *SYNE1* gene, which is found on chromosome 6, for triglycerides (*rs998147*, $p = 5.3 \times 10^{-7}$) and an area near *MAD2L1* gene on chromosome 4 for HDL-C (*rs4568220*, $p = 7.1 \times 10^{-7}$) [34, 35].

Conclusions

T2D is a complex disease that presents differences in prevalence between populations. Epidemiological data indicate that the risk of suffering the disease is higher in Amerindian populations than those of European origin. There is evidence on the influence of genetic factors in populations; to date, over 80 loci associated with T2D have been identified, which do not always replicate among populations. Analysis by admixture mapping has been specifically designed to identify genes involved in complex diseases that show differences in prevalence among populations. Given the history of miscegenation in Mexican population, admixture mapping is an ideal method for identifying the genetic factors that increase the risk of suffering T2D. The first GWAS performed in patients with T2D in Mexico showed that less than 10% of the 46 candidate genes reported in 2011 in European population were found associated in our population. These populations are characterized mainly by low levels of HDL-C, high levels of LDL-C, and elevated triglycerides. The genetic factors most associated with these alterations have been variants of *ZNF259/APOA5* genes, such as rs964184, associated with triglycerides, rs2367970 of the same gene, and rs2472386 of *ABCA1* gene associated with HDL.

It is a priority to establish the genetic history of the Mexican, in order to have risk markers for developing T2D, markers associated with complications and metabolic disorders, a condition very evident in our population thanks to current lifestyles.

Multiple Choice Questions

1. A gene is considered as:
   (a) A sequence of nitrogenated bases
   (b) The unit of genetic and inherited information
   (c) The chromatid unit that forms chromosomes
   (d) A sequence of nucleosides
   (e) Triplets of bases
2. What percentage of DNA sequence is identical among humans?
   (a) 99.9
   (b) 98.0
   (c) 95.0
   (d) 98.5
   (e) 99.0
3. The main difference between mutation and a SNP is:
   (a) A mutation is lethal and a SNP no
   (b) In mutation there is a change of various bases
   (c) SNPs occur only in introns
   (d) The frequency of a SNP is greater than 1%
   (e) A SNP is presented at any stage of life
4. All are characteristics of SNPs except:
   (a) They are generally biallelic
   (b) They are presented throughout the structure of the gene
   (c) They are only present in exons and introns
   (d) They are inherited
   (e) They allow identification of an individual
5. The gene most frequently associated with T2D worldwide is:
   (a) IRS-1
   (b) CAPN10
   (c) TCF7L2
   (d) PPARg
   (e) FTO
6. Which is the action mechanism of variant rs1801282 of the gene *PPARγ*?
   (a) Transcriptional modulation in the change of alanine
   (b) Oxidation of free fatty acids
   (c) Transcriptional modulation of the signaling pathways of TZD
   (d) All of the above
   (e) None of the above
7. What is the main problem of low replication of the association of obesity with T2D of the various genetic variants of the gene *FTO* upon analyzing it in different populations?
   (a) The loss of statistical power in meta-analysis
   (b) The ancestry of various populations
   (c) The time of evolution of the disease and the difficulty in performing metabolomics studies
   (d) All of the above
   (e) None of the above
8. Why is it important to determine the genetic component in metabolic diseases?
   (a) To identify risk or protector markers associated with the disease
   (b) To perform studies in metabolomics
   (c) All of the above
   (d) None of the above
9. What is the function of the gene of *CAPN10*?
   (a) Participate in apoptosis, exocytosis, mitochondrial metabolism, and remodeling of the cytoskeleton
   (b) The gene codes for calpain-10, an atypical cysteine-protease that participates in the mechanism of insulin secretion
   (c) Participate in the oxidative use of glucose for skeletal muscle
   (d) All of the above
   (e) None of the above
10. Characteristics of gene *SLC30A8* include:
    (a) The transporter is coded on chromosome 8q24.11. It is expressed at high level in the pancreas, particularly in the Islets of Langerhans
    (b) It participates mainly in the packaging of proinsulin in secretory granules, the hepatic liberation and elimination of insulin
    (c) It processes and requires the presence of ions Zn2+ and Ca2+ which form complexes with proinsulin
    (d) All of the above
    (e) None of the above

Correct Answers

1. (b) The unit of genetic and inherited information
2. (a) 99.9
3. (d) The frequency of a SNP is greater than 1%
4. (c) They are only present in exons and introns
5. (c) *TCF7L2*
6. (a) Transcriptional modulation in the change of alanine
7. (d) All of the above
8. (d) All of the above
9. (d) All of the above
10. (d) All of the above

Glossary

Some definitions are found on the page: https://ghr.nlm.nih.gov/.

Ancestry refers to the geographical origin of populations, for example, "individuals of European ancestry" or the line of heritage or descent of a group.

Diabetes is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of different organs, especially the eyes, kidneys, nerves, heart, and blood vessels (American Diabetes Association).

Genetic marker is a gene or (a fragment of) DNA sequence having a known location on a chromosome. It has an easily identifiable phenotype and whose inheritance pattern can be followed. Genetic markers act as chromosomal landmarks. They are used to trace or identify specific region of a gene (especially one that is associated with an inherited disease) on a chromosome. They are also used to determine a linkage group or a recombination event.

Genome-wide association study (GWAS) is a relatively new way to identify genes involved in human disease. This method searches the genome for small variations, called single nucleotide polymorphisms or SNPs (pronounced "snips") that occur more frequently in people with a particular disease than in people without the disease. Each study can look at 100 or 1000 of SNPs at the same time. Researchers use data from this type of study to pinpoint genes that may contribute to a person's risk of developing a certain disease.

Microarrays is a hybridization of a nucleic acid sample (target) to a very large set of oligonucleotide probes, which are attached to a solid support, to determine sequence or to detect variations in a gene sequence or expression or for gene mapping.

Single nucleotide polymorphisms (SNPs) are the most common type of genetic variation among people. Each SNP represents a difference in a single-DNA building block, called a nucleotide. For example, a SNP may replace the nucleotide cytosine (C) with the nucleotide thymine (T) in a certain stretch of DNA.

Gene Expression Modifications in Type 2 Diabetes

10

Fernando Suarez-Sanchez and Jaime Gomez-Zamudio

Chapter Objectives

- Understand changes in gene expression that underlie the phenotype of T2D.
- Review the deregulation of inflammation, oxidative phosphorylation, carbohydrate and lipid metabolism, and mitochondrial function in four key organs in the development of T2D.
- Discuss the emerging role of micro RNAs as local and distant regulatory molecules in T2D.

Introduction

The pathogenesis of type 2 diabetes (T2D) is not completely clear, and it has been shown that environmental factors such as obesity, physical inactivity, unhealthy diet, and aging, in addition to genetic factors, play important roles in the genesis of T2D. The evolution of the technology in genomic analysis has made possible to find T2D susceptibility genes using genome-wide association study (GWAS) approaches. To date, more than 90 loci has been identified related to T2D susceptibility or T2D-related glycemic traits. Many of these loci have been associated with impaired β-cell function and insulin secretion. However, T2D is a complex metabolic disorder and is clear that several genes play important roles in this polygenic disease. It is not completely understood how those genomic variants (SNPs) are associated with T2D, if they are involved in the pathogenesis of the disease or act simply like risk markers. Only about 10% of the total variance of T2D is explained by the common variants identified by GWAS, and interestingly, most of the identified variants (>85%) fall in noncoding regions of the genome. This finding highlights their potential role in gene regulation.

Adipose Tissue

The participation of adipose tissue in the development of insulin resistance and T2D is tightly linked to two distinct groups of cells: adipocytes and immune cells. Adipose tissue has been recognized as an organ whose function is not limited to the sole storage of fat but has endocrine functions. The complex and still not well-understood communication between these two groups of cells during obesity triggers changes that end up with alterations in glucose homeostasis. These modifications are accompanied by the release of several signaling molecules such as adipokines and cytokines that can travel through the bloodstream allowing them to reach local and distant organs where they may exert their effects. Among an ample range of effects, these molecules may be able to modulate cell signaling and regulate expression of single or most often groups of genes in response to certain stimuli.

One of the most recognized molecules that is expressed differentially between lean and obese people is adiponectin. The concentration of this protein in circulation is inversely proportional to the body mass index (BMI). Furthermore, it has been reported that adiponectin gene expression is downregulated in obesity due to DNA hypermethylation of a region in its promoter [1]. This regulation is mediated by the DNA methyltransferase 1 (DNMT1) whose expression is elevated in adipocytes of obese individuals. Other studies have indicated that the leptin gene (its product has been classified as an adipokine which increases in concentration in obesity) may be regulated by DNA methylation [2]. In addition, protein-DNA affinity studies have identified the transcription factor *FOSL2* as an important regulator of *LEP* [3]. Leptin is a hormone that inhibits food intake and stimulates energy expenditure in lean individuals, but its function is lost or decreased in obesity where an increase in concen-

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_10

tration is observed to try to compensate for the development of leptin resistance. However, this increase in leptin levels generally does not improve obesity. The same pattern of expression has been observed with resistin which is a hormone that can cause insulin resistance and decrease adipocyte differentiation. The transcriptional regulation of this gene is related to the transcription factor FOXO1. The non-phosphorylated, active form of FOXO1 can activate the resistin promoter by binding to two regions upstream of the transcription start site (−1539 to −1366 bp and −1016 to −835 bp) [4].

There are a number of other genes whose expression is modified in obesity. For example, Hoggard et al. [5] performed a study in which they compared the gene expression between visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) obtained from obese individual. They found 22 genes that showed gene expression differences equal or greater than 5x in omental adipose tissue compared with SAT. Three of them codify secreted proteins (*GREM1*, *PTN* y *SLPI*), but their function in adipose tissue has not been completely elucidated. However, recent data indicates that *GREM1* blocks *BMP4* which in turn decreases the expression of *PPARγ* and *C/EBPα*. These two transcription factors are key regulators in adipocyte differentiation. Thus, impairment of adipocyte differentiation in subject with fat-rich diets promotes the storage of excess of energy in enlarged adipocytes. Adipose tissue hypertrophy is generally viewed as more negative than storage of energy in hyperplastic adipose tissue [6]. Indeed, it has been observed that adipose tissue hypertrophy is more frequent in diabetic subjects compared to nondiabetic subjects [7]. Regarding the PTN gene, one association study has found that the SNP rs161339 near the PTN gene is significantly associated with BMI [8]. PTN is able to induce the production of inflammatory cytokines thus it may be involved in the inflammatory response classically observed in obesity [5]. Recently, it has been reported that PTN and ADAMS1 inhibit the initiation of adipocyte differentiation which may further contribute to adipose tissue impairment [9]. The third differentially expressed gene, SLPI, codify a protein with anti-inflammatory properties which may be produced to counteract the obesity-associated adipose tissue inflammation. This is supported by reports showing a positive association between circulating levels of SLPI and progression of metabolic dysfunction [10].

Other studies have shown that the genes *CIDEC/FSP27* (whose gene expression correlated with insulin sensitivity) and *PLIN1* (its dephosphorylated form inhibits lipolysis) are mainly expressed in the SAT, and their levels in the VAT are negatively regulated by BMI, fat in depots, homeostatic model assessment (HOMA), and fasting glucose and are positively associated with genes that play a role in adipogenesis such as *PPARγ*, *GLUT4*, *FASN*, and *ACACA* and mitochondria biogenesis such as *PPARGC1A*, *PPARGC1B*, *TFAM*, and *MT-CO3* [11]. It has been demonstrated that TNF-α, a proinflammatory molecule usually found in obesity, decrease the expression of *CIDEC* by modifying the activation of the transcription factor PPARγ [12].

A study in subcutaneous adipose tissue from postmenopausal woman subjected to a loss weight regime for 6 months indicates that a greater weight loss is associated with a decrease in 17b-hydroxysteroid dehydrogenase-1 (*HSD17B1*) and leptin (*LEP*) expression and marginally significant increased expression of estrogen receptor-1 (*ESR1*) and insulin-like growth factor binding protein-3 (*IGFBP3*) [13]. HSD17B1 is an important component of the estrogen metabolism pathway because it catalyzes the conversion of less active estrone to estradiol [13]. Other pathways that were regulated during weight loss in postmenopausal woman were the mTOR and IGF-1 signaling pathway [13].

Changes in expression of transcription factors during obesity and T2D excerpt broad effects in the cells since a single transcription factor is able to regulate several other genes. However, due to its broad effect, it is sometimes challenging to fully understand its functions. For example, in adipogenesis, the expression of the transcription factor MAFB is upregulated. It increases with BMI in WAT and correlated with adverse metabolic features such as proinflammatory gene expression in adipocytes and macrophages of the adipose tissue. Weight loss decreases its expression [14]. However, these results do not agree with observations in mice where deficiency of this transcription factor lead to increased body fat due to larger adipocyte size and serum cholesterol levels. Possibly, this association is mediated by a reduction in AIM (apoptosis inhibitor of macrophages), which is an inhibitor of lipogenesis in adipocytes [15]. Another transcription factor which is regulated by hypoxic conditions in obesity is the HIF1. Reports by Jiang et al. (2011) showed that HIF1 inactivation in the adipose tissue reduced obesity and insulin resistance [102]. These results point to this transcription factor as a potential therapeutic target to treat T2D and obesity. Other transcription factors that are regulated in obesity are PPARγ and C/EBPα; both are important regulators of adipocyte differentiation and inflammation.

It is well established that low-grade chronic inflammation is a hallmark of obesity and T2D. However, the signals that trigger the inflammation in the adipose tissue are not well understood, but one molecule that has shown a great capacity to elevate expression levels of chemokines and cytokines in subcutaneous adipose tissue is the nutrient-induced intestinal hormone glucose-dependent insulinotropic peptide (GIP). Reports indicate that GIP may be involved in the crosstalk of adipocytes and macrophages by the stimulation of the GIP receptor in monocytes and the increase of *MCP-1* mRNA expression

[16]. Other genes whose expression was elevated were *MCP-2*, *IL-6*, *IL-6R*, and *TNF-α* [16, 17]. This observation was confirmed in co-cultures of 3T3L1 adipocytes and RAW 264.7 macrophages but not in isolated cell lines which further supports the hypothesis of a crosstalk between macrophages and adipocytes [16]. Expression of IL-6 and its receptor in subcutaneous adipose tissue (SAT) is positively modulated by obesity and correlates with the expression of *CD11b* (subunit of a complex involved in leukocyte adhesion and migration), *CD163* (marker of the monocyte/macrophage lineage), *TNF-a, MCP-1*, and *IP-10* (or *CXCL10*) (role in chemoattraction of immune cells in response to IFN-γ) [17]. Adipose tissue accounts for the expression of approximately 30% of systemic IL-6 [18]. Higher concentration is associated with insulin resistance and T2D development [18].

Another molecule that has been demonstrated that is able to positively regulate the expression of inflammatory genes such as *TNF*, *IL6*, *STAMP2*, *LBP*, *MCP1*, and *NF-κB* in adipose tissue is *DBC1* [19]. Particularly, regulation of *NF-κB* is mediated through the interaction of DBC1 with sirtuin 1 and inhibition of its deacetylase activity [20]. Decrease in sirtuin 1 action is also associated with macrophage recruitment in adipose tissue [20]. In humans, expression of *DBC1* is associated with adipose tissue senescence in morbid obese subjects [19]. Other inflammation-related genes expressed in adipocytes of obese patients are part of the NOD-like receptor pathway which has been identified as one group of genes associated with inflammation in adipose tissue. NOD-like receptors are intracellular sensors of pathogen-associated molecular patterns (PAMPs) or damage-associated molecular patterns (DAMPs) which regulate caspase-1-mediated IL-1β secretion. Particularly, it has been reported that the expression of *NLRP3* and *PYCARD* (two important proteins required for the NLRP3 inflammasome activity) and the class II major histocompatibility complex (MHCII) correlate with adiposity phenotypes [21]. Activation of the NLRP3 inflammasome in hypertrophic adipocytes may be partially responsible of the adipocyte death by pyrosis which is an inflammation programmed cell death which is observed in adipose tissue of obese individuals. The important role of NLRP3 in the development of T2D becomes clear in experiments where attenuation of the NLRP3 inflammasome was performed. The results showed a delay in the progression of diabetes, improved hyperglycemia, insulin signaling, and attenuated IL-1b secretion [22, 23]. When NLRP3 is not present, a reduction in the expression of other proinflammatory genes as well as the chemokine *CCL2*, *MCP-1*, and its receptor *CCR2*, which play an important role in macrophage chemotaxis, was observed [24]. On the other hand, recent findings point to an important role of MHCII in the CD4(+) T-cell activation and induction of IFNγ-dependent adipocyte IL-1β secretion which results in a diet-induced early insulin resistance in adipose tissue [25–27]. Interestingly, expression of MHCII is higher in hypertrophic adipocytes which are commonly found in metabolically abnormal obese when compared to metabolically healthy obese patients [27].

Whole gene expression studies by van Greevenbroek et al. [28] performed in SAT obtained from subjects with familial dyslipidemia showed higher expression of genes of the complement system and genes that regulate such system. The activation of the complement system by local cues in adipose tissue could facilitate the recruitment of immune cells and induce inflammation and insulin resistance in the adipose tissue. Involvement of the complement system in immune cell recruitment is supported by studies with C3a receptor knockout mice which are protected from high-fat diet insulin resistance and decreased macrophage infiltration.

Studies performed in adipose tissue from subject with insulin resistance have identified the increase in the expression of *SELS*. This correlated with expression levels of cytokines in the adipose cells. It has been suggested that this protein is a serum amyloid-A protein receptor (which is bound to high-density lipoprotein, HDL) which can trigger the onset of insulin resistance. However, the exact functional relationship of this protein with insulin resistance is still under debate [29, 30]. Another protein regulated during insulin resistance and T2D is GSTA4 which plays a role in the elimination of lipid peroxidation products. Levels of GSTA4 decrease with the onset of insulin resistance and T2D since the primary enzymatic method for lipid aldehyde detoxification is via GSTA4-dependent glutathionylation. In part, it may explain the increase in protein carboxylation, reactive oxygen species (ROS) production, and mitochondrial dysfunction observed in such metabolic diseases [31].

Intake of n-3 polyunsaturated fatty acid (PUFA) by mice also downregulates the expression of proinflammatory genes such as caspase 1, *Nlrp3*, and *Il1b*, and it is thought that something similar occurs in humans [32].

Other studies have reported increase in gene expression of oxidative phosphorylation and ribosome genes and decrease in expression of genes coding proteins participating in the WNT and MAPK signaling pathways in adipose tissue in response to exercise, which is recommended to persons with risk of developing metabolic alterations and obesity [33].

Another study in patients that underwent two steps bariatric surgery (BS) separated by 12 months indicated an increased expression of cell death-inducing DFFA-like effector A (CIDEA) and LPIN1. Both genes are involved in the formation of lipid droplets in fat depots in response to significant weight loss as well as after treatment with the PPARγ agonist rosiglitazone [34]. Adequate triacylglycerides (TG) deposition in adipose tissue is necessary to prevent fatty acid overload in skeletal muscle and liver [35]. Another gene associated with TG metabolism whose

expression is augmented in adipose tissue of patients that underwent loss weight due to laparoscopic gastric banding surgery is the gene *PNPLA3*. This gene negatively correlated with BMI, fasting glucose, and fasting insulin and encodes a triacylglycerol lipase that mediates triacylglycerol hydrolysis in adipocytes and has been associated with nonalcoholic fatty liver disease (NAFLD) [36]. It has been demonstrated that Lpin-1 expression levels in adipose tissue correlate with a favorable metabolic profile and expression of fatty acid oxidation genes [37]. Those two genes correlate positively with whole-body insulin sensitivity [34]. The same study observed that expression of the genes associated with metabolic reactions involved in NAD+ (NMNAT2) and glutathione (NNT) is significantly increased in adipose tissue depots after surgery-induced weight loss. This can explain the better response toward ROS which is observed after BS [34]. Another distinctive observation was the modulation of expression of genes associated with branched chain amino acid metabolism (*BCAT1* and *BCAT2*). Both genes participate in the catabolism of chain branch amino acids (BCAA) whose levels increase in plasma from obese patients.

In animal models with rats which underwent Roux-en-Y gastric bypass (RYGB), the improvement of metabolic parameters was accompanied by a decrease in the expression of *NLRP3* and other inflammation-related genes (*IL-6*, *MCP-1*, *IL-18*, caspase-1, and apoptosis-associated speck-like protein) in omental fat [38]. This observation straightens the role of inflammation in the downregulation of glucose homeostasis. This coincides with the observations of diabetes remission accompanied with an improvement of inflammation, insulin resistance (IR), and other relevant parameters reported in diabetic patients that underwent the same surgery [39].

In adipose tissue of diabetic patients, similarities with the gene expression profile of obese individuals were found. Decrease in the expression of genes related to oxidative phosphorylation (carbohydrate, amino acid, and lipid metabolism) and an increase in expression of genes involved in inflammation and glycan degradation were found [40]. Among all the differentially expressed genes, *ELOVL6*, *GYS2*, *FADS1*, *C12orf39*, *SAA1*, *STOX1*, *CASQ2*, *AGPAT9*, *FADS2*, and *B4GALT6* show a lower expression in diabetic patients, while *SPP1 (OPN)*, *TM4SF19*, *MMP9*, *CCL18*, *PRG4*, *IL1RN*, *PLA2G7*, *MSR1*, *VSIG4* and *LGI2* show a higher expression in diabetic compared with nondiabetic patients [40]. This same study reported that the most regulated pathways in diabetic patients are genes participating in the amino acid metabolism, carbohydrate metabolism, lipid metabolism, and energy metabolism, and some basal transcription factors are downregulated, while genes in the glycan biosynthesis, immune system, and signaling molecules pathways were upregulated [40]. These results in gene expression are very similar to the profiles described with diet, BMI, IR, exercise, and bariatric surgery. This shows the strong relationship between T2D, bad dietary and exercise habits, and the increase in risk factors.

Pancreas

The pancreas is an endocrine gland which has important roles in glucose homeostasis. It has the capacity of producing hormones such as insulin, glucagon, somatostatin, and pancreatic polypeptide but also secretes other enzymes involved in digestion. This gland contains specialized cells such as β-cells, α-cells, and γ-cells, PP cells, and epsilon cells; each can secrete certain hormones. Failure in the functions of this gland leads to the development of type 1 and 2 diabetes. T1D is characterized by a complete ablation of insulin secretion, while T2D is characterized by partial impairment of insulin secretion and insulin resistance that worsens with time. In this chapter, we will focus on the review of gene expression changes that occur in human pancreas when T2D develops.

Although pancreas is a highly specialized organ, one study indicates that only 0.7% of all the genes coded in the genome are enriched in pancreas. This represents approximately 146 genes, but its expression accounts for up to 68% of all the mRNA found in pancreas. A significant quantity of these expressed genes is secreted proteins and involved in digestive metabolism. Forty three additional genes mainly associated with neuroendocrine functions were enriched specifically in Langerhans islets [41]. Some of the genes that show the most elevated expression of mRNA are shown in Table 10.1.

The same study found that gene expression in β-cells is responsive to inflammatory cytokines. When exposed to proinflammatory molecules, 20% of the transcripts showed modification in expression levels [41]. Many of these regulated transcripts were related to apoptosis and inflammation. This is highly relevant since diabetes is characterized by the development of low-grade chronic inflammation which provides a proinflammatory environment in several tissues. Inflammation is accompanied by a decrease in the production of insulin which in turn may be secondary of β-cell death. This is in agreement with observations that T2D patients have a reduced β-cell mass, partially due to an increased apoptosis rate which is the results of factors such as gluco- and lipotoxicity and increase in inflammatory cytokines. It has been reported that during the evolution of T2D, the pancreatic stone protein/regenerating protein (PSP/reg) is upregulated in β-cells, and its levels correlated with the duration of diabetes. This protein is related to islet cell regeneration and diabetogenesis [42]. Another gene whose product participates in the regulation of

Table 10.1 Genes whose expression is most elevated in the islets of Langerhans

Gene	Description	Function
INS	Insulin	Lowering blood glucose
GCG	Glucagon	Elevating blood glucose
SST	Somatostatin	Regulation of endocrine system
PPY	Pancreatic polypeptide	Regulation of pancreatic and gastrointestinal functions
NKX6-1	NK6 homeobox 1	Transcription regulation in β-cells
PAX6	Paired box 6	Development and differentiation of α-cells
NPTX2	Neuronal pentraxin II	Excitatory synapse formation
SCG5	Secretogranin V (7B2 protein)	Regulation of secretory pathways
SCGN	Secretagogin, EF-hand calcium binding protein	Calcium influx and cell proliferation
GAD2	Glutamate decarboxylase 2 (pancreatic islets and brain, 65 kDa)	Autoantigen in diabetes
PTPRN	Protein tyrosine phosphatase, receptor type, N	Autoantigen in diabetes
IAPP	Islet amyloid polypeptide	Inhibition of insulin-stimulated glucose utilization and glycogen deposition
CFC1	Cripto, FRL-1, cryptic family 1	Embryonic development
FAM159B	Family with sequence similarity 159, member B	Unknown
RBPJL	Recombination signal binding protein for immunoglobulin kappa J region-like	Putative transcription factor
RGS9	Regulator of G-protein signaling 9	Regulation of dopamine/opioid signaling

Adapted from [41]

β-cell apoptosis is *MST1* which under diabetologic conditions is transcribed and translated. Its activation leads to the ubiquitination of the important transcription factor PDX1 and induces the mitochondrial-dependent pathway of apoptosis. Downregulation of *PDX1* has an impact in the expression of insulin and *GLUT2* [43]. The potential of the transcription factor Pdx1 to induce the differentiation of acinar cells into β-cells was tested by creating transgenic mouse where *Pdx1* expression was inducible. The result was the generation of endocrine precursor cells which migrate into the pancreatic islets and differentiate into insulin-, somastatin-, and PP (pancreating polypeptide)-producing endocrine cells [44]. Thus, deregulation of this transcription factor results in hyperglycemia worsening [45].

In β-cell fractions from diabetic patients, the expression of *UCHL1* (an important component of the deubiquitin system) is lower than in cells from nondiabetic individuals. This results in endoplasmic reticulum stress due to an additional reduction in proteasomal activity. Higher expression of the endoplasmic reticulum stress proteins *BIP*, *CHOP*, and *GADD34* was found in β-cell fractions from T2D patients which is in agreement with the observed reduction in β-cell function and survival described in diabetic patients [46]. Inflammatory cytokines produced during the development of T2D are other source of damage to the pancreas. It has been demonstrated that treatment of nondiabetic human islets with palmitate (saturated fatty acid associated with cardiovascular risk) results in the development of an inflammatory response characteristic in T2D patients. This comprises the induction of chemokines and cytokines such as IL-1β, TNF-α, IL-6, IL-8, chemokine (C-X-C motif) ligand 1 (CXCL1), and chemokine (C-C motif) ligand 2 (CCL2). It is proposed that palmitate-induced NF-kB activation and signaling through IL-1β is key to the inflammatory process [47]. In addition, some data indicate that during fatty acid-induced β-cell apoptosis, NF-kB activation is responsible for the downregulation of *PGC-1α* expression which acts as a transcriptional coactivator in the regulation of energy metabolism genes [48].

One feature of T2D is an abnormal lipid profile. Particularly, lipotoxicity due to exposure to saturated fatty acids is a predictor of development of insulin resistance and T2D. Chronic exposure to palmitate, the most common saturated fatty acid, impairs β-cell function in part by inhibition of the expression of the insulin gene [49]. However, this is not the only gene whose expression is altered due to continuous exposure. Pathway analysis showed upregulation of genes belonging to functions such as cell death, cellular movement (mainly chemokines), cellular development, gene expression, and lipid metabolism, while downregulated genes correspond to categories of cellular movement, cell morphology, lipid metabolism, molecular transport, and small molecule biochemistry. Palmitate inhibited expression of important transcription factors in β-cells such as *PDX1*, *PAX4*, *PAX6*, *FOXA2*, *MAFA*, *MAFB*, and *NEUROD1* [50]. PDX1 and PAX4 have important roles in development and maintaining pancreatic islet function [43, 51], and SNPs in these genes have been associated with maturity-onset diabetes of the young (MODY) [52]. Mutations in *PAX6* cause abnormal glucose metabolism by deregulating the proinsulin processing via modulation of *PC1/3* production which is a protein cleaving enzyme [53]. *FOXA2* and *FOXA1* are major regulators of glucose homeostasis, the first by controlling the expression of glucagon, *MAFB*, and the ATP-sensitive channel KIR6.2 which controls insulin secretion in β-cells [54]. Other observations indicate that alleviation of hyperglycemia in mouse models is beneficial for the expression of the transcription factors *Pdx1* and *Mafa* and their targets insulin 1, glucose transported (*Slc2a2*), and Glp-1 receptor (*Glp1r*) in islets [55].

Palmitate inhibited expression of other genes associated with T2D (*ASB9*, *GLRA1*, *MIA2*, *PRSS35*, *RAB15*, *RASGRP1*, *SEMA6D*, *TBC1D4*, *TSPAN4*, *TSPAN8*, *KCNK16*, *ADCY5*, *ADRA2A*, *TP53INP1*, *CDC123*, *PRC1*, *TCF7L2*, *GLIS3*, *HNF1B*, and *SLC30A8*). On the contrary, palmitate upregulated the expression of *LOC388022*, *C2CD4A*, *ADAMTS9*, and *SPRY2* [50, 56–58]. Islets exposed to palmitate also showed a reduction of proteasome activity, lower stimulated insulin secretion, and higher caspase activity [46, 57]. To counteract the negative impact of lipotoxicity in β-cell survival, they have evolved a mechanism in which the enzyme prohormone convertase 1/3 (*PC1/3*) is upregulated. This enzyme is key in the processing of proglucagon into GLP-1 peptides in α-cells which is able to enhance cell survival through its interaction with its receptor GLP-1R [59, 60].

Hall[57] found that a short exposure of islets to palmitate have an impact in the expression of genes in the glycolysis/gluconeogenesis, pyruvate metabolism, and biosynthesis of unsaturated fatty acid pathways. Downregulation of several genes that are part of the respiratory chain was described too. This may have a negative impact in ATP production and insulin secretion [57]. Palmitate also has an impact on the overall methylation of DNA which has been demonstrated to have a close correlation with gene expression [57]. In fact, studies comparing DNA methylation between diabetic and nondiabetic T2D donors have identified candidate genes that influence insulin secretion which is a hallmark of T2D. Hypermethylation of CpG sites was found in 853 genes. Some of those are demonstrated T2D susceptibility genes such as *TCF7L2*, *FTO*, and *KCNQ1*. From the differentially methylated genes, *CDKN1A*, *PDE7B*, *SEPT9*, and *EXOC3L2* also showed differential expression in islets from T2D and nondiabetic donors. Overall, the study found that many of the hypermethylated regions that showed difference between T2D and nondiabetic donors are located in the intergenic regions, around the transcription start site (TSS) and the 3′UTR region. It is worth to notice that several of the SNPs associated with T2D that have been found in GWAS are located in intergenic regions where silencers or enhancers are regularly placed. This may be an indication of a link between these variants, methylation of DNA and gene expression [61].

Alterations in epigenetic regulation influence insulin secretion as well. Previous studies have shown that epigenetic regulation in islets from T2D patients leads to a lower expression of *PPARGC1A* which results in decreased insulin secretion [62]. Other genes that have been associated with a decrease in insulin secretion are *CHL1*, *LRFN2*, *RASGRP1*, *PPM1K*, *TSPAN33*, *NT5E*, *TMED6*, and *PAK7* [63].

T2D is characterized by an increase in glycosylated hemoglobin (HbA1c) which is an indicator of historic glucose levels in the patients. Thus, HbA1c values are a good indicator of noncontrolled T2D and indirectly could be related to pancreatic function. To date, efforts to identify variants associated with HbA1c allow explaining only a small portion of the increase in HbA1c, but gene expression analysis comparing islets from diabetic and nondiabetic patients has allowed identification of ten genes which in conjunction can explain 24% of the variance in HbA1c. These genes are *JAZF1*, *CHL1*, *LRNF2*, *RASGRP1*, *ABCC8*, *RASGRF1*, *KLHDC5*, *ELAVL4*, *KCNJ11*, and *SLC2A2* [50]. This is highly significant since a detailed study of the function of these few genes may render clues on the pathophysiology of T2D.

No protein-coding genes have been implicated in pancreatic damage as well. Multiple studies have demonstrated that long noncoding RNAs (lncRNAs) have a role in gene regulation, mainly by controlling the transcription of protein-coding genes in *cis*. These transcripts are synthetized by the cell, but they do not contain any protein-coding sequence. When ill-regulated, they are associated with pathogenic roles. Particularly, it has been shown that expression of the lncRNA *KCNQ1OT1* is increased, while *HI-LNC45* is decreased in T2D islets. *HI-LNC45* regulates the expression of the transcription factor *GLIS3* which contains variants in the gene body that are associated with T2D. *GLIS3* is mutated in a form of monogenic diabetes as well [64]. *GLIS3* can regulate the expression of *MAFA*, *INS2*, and *GLUT2* and inhibit glucose oxidation and insulin secretion and is involved in the development of β-cells and modulates pancreatic β-cell apoptosis [65]. On the other hand, *KCNQ1OT1* is involved in the silencing of the *KCNQ1* gene which has variants associated with T2D, gestational diabetes, and glucose levels [66–68]. The conserved long noncoding RNA *βlinc1* is able to regulate hormones such as insulin and somatostatin as well as a number of nearby islet-specific transcription factors needed for the proper development and function of Langerhans islets [69]. Although lncRNAs are regulators of other genes, it has been demonstrated that some lncRNA genes are subjected to epigenetic modifications and transcriptional regulation as well [70]. microRNAs (miRNAs) have also been associated with transcriptional regulation of several genes in pancreas. This double layer of gene regulation may reflect its importance of such genes in the right function of processes such as insulin production and secretion, differentiation and proliferation, and apoptosis and survival.

Skeletal Muscle

The skeletal muscle is considered the major site of glucose uptake in the organism, approximately 75% of glucose uptake after a meal occurs and is metabolized in the skeletal muscle where insulin play a key role. In normal conditions,

insulin binds to the insulin receptor (IR) which is self-phosphorylated and activates the signaling pathway which results in the glucose transporter 4 (GLUT4) translocation to the membrane. The presence of GLUT4 in the membrane is required to transport glucose into the cells of organs with sensitivity to insulin such as skeletal muscle and adipose tissue. However, T2D is characterized by a phenomenon called insulin resistance which is characterized by the loss of the insulin capacity to trigger the glucose uptake into the cells, despite normal or high serum insulin concentrations. Multiple pathways have been described to contribute to the pathogenesis of insulin resistance: alterations in the insulin signaling, mitochondrial oxidative metabolism and ATP production, fatty acid oxidation, proinflammatory signaling, as well as modifications in β-cell development and metabolism.

It is known that T2D is a multigenic disease and involves changes in the expression of several genes in different biological pathways. For this reason, the transcriptomic analysis has been useful to identify gene expression profiles on specific tissues that are related to the pathogenesis of this disease to predict possible complications or provide new therapeutic targets for the treatment of T2D. However, due to the large list of genes that are reported to change their expression in T2D and that the gene expression can vary depending of several factors such as diabetes model, ethnicity, age, gender, pharmacological treatment, stage of diabetes, etc., it is difficult to interpret the results obtained by transcriptomic studies. In Table 10.2, we summarized the most commonly expressed genes in skeletal muscle, arranged by metabolic pathway, from studies with diabetic patients or murine models of diabetes [71–76].

Carbohydrate Metabolism Most of the studies in gene expression of skeletal muscle have found an impaired expression of important genes involved in transport of glucose, insulin pathway, and metabolism of glucose, for example, insulin receptor substrate-1 (*IRS1*), glycogen synthase (*GYS1*), uncoupling protein 3 (*UCP-3*), GLUT4 (*SLC2A4*), hexokinase II (*HK2*), phosphatidylinositol 3-kinase (*PI3K*), mitogen-activated protein kinase (*MAPK*), and serine-threonine kinase (*AKT*). Although several of these genes have showed changes in their expression in T2D in previously studies, none has emerged as the leading candidate for causing diabetes. Several authors have proposed that the study of coordinated pattern of gene expression could be more useful to identify the mechanisms involved in the pathogenesis of the disease and to propose potential new targets for therapy of diabetes.

Lipid Metabolism The metabolism in skeletal muscle in T2D involves an increased demand of fatty acid oxidation for its energy needs when glucose is not available. This alteration in lipid metabolism has been related to accumulation of lipids in skeletal muscle, a key mechanism involved in insulin resistance development. The expression profiles observed in different studies on skeletal muscle samples from human or murine models of diabetes were controversial; some of them agree with a significant increase in the mRNA for proteins involved in the fatty acid oxidation pathways, whereas some others described a significant decrease on the same genes. Similar discrepancies were found on the expression of β-oxidation pathway genes.

An altered lipid metabolism is also present in obesity, which has been considered one of the main factors related to insulin resistance and T2D development. In this regard, the fat mass and obesity-associated gen (*FTO*), a well-characterized gene associated with the increase in obesity risk in GWAS, is expressed in tissues related to metabolic diseases, including skeletal muscle and adipose tissue. However, there are many inconsistences when the *FTO* expression in adipose tissue is related to obesity. On the other hand, some gene polymorphisms in the *FTO* gene have been associated with T2D in several populations, and their expression was related to defects in glucose and lipid metabolism in skeletal muscle and adipose tissue. In a study where the *FTO* expression in skeletal muscle from obese nondiabetic subjects was compared with T1D and T2D patients, it was found that in T2D patients, *FTO* increase their expression at mRNA and protein levels, whereas the expression in obese nondiabetic subjects and T1D patients was unchanged. To probe the specific actions of *FTO* expression, it was overexpressed in myotubes, resulting in decrease expression of oxidative phosphorylation and antioxidant genes, increased lipid accumulation, and increased oxidative stress, similar to what was observed in diabetic skeletal muscle, suggesting that FTO may contribute to the muscle alterations observed in T2D. Interestingly, *PGC-1α* gene was downregulated in diabetic patients, as was reported previously, but *FTO* overexpression did not modify the expression of *PGC-1α* in human myotubes [77].

Mitochondrial Function It is important to note that despite the differences in experimental methods and ethnicity in the analyzed subjects from several studies, they agree that there is a significant decrease in the expression of genes involved in mitochondrial function. These studies in muscle biopsies from diabetic patients have reported a decrease of multiple components of the mitochondrial respiratory chain and, mainly, the oxidative phosphorylation (OXPHOS) pathway. Mitochondrial OXPHOS is an important source of reactive oxygen species (ROS) such as superoxide anions, hydrogen peroxide, and hydroxyl radicals that are formed by products of cellular metabolism. The ROS have been implicated in the development of insulin resistance. Interestingly, patients

Table 10.2 Summary of genes with altered expression in skeletal muscle samples from diabetic patients or animal models of diabetes

Gene	Description	Function	Expression
Carbohydrate metabolism			
SLC2A4	Solute carrier family 2 member 4 (GLUT4)	Glucose transport into the cells	↓
INSR	Insulin receptor	Insulin pathway	↓
AKT1	Serine/threonine kinase	Insulin pathway	↓
IRS-1/2	Insulin receptor substrate 1/2	Insulin pathway	↓
PIK3	Phosphatidylinositol 3-kinase	Insulin pathway	↓
GYS1	Muscle glycogen synthase	Glucose storage	↓
PTPN11	Protein tyrosine phosphatase, non-R type 11	Insulin pathway	↓
MAPK 4, 8, 12	Mitogen activated protein kinases	Insulin pathway	↓
PKC-ζ	Protein kinase C (PKC)-ζ	GLUT4 translocation	↓
HK2	Hexokinase II.	Phosphorylates the glucose after uptake by the cell	↓
FBP2	Fructose-1,6 bisphosphatase 2	Glucose metabolism	↑↓
Lipid metabolism			
FABP1	Fatty acid transporter type 1	Regulates the uptake of long chain fatty acids to muscle cells	↑
LIPE	Hormone sensitive lipase	Contributes to increase the pool of nonsterified fatty acids in the cytosol	↑↓
LPL	Lipoprotein lipase	Hydrolyses triglycerides	↑↓
MGLL	Monoglyceride lipase	A key enzyme in triglyceride hydrolysis	↑↓
ACADM	Acetyl-CoA dehydrogenase	It is a rate-limiting enzyme catalyzing the first dehydrogenation of fatty acids	↑
ETFB	Electron transfer flavoprotein-β	It is an electron acceptor protein for many dehydrogenases in the mitochondria	↑
ECI	Δ^3, Δ^2-enoyl-CoA isomerase	Required for β-oxidation of unsaturated fatty acids	↑↓
SCD	Stearoyl-CoA desaturase	A rate-limiting enzyme in unsaturated fatty acid synthesis	↓
LOC51706	Cytochrome b_5 dehydrogenase.	A rate-limiting enzyme in unsaturated fatty acid synthesis	↓
OXCT1	Succinyl-CoA:3-oxoacid-CoA transferase.	A rate-limiting first step in extra hepatic metabolism of ketone bodies	↓
PPARα	Peroxisome proliferator activated receptor α	Lipid metabolism	↓
Mitochondrial function			
PKM	Pyruvate kinase	Protein involved in glycolysis	↓
PDHA	Pyruvate dehydrogenase	Catalyzes conversion of pyruvate to acetyl-CoA and CO_2	↓
ATP5B	ATP synthase, H+ transporting, mitochondrial F1 complex, beta polypeptide	Synthesis of ATP	↓
SLC25A4	Solute Carrier family 25 member 4	Involved in ADP/ATP flux between cytosol and mitochondria	↓
PGC1α.	PPARγ coactivator 1α	Transcriptional coactivator that regulates genes involved in energy metabolism	↓
PGC1β.	PPARγ coactivator 1 β	Transcriptional coactivator that regulates genes involved in energy metabolism	↑↓
UCP3.	Uncoupled protein 3	Mitochondrial protein expressed mainly in skeletal muscle, participate in the fatty acid metabolism	↓
SOD2	Superoxide dismutase 2	Mitochondrial protein with antioxidant properties	↓
NDUFB2	NADH dehydrogenase-ubiquinone 1 beta subcomplex, 2	Electron transport chain	↓
NDUFB5	NADH dehydrogenase-ubiquinone 1 beta subcomplex, 5	Electron transport chain	↓
NDUFC2	NADH dehydrogenase-ubiquinone 1, subcomplex, 2	Electron transport chain	↓
SDHB.	Succinate dehydrogenase cytochrome b subunit	Electron transport chain	↓
NNT	Nicotinamide nucleotide transhydrogenase	NADPH production and involved in the antioxidant system	↓

HSP70	Heat shock protein 70	Involved in protein folding process	↑↓
NRF-1	Nuclear respiratory factor 1	Transcription factor	↓

The arrows represent up (↑)- or down (↓)-regulated genes, whereas the red arrows (↑↓) are controversial results observed between published works [71–76]

without T2D but with a family history of diabetes have a decrease expression in genes of OXPHOS pathway, suggesting that alterations in gene expression of this pathway could be related to the initial steps for T2D development [76].

Most of the genes involved in OXPHOS pathway are encoded in the nuclear genome, and their expression is regulated by transcription factors. Particularly, the expression of the nuclear respiratory factor-1 (NRF-1) has demonstrated a key role in diabetes. In skeletal muscle from diabetic patients, the expression of the nuclear respiratory factor-1 (NRF-1) was decreased as well as genes regulated by the NRF transcription factor family. The promoter region from several OXPHOS genes has been reported to contain binding sites for NRF-1, suggesting that this gene contributes to the diabetes-related expression pattern in diabetes. In this regard, NRF-1 has been proposed as an important gene that modulates mitochondrial biogenesis, respiratory capacity, and the glucose transporter protein GLUT4 [76].

In addition, the peroxisome proliferator-activated receptor (PPAR) gamma coactivator-1 (*PGC-1α*) gene has been proposed as a master regulator of mitochondrial gene expression that mediates the oxidative phosphorylation expression phenotype in prediabetic and diabetic patients. The PGC-1α is a transcriptional regulator that does not bind directly to the DNA but influence transcription by interacting with other transcription factors, modifying the chromatin or altering protein-protein interactions within the transcriptional complex. In diabetes, PGC-1 not only activates NRF but also PPARα, PPARγ, hepatocyte nuclear factor 4, and other transcription factors critical for the metabolic function [76, 78]. Interesting, members of the PGC-1 family, PGC-1α and PGC-1β had a significantly reduction on their expression that correlates with a decrease in OXPHOS genes expression in patients with T2D [79]. On the contrary, when the PGC-1α was overexpressed in a muscle cell line, an upregulation of OXPHOS genes were observed in a time-dependent manner [78].

Role of Insulin in Gene Expression The changes in glucose metabolism observed in T2D are related to insulin resistance, which has been proposed as one of the initial steps related to T2D development. Insulin is a hormone released by the pancreas, specifically by β-cells, which has an extensive capability to regulate gene expression. Some paper indicate that insulin action in skeletal muscle may modify the expression of around 800 genes related to signal transduction, vesicular traffic and cytoskeletal function, and fuel metabolic pathways [80, 81]. These effects have been related with changes on at least 70 transcription factors related to insulin response. Some of them that stand out are *RRAD*, *IGFBP5*, *INSIG1*, and NGF1-B (*NR4A1*), which were upregulated in L6 skeletal muscle cells [81].

As was mention before, the action of insulin on gene expression is very important to regulate genes on specific metabolic pathways. To determine the direct contribution of insulin on the altered expression in T2D, the group of Yechoor et al. analyzed the gene expression profiles on a muscle insulin receptor knockout mice (MIRKO) and compared it to controls (Lox-controls) under three different conditions: (1) at basal state, (2) after streptozotocin (STZ)-induced diabetes, and (3) after STZ-induced diabetes rendered euglycemic with insulin treatment. The results obtained demonstrated that insulin action has a role in maintaining basal expression levels in 1% of the genes in comparison to 4% of genes that are altered in diabetes. Although insulin is not associated with these changes at basal state, it was observed that insulin receptor is required to reverse the effects induced by diabetes. Suggesting that the presence of an intact insulin-signaling system is needed to return its expression toward normal [75]. This phenomenon was also observed in humans where at early stages of T2D, high serum insulin levels are commonly observed and were related to an increase in the expression of insulin pathway genes, possibly as a mechanism to compensate elevated serum levels of glucose. However, this compensatory effect is lost in people with T2D where the expression of insulin signaling molecules is reduced [72].

Liver

The liver is an important organ that participates in the homeostasis and metabolism of glucose. Hepatic glucose metabolism includes glucose transport, glycolysis, gluconeogenesis, glycogen synthesis, and glycogenolysis. In fed state, the liver synthesizes and stores glycogen in response to insulin stimulation, whereas, in fasting state, the liver activates the gluconeogenesis and releases glucose in response to glucagon stimulation. An imbalance in the metabolism of hepatic glucose has been related to the T2D development, where hyperglycemia correlates with hepatic insulin resistance.

The hepatic glucose homeostasis is maintained by many enzymes involved in hepatic glucose metabolism that have been proposed as potential targets in diabetes, for example, glucokinase (*GCK*) the key enzyme of glycolysis, fructose-1,6-biphosphatase (*FBP1*), phosphoenolpyruvate carboxykinase (*PCK1* and *PKC2*), and glucose 6-phosphatase (*G6PC*) control key points in the gluconeogenesis pathway. Glycogen phosphorylase (*PYGL*) is a rate-limiting enzyme of glycogenolysis [82]. G6PC and GCK act in opposition to regulate the intracellular levels of free glucose. An increased ratio of G6PC/GCK promotes a glucose efflux to the bloodstream, whereas a decreased ratio causes glucose influx. The GCK activity has been reported to decrease in patients with T2D. A

decrease of 60% in *GCK* expression has been observed in diabetic subjects with HbA1c > 7.0, which also correlates negatively with Hb1Ac and fasting glucose, suggesting an important dysregulation of hepatic *GCK* expression in diabetes [83]. On the other hand, in fasting conditions, normoglycemia is maintained by hepatic gluconeogenesis, controlled by rate-limiting enzymes such as *FBP1*, *PCK1*, and *G6PC* that are regulated by insulin. An alteration in gluconeogenesis is observed in T2D. It has been related to an increased expression of *FBP1*, *PCK1*, and *G6PC* due to the incapacity of insulin to suppress their expression due to hepatic insulin resistance.

It has been described that transcriptional activation of *PCK* requires the coactivation of the glucocorticoid receptors and the liver-enriched transcription factor hepatic nuclear factor-4α (*HNF4A*) by *PGC-1α* [84]. The *PGC-1α*, as mentioned before, is a key regulator of the OXPHOS-related genes in other tissues such as skeletal muscle, producing a downregulation of the OXPHOS pathway in T2D. On the contrary, several genes in the OXPHOS pathway appear to be upregulated in liver from diabetic patients (Table 10.3). However, no correlation was observed between the expression of *PGC-1α* and the upregulation of genes involved in OXPHOS in the liver of patients with T2D [85].

Like OXPHOS pathway, other metabolic pathways have been shown to differ in their expression pattern when compared with other insulin-sensitive tissues. For example, several genes co-expressed in the liver, skeletal muscle, and adipose tissue related to glycolysis/gluconeogenesis, fatty acid beta oxidation, tricarboxylic acid cycle, and electron transport chain pathways are downregulated in skeletal muscle and in adipose tissue but are upregulated in liver from diabetic patients [74].

The lipid metabolism is well known to be altered in diabetic liver. Interestingly, none of the expression enzymes related to fatty acid metabolism, including fatty acid oxidation, fatty acid synthesis, and fatty acid storage, were downregulated in the liver of diabetic mice. On the contrary, enzyme genes involved in fatty acid oxidation (*CPT1a*, *CPT2*, *EHHADH*, ACOT2, *ACOT3*, *ACOT4*, *ACOT5*, *ACOT6*, and *PPARα*) and fatty acid storage (*ELOVL6*, *SCD1*, *GPAT*, *DGAT1*, and *DGAT2*) were significantly upregulated, whereas the enzyme genes involved in fatty acid synthesis (*ACLY* and *FASN*) showed no significant changes. In addition, genes related to fatty acid transport (*CD36* and *SLC27a2*) were also upregulated in the liver of diabetic mice, showing that enhanced fatty acid transport is consistent with the increased expression of enzyme genes in fatty acid storage. These data suggest that diabetes enhances liver fatty acid oxidation, which has been reported to stimulate gluconeogenesis and suppress glycolysis. In this sense, it was reported that key enzymes in glycolysis such as pyruvate kinase, phosphofructokinase, and glucokinase enzyme activity and mRNA expression are decreased in diabetes. However, in the liver of diabetic mice, non-changes in pyruvate kinase or phosphofructokinase expression were observed. On the contrary, the *PKLR* gene that encodes the rate-limiting enzyme pyruvate kinase was significantly upregulated, suggesting an increased glycolysis activity in the liver. But this enhanced glucose consumption is not sufficient to decrease the hepatic glucose levels because gluconeogenesis and glycogenolysis were also enhanced to produce more glucose [82].

On the other hand, the inflammation is one important factor that leads to diabetes. Surprisingly the downregulated genes found in diabetic mice liver were mainly enriched in immune-related process, such as adaptive immune response and lymphocyte-mediated immunity. However, the results showed that besides inflammatory signaling, another hepatic immune-related pathway is also correlated to T2D. For example, the downregulated genes in diabetic mouse liver were also enriched in pathways related to cancer, hepatitis, adenovirus infection, and liver tumor. These data are consistent with previously reported data that reported an increase in the frequency of hepatitis B and C virus infection in diabetic patients. That is in line with the association of hepatitis with T2D. Furthermore, epidemiological studies have reported that liver cancer is increased in diabetic patients; however, the biological mechanism is still unknown [82].

Table 10.3 OXPHOS genes upregulated in patients with T2D [85]

Gene	Description	Function
NDUFA6	NADH: ubiquinone oxidoreductase subunit A6	Electron transport chain
SDHC	Succinate dehydrogenase complex subunit C	Electron transport chain
UQCRB	Ubiquinol-cytochrome c reductase binding protein	Electron transport chain
COX4i1	Cytochrome c oxidase subunit 4i1	Electron transport chain
ATP5B	ATP synthase, H+ transporting, mitochondrial F1 complex, beta polypeptide	ATP synthesis

Whole Blood Gene Expression in T2D

Studies of gene expression in peripheral blood mononuclear cells (PBMCs) have identified changes in more than 1000 genes which are differentially expressed in diabetic patients. Those genes were grouped according to their function, and changes in profile expression of several signaling pathways were observed when compared with subjects without diabetes.

The most important pathways altered in T2D patients were OXPHOS, MAPK, electron transport chain pathways,

Table 10.4 Genes expressed in WBC, adipose tissue, liver, and skeletal muscle related to the progress of T2D

Gene	Description	Function
FABP5	Fatty acid binding protein 5	Protein involved in the fatty acid uptake, transport, and metabolism has been associated with development of insulin resistance and T2D in obesity
CFD	Complement factor D	Serine peptidase protein secreted by adipocytes that has been implicated with insulin secretion in mice
PC-1	Ectonucleotide pyrophosphatase/phosphodiesterase 1	Transmembrane protein that acts as an inhibitor of the insulin pathway and has been related to insulin resistance
UCP3	Uncoupling protein 3	Mitochondrial protein expressed mainly in skeletal muscle, it participates in the fatty acid metabolism and has been observed a decrease in their expression in patients with T2D

fatty acid metabolism, inflammatory response, and DNA repair [84, 86]. However, some of the altered genes were involved among two or more biological process, such as *RELA*, *UCP3*, *STAT5B*, *PLD2*, *PSEN2*, *IL17A*, and *CRCP* (upregulated genes involved in inflammation, response to hypoxia and oxidative stress, and fatty acid response), as well as *ARNT*, *CAT*, and *MDH2* (downregulated genes implicated in response to oxidative stress, DNA repair, and response to hypoxia) [86]. Interestingly, the pathways involved in stress response, such as MAPK, TNF signaling, apoptosis, and mTOR signaling, were significantly altered after glycemic control [84].

The ceramide and adipocytokine signaling pathways were significantly upregulated in T2D patients, probably as a result of the presence of obesity in the patients. In the case of ceramides, they are lipids related to structural components of the cell membrane. However, an increase of ceramide production has been associated with different stress stimuli such as inflammatory mediators, heat, UV radiation, hypoxia, chemotherapeutics, and oxidative stress. High levels of ceramides are involved to the inhibition of AKT/PKB, resulting in insulin resistance. It suggests an important link between obesity and diabetes. In addition, the adipose tissue releases several factors including FFA and proteins called adipocytokines (TNF-α, IL-6, and resistin) that control various metabolic functions. Those adipocytokines and the proinflammatory cytokines secreted by the macrophages residing in adipose tissue have been related to insulin resistance development. This phenomenon occurs by the activation of JNK and NF-κB pathways that impair the insulin action by interfering with the insulin binding to its receptor [86]. In this sense, genes related to the JNK pathway were coordinately upregulated by diabetes; however, after glycemic control a downregulation in this pathway was observed. The gene expression of JNK genes was also significantly correlated to fasting glucose levels and HbA1c. It suggests that the upregulation of the JNK genes in the PBMCs may be associated with hyperglycemia. In this regard, diabetes and hyperglycemia have been related to oxidative stress which causes activation of the JNK pathway by endoplasmic reticulum stress in pancreatic β-cells and hepatocytes. Besides, JNK activation suppresses insulin biosynthesis and impairs insulin action.

On the other hand, the OXPHOS pathway was significantly downregulated in diabetes. However, it was not altered by glycemic control. The altered expression in OXPHOS pathway was correlated with neither fasting glucose nor HbA1c. It suggests that OXPHOS may predict the existence of diabetes, because it was coordinately downregulated in PBMCs of patients with T2D but was not altered by glycemic control. These data are in agreement with the profile expression observed in skeletal muscle and adipose tissue, where the OXPHOS is one of the main pathways that suffer alteration in gene expression in diabetes [84].

To compare if the gene expression observed in WBC was related to the gene expression in insulin-sensitive tissues such as the liver, adipose tissue, and skeletal muscle, a microarray analysis was performed in OLETF rats. The results showed that more than 300 genes were differentially expressed in blood cells, and only 4 genes were related to the insulin-signaling pathway: *Pc-1*, *Sihps-1*, and *Grb2* were upregulated, and *Pten* was downregulated. In addition, 57 genes were concurrently expressed in the analyzed tissues with the adipose tissue showing the best correlation with WBC, sharing 41 genes. It was followed by the liver with 25 genes and 14 genes with the skeletal muscle. From these 57 genes, only 4 genes have been well related to the progress of T2D (Table 10.4) [87].

Whole Blood Gene Expression as a Possible Tool for Early Detection of T2D

The Otsuka Long-Evans Tokushima Fatty (OLETF) rat is an animal model of spontaneous type 2 diabetes.

This rat model of T2D is characterized by mild obesity with visceral fat accumulation and late-onset insulin resistance, it resembles human obese patients with type 2 diabetes.

The diagnosis of T2D is generally obtained by measuring fasting glucose levels, oral glucose tolerance test (OGTT), or percent of HbA1c. However, these methods do not determine the risk to develop T2D at early stages. The expression profile has been proposed as a very good tool to evaluate the risk to develop T2D. However, lack of samples from specific tissues makes difficult this kind of studies. It is not ethically

correct to obtain tissue samples from organs involved in the pathogenesis of the disease from healthy humans only for an early diagnosis. For this reason, recent studies have been focused to determine the expression profile on whole blood cells (WBC), which are very accessible. This is a tissue that may show the oxidative stress caused by high levels of glucose, insulin, free fatty acids, and tissue-derived circulating bioactive mediators.

The studies on WBC have demonstrated that gene expression profile in diabetes is different from other pathologies such as metabolic syndrome or coronary artery disease. Suggesting that gene expression profiles in WBC can be useful to identify the altered pathways involved in the pathophysiology of T2D and preclinical symptoms of T2D. Gene expression technology can also be used as a new diagnosis method that could predict the progression of the disease.

miRNAs in Blood Samples

Today it is widely recognized that not all the RNAs are traduced to proteins; there are noncoding RNAs named microRNAs (miRNAs). They are involved in gene regulation of specific target genes. The miRNAs are a class of 19–24 nucleotides of RNA, which mediate posttranscriptional gene silencing by binding to the 3′-UTR or open reading frame (ORF) region of target mRNAs. The involvement of miRNAs has been reported in several biological activities including cell proliferation, cell differentiation, cell migration disease initiation, and disease progression [88]. Increased levels of specific miRNAS have been associated with a variety of diseases including cancer, obesity, diabetes, and cardiovascular disease. In the case of diabetes, several studies have reported that miRNAs play a critical role in glucose homeostasis and T2D pathogenesis, because a vast number of miRNAs are implicated in pancreatic development (miR-124a, miR-15a/b, miR-192, miR-375), insulin secretion (miR-9, miR-124a, miR-375), glucose transport (miR-29a/b), and β-cell dysfunction (miR-124a). In addition to the hyperglycemia, miRNAs also participate in the inflammatory response, vascular endothelial damage, and fibrosis processes that are involved in T2D complications. There is evidence that demonstrate that T2D complications are associated with miRNA dysregulation in various target tissues, especially the brain, eyes, nerves, and kidneys. For example, the miR-133 highly expressed in diabetic hearts has been associated with long QT syndrome and cardiac hypertrophy, whereas upregulation of miR-192 has been implicated in diabetic nephropathy [89].

In addition to the expression of miRNAs in tissues, they are expressed in many biological fluids such as saliva, urine, breast milk, and blood where its expression is stable. They are found packed into exosomes or microvesicles and as extracellular miRNAs that are loaded into high-density lipoprotein (HDL) or bound to an argonaute protein (AGO2) outside of the vesicles. These conformations protect the miRNAs from degradation and confer them stability in those fluids. The work published by Wang et al. [90] investigates whether there were differences in the serum miRNA expression profiles between T2D patients with or without diabetic microvascular complications, in comparison with nondiabetic patients. The results showed that serum miRNA expression profiles varied among diabetic patients and the healthy group. From the 754 miRNAs evaluated in the array, 25 miRNAs were upregulated, and 118 were downregulated in the 2 T2D patient groups compared with the nondiabetic controls. The validation analysis showed that five miRNAs (showed in Table 10.5) were significantly increased in both T2D patients with and without complications relative to healthy controls. Furthermore, those five miRNAs were higher in T2D patients with complications than in those who were free of complications [90].

Table 10.5 Significantly upregulated miRNAs found in T2D patient groups in comparison with nondiabetic group [90]

miRNAs	Diabetic complication
miR-661	Regulation of insulin biogenesis and the SNAIL-triggered epithelial to mesenchymal transition that has been related to microvascular complications
miR-571	Chronic liver disease by their participation in fibrogenic and inflammatory process in the liver Contribute to kidney fibrosis that is related to diabetic nephropathy
miR-770-5p	Retinopathy and neurological diseases
miR-892-b	Retinopathy and neurological diseases
miR-1303	Tumor/cell cycle-related miRNAs

Recently, a study in adipose tissue of Dicer KO mice (AdicerKO) demonstrated that miRNAs released to the circulation can act by regulating gene expression in other tissues. For example, the miR99b produced and released to the circulation by the adipose tissue was responsible to modulate the expression of the fibroblast growth factor 21 (FGF21) gene in adipose tissue, as well as in the liver, muscle, and pancreas, suggesting that miRNAs secreted by the adipose tissue may act at paracrine and endocrine levels [91]. Interestingly, the Dicer KO mice used in this study showed an alteration in glucose levels and insulin resistance. Thus, the miRNAs released by the adipose tissue may affect the glucose metabolism possibly by their influence in insulin-sensitive tissues.

To summarize, the publications reviewed propose that miRNAs detected in the circulation can be used as potential noninvasive biomarkers for various diseases, including T2D and its complications. However, more studies are necessary to validate this hypothesis.

Concluding Remarks

- Changes in the expression of several genes arise before phenotype changes are observed.
- Insulin resistance and insulin secretion are linked to modification of gene expression in pancreas, liver, adipose tissue, and muscle.
- Inflammation, oxidative phosphorylation, carbohydrate and lipid metabolism, and mitochondrial function are distinctive pathways that are deregulated during T2D progression.
- Gene regulation in distant organs can be achieved by secreted hormones as well as micro RNAs.

Multiple-Choice Questions

1. Two transcription factors that participate in the regulation of adipocyte differentiation.
   (a) PPARγ and C/EBPα (Both molecules coordinately regulate the expression of many 100 of genes responsible for establishment of the mature adipocyte phenotype)
   (b) FOXO1 and HIF1
   (c) PDX1 and PGC-1α
   (d) FOXO1 and PDX1
   (e) HIF1 and PDX1
2. One role of NOD-like receptors in adipocytes of obese individuals is:
   (a) Decrease the expression of inflammation-related genes
   (b) Induce adipocyte death by pyrosis (activation of caspase-1 leading to membrane breakdown and pro-inflammatory cytokine processing)
   (c) Increase lipid-uptake
   (d) Increase adipogenesis
   (e) Sense blood glucose
3. A main difference in the expression of inflammation-related genes in obese vs lean individuals is:
   (a) Inflammation-related gene expression is lower in obese than in lean individuals
   (b) Inflammation-related gene expression is the same in obese than in lean individuals
   (c) Inflammation-related gene expression is higher in obese than in lean individuals (this enhanced expression of inflammatory genes is linked to the development of insulin resistance)
   (d) Inflammation-related gene expression is not related to obesity
   (e) Inflammation-related gene expression is not relevant
4. Saturated fat consumption exerts the following effects in the pancreas:
   (a) Increases the expression of transcription factors such as PDX1 and PAX4
   (b) Positively regulates ATP production in the pancreas
   (c) It decreases the expression of insulin and induces apoptosis of β-cells (inflammation and saturated fat consumption inhibit the expression of important transcription factors in β-cells)
   (d) Induces macrophage recruitment
   (e) Triggers mechanism to protect from inflammation-induced damage
5. The most distinctive pathways deregulated in type 2 diabetes.
   (a) Inflammation, urea cycle, carbohydrate, lipid metabolism, and mitochondrial function
   (b) Inflammation, oxidative phosphorylation, carbohydrate metabolism, nucleotide metabolism, and mitochondrial function
   (c) Xenobiotics degradation, oxidative phosphorylation, nucleotide metabolism, lipid metabolism, and mitochondrial function
   (d) Inflammation, oxidative phosphorylation, carbohydrate, lipid metabolism, and mitochondrial function (Deregulation of genes in these pathways has been observed in the main tissues associated with T2D)
   (e) Inflammation, oxidative phosphorylation, urea cycle, lipid metabolism, and polar amino acids
6. Which two genes are considered key regulators of the expression of OXPHOS pathway related genes?
   (a) *GLUT4* and *FTO*
   (b) *PGC1α* and *SOD2*
   (c) *NRF-1* and *PGC-1α* (downregulation of OXPHOS genes in diabetes is associated with low expression of NRF-1 and PGC1α genes)
   (d) *PGC-1β and IRS*
   (e) *PPARα* and *FASN*
7. How PGC-1α can influence gene transcription?
   (a) Direct binding to DNA and activate transcription in target genes
   (b) Interacting with other transcription factors such as *PPARα*, *PPARγ*, and *HNF4* (The *PGC-1α* is a transcriptional regulator that does not bind directly to DNA but influence transcription by interacting with other transcription factors including *NRF-1*, *PPARα*, *PPARγ*, and *HNF4*)
   (c) Activating directly specific sites of the RNA polymerase II increasing their affinity to DNA
   (d) Inhibiting the union site of the transcription factors in the DNA
   (e) Stabilizing mRNA and inhibiting its degradation

8. Besides of expression pattern in the OXPHOS pathway, what other pathways are downregulated in skeletal muscle and adipose tissue but upregulated in the liver of diabetic patients?
   (a) Fatty acid beta oxidation, tricarboxylic acid cycle, glycolysis/gluconeogenesis, and electron transport
   (b) Inflammation, urea cycle, carbohydrate, lipid metabolism, and mitochondrial function
   (c) Inflammation, carbohydrate metabolism, nucleotide metabolism, and mitochondrial function
   (d) Xenobiotics degradation, oxidative phosphorylation, nucleotide metabolism, lipid metabolism, and mitochondrial function
   (e) Fatty acid transport, urea cycle, glycogenolysis, insulin transport, and glucose uptake
9. What is the tissue with the best expression pattern correlation with whole blood cells in diabetes?
   (a) Skeletal muscle
   (b) Pancreas
   (c) Liver
   (d) Brain
   (e) Adipose tissue (adipose tissue and WBC share the expression of 41 genes, followed by the liver with 25, and skeletal muscle with 14)
10. What is the reason why miRNA detection in the bloodstream would be a potential risk marker of diabetes?
    (a) Because they are small noncoding RNAs that can be detected in blood samples
    (b) Because miRNAS are very stable to degradation in blood sample
    (c) Because miRNAs expression is increased in blood samples from DT2 patients
    (d) Because some miRNAs detected in the circulation are related to gene regulation in altered pathways in diabetes and diabetes complications
    (e) Because adipose tissue can release miRNAs to bloodstream

Correct Answers

1. (a) PPARγ and C/EBPα (Both molecules coordinately regulate the expression of many hundreds of genes responsible for establishment of the mature adipocyte phenotype)
2. (b) Induce adipocyte death by pyrosis (Activation of caspase-1 leading to membrane breakdown and proinflammatory cytokine processing)
3. (c) Inflammation-related genes expression is higher in obese than in lean individuals (This enhanced expression of inflammatory genes is linked to the development of insulin resistance)
4. (c) It decreases the expression of insulin and induces apoptosis of β-cells (inflammation and saturated fat consumption inhibit the expression of important transcription factors in β-cells)
5. (d) Inflammation, oxidative phosphorylation, carbohydrate, lipid metabolism and mitochondrial function (Deregulation of genes in these pathways has been observed in the main tissues associated with T2D)
6. (c) *NRF-1* and *PGC-1α* (down regulation of OXPHOS genes in diabetes are associated with low expression of NRF-1 and PGC1α genes)
7. (b) Interacting whit other transcription factors such as *PPARα, PPARγ* and *HNF4*. (The *PGC-1α* is a transcriptional regulator that does not bind directly to DNA but influence transcription by interacting with other transcription factors including *NRF-1, PPARα, PPARγ* and *HNF4)*
8. (a) Fatty acid beta oxidation, tricarboxylic acid cycle, glycolysis/gluconeogenesis and electron transport
9. (e) Adipose tissue (adipose tissue and WBC share the expression of 41 genes, followed by the liver with 25, and skeletal muscle with 14)
10. (d) Because some miRNAs detected in the circulation are related to gene regulation in altered pathways in diabetes and diabetes complications

Glossary

3′-UTR region Untranslated regions (UTRs) at the 3′end of mRNA contain important sequences that are related to the regulation of gene translation. The 3′-UTR plays a critical role in the stability of mRNA and in posttranscriptional regulation.

Apoptosis Is a process of programmed cell death, which is considered to be important in several processes including normal cell turnover, development and function of immune system, hormone-dependent atrophy, embryonic development, and chemical-induced cell death. Human conditions such as neurodegenerative diseases, ischemic damage, autoimmune disorders, and many types of cancer are related to inappropriate apoptosis.

Bariatric surgery Is a surgical process employed to reduce weight in obese patients, by restricting the amount of food the stomach can hold, causing malabsorption of nutrients. The most common bariatric surgery procedures are gastric bypass, sleeve gastrectomy, adjustable gastric band, and biliopancreatic diversion with duodenal switch.

Damage-associated molecular patterns (DAMPs) Are cell-derived molecules that can initiate and perpetuate immunity in response to trauma, ischemia, and other setting of tissue damage in the absence of overt pathogenic infection. DAMPs can be found into the nucleus and cytoplasm (HMGB1), cytoplasm alone (S100 pro-

teins), exosomes (HSP), extracellular matrix (hyaluronic acid), and in plasma such as complement (C3a, C4a, and C5a). Examples of nonprotein DAMPs include ATP, uric acid, heparin sulfate, RNA, and DNA. Increased levels of DAMPs are associated with inflammatory diseases such as sepsis, arthritis, atherosclerosis, systemic lupus erythematosus, Crohn's disease, and cancer.

Deacetylation Histones acetylation has been linked to transcriptional activation. The enzymes regulating the histone acetylation are the histone acetyltransferases (HATs). On the contrary, the deacetylation by histone deacetylases (HDACs) is related to transcriptional repression.

DNA hypermethylation DNA methylation is a heritable epigenetic mark that involves the covalent transfer of a methyl group to a cytosine ring of DNA. The methylation reaction is catalyzed by a family of DNA methyltransferases (DNMTs). DNA methylation is associated with decreased transcriptional activity.

Enhancer Is a DNA sequence that activators or transcriptional factors bind and increase gene transcription. Its location is variable in the gene; it can be present in the 5′-UTR, 3′-UTR, or into the coding region of the gene.

Epigenetics Epigenetics is the study of biological mechanisms that switch genes on and off. There are three major levels of epigenetic changes: (1) chemical modification at nucleotide level (DNA methylation and RNA interference), (2) modifications at histone level, and (3) nucleosome remodeling.

Glycosylated hemoglobin (HbA1c) Is also known as glycated hemoglobin. The glycation of hemoglobin consists in a nonenzymatic interaction between glucose and the amino groups of the valine and lysine residues in hemoglobin. This interaction is irreversible and is a test that indicates the exposition of the proteins to glucose for the last 3 months.

Genome-wide association studies (GWAS) Are studies that identify DNA markers (SNPs) in the whole genome that are common to the human genome and to determine how these SNPs are distributed across different populations. GWAS are used to determine genetic risk markers associated with a disorder, for example, diabetes, obesity, hypertension, or cancer.

Knockout mice Is a model used in the laboratory in which a mouse has inactivated or "knocked out" an existing gene by replacing it or disrupting it with an artificial piece of DNA.

Maturity-onset diabetes of the young (MODY) Is a rare form of diabetes different from both type 1 and type 2 diabetes and runs strongly in families. It is caused by a mutation in a single gene.

OLEFT rats The Otsuka Long-Evans Tokushima Fatty (OLETF) rat is an animal model of spontaneous T2D. This rat model of T2D is characterized by mild obesity with visceral fat accumulation and late-onset insulin resistance. It resembles human obese patients with T2D.

Pathogen-associated molecular patterns (PAMPs) Are derived from microorganisms and recognized by pattern recognition receptor (PPR)-bearing cells of the innate immune system as well as many epithelial cells. Major PAMPs are microbial nucleic acids, including DNA, double-stranded RNA (dsRNA), single-stranded RNA (ssRNA), and 5′-triphosphate RNA, as well as lipoproteins, surface glycoproteins, and membrane components (peptidoglycans, lipoteichoic acid, lipopolysaccharide, and glycosylphosphatidylinositol).

Promoter The promoters are sequences in the DNA that define the start point in the transcription of a gene.

Reactive oxygen species (ROS) Are radical and non-radical oxygen species formed by the partial reduction of oxygen, for example, superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical (HO•). They are generated endogenously by the oxidative phosphorylation process in the mitochondria or are produced from interactions with exogenous sources such as xenobiotic compounds.

Roux-en-Y gastric bypass (RYGB) Is often called gastric bypass and is considered the "gold standard" of weight loss surgery. This surgery consists to create a new stomach pouch, using a small portion of the stomach. The smallest stomach is connected directly to the middle portion of the small intestine (jejunum), bypassing the rest of the stomach and the upper portion of the small intestine (duodenum).

Single nucleotide polymorphisms (SNPs) Are a variation in a single position in a DNA sequence among individuals. This variation has to be present in almost 1% of a population to be considered as a SNP.

Streptozotocin (STZ)-induced diabetes Streptozotocin is a glucosamine-nitrosourea compound derived from *Streptomyces achromogenes*. STZ is employed to induce cellular damage specifically in β-cells, resulting in hypoinsulinemia and hyperglycemia.

Transcriptomic The transcriptome is the complete set of expression products transcribed from the genome in a specified tissue or populations of cells. Transcriptomic has emerged as a powerful technic that analyzes 1000 of genes in one sample using RNA microarrays. This technic has allowed the study of gene expression patterns on several tissues involved in the pathogenesis of the T2D and to identify genetic markers for the early diagnosis of T2D.

The Immune System and Inflammation in Type 2 Diabetes

11

Rebeca García-Macedo

Chapter Objectives

- Obesity-associated inflammation as a major contributor toward the progression to IR and T2D.
- Relevance of adipocytes and some classes of immune cells in obese adipose tissue as mediators of inflammatory state.
- Several proinflammatory markers expressed by immune cells have been considered as potential risk factors for developing T2D.
- Anti-inflammatory therapeutic approaches to alleviate IR and T2D.

Introduction

This chapter focuses on immune cells participation during type 2 diabetes (T2D) development. Obesity is a major driver of T2D. However, obesity per se does not necessarily lead to T2D, but rather to individual differences regarding body composition, fat distribution, and adipose tissue (AT) function.

Most findings demonstrating the correlation between AT dysfunction and T2D have been observed on mouse models or obese subjects and/or those with impaired insulin sensitivity. It is also known that increasing overweight and obesity incidence have been linked to increasing amounts of T2D cases. It is a well-recognized fact that chronic low-grade inflammation is correlated to obesity-associated comorbidities. Furthermore, adipose tissue (AT) is an important immunologically active organ that contributes during inflammation processes.

The development of T2D results from a combination of IR and pancreatic beta cell failure, thus resulting in hyperglycemia. A chronic activation of the innate immune system is associated with T2D, and there is evidence suggesting that both IR and beta cell failure are regulated by this inflammatory status in humans [1–3].

Some intervention studies have shown that therapies for obesity-induced T2D relying on immune markers include those approaches intended to increase insulin sensitivity by blocking the activity of inflammatory mediators, e.g., interleukin (IL)-1α, IL-1β, IL-6, tumor necrosis factor (TNF-α), and macrophage chemoattractant protein 1 (MCP-1) [4–6].

Increased adipocyte size is associated with a decreased population of precursor cells able to differentiate into adipocytes. Large adipocytes are more frequently found in subjects with impaired glucose tolerance and T2D in comparison to those with a similar degree of adiposity but with normal glucose tolerance. Impaired adipocyte differentiation appears to be one of the most important factors for T2D progression [1]. The presence of proinflammatory cytokines in blood hampers the capacity of the insulin receptor to convey signals within insulin-sensitive tissues.

Insulin has several functions in its target tissues including nutrient transport as well as the regulation of gene expression and energy homeostasis. It acts on a several target tissues and through many different intracellular signaling cascades. Elevated levels of intracellular free fatty acids (FFAs) may blunt the response toward insulin and its subsequent metabolic effects. The insulin receptor substrate (IRS)-1 is a key molecule in this signaling pathway and failure to activate it leads to systemic IR [7]. Inflammatory cytokines such as TNF-α and IL-6 may induce an inhibitory phosphorylation of IRS-1. A similar response is achieved by activating the receptors of the innate immune system, such as the Toll-like receptors (TLR), or by the presence of intracellular molecules, e.g., lipids and reactive oxygen species (ROS). By interacting with their respective receptors, TNF-α and IL-6 activate the nuclear transcription factor κB (NFκB) and the Janus kinase (JNK), both of them important inflam-

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_11

mation activators. JNK is also activated by FFAs and endoplasmic reticulum stress. Interestingly, these factors are associated with obesity [8]. The regulator of cytokine function known as the suppressor of cytokine signaling (SOCS) inhibits insulin effects on IRS-1, either by interfering with tyrosine phosphorylation or by targeting IRS-1 for proteasomal degradation [9].

Ectopic lipid accumulation in the pancreas, concomitantly with a decreased activation of the insulin receptor in adipocytes, minimizes insulin production and impairs insulin-stimulated glucose transport, its anti-lipolytic effect, as well as lipoprotein lipase production and activity, whereas it increases the release of FFA and hampers pre-adipocyte differentiation. All these effects will lead to IR and T2D development, including cardiovascular diseases.

Types of Adipose Tissue

Systemic inflammation induced by obesity is predominantly originated at the AT. Mammalian body contains several types of fat reservoirs, classified as white and brown fat. White adipose tissue (WAT) is in turn classified as subcutaneous and visceral adipose tissue (VAT). The former stores the calorie surplus, and it may be further classified as upper and lower body obesity. On the other hand, VAT (omental and mesenteric) supplies energy to all organs. Subcutaneous AT predominates over VAT by a 3–4 factor [10].

WAT stores nutrients within a single large fat droplet. This tissue is one of the main endocrine organs in the organism. VAT is located in the abdominal cavity, it is the main source of chronic systemic inflammation, and it is of utmost importance for T2D establishment. When the perigonadal fat pads from obese mice fed with a high-fat diet (HFD) (a model of obesity-induced T2D) were removed, a significant decrease of glucose intolerance and IR was observed. The content of specific immune cells in VAT is modified when obesity develops [11–13].

Brown adipose tissue (BAT) is mostly found in newborn humans, even though adults possess small amounts of this type of fat. In spite that WAT and BAT share many metabolic features, the former stores energy, whereas the latter dissipates energy and produces body heat [14]. In BAT, the signaling mediated by the mammalian target rapamycin complex 2 (mTORC2) stimulates cold-induced glucose uptake and glycolysis [15].

Ectopic Fat Accumulation

Fat is accumulated in specific regions along the body when obesity develops. Normally, the abundance of AT is low in these zones.

Ectopic fat is defined as a triglyceride deposition within non-adipose tissue cells that normally contain small amounts of fat. Liver, skeletal muscle and pancreas contain an excessive lipid accumulation. In skeletal muscle, this fat accumulation is correlated with IR and cardiovascular disease [16].

Lipid accumulation in the liver and muscle is an early sign of T2D, whereas it has been shown to precede the suppression of glucose-mediated insulin production by the pancreas [17]. In cardiac tissue a lipid overload has been shown to produce a metabolic deregulation, and it may induce IR resulting in impaired glucose oxidation and, consequently, heart failure [18].

Epicardial Adipose Tissue

This specific tissue possesses some anatomical and metabolic features that distinguish it from other visceral fat depots, such as increased fatty acid metabolism and a transcriptome including genes associated with inflammation and endothelial functions. Some bioactive adipokines such as adiponectin, TNF-α, IL-1, IL-6, neural growth factor (NGF), and resistin, as well as FFA from epicardial AT, may impact on cardiovascular function and morphology. Therefore, they may directly contribute to cardiovascular complications and IR [19].

Perivascular Fat

The perivascular adipose tissue surrounding blood vessels is produced from vascular lamina adventitia in response to circulating factors and local stimuli. This fat tissue has been considered a largely passive structural support for arteries. Nevertheless, it can play an active role to regulate vascular tone and the release of adipocyte-derived vascular relaxing factors into the blood vessels [20].

Obesity, Acute, and Chronic Inflammation

Inflammation is a series of cellular and molecular responses in order to protect the body from infections or other insults. The inflammation process is continuous over a time period. Acute and chronic are terms used to describe different inflammation stages. This event is triggered by a stimulus, and, when it ceases, inflammation is attenuated. If it does not remain in the acute period, it becomes chronic.

When compared to acute inflammation induced by bacteria or viruses, chronic inflammation may be driven by an abnormal reaction toward the presence of endogenous factors, including metabolic factors as advanced glycation end products (AGES), modified lipoproteins, type 2 T helper cells (Th2), cytokines, hyperglycemia, and others [21–23].

Monocytes, one of the key cell types on the innate immune system, recognize the presence of these factors in the bloodstream, they migrate to the respective tissues, and they may recruit macrophages with pathological functions. Obesity-associated inflammation is characterized by an increased amount of macrophages and proinflammatory cytokines in the AT.

It has been shown that one type of monocytes (CD16+) was increased in patients with metabolic disorders, and it positively correlates with body mass index, insulin resistance, diabetes, and intima-media thickness. Conversely, when severe obese patients lose weight after being submitted to a bypass surgery, this type of monocytes decreases significantly [24, 25].

Inflammation is the response of living tissue towards injury. It involves a well-organized cascade of humoral and cellular changes within living tissue. Blood is the primary delivery system for inflammatory components such as adipokines TMF-α, IL-6, leptin, resistin and adiponectin.

Obesity and its associated metabolic pathologies such as IR, T2D, and atherosclerosis [26] are chronic and concomitant with inflammatory responses such as increased acute-phase reactants as the C-reactive protein (CRP); activation of inflammatory signaling pathways; high levels of circulating inflammation biomarkers as interleukin (IL)-6, IL-1β, and plasminogen activator inhibitor-1 (PAI-1); and low adiponectin levels (an anti-inflammatory adipokine). The latter may predict the future establishment of T2D [27–31]. The inflammatory response is mainly located in adipose tissue, and it is triggered therein, although other tissues may be involved when T2D is developing.

In the AT, immune cells participate on tissue remodeling and homeostasis, and these roles are controlled by inflammation. AT is considered a complex endocrine tissue containing multiple cell types, including its precursors, vascular, immune, and neuronal cells. All of them contribute to the inflammatory response occurring in obesity. A nutrient excess promotes adipocyte expansion, resulting in its dysfunction. Cytokines, chemokines, and adipokines secreted by adipocytes induce immune cell accumulation in the AT and trigger local and systemic inflammation, being one of the causes contributing to IR [32, 33].

Type 2 Diabetes and Immune Cells

Immune function has been classified as innate and adaptive immunity. The former represents a rapid response toward some stimuli, and it is characterized by physical, chemical, and biological barriers, specialized cells, and soluble molecules. They occur in all individuals, regardless of their previous contact with harmful agents or immunogens, and they do not qualitatively or quantitatively change after contact [34].

The human leukocyte antigen (HLA) constitutes a system also known as the major histocompatibility complex MHC. This is a protein set derived from highly polymorphic genes linking innate and adaptive responses. The human genes are allocated in classes I, II, and III. Only those of classes I and II participate to present antigen proteins to T cells. All MHC molecules found on the cell's surface contain an associated peptide.

Those from class I possess one α-chain coded by the HLA-A, HLA-B, or HLA-C genes and a small non-variable chain: the β2-microglobulin. HLA class II possess two chains: α and β. HLA discriminates between intrinsic and foreign elements, and they ensure a suitable immune response in order to protect against external agents capable to generate an infection.

Adaptive or acquired immune response depends on the activation of specialized cells and the soluble molecules produced by them. The main features of the acquired response are memory, specificity and diversity of recognition, self-restraint, specialized response, and tolerance to the components of the organism itself. The cells that are mainly involved on the acquired immune response are lymphocytes. Antigen-presenting cells (APCs) play a key role during lymphocyte activation by presenting them with antigens bound to the major histocompatibility complex (MHC) molecules [35]. Lymphocytes type T recognize antigenic fragments derived from pathogens that previously entered the cells, but only when are associated with the major histocompatibility complex proteins. In humans, the latter is termed the human leukocyte antigen (HLA). Concomitantly with the innate immune system signs, it triggers the T cell-mediated immune response.

Macrophages, neutrophils, dendritic cells, and natural killer (NK) cells are the main effectors of innate immunity. The central mechanisms of innate immunity comprise phagocytosis, the release of inflammatory mediators, activation of the complement system proteins, as well as synthesis of acute-phase proteins, cytokines, and chemokines. These are activated by specific stimuli, such as the lipopolysaccharides commonly found on the outer membrane of microorganisms.

AT is comprised of mature adipocytes (≈50%) and other cells (≈50%) from the stromal vascular fraction (SVF) that contains pre-adipocytes, fibroblasts, endothelial cells, and immune cells, e.g., macrophages [36–43].

After analyzing several adipose reservoirs, it was observed that immune cells represent approximately two thirds of the SVF, containing approximately 2–5 million cells/g of tissue [44]. In morbidly obese subjects, AT represents up to 50% of total body mass, and it is the main compartment of the immune system having an effect on systemic inflammation.

Cell populations within the AT display a plasticity that is regulated by both acute and chronic stimuli including body weight status, diet, feeding, and fasting [8, 36, 42, 45, 46]. Mice fed with a HFD recruit immune cells to AT in distinct time periods. It appears that neutrophils are recruited within 3 days and macrophages within 2 weeks, whereas B and T cells increase within 4 weeks [42].

Xu et al. (2003) and Weisberg et al. (2003) [36, 47] demonstrated that obesity and insulin resistance are concomitant with macrophages infiltrating the AT. In addition to these, other immune cell populations change in obese AT, and they affect insulin sensitivity. Some of them have an impact on inflammation by altering AT macrophage recruitment or activation. Lean AT also contains regulatory cells such as eosinophils and invariant natural killer (iNK) cells. These preserve tissue homeostasis by excreting type 2 cytokines, such as IL-4, IL-5, and IL-13, whereas they keep AT macrophages in an anti-inflammatory status (M2). When diet-induced obesity develops, AT homeostasis is disrupted, and a type 1 inflammatory response in VAT is engaged. This is characterized by the presence of interferon gamma (IFN-γ), a shift toward a proinflammatory profile (MI) by most of the recruited macrophages [48], and the loss of regulatory T cells (Treg) [49]. Further sections show the interrelation of major immune cells and obesity-related T2D.

Macrophages

In vertebrates, innate immunity greatly depends on myeloid cells as they engulf and destroy pathogens. Mononuclear phagocytes, macrophages derived from blood monocytes, and polymorphonuclear phagocytes are comprised within myeloid cells. Macrophages are distributed throughout the body, and in some cases, they are located within the parenchyma of some major organs (e.g., the heart, brain, lungs, and liver) adopting diverse morphologies such as spindle-shaped tissue histiocytes, Küpffer cells of hepatic sinusoids, and stellate microglial cells of the central nervous system. Macrophages are within the periphery of invasive organism or at the site where a chemical or biological insult occurs. As such, they are also involved on IR, T2D, and atherosclerosis development.

> Histiocytes are derived from the bone marrow; they circulate throughout the body to subsequently infiltrate some organs where they undergo differentiation into histiocytes (e.g., macrophage or dendritic cells).

In lean mice, approximately 10–15% of all cells express the macrophage marker F4/80+, whereas they constitute about 45–60% of cells in adipose tissues of obese animals. This indicates that obesity significantly modifies the macrophage/adipocyte ratio. Macrophages are normally located in lean AT in which they participate in normal remodeling; they are the primary source of TNF-α and significant amounts of inducible nitric oxide synthase and IL-6. Approximately 30% of the encoded proteins by the perigonadal AT genome are typical of macrophages. Nutrient overlap triggers AT remodeling and inflammation in this tissue. Macrophage-specific gene expression is markedly upregulated in WAT from obese mice. When diet-induced obesity occurs, this phenomenon precedes to an increase of circulating insulin levels [50].

The macrophage proportion on the SVF is estimated to increase from ≈10% in lean conditions to ≈40–50% in obese AT [51]. Furthermore, obesity induces a macrophage phenotype switch from M2 (producing anti-inflammatory cytokines as IL-10) to the M1 type (producing proinflammatory cytokines as IL-12, inducible nitric oxide synthase, and major histocompatibility complex class II). The latter is associated with IR in both mice and humans [48, 52, 53]. Endoplasmic reticulum stress or hypoxia may contribute to the M2-M1 transition of macrophages. In addition to increased inflammatory responses, the factors released by macrophages also modulate adipokine production, and they inhibit adipogenesis [51, 54, 55].

Infiltration of proinflammatory macrophages in association with obesity does not only occur in WAT but also on the skeletal muscle, bone (osteoclasts), liver (Küpffer cells), and pancreas. In the latter, they contribute to IR and to β-pancreatic cells dysfunction by activating inflammatory processes [56, 57]. During T2D development, macrophage recruitment seems to occur in several tissues, implying a general inflammation status rather than a WAT-specific inflammation.

Mast Cells

Mast cells contribute to antimicrobial defense by secreting granules rich in histamine, serine proteases, and cytokines, mainly TNF-α and IL-1β. These cells have a role in anaphylaxis and allergy. In obesity models fed with a HFD, mast cells are recruited to AT, and they contribute to inflammation,

whereas they participate in IR by secreting inflammatory cytokines [39, 58]. Mast cell deficiency in diet-induced obese mice protects from weight gain and IR, possibly because of a decrease of inflammatory cytokines, MCP-1, and matrix metalloprotease-9 in both VAT and serum [39]. Additionally, human mast cells cultured in vitro in presence of high glucose levels are activated and highly express proinflammatory cytokines, including TNF-α, IL-1β, and IL-6 [59]. Nevertheless, a recent work has presented contradictory conclusions regarding mast cell involvement in IR, as phenotypes may be more dependent on the Kit mutation used in those mouse models rather than a mast cell deficiency per se [60]. WAT obtained from morbidly obese patients displays a mast cell increase regardless of IR. Furthermore, mast cells do not contribute neither to inflammation caused by obesity, glucose intolerance, or IR, as these were observed on mast cell-deficient mice with diet-induced obesity [61].

Eosinophils

The stromal vascular fraction (SVF) of lean AT contains eosinophils, although they rapidly decline during obesity onset, as shown in a DIO model. In the lean state, eosinophils repress AT inflammation by producing IL-4, a key driver of alternative M2 macrophage polarization in order to preserve a "lean phenotype." When fed with a HFD, eosinophil-deficient mice exhibit a significant weight gain, impaired glucose tolerance, and IR. Conversely, transgenic mice engineered to content high eosinophil levels were protected against obesity and IR when a HFD was supplemented. This highlights the importance of eosinophils in order to prevent IR [43, 62].

Lymphocytes

A lymphocyte is a white blood cell that triggers an immune response when activated by a foreign molecule (antigen). The different T lymphocyte types are distinguished by a differential expression of their transmembrane proteins or co-receptors known as CD. T lymphocytes are generated in thymus, and they are responsible for cell-mediated immunity. They comprise innate (γδ T, NK) and adaptive immune (CD4+, CD8+ T lymphocytes, and B lymphocyte) cell subpopulations. CD4+ T lymphocytes are further subclassified as T helper (Th) type 1 (Th1) (they secrete IFN-γ and IL-2), Th2 (they secrete IL-4, IL-5, and IL-13), Th17 (a subset of Th CD4 cells that mainly express IL-17, IL-21, and IL-22), and T regulatory cells (Treg). Th cells display the CD28 co-receptor on its surface. Additionally, activated Th cells express a CD40 ligand on its surface, but not in their nonactivated form [63–66].

In adult animals, T and B lymphocytes in secondary lymphoid organs are comprised of a mixture of cells in at least three maturation stages. They are designated as virgin (or naïve cells), memory cells, and activated cells. When virgin cells are exposed to an antigen for the first time, some of them are stimulated in order to multiply and mature to become activated cells. These are defined as those cells engaged in a response (activated T cells carry out cell-mediated responses, or they secrete mediators, whereas activated B cells secrete antibodies).

During the inflammatory events occurring in obesity, IR, and T2D, some lymphocyte subpopulations display abnormalities. In patients undergoing T2D onset, IL-22(+) CD4(+) T cell populations were higher when compared to healthy individuals, and they may contribute to the early stages of the disease [67]. Proinflammatory γδ T, Th1, and CD8+ T cells were increased in response to a HFD, including a decrease of anti-inflammatory NK, Th2, and Treg cells [68–70]. Th1 and Th17 cells expressed the IFN-γ and IL-17proinflammatory cytokines, previously associated with IR [68, 71, 72]. In morbidly obese subjects, there was a selective increase of CD4+ T cells concomitant with increased IL-17 plasma levels [73]. Impaired activation of NK cell receptor has been also reported in patients diagnosed with T2D [41]. Differentiation of Treg and Th17-cell are events that often counteract each other, whereas Treg cells abundance is decreased in obesity.

When compared to lean conditions, CD8+ T cell proliferation was induced in vitro in the AT of obese subjects and the amount of CD4+ and CD8+ T cells increased in response to diet-induced obesity (DIO) to become the predominant lymphocytes in VAT. After the first weeks of DIO treatment, CD4+ T cells preserve a Th2 phenotype that contributes to inhibit VAT inflammation. CD8+ T cells promote macrophage recruitment mediated by MCP-1 production, and its deletion significantly decreases systemic inflammation and IR in mice submitted to DIO. T and NK cells are an important source of IFN-γ in VAT [37, 71, 74, 75].

Immune cells may increase glucose utilization during diabetes progression. Possibly they control their own activation and polarization in order to acquire proinflammatory phenotypes. For instance, T helper 17 (Th17) cells are dependent on glycolysis, and its inhibition shifts T cell differentiation from proinflammatory Th17 cells to anti-inflammatory Treg cells [76]. Similarly, glucose metabolism is required by mouse macrophages in order to secrete IL-1β [77].

The abundance of CD8+ effector T cells as well as that of proinflammatory macrophages infiltrating adipose tissues increased in mice receiving a HFD. Simultaneously, regulatory and CD4+ Th cell levels were decreased [49, 71]. In T2D patients the Treg/Th1 and Treg/Th17 ratios significantly decreased when compared to healthy controls. T2D patients with coronary heart disease (CHD) showed a significant

decrease of Treg/Th1 regarding T2D patients without a CHD diagnosis [78]. Subsequently, AT in obesity conditions exhibit some typical symptoms of chronic inflammation, thus leading to systemic IR, T2D, and cardiovascular diseases.

Cipolleta et al. (2012) [74] have shown that Treg cells in AT express high PPARγ levels. When mice receiving a HFD were treated with pioglitazone, a PPARγ agonist, the number of Treg cells increased in TA along with an inflammation decrease. In obesity conditions Treg may be critical regulators of immune cell components in the VAT. The evidence reveals that their modulation may represent a potential novel strategy to treat obesity-related metabolic disorders, such as IR and T2D.

B Cells

In mammals, B cells or B lymphocytes are produced in the bone marrow, and they secrete circulating antibodies. B cells are responsive to bacterial products such as lipopolysaccharide (LPS), and thus they are considered one of the first lines of defense against bacterial pathogens. Similar to T cells, B cells are comprised of different subsets with distinct surface phenotypes, functions, and cytokine secretion profiles. B cells may be classified into two broad types, B-1 or B-2 cells, based on their development, phenotypes, functions, and cytokine secretion profiles.

B-1 cells have been found in fatty tissues such as omentum, in the fat pads near the peritoneal cavity, and in mucosal tissues. B-1a cells are major producers of natural IgM antibody, and they are responsible for adaptive humoral immune responses toward T cell-independent antigens. In the steady state, there is constant B-1 cell trafficking between the peritoneal cavity and the abdominal VAT, such as the omentum [79, 80].

B cell populations infiltrate inflamed tissues such as VAT in mice fed with a HFD, and they subsequently undergo functional and phenotypic changes. B cell infiltration is thought to precede that of T cells into VAT. Once in there, they may regulate systemic and local inflammation, concomitant with antibodies and cytokines secretion. Similar to macrophages, B cells express the major histocompatibility complex II (MHCII), and they possess the ability to present antigens to T cells [47, 81].

B-2 cells produce several cytokines, and some populations are able to produce proinflammatory cytokines such as IFN-γ, IL-12, and TNF-α, whereas other populations produce IL-2, IL-4, and IL-13 [82]. More recently, the presence of regulatory B cells ("Breg" cells) that possess the ability to suppress inflammatory responses has been described [83]. One subset of these includes a type of B cells termed "B10" that produce a high amount of IL-10.

B cells may modulate T cell and macrophage polarization and cytokine production at multiple levels; thus they represent a potential attractive target for immune therapy to treat insulin resistance. During the early stages of the disease, the depletion of B cell co-receptor caused by a CD20 antibody induces a therapeutic and beneficial effect on glucose metabolism. Additionally, T cell activation was hampered, and both IFN-γ and TNF-α levels were decreased in VAT. Conversely, detrimental effects on metabolic disease are mediated by B cells by producing pathogenic IgG [84, 85].

Natural Killer T Cells

Natural killer (NK) T cells are a subtype of innate T lymphocytes, they exhibit both innate and adaptive features, and they mediate the consequent immune responses. NK cells are the body's sentinels searching for signs of cellular stress, activating the immune system in response to viral infection or oncogenic transformation. They recognize peptides presented by the MHC molecules. NK cells also recognize lipids presented by CD1d molecules. The latter is a non-polymorphic MHC class I-like molecule that is mainly expressed by dendritic cells (DCs) and other cell types. NK lymphocytes are classified into three groups, invariant (iNK), type II, and NK-like lymphocytes, based on their antigen specificity and the expression of their T cell receptor (TCR) [86].

NK cells are located within the AT. It has been recently shown that NK cells are associated with obesity and diabetes. In several obesity models and in obese patients, NK cells are increased, and they drive proinflammatory M1 macrophage polarization mediated by IFN-γ production, and subsequently they promote IR [87, 88].

When activated, NK cells promote the death of a target cell by releasing cytolytic granules [89]. NK cell activity is controlled by the balance of signals received from receptors on the cell's surface that convey either activating or inhibitory signals. Under normal physiological conditions, NK cell activation is inhibited by ligands expressed by healthy cells that engage the inhibitory NK receptors. In stressed cells the expression of these ligands is decreased leading to NK cell activation. Furthermore, diet-induced IR may be delayed by preventing NK cell activation using a soluble NK cell-activating receptor (NCR1). Mice fed with a HFD exhibit an increased number of NK cells concomitantly with an enhanced production of proinflammatory cytokines, particularly TNF-α in epididymal but not in subcutaneous fat depots. Additionally, NK cells are an important source of IFN-γ in VAT [71].

Invariant Natural Killer T

iNKT cells are a specialized subset of innate T cells highly abundant in the liver, and they are readily activated by lipid antigens. These cells are potent transactivators of other immune cells, and they serve as a bridge between innate and adaptive immunities. They are highly conserved in mam-

mals, they are part of human and murine AT, and they display a unique phenotype characterized by a surface marker. iNKT recognize glycolipids presented by CD1d, and they participate to preserve AT homeostasis through both immune and metabolic pathways. These cells have an anti-inflammatory role in VAT as they produce IL-4 and IL-13. In obese patients iNKT cells are decreased when compared to lean controls. This effect has been also observed in DIO and genetic obesity models. The activation of iNKT cells mediated by the lipid agonist α-galactosylceramide (αGC) led to macrophage polarization to a M2 phenotype, and it improved glucose sensitivity through anti-inflammatory cytokine signaling. Furthermore, the number of iNK cells is recovered after weight loss, whereas proinflammatory macrophage infiltration is decreased [90–93].

The decreased amount of iNKT cells in the liver of obese mice contributes to hepatic IR. Conversely, their increase in obese liver results in improved hepatic steatosis and glucose tolerance [94, 95].

Bendelac et al. (2007) point out that iNKT cells are linked to obesity-induced IR [96]. However, the role of iNKT cells during HFD-induced inflammation and IR is still controversial as previous reports showed that iNKT cells are not necessary to suppress the HFD-induced inflammation IR [75, 97].

iNKT cells are decreased in obesity, although their activation leads to improved glucose control, insulin sensitivity, and even weight loss, and they represent a therapeutic possibility to restore homeostasis in obese adipose tissue [98].

Dendritic Cells

There are three subpopulations of dendritic cells (DC): myeloid, CD4+, and CD8+. DCs play an important role for the transition between innate and adaptive immunity by presenting antigens to the T cell receptors (TRs) of CD4 Th cells via MHC II [99]. In AT of obese animals it has been observed a decrease of DC population. Dendritic cells isolated from AT of obese animals and humans may induce Th17 cell differentiation in vitro [40]. Murine adipose tissue contains a novel CD11c+ dendritic cell subset that is distinguished by an immature phenotype. AT from mice fed with a HFD contained an increased number of CD11c+ DCs and CD4+IL-17+T cells regarding lean controls. A link between CD11c+ DCs and AT inflammation caused by Th17 cells may exist in obesity conditions [100].

Markers of Inflammation

T2D as an inflammatory process is concomitant with increased levels of circulating proinflammatory immune mediators that lead to impaired insulin signaling and the selective destruction of insulin producing β-cells, a process in which cytokines play an important role. Generally, some of the inflammatory markers playing a pathogenic role in T2D are expressed in both adipocytes and immune cells. Among these are proinflammatory molecules as TNF-α, IL-1β, IL-4, IL-6, IL-18, resistin, and leptin. Anti-inflammatory molecules are also involved such as the IL-1 inhibitor or IL-1 receptor antagonist A (IL-1RA), transforming growth factor-β1 (TGF-β1), IL-10, and adiponectin [33, 101, 102].

Regarding the activation status of WAT macrophages, mice with DIO display a M2 to M1 shift, as previously indicated. The former is characterized by the expression of anti-inflammatory cytokines (e.g., IL-10, IL-1Ra), whereas the latter are distinguished by an elevated production of proinflammatory cytokines (e.g., TNF-α and IL-6) [102].

Some of the proinflammatory and anti-inflammatory proteins have been implicated in obesity, IR, and T2D, and their respective functions are described below.

The cytokines expressed by adipocytes and immune cells, such as TMF-α, IL-1β, and IL-6, either impair insulin signaling or induce β-cell apoptosis [103, 104]. TNF-α and IL-18 are considered potential risk factors for T2D development and its associated metabolic complications [105, 106].

TNF-α

TNF-α is a classical proinflammatory cytokine that actively participates during the development of obesity-related diseases. It is secreted by mature adipocytes, although it is also expressed by macrophages. It has been implicated in obesity and T2D development. The expression of TNF-α mRNA increases in AT reservoirs, and it correlates with IR, body mass index, percentage of body fat, and hyperinsulinemia. On the other hand, a short-term treatment with a TNF-α inhibitor decreased systemic inflammatory markers without improving insulin sensitivity in obese patients. Moreover, this cytokine is not increased in the serum of obese subjects who lost weight [107–109].

High TNF-α levels were also found in the AT from obesity experimental models: rat (fa/fa), mouse (ob/ob), and mice fed with a HFD. In obese fa/fa rats, the impairment of TNF-α expression increased insulin effect on glucose uptake. Similar results were observed in two murine obesity models: significantly improved insulin sensitivity was detected in animals lacking TNF-α or its receptors when compared to their obese wild-type counterparts. The mechanisms underlying insulin resistance mediated by TNF-α may involve the phosphorylation of insulin receptor substrate (IRS)-1 on its serine residues, as they inhibit normal phosphorylation of IRS-1 on tyrosine residues, thereby

blocking insulin signaling. In vivo studies with mouse models clearly show that inhibition of TNF-α function improves obesity-induced inflammation [110–112].

TNF-α contributes to the development of peripheral insulin resistance on AT and liver by stimulating lipolysis mediated by cyclic adenosine monophosphate (cAMP) and by stimulating the activity of the hormone-sensitive lipase. In WAT, TNF-α induces a decrease of lipoprotein lipase as well as GLUT-4 expression and activity. In liver, TNF-α stimulates the expression of genes involved in cholesterol and FA de novo synthesis, whereas it inhibits those genes involved in glucose uptake and metabolism as well as FA oxidation. The effects promoted by this cytokine on lipid metabolism result in high FFA plasma levels and fatty acid deposition in non-adipose fat reservoirs, including muscle. Therefore, they might contribute to IR observed in obesity [113, 114].

TNF-α-mediated processes may be involved in complications associated with T2D such as cardiovascular disease [115].

IL-1β

IL-1 family is a group of cytokines that play a central role to regulate immune and inflammatory responses. Additionally, other circulating inflammatory markers and high IL-1β levels have been reported on humans with IR [116].

IL-1β may drive sterile inflammation, and it is considered a metabolic disease initiator. Studies conducted on humans and animal have found that IL-1β or inflammasome (a complex required for the IL-1β secretion) is increased in metabolic diseases. Moreover, treatment with IL-1β antagonists can improve glycemia in T2D animal models and in adults diagnosed with the disease.

Human pancreatic β-cells are able to produce the proinflammatory cytokine (IL-1β) when cultured in presence of high glucose levels, thus impairing its function and inducing apoptosis. In a clinical trial, it was observed that the administration of an IL-1-receptor antagonist (IL-1Ra) improved glycemia on T2D patients [117, 118].

IL-1β interferes with insulin signaling in both adipocytes and hepatocytes, it suppresses insulin-induced glucose uptake, and it inhibits lipogenesis and decreases adiponectin release [119, 120]. Some contradictory results have been observed on beta cells as low IL-1β doses improve insulin secretion, enhance β-cell replication, and decrease β-cell apoptosis. Conversely, high IL-1β levels induced by high glucose and/or FFA levels have the opposite effects on islets [121]. These effects must be taken into account, as possible diabetes treatments using IL-1β blocking as a strategy may cause a severe abrogation of its signaling pathway that will have severe consequences and they may compromise insulin secretion even further in patients with severely damaged or destroyed beta cells.

Pancreas from T2D patients, but not from control subjects, expresses IL-1β. The treatment with the IL-1 receptor antagonist (IL-1Ra) improved beta cell insulin secretion in patients with T2D [122].

IL-6

IL-6 is a single polypeptide chain comprised of 185 amino acids; its molecular weight ranges from 21 to 28 kDa depending on its phosphorylation and glycosylation status. It is a pleiotropic cytokine secreted by a wide variety of cells: endothelial cells, β-pancreatic cells, keratinocytes, osteoblasts, myocytes, adipocytes, fibroblasts, activated leukocytes, monocytes, macrophages, and other cells, including a few tumor cells [123–125]. IL-6, expressed by type 2 T helper cell (Th2), specifically regulates the Th1/Th2 balance [126].

The main progression step toward T2D is insulin resistance, and it has been linked to increased circulating cytokine levels. One of them is IL-6, an inflammatory marker induced by TNF-α in cultured subcutaneous adipose cells. High IL-6 levels have been correlated with IR [127]. Additionally, IL-6 serum levels increase in T2D, in mice with DIO and in obese individuals [126, 128–131]. IL-6 is an important inflammation mediator, and it has an essential role during the acute phase of the inflammatory response by stimulating CRP synthesis in liver [130].

The basal circulating IL-6 levels are released from the subcutaneous AT in healthy humans, mainly from macrophages [131, 132]. The latter express higher amounts of TNF-α and IL-6 when compared to adipocytes in the AT of obese mice (ob/ob). These facts contribute to a chronic low-grade inflammation status in obesity [47].

IL-6 in obesity is generally considered to be a proinflammatory mediator, and it antagonizes insulin action by inhibiting insulin-stimulated glucose transport [127]. Mice deficient in IL-6 develop obesity that is associated with altered carbohydrate and lipid metabolism as well as leptin resistance, and it is partially reversed by a treatment with IL-6 [133].

IL-6 functions are consequence of its interaction with its receptor, comprised of the gp130 and IL-6R subunits. IL-6 may directly bind to this receptor complex, or it can bind to a soluble form of gp130 in order to be presented to cells expressing only IL-6R. In this regard, macrophages express high levels of this receptor. IL-6 bound to gp130 has an important participation for macrophage accumulation in AT [134, 135]. Conversely, IL-6-deficient mice develop late-onset glucose tolerance. IL-6 also stimulates the expression of the IL-4 receptor (IL-4R) on macrophages, thereby promoting M2 polarization. Thus, IL-6 appears to function as

anti-inflammatory mediator by preventing M1 macrophage formation in homeostasis. Therefore, IL-6 effects for T2D development seem to be time- and concentration-dependent [133].

The presence of IL-6 has been shown to correlate with a risk of vascular complications or mortality in T2DM, probably because of its participation regulating lipid metabolism and CRP production, both of them are known risk factors for cardiovascular disease (CVD) [131, 136]. IL-6 is also linked to risks of cardiovascular events only in T2D patients with renal dysfunction. In addition, IL-6 levels showed a significant correlation with macrovascular complications in T2D patients [137].

IL-6 mediates several steps during the activation of inflammatory responses by regulating proinflammatory cytokines synthesis. However, it also promotes that of anti-inflammatory cytokines such as IL-1Ra and IL-10 [138, 139]. Therefore, IL-6 exhibits dual properties.

An acute transient IL-6 increment along with other inflammatory markers also occurs during physical activity [140] concomitantly with their release. However, unlike sepsis and infection, an increase of proinflammatory cytokines such as TNF-α and IL-1β is not typical [141, 142]. Plasma IL-6 concentrations increased approximately 100-fold during exercise, and the extent of such increase depends on its duration and intensity [143]. In this case, the transient IL-6 increase does not have negative effects on tissues, and the endogenous upregulation of this cytokine in response to exercise improves insulin sensitivity.

IL-18

IL-18 is a member of the IL-1 cytokine family. It is produced by several hematopoietic and non-hematopoietic cells. IL-18 was identified in human atheroma tissues, and it is an important regulator of innate and acquired immune responses. It induces the expression of several inflammatory molecules in vascular smooth muscle, endothelial cells, and macrophages. The regulation of IL-18 synthesis, its effect on cytokine release, and its mechanisms are still unknown [144].

IL-18-deficient mice develop obesity as consequence of increased food intake [145]. They also developed insulin resistance in liver, muscle, and adipose tissue because of an enhanced glucose production. Replacement of IL-18 in the brain reduced food intake and reversed hyperglycemia [145].

In addition to its role during the inflammatory response toward microorganisms, IL-18 is an important factor in human autoimmune and metabolic diseases. IL-18, IL-4, and IL-12 were significantly higher in diabetic patients regarding healthy subjects. High serum IL-18 levels were correlated with poor glycemic control (assessed as HbA1c), prolonged diabetes, and atherogenic index. Furthermore, IL-18 may be used as a predictor for preclinical atherosclerosis and poor glycemic control in T2D [146].

IL-18, TNF-α, and CRP are considered potential risk factors for T2D and its associated metabolic complications [105, 106]. IL-18 has been directly implicated in renal injury induction on diabetic nephropathy [147].

The increased IL-18 levels observed on adipocytes from individuals with regular and morbid obesity declined after weight loss [148–150]. After considering age, gender, body mass index, and insulin, IL-18 was also independently correlated with MetS, a known risk factor for CVD [151]. A prospective study showed that IL-18 was correlated with coronary events in males, regardless of age, body mass index, inflammatory biomarkers, and classic lipid predictors [152].

TGF-β1

Initially, TGF-β is produced as an intracellular inactive protein complex that is modified before its secretion. One of the most relevant modifications is the C-terminal pro-region cleavage from the N-terminal. The pro-region is known as the latency-associated peptide (LAP), whereas the N-terminal region is the mature or active TGF- β. The latter belongs to a molecule family displaying a wide of roles in several cell types. More than 40 protein members of this family are known, they have a dimeric structure, and they are clustered in several subfamilies. The TGF-β subfamily includes six isoforms, three of them are expressed in mammals [153, 154]. Among these isoforms, TGF-β1 is involved in embryogenesis, and it has a prominent role in the immune system by controlling several aspects of inflammatory responses, T cell differentiation, and switching between B cell isotypes.

TGF-β and retinoic acid are produced by CD103+ DCs located at the small intestine, and they are inducers of Treg cells. TGF-β also induces naive T cell differentiation into pathogenic TH17 cells while inhibiting the generation of Th1 and Th2 cells [155–157].

TGF-β1 is synthesized as a precursor protein. As it has been associated with the pathogenesis of numerous diseases, the multiple mechanisms of latent (L)-TGF-β activation represent an opportunity to control TGF-β activity within an organ involved in a specific disease process. It is difficult to retrieve reliable epidemiological data on TGF-β1 as it circulates in the bloodstream mainly as its latent form that needs to be proteolytically modified to its active form [158].

In the MONICA/KORA study, high serum TGF-β1 levels were correlated with a high risk of T2D, after adjustment for age, sex, BMI, lifestyle factors, hypertension, lipids, and parental diabetes history [159].

Resistin

Resistin was discovered in 2001, and it is a small peptide (12.5 kDa) comprised of 108 amino acids containing several cysteine residues. It is a member of a small family of secreted proteins characterized by a unique spacing of 10–11 cysteine residues on their structure. They are known as resistin-like molecules (RELMs) or as found in inflammatory zone (FIZZ) proteins. Resistin is a cytokine almost exclusively expressed in white adipocytes in rodents, whereas human resistin is predominantly expressed in macrophages, and it is regulated by the nutritional status [160, 161]. It is also expressed by the non-adipocyte stromal vascular fraction in WAT and fibrotic liver and also on atherosclerotic lesions. These findings support the role of macrophages as the main source of resistin in humans [162, 163].

Resistin levels are decreased during human adipocyte differentiation [164], and they represent a link between obesity, insulin resistance, and T2D. The antidiabetic drugs thiazolidinediones (TZD) downregulate human resistin expression in macrophages, or they induced a decrease of resistin levels in serum [165].

In obese mice models, circulating resistin levels are higher when compared to lean controls [166]. They increase in diet-induced and genetic forms of obesity. The administration of exogenous resistin or its transgenic overexpression leads to decreased insulin sensitivity. Conversely, blocking resistin activity or by genetically decreasing its levels improves insulin sensitivity and restores glucose homeostasis [167].

There are contradictory reports regarding the correlation between resistin and obesity or between resistin and T2D in humans [168, 169]. Some reports show that resistin levels are higher in subjects with T2D, but other studies show no correlation with IR or fasting insulin levels [170–172]. Serum resistin does not change significantly between obese and normal children, and it is not affected by body mass index over time [173, 174].

On the other hand, resistin levels were correlated with increased risk for T2D, even after adjusting for known diabetes risk factors in three large American case-control studies (Nurses' Health Study and both the Women's Health Study and the Physicians' Health Study) with follow-ups after 12, 10, and 8 years [175, 176].

Additionally, resistin also stimulates endothelial cells to secrete substances such as inflammatory cytokines, monocyte chemoattractant protein-1 (MCP-1), vascular cell adhesion molecule 1 (VCAM-1), and intercellular adhesion molecule 1 (ICAM-1). Thus, it seems that resistin acts as an adiponectin antagonist [177, 178]. In human vascular cells, resistin impairs insulin signaling, modifies the oxidative stress response, and stimulates cell proliferation. These effects involve the activation of the p38 mitogen-activated protein kinase (MAPK) [179–181]. Furthermore, plasma resistin levels correlate with inflammation markers, and they may be predictive of coronary calcification, an indicator of the atherosclerosis extent [182].

The resistin receptor remains unidentified, although a recent report has suggested that resistin may bind to the endotoxin receptor TLR-4 [183].

Leptin

Leptin is involved in inflammation, immune cells, obesity, and T2D. This peptide is one of the most important WAT-derived hormones, it is the product of the ob gene, and structurally and functionally, it may be classified as a cytokine. Leptin has a wide range of biological functions including both innate and adaptive immunity [184, 185]. In combination with cytokines and other molecules, it acts on the central nervous system partially regulating food behavior and energy balance. It has an effect on energy metabolism in other tissues such as liver and muscle [186].

Leptin controls food intake by interacting with anorexigenic molecules in the hypothalamus. These molecules are produced by cells secreting proopiomelanocortin (POMC) and by neurons releasing cocaine- and amphetamine-regulated transcript (CART), orexigenic molecules such as neuropeptide Y (NPY), and agouti protein (AgRP) [187]. Animal models fed with a HFD show hyperleptinemia that generates a blockade of hormone functions resulting in resistance toward leptin, higher food consumption, and obesity [188].

Leptin acts by binding to a receptor (Ob-R). The latter is a class I cytokine receptor that was isolated for the first time from murine choroid plexus [188]. Leptin receptors have been also detected in hypothalamic regions such as the arcuate and both paraventricular and ventromedial nuclei. These regions regulate energy balance [189]. The human leptin LEP-R receptors are coded by at least six homologue genes producing several mRNA variants [190]. It is also expressed on most immune cells, including neutrophils, macrophages, and NK cells. In the hypothalamus, leptin binds to its receptor on the plasma membrane thus triggering a phosphorylation cascade. One important function of leptin in the hypothalamus is to regulate body weight.

Obesity animal models lacking leptin or its receptor develop obesity due to hyperphagia caused by abnormal leptin/leptin receptor signaling, and subsequently T2D-like manifestations appear. These effects are secondary to genetic mutations that do not reflect the disease's etiology in humans, as leptin or leptin receptor deficiency is nor relevant for T2D. For more details, see review [191].

During food intake, leptin expression is stimulated in the TA. Conversely it is decreased during fasting and diabetes.

Leptin synthesis is positively regulated by insulin, glucocorticoids, and estrogens, whereas catecholamines (through their β3-adrenergic receptors), androgens, and long-chain fatty acids inhibit its synthesis [187, 192–194]. Insulin-stimulated leptin secretion and the consequent stimulation of lipolysis and fatty acid release are suppressed by several agents: lipolytic hormones (adrenocorticotropic hormone (ACTH) and thyroid-stimulating hormone (TSH)), phosphodiesterase inhibitors (caffeine, theophylline), adenylate cyclase modulators (forskolin and pertussis toxin), and non-hydrolyzable cAMP analogs [195].

Leptin and insulin are mutually regulated. Thus, leptin inhibits insulin production in pancreatic β cells, whereas insulin stimulates leptin production by adipocytes. When resistance toward leptin occurs, as characterized by hyperleptinemia, the homeostatic balance between these molecules is disrupted. Consequently, insulin production is not affected by leptin, and this results in hyperinsulinemia and resistance to this hormone [196, 197].

In human and mice, blood leptin levels closely correlate with AT mass [185]. In addition to its central effects, leptin may modulate the immune response. This hormone affects both the innate and adaptive branches of the immune system. Regarding innate immunity, leptin modulates the activity of NK cells, macrophages, and neutrophils by enhancing their function and promoting the production of proinflammatory cytokines [198, 199]. Regarding adaptive immunity, several in vitro and in vivo experiments demonstrate that leptin positively impacts T cell proliferation and increases Th1 cytokine production while suppressing that of Th2 [200]. In monocytes, leptin increases the expression and release of the IL-1Ra anti-inflammatory cytokine [201] and vice versa: IL-1Ra decreases leptin expression at both mRNA and protein levels [202]. In healthy individuals, it preserves the balance between inflammatory markers. However, when resistance to leptin occurs, this cytokine has a proinflammatory effect, and the balance is shifted toward the chronic inflammatory state particular of T2D and obesity.

Leptin-deficient mice (ob/ob) and those lacking its receptor (db/db) are obese because of their increased food intake resulting from impaired satiety. Additionally, they exhibit an important decrease of functional immune cell populations, such as NK cells, dendritic cells, and Treg cells [203, 204]. T and B cells have been shown to increase LEP-R expression when activated. Moreover, when leptin is included in the cell culture media, it increased survival of activated lymphocytes [205].

Macrophage and NK cell populations increase during the first weeks after feeding a HFD, specifically in VAT. Conversely, this is not observed in ob/ob mice [206]. Furthermore, leptin promotes NK cell survival in the bone marrow; it attenuates macrophage infiltration and inflammatory gene expression in AT, in spite of weight gain and adiposity [207]. However, leptin does not affect weight gain and macrophage infiltration in this tissue [205, 206]. Different background strains, potential effects caused by gut microbiota, different body weight baselines, and differing fat percent in the diet may be the underlying cause of such contrasting results [207]. These elements must be considered to further evaluate the role of leptin in macrophages.

Finally, all results support the concept that inflammation plays a role for T2D pathogenesis and proinflammatory mediators produced by adipocytes and immune cells actively participate in this phenomenon.

IL-1Ra

The IL-1Ra cytokine is a natural IL-1β inhibitor. The expression and release of the former are induced by the latter, so this cytokine is usually controlled by its antagonist. Several cell types and tissues throughout the body express IL-1Ra; thus its high levels are probably needed in order to suppress the deleterious effects generated by the potent proinflammatory activity of IL-1β. When IL-1Ra competitively binds to the IL-1 receptor, IL-1β binding is blocked, and the conveying of proinflammatory signals from its receptor is hampered. Some evidences suggest that anti-inflammatory IL-1Ra counteracts the inflammatory effects mediated by IL-1β, and it preserves cell function in both types of diabetes [208].

Elevated circulating IL-1Ra levels are correlated with T2D incidence. In a nested case-control study, those subjects who developed T2D during the 11.5-year follow-up period displayed higher IL-1Ra levels when compared to individuals who remained diabetes-free. The authors hypothesized that individuals with high risk of T2D are characterized by the presence of an early compensatory, anti-inflammatory response preceding the full development of the disease [209]. The correlation between IL-1Ra levels and risk of T2D was also observed in subjects with metabolic syndrome in both cohorts. After adjustment for multiple confounders, IL-1Ra was significantly associated with metabolic syndrome (MetS) to T2D progression in males from both cohorts and in females from the FINRISK 97 cohort only. IL-1Ra displayed a significant correlation with risk of T2D in both cohorts when the data obtained from males and females was pooled [210].

IL-1Ra improved β-cell function and glycemic control in patients with T2D. These positive effects of IL-1Ra were also observed on Goto Kakizaki (GK) rats (a spontaneous, no obese T2D model) and mice, as treatment with exogenous IL-1Ra protected them from increased proinflammatory cytokine expression in islets (IL-1β, IL-6, and TNF-α), chemokine expression, and macrophage infiltration in islets, and they also exhibited improved insulin processing. Treatment

with IL-1Ra is not linked to body weight changes, either in patients or in animal models [211–213]. Probably the exogenous IL-1Ra does not have an effect on the hypothalamus.

Thus, when the IL-1β activity is blocked during T2D, both pancreatic β-cell function and insulin resistance are protected from the direct toxic effects caused by this cytokine and/or by antagonizing its inflammatory response. Therefore, IL-1Ra could be a new therapeutic agent to treat T2D.

IL-4

IL-4 is an anti-inflammatory cytokine secreted by Th2 lymphocytes, basophils, and mast cells. It has pleiotropic functions as it promotes the Th1/Th2 balance, B cell proliferation, and immune responses by regulating the proinflammatory mediators (IL-1β, TNF-α, and IL-6) produced by macrophages. IL-4 secreted by adipocytes and hepatocytes is able to modulate the local immune response and insulin sensitivity [214–217].

IL-4 may regulate insulin sensitivity, glucose tolerance, and lipid metabolism, and it could be involved in diabetic susceptibility and its complications. IL-4 regulates energy metabolism by promoting catabolism rather than energy storage through its anti-lipogenic effect, by suppressing adipocyte differentiation and by promoting lipolysis in mature adipocytes. Some proteins were upregulated, and others were downregulated by IL-4 in 3 T3-L1 cells [218–220].

Insulin sensitivity and glucose tolerance were improved in mice overexpressing IL-4. Triglyceride accumulation in fat tissues was also inhibited, leading to decreased weight gain and fat mass [221]. Additionally, there is a correlation between IL-4/IL-4 receptor (R) genotypes and T2D and also between IL-4 genotypes and high-density lipoprotein cholesterol (HDL-C) [222, 223]. This data reveals the previously overlooked roles of IL-4 in metabolism.

IL-10

IL-10 possesses multiple anti-inflammatory properties, including macrophage and T cell inactivation, and it has a protective effect against atherogenesis. Adiponectin displays antiatherogenic effects, partially by inducing IL-10 expression in human macrophages [224–226].

Initially they were described as a product from Th2 cells that inhibits Th1 cell function. Currently, it has been identified that IL-10 is produced by most lymphocyte populations and the cells of the innate immune system, such as the antigen-presenting cells (DCs and macrophages), B cells, monocytes, and granulocytes affecting most hematopoietic cell types [224, 227–229].

In lean adipose tissue, iNKT cells and Tregs are abundant, and they produce IL-10. During the adipose expansion occurring in obesity, iNKT cells and Treg populations are depleted thus resulting in less IL-10 and a more inflammatory environment. This correlates with a proinflammatory macrophage accumulation. The decrease of iNKT and Tregs cells in obese AT contributes to local and systemic inflammation and eventually to T2D [230].

IL-10 may protect against diabetes. In this regard, it was demonstrated that IL-10 overexpression in mice skeletal muscle prevented macrophage infiltration into the AT caused by a HFD. Subsequently, IL-10 restricted the expression of proinflammatory cytokines, and it promoted insulin sensitivity regarding control mice [231]. The data obtained from humans attempting to correlate IL-10 and T2D are limited to a few cross-sectional studies. In a study conducted on 85-year-old subjects, it was observed that an elevated capacity of IL-10 production in whole blood was correlated with lower HbA1c levels and lower T2D prevalence [232]. Additionally, serum IL-10 inversely correlated with BMI and body fat, whereas a positive correlation was observed with insulin sensitivity when a euglycemic-hyperinsulinemic clamp was performed on subjects with impaired glucose tolerance or T2D [233]. Conversely, no associations between serum IL-10 and BMI or T2D were found by other two studies [234, 235].

In a cohort of the Prospective Study of Pravastatin in the Elderly at Risk (PROSPER), baseline blood IL-10 levels were positively correlated with the CRP and IL-6 proinflammatory mediators. During the follow-up period, IL-10 levels were increased, and they were associated with higher risk of cardiovascular events (death from coronary heart disease, myocardial infarction, and stroke) [235].

T2D patients showed increased numbers of circulating IL-10- and IL-17-producing CD3+ T cells when compared to controls, although there was no difference regarding the frequency of lymphocyte subsets. The authors suggest that these cytokines are involved on the immune pathology of this disease [236].

IL-10 is an interesting cytokine because of its potent anti-inflammatory effects. However, the reported data are contradictory, and currently it is not clear whether elevated circulating IL-10 levels are effective to negatively regulate proinflammatory reactivity and to confer protection against T2D or whether increased IL-10 levels are merely indicative of proinflammatory processes without providing a metabolic benefit.

Adiponectin

Adiponectin is highly expressed by adipocytes displaying potent anti-inflammatory properties. The ADIPOQ gene codes for adiponectin. This protein possesses a collagen-like

domain N-terminal and a complement factor C1q-like globular domain C-terminal. It is highly expressed during adipocyte differentiation, and it is one of the main products secreted by adipocytes. In the bloodstream, it seems to occur as several isoforms: as a low molecular weight (LMW) trimer, as a medium molecular weight (MMW) hexamer (trimer-dimer), and as a high molecular weight multimeric (HMW) isoform [237, 238].

Many studies have revealed that plasma adiponectin levels are significantly decreased in obesity, IR, and T2D, being a key component for the interplay between adiposity, IR, and inflammation [239, 240]. Adiponectin improves whole-body insulin sensitivity, and its decreased levels occurring in obese rodents and humans are caused by the presence of proinflammatory factors such as TNF-α, IL-6, ROS, and hypoxia, as they suppress adiponectin expression in adipocytes [237]. Conversely, PPARγ antagonists stimulate this expression [241]. Independently, a meta-analysis study showed that increased risk of T2D was strongly associated with low adiponectin levels and high of inflammatory cytokine levels (TNF-α, IL-1β, IL-6, IL-18, CRP) [242].

Several studies described a significant negative correlation between adiponectin and obesity parameters [243, 244]. The chromosome 3q27 locus, where ADIPOQ is located, is linked to T2D, and it is considered a key MetS component [245]. Serum adiponectin levels decrease when MetS components increase [246]. Additionally, urinary excretion of HMW-adiponectin is an independent predictor of kidney disease progression in T2D patients affected by early kidney disease [247].

Adiponectin beneficial effects on lipid and glucose homeostasis are caused by multiple mechanisms, mainly by ceramidase activity and adenosine monophosphate-dependent kinase (AMPK)/sirtuin 1 (SIRT1)-dependent activation of the PPAR cofactor 1α (PGC-1α) [248, 249]. In obesity models, fatty acid oxidation and glucose uptake in skeletal muscle and AT are stimulated by adiponectin, and it was shown that they are dependent on AMPK signaling. Adiponectin is also involved in hepatic glucose outsuppression mediated by AMPK activation [250].

Obesity is correlated with increased cardiovascular risk, especially when it is concomitant with T2D. Patients with coronary artery disease (CAD) significantly showed reduced adiponectin levels when compared to controls with matching ages and body mass indexes [251]. It was also correlated with a low risk of myocardial infarction, although it was attenuated when adjusted for HDL-C and low-density lipoproteins cholesterol (LDL-C) [252].

In addition to its antidiabetic functions, adiponectin also suppresses atherosclerosis, fatty liver diseases, and liver fibrosis [253, 254]. Adiponectin administration blocked the effect of proinflammatory agents, e.g., TNF-α and IL-6, and it directly improved endothelial dysfunction by increasing the production of nitric oxide (NO) [245, 255].

Adiponectin acts as an immunomodulator; it promotes the differentiation of anti-inflammatory M2 macrophages and phagocytosis in order to remove apoptotic cells [256, 257]. This adipokine also modulates T cell activation and the inflammatory function of NK cells. Adiponectin receptors are upregulated on the surface of human T cells after an antigen-mediated stimulation, and they mediate apoptosis of antigen-specific T cells, subsequently suppressing T cells expansion [258]. Furthermore, adiponectin suppresses TLR-mediated IFN-γ production in NK cells without affecting cytotoxicity [259]. Adiponectin inhibits LPS-induced TNF-α production in macrophages by inhibiting NF-κB activation and by stimulating anti-inflammatory IL-10 secretion [260, 261]. Therefore, adiponectin may contribute to this role by reducing inflammation within AT.

Two adiponectin receptors have been identified: AdipoR1 and AdipoR2. They possess seven transmembrane domains, although they differ structurally and functionally. Liver expresses AdipoR2, whereas skeletal muscle contains AdipoR1 and AdipoR2. The biological effects caused by these receptors depend not only on adiponectin blood levels but also on tissue specificity. By interacting with its receptors, ADIPO R1/2, adiponectin activates AMPK to enhance fatty acid oxidation and glucose uptake in muscle and to suppress gluconeogenesis in liver [262]. Moreover, adiponectin regulates energy expenditure by activating AMPK in the hypothalamus, where AdipoR1 and AdipoR2 co-localize with the leptin receptor, Ob-R [263]. It has been previously demonstrated that adiponectin stimulates appetite and decreased energy expenditure. These effects were eliminated following the ablation of AdipoR1 small interfering RNA (siRNA) or AMPK signaling (AMPK dominant negative) [264].

Perspectives onT2D Immunotherapy

The use of several anti-inflammatory methods has been implemented on obese subjects with IR. Based on this, salsalate (a salicylate analogue) has been shown to improve insulin sensitivity [265, 266]. The thiazolidinediones antidiabetics (e.g., rosiglitazone and pioglitazone) induced a decrease of adipose tissue macrophage populations [267] and increased adiponectin and fibroblast growth factor 21 (FGF21) blood levels, thereby mediating the redistribution of lipid reservoirs in AT [268, 269].

In patients with T2D, after a 12-week treatment with trelagliptin (an oral dipeptidyl peptidase (DPP)-4 inhibitor), serum adiponectin levels significantly increased [270]. Anti-TNF antibodies were proved to decrease blood glucose in obese subjects [5]. Anti-IL-1β monoclonal antibody therapy improved glycemic condition and β-cell insulin secretion [271, 272].

Inflammation, improved insulin sensitivity, and normalized glucose tolerance were observed on obese mice fed with a HFD supplemented with ω-3 fatty acids [273]. In human studies, a supplementation with fish oil yielded mixed results regarding metabolic end points. A limitation of some of these studies has been the lack of discrimination between fatty and lean fish [274, 275].

IL-1 β, the main macrophage-derived cytokine, increases in T2D obese subjects, and it enhances IL-17 and IL-22 release by AT CD4+ T cells. IL-22 stimulated pro-IL-1β transcription leading to enhanced IL-1 β production by human VAT macrophages. Early clinical data describe promising effects caused by blocking IL-17 in several autoimmune diseases. An immunotherapy has been proposed by using an anti-IL-1 β and anti-IL-22 antibodies mixture in order to improve inflammation in human obesity-linked T2D [276].

Concluding Remarks

- Obesity, through adipose tissue expansion, may contribute to the development of insulin resistance and type 2 diabetes.
- Adipose tissue is considered an important immunologically active organ and is constituted by adipocytes and immunological cells as macrophages, eosinophils, lymphocytes, etc.
- Immune cells participate on inflammatory processes, and they are the most represented cell types within adipose tissue.
- IL-1β, TNF-α, IL-6, and other cytokines expressed in immune cells and in adipocytes are promoters of inflammation.
- Insulin signaling is altered by proinflammatory cytokines and adipokines, and they are important key targets to control or delay the T2D advance.

Multiple-Choice Questions

1. The inflammation associated with type 2 diabetes and obesity is mainly generated in this tissue or organ.
   (a) Heart
   (b) Kidney
   (c) Adipose
   (d) Muscle
   (e) Brain
2. Immune cells involved in diabetes.
   (a) Myocytes
   (b) Cardiomyocytes
   (c) Astrocytes
   (d) Lymphocytes
   (e) Hepatocytes
3. Proinflammatory markers occurring in inflamed tissue.
   (a) Glucose and sucrose
   (b) Gamma interferon and interleukins
   (c) Phospholipids and HDL
   (d) Leucine and proline
   (e) Insulin and glucagon
4. Change that TNF-α undergoes between the lean and obese status.
   (a) Inhibition
   (b) Activation
   (c) Inflammation
   (d) Polarization
   (e) Suppression
5. Effect caused by adiponectin on the arteries.
   (a) Antiatherogenic
   (b) Proinflammatory
   (c) Insulin receptor-serine phosphorylation
   (d) Adipocyte dysfunction
   (e) Insulin deficiency
6. Functions of mast cells.
   (a) Secrete anti-inflammatory cytokines
   (b) Protect tissues from inflammation
   (c) Secrete granules rich in histamine and serine proteases
   (d) Express adiponectin mRNA
   (e) Protect from weight gain
7. This effect has been demonstrated during development of type 2 diabetes.
   (a) Inhibition of adipocytes accumulation
   (b) Macrophage recruitment in adipose tissue
   (c) Decreased adiponectin expression in adipocytes
   (d) Increased serum IL-R1a
   (e) Inhibition of TNF-α activity
8. Invariant NKT (iNKT) cells.
   (a) Innate immune cells activated by lipids
   (b) Cells that express INFγ
   (c) The level of these cells increases in obesity
   (d) These cells produce high amount of IL-10
   (e) These cells are suppressed during obesity outset
9. Is a mouse macrophage marker?
   (a) CD28
   (b) CD40
   (c) F4/80+
   (d) CD4+
   (e) Th2
10. Regulation of this subtype of T cell is considered a novel target to treat type 2 diabetes.
    (a) B cells
    (b) Th1
    (c) Th2
    (d) Treg
    (e) Th17
    (f) Mast cells

Correct Answers

1. (c) Adipose
   Inflammatory molecules are derived mainly on adipocytes and immune cells that constitute the adipose tissue.
2. (d) Lymphocytes
   In obesity-associated diabetes the number of lymphocytes increases.
3. (b) Gamma interferon and interleukins
   Here, only interferon and interleukins are markers associated with inflammation.
4. (b) Activation
   TNF-α is activated during obesity and participates on insulin resistance development.
5. (a) Antiatherogenic
   Adiponectin is considered antiatherogenic due to its effects on endothelial function by inhibition of ROS production and on monocyte adhesion.
6. (c) Secrete granules rich in histamine and serine proteases
   Mast cells secrete granules rich in histamine, serine proteases, and cytokines as a defense mechanism.
7. (b) Macrophage recruitment in adipose tissue
   There is a significant increase in the number of macrophages on adipose tissue from subjects with type 2 diabetes, which contributes to inflammatory process.
8. (a) Innate immune cells activated by lipids
   iNKT cells are innate lipid sensors, and their activation, using their prototypic ligand α-galactosylceramide.
9. (c) F4/80+
   F4/80+ are molecules found only on macrophage surface.
10. (d) Treg
    Regulatory T cells (Tregs) are essential negative regulators of inflammation.

Glossary

Adipokine A cytokine or hormone that is secreted by adipose tissue.

Chemokines Are signaling proteins secreted by cells, whose main function is to act as a chemoattractant to guide the migration of near cells. They are implicated in various diseases, such as cancer, autoimmune disorders, and diabetes.

Cytokine Small proteins secreted and released by cells, they have a specific effect on the interactions and communications between cells.

Diet-induced obesity (DIO) Obesity mouse model induced by high-fat diet.

FA A carboxylic acid with aliphatic chains of 4–28 carbons, which can be esterified with glycerol to form triacylglycerols, the main stored form of lipids.

IgG, IgM Are members of immunoglobulin (Ig) superfamily; they are ubiquitously present in several cells and tissues of vertebrates and share structural homology with cell adhesion molecules and some cytokines.

Innate immune cells Are white blood cells that mediate innate immunity and include basophils, dendritic cells, eosinophils, mast cells, monocytes, macrophages, neutrophils, and natural killer cells.

Mitogen-activated protein kinase (MAPK) a mammalian Ser/Thr protein kinase.

NF-κB (Nuclear factor-κB) is a ubiquitous transcription factor involved in the control of processes, such as immune and inflammatory responses, developmental, cellular growth, and apoptosis. The NF-κB pathway has been considered as proinflammatory signaling pathway, based on the role of NF-κB in the expression of proinflammatory genes including cytokines, chemokines, and adhesion molecules.

Omental adipose tissue The fat depot found within the peritoneum, in close association with the stomach and other internal organs.

PPARγ (Peroxisome proliferator-activated receptor gamma) is an essential transcription regulator of the adipocyte differentiation and is required for mature adipocyte function.

Salicylates A group of derivatives of salicylic acid, including aspirin and acetylsalicylic acid, which are widely used as analgesics, and anti-inflammatory medicaments

Thiazolidinediones Antidiabetic drugs used therapeutically, which are known to be high-affinity ligand activators of PPARγ.

White adipose tissue (WAT) The predominant fat storage tissue in animals, consisting mostly of adipocytes but also other cell types as mast cells and macrophages.

Abbreviations

$^{\circ}$OH	Hydroxyl radical
8-OHdG	8-hydroxy-2′-deoxyguanosine
AGE	Advanced glycation end products
AIF	Apoptosis-inducing factor
Apaf-1	Apoptotic protease-activating factor 1
ATF6	Activating transcription factor 6
ATM	ATM serine/threonine kinase protein
Bak	Bcl-2 homologous antagonist killer
Bax	Bcl-2-associated X protein
Bcl-2	B-cell lymphoma 2
Bcl-xl	B-cell lymphoma-extra large
BH (1–4)	Bcl-2 homology 1–4 domains
Bok	Bcl-2 related ovarian killer
Caspase	Cysteine-aspartic proteases, cysteine aspartases
CHOP	C/EBP homologous protein
ChREBP	Carbohydrate response element binding protein
Drp1	Dynamin-related protein 1
eif2α	Eukaryotic translation initiation factor 2α
ER	Endoplasmic reticulum
ERS	Endoplasmic reticulum stress
EZH2	Enhancer of zeste homologue 2
FADD	Fas-associated death domain
Fas	Death receptor
FFA	Free fatty acids
Fis1	Mitochondrial fission 1 protein
FOXA1/2	Forkhead box A1/2
G3P	Glyceraldehyde 3-phosphate
GADD34	Downstream growth arrest and DNA damage-inducible protein
GAPDH	Glyceraldehyde 3-phosphate dehydrogenase
GATA4/6	GATA-binding protein 4/6
GLUT	Glucose transporter
GSIS	Glucose-stimulated insulin secretion
H3K27me3	Histone H3 tri methyl K27
HNF1β	Hepatocyte nuclear factor 1β
IAPP	Islet amyloid polypeptide
IFNγ	Interferon gamma
IGF1	Insulin-like growth factor 1
IL-1β	Interleukin 1 beta
iNOS	Inducible nitric oxide synthases
Ins	Insulin gene
INS1	Insulin-secreting beta cell-derived line
IRE1α	Inositol-requiring enzyme 1α
IRS-2	Insulin receptor substrate-2
Isl	Islet
MafA	Musculoaponeurotic fibrosarcoma protein A
Mdm2	Murine double minute 2
Mff	Mitochondrial fission factor
Mfn	Mitofusin
Mouse *db/db*	Model of obesity, diabetes, and dyslipidemia with a mutation in leptin receptor
mTOR	Mammalian target of rapamycin
NAD^+	Nicotinamide adenine dinucleotide
NADH	Nicotinamide adenine dinucleotide reduced
NADPH oxi	Nicotinamide adenine dinucleotide phosphate-oxidase
NeuroD1	Neurogenic differentiation 1
NF-κB	Nuclear factor kappa B
Nkx	Homeobox protein
NLRP3	NACHT, LRR, and PYD domains-containing protein 3
NLRs	Nucleotide oligomerization domain (NOD)-like receptors
NO	Nitric oxide
NOD	Nucleotide oligomerization domain
Notch	Transcription factor
O^{-2}	Superoxide anion
O-GlcNAc	O-linked β-N-acetylglucosamine
Opa1	Opa1 mitochondrial dynamin like GTPase
P/CAF	P300/CBP-associated factor
p16	Cyclin-dependent kinase inhibitor 2A, multiple tumor suppressor 1

p21	Cyclin-dependent kinase inhibitor 1 or CDK-interacting protein 1
p27	Cyclin-dependent kinase inhibitor 1B
p300/CBP	E1A binding protein p300/CREB-binding protein
p38 MAPK	P38 mitogen-activated protein kinases
p53	Tumor protein p53
PARP	Poly (ADP-ribose) polymerase
Pax4	Transcription factors paired box gene 4
Pdx1	Pancreatic and duodenal homeobox 1
PERK	Protein kinase-like ER kinase
PI3k	Phosphatidylinositol-3-kinase
PKC	Protein kinase C
PP-1	Protein phosphatase-1
Ptf1α	Pancreas transcription factor 1α
RAMP1	Receptor activity-modifying protein 1
Rfx 6	Regulatory factor x 6
RING finger	Really Interesting New Gene
RINm5F	Rat insulinoma cells
ROS	Reactive oxygen species
Sox9 SRY	Sex-determining region Y-box 9
SPT	Serine C-palmitoyltransferase
T2D	Type 2 diabetes
TLRs	Toll-like receptors
TNFRI	Tumor necrosis factor receptor type I
TNFα	Tumor necrosis factor alpha
TXNIP	Thioredoxin-interacting protein
UCP2	Uncoupling protein 2
UDP-GlcNAc	Uridine diphosphate N-acetylglucosamine
UPR	Unfolded protein response
ΔΨm	Mitochondrial membrane potential

Chapter Objectives

- To briefly describe the embryonic development of pancreatic β
- To analyze the universal literature on the mechanisms that underlie the loss of pancreatic β-cell mass
- To provide information on the regulation of p53 by hyperglycemia and its participation in the induction of pancreatic β-cell apoptosis

Introduction

Insulin produced and secreted by β-cells is responsible for blood glucose level regulation. The major stimulus for insulin secretion is glucose itself. When the latter is taken by β-cells in a process mediated by the glucose transporter 2 (GLUT 2), it enters the glycolytic pathway, the Krebs cycle, and oxidative phosphorylation, and it promotes the increase of the ATP/ADP ratio. Subsequently, this leads to the closure of the ATP-dependent potassium channels, to membrane depolarization, and to Ca^{2+} influx through the voltage-dependent Ca^{2+} channels. An increase of cytosolic Ca^{2+} is the signal that triggers glucose-stimulated insulin secretion (GSIS). Alterations of insulin secretion and glycemia increases lead to the settlement of type 2 diabetes (T2D). Additionally, this disease depends on external factors such as diet, body weight, and genetic background that may delay or enhance all clinical sings of the disease. It is known that, in modern society, an increased carbohydrate intake and the lack of exercising lead to the development of obesity. This condition increases insulin demand in order to maintain normal glycemia, thus the ability of β-cells in order to fulfill the insulin requirements is critical to preserve glucose homeostasis. The initial response toward an increased insulin demand is adaptive *hyperplasia* and an increased synthesis of the hormone. However, if *insulin resistance* persists during extended time periods, β-cells become exhausted and their mass decreases due to an increase of the apoptotic rate and consequently hyperglycemia appears. This latter condition activates several metabolic pathways impairing β-cells, such as glucolipotoxicity, mitochondrial alterations, reactive oxygen species (ROS) as well as oxidative stress and endoplasmic reticulum stress (ERS), proinflammatory cytokines, deposition of amyloid polypeptide, and p53 translocation to mitochondria (Fig. 12.1). Recently, it has been proposed that p53 protein is a major apoptosis trigger in β-cells during hyperglycemia conditions [1, 2]. These events impair β-cells by hampering their proliferative ability and also by decreasing insulin expression and secretion and promoting their death. Several of these alterations, either separate or combined, may be observed in T2D models, thus it is likely that β-cell loss in humans is linked to the activation of the aforementioned mechanisms and not to just one of them [3].

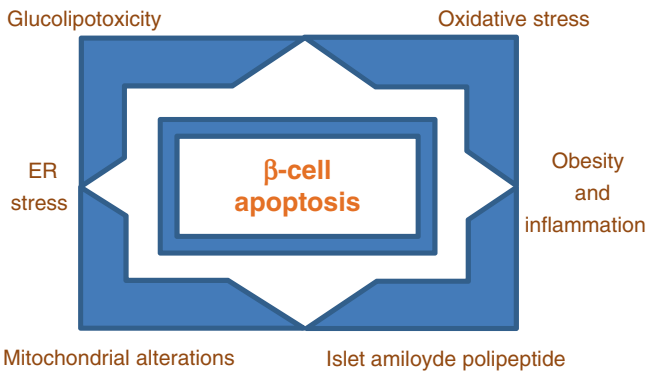

Fig. 12.1 Metabolic pathways by hyperglycemia-induced β-cell death. ER endoplasmic reticulum

The contribution from each one of such mechanisms to the decrease of pancreatic β-cell amounts will be reviewed in this chapter.

The Origin of β-Cells

Embryonic Development and Differentiation

During embryonic development or even during the first postnatal days, β-cell may be generated by stem or progenitor cells within the pancreatic ducts, bone marrow, or even pancreatic islets. Islet genesis initiates on the week 12 of gestation in humans. In weeks 13–16, the early endocrine precursor cells on the duct's wall form cell aggregates and generate an early islet. In weeks 17–20, the connection between islets and duct is lost and the islets are properly formed. At this stage, they contain only pancreatic polypeptide, somatostatin and glucagon derived from immature precursor cells. In weeks 21–26, β-cells are located at the islet center [4].

Studies conducted on rodents have allowed the identification of the molecular mechanisms regulating pancreatic β-cell establishment and differentiation. In mouse, it begins on the E8.5 day of development, and it depends on several factors secreted by neighboring early gut cells and mainly from vessels. During pancreas development several transcription factors intervene, such as the pancreatic transcription factor (Ptf1a) and the pancreatic and duodenal homeobox (Pdx1). Other factors such as SRY (sex-determining region Y)-box 9 (SOX9), forkhead box (FOX) A1/2, hepatocyte nuclear factor (HNF) 1β, and GATA4/6 have a critical participation during the establishment of the pancreatic progenitor cell pool. The development of endocrine progenitors requires Notch activation, whereas the formation of β-cells depends on Nkx 6.1, NeuroD1, the regulatory factor x (Rfx) 6, islet 1(Isl), Nkx2.2, and Pax4. The first hormone-producing cells are detected on E9.5 and their numbers increase by E13.5. At that time, the expression of β-cell-specific genes may be observed, such as GLUT 2 [5, 6].

Postnatal Development of the Pancreas

After birth, when feeding initiates, pancreatic mass increases because of the rapid expansion of the exocrine tissue. During the first 2 years of life, β-cell population keeps a 3–4% replication rate, and the pancreas reaches its maximum volume by 5–10 years old due to a decreased replication rate (0.05–0.1%) [7]. By the third decade of life, pancreatic mass is stabilized and constant until approximately 60 years of age. From that moment on, pancreas size begins to decrease [8] because of an increase of cell proliferation inhibitors such as p16, p26, p27, and cyclin D3, whereas Pdx1 decreases. The latter is needed for β-cell differentiation [4]. In rodents, the β-cell population is established during the first 4 weeks of life. In rats, between postnatal days 3 and 24, a proliferation rate of 3% occurs, and during this period apoptosis also contributes to β-cell population curtailing. However, this stage is highly influenced by the prevailing nutritional environment [9].

In adults, during physiological conditions such as pregnancy or during adaptation toward weight increase, it is possible to observe an increase of β-cell replication rates [10]. It has been demonstrated that β-cell replication may be induced in rodents by providing a high-fat diet or a chronic glucose in*fusion* [11]. Hyperglycemia also stimulates cell proliferation by activating glycolysis and by shortening the quiescence period of the cell cycle and also by promoting the G1-S transition through the activation of the ChREBP (carbohydrate response element binding protein) transcription factor [3]. This confirms β-cell adaptive ability when facing a metabolic demand.

β-Cell Dysfunction and the Loss of Pancreatic B-Cell Mass

Chronic exposition of β-cells to high glucose levels impairs their functions, and it may induce dedifferentiation and even death and a decreased pancreatic β-cell mass (β-cell failure). The onset of β-cell progressive deterioration and loss of function occurs at an earlier stage, before TD2 symptoms even appear, which are evident due to decreased insulin synthesis and secretion [12]. Postmortem studies on human pancreas from patients with a clinical history of fasting glucose alterations demonstrated approximately a 50% decrease of β-cell mass caused by apoptosis [13]. Similarly, an increased glucose-stimulated insulin secretion was observed due to the remaining 50% [14]. However, the decreased β-cell mass is not only induced by an enhanced apoptosis as alterations of cell proliferation rates have also been documented. Additionally, during hyperglycemia conditions other studies have reported that β-cell undergo dedifferentiation or regression processes characterized by a decreased expression of the specific genes for these cells [15].

β-Cell Apoptosis

Apoptosis is a physiological mechanism for cell suppression that enables the elimination of some cells without affecting neighboring cells and without releasing the cell contents, unlike *necrosis* that is concomitant with an inflammatory reaction (Table 12.1). Apoptosis may be triggered through the activation of two major pathways: intrinsic or extrin-

Table 12.1 Apoptosis vs. necrosis

Apoptosis	Necrosis
Single cells	Cells group
Cell shrinkage	Cell swelling
Lysosomal enzymes are not involved	Involvement of lysosomal enzymes
Oligonucleosomal nucleus fragmentation	Complete nucleus dissolution
Apoptotic bodies	Cell disintegration
Phagocytosis by adjacent cells	Intracellular content release

sic. The latter is activated by death ligands that bind to cell surface receptors, thus transmitting death signals. Fas and TNFRI are the best described death receptors. They possess a cysteine-rich extracellular domain and a cytoplasmic death domain. Fas ligand (FasL) binds to one of three Fas molecules, and it promotes receptor oligomerization and FADD (Fas-associated protein with death domain or Mort-1) interaction with the receptor's death domain. Subsequently, FADD binds to procaspase-8 leading to its activation. In turn, *caspase*-8 leads to the activation of other caspases, such as caspase-9. These are located within cytoplasm as inactive *proenzyme*s, and they may be activated by other caspases, death receptors, or *cytochrome c* [16] through its interaction with the apoptosis protease-activating factor 1 (Apaf-1) and procaspase-9, thus leading to *apoptosome* formation and the triggering of the caspase-activating cascade.

The extrinsic pathway initiates with the release of several proapoptotic factors, such as cytochrome c, from the mitochondrial intermembrane space toward cytosol. As mentioned above, this event leads to caspase activation through the formation of the apoptosome, the activation of caspase-9, and the subsequent activation of executing caspases 3, 6, and 7 and with these the apoptosis proteolytic cascade. Mitochondria also release the apoptosis-induced factor (AIF), a *flavoprotein* that translocate to the nucleus where it triggers chromatin condensation and DNA fragmentation. Mitochondrial membrane potential ($\Delta\Psi m$) alterations are also observed as well as respiratory chain uncoupling, all of them identified as early dysfunctions leading to cell death. Ceramides, oxidative agents, and pathologic increases of cytosolic Ca^{2+} may also induce the disruption of mitochondrial external membrane. Other proteins involved in permeabilization the mitochondrial membrane are those belonging to the Bcl-2 family. All of its members possess one to four preserved residues, known as the Bcl-2 homology domains (BHI to BH4). The apoptosis inhibitors Bcl-2 and BcI-xl possess BH1 and BH2, whereas apoptosis inducers such as Bax, Bak, and Bok display BH1, BH2, and BH3. There are some other proteins that only possess BH3 also known as death proteins. The Bcl-2 family members either promote or inhibit apoptosis in response to different stimuli such as lack of growth factors, Apaf-1 sequestration, and oxidative stress, among others [17].

At physiologic level, apoptosis is crucial for pancreas remodeling in newborns [18]. In adults, β-cell mass may increase and subsequently return to their normal size during some physiologic situations such as pregnancy and depending on the organism requirements. In other conditions as obesity and insulin resistance, it has been proposed that β-cell hyperplasia may be reverted by body weight decreases and the increase of the apoptosis rate [19].

Whereas glucose-mediated stimulation is essential for physiologic maintenance of β-cells, chronic hyperglycemia induces severe damage to these cells, and it creates a vicious cycle contributing to the progressive loss of functional β-cell mass. Chronic hyperglycemia decreases β-cell sensibility toward glucose and induces exhaustion and toxicity. Desensitizing is a reversible protective mechanism facing a steady demand for insulin. When glycemia levels are restored and stimulation ceases, β-cells may regain their sensibility toward glucose [20]. Conversely, if hyperglycemia persists, β-cells become exhausted, thus implicating the loss of insulin granules and that of two transcriptional factors regulating insulin expression: the musculoaponeurotic fibrosarcoma protein A (MafA) and PDX-1. It is important to mention that these effects may also be restored when glycemia decreases [21, 22]. However, if insulin resistance is persistent and glycemia increases, an overstimulation of β-cells occurs, thereby altering their functions and mainly the mechanisms for insulin synthesis and secretion [1, 19, 23–25]. If hyperglycemia is not adequately controlled, persistent stimulation of β-cells may eventually lead to degranulation, exhaustion, and apoptosis. In vitro studies have shown that culturing insulin-producing cells (RINm5F) in the presence of high glucose levels, an increased ROS production is observed and it triggers apoptosis [1]. In these conditions, Bax oligomerization also increases along with cytochrome c release and caspase-3 activation [19], but the precise mechanisms involved in β-cell apoptosis have not been completely elucidated.

Glucolipotoxicity

However, free fatty acids (FFA) in physiologic levels contribute to preserve glucose-stimulated insulin secretion (GSIS), exposition toward high FFA levels for prolonged periods, along with hyperglycemia, affects the expression of the *Ins* gene and induces insulin resistance and also pancreatic β-cell dysfunction. FFA contribute to apoptosis triggering in β-cells through activation of protein kinase C (PKC, apoptosis mediator), increases in ceramide synthesis and Bcl-2 inhibition [26], as well as increased levels of the type 2 uncoupling protein (UCP2) [27], thus decreasing ATP production [28]

and glucose-stimulated insulin secretion, besides contributing to both oxidative stress and endoplasmic reticulum stress [29, 30]. It has been observed that unsaturated fatty acids (e.g., palmitic acid) are more toxic when compared to their monounsaturated counterparts (e.g., palmitoleic acid), as the latter may even exhibit a protective effect because they are rapidly esterified in order to form *triacylglycerols* [31]. However, it is currently accepted that FFA-induced damage depends on concentration, exposure time, and blood glucose levels [30, 32]. When these factors converge, fatty acids and glucose compete for metabolism through the glycolytic pathway. During hyperglycemia, oxidative phosphorylation becomes saturated with glycolytic products, thus promoting the formation of malonyl-CoA that inhibits the β-oxidation of fatty acids. This effect forces β-cells to divert fatty acids to other metabolic pathways in order to metabolize them; thereby it increases the production of esterified fatty acids such as *ceramides* [33]. Accumulation of the latter occurs from sphingomyelin cleavage and/or de novo ceramide synthesis by condensing serine and non-oxidized palmitoyl-CoA through the activity of serine C-palmitoyltransferase (SPT) located in mitochondria and endoplasmic reticulum. Ceramides affect mitochondrial membrane potential and permeability and they represent a ROS production mechanism. They also enable the release of apoptosis induction factors such as cytochrome c and procaspases, thus leading to β-cell death [34]. Some experiments have demonstrated apoptosis induction mediated by ceramides after inhibiting their synthesis. In such conditions fatty acid-induced apoptosis also decreases [33]. Additionally, ceramides induce the activation of the NF-κB transcription factor that increases inducible nitric oxide synthase (iNOS) and nitric oxide (NO) production. The interaction between NO and superoxide anion (O_2) produces peroxynitrite, thus inducing DNA damage and the activation of poly (ADP-ribose) polymerase (PARP), a NAD^+-dependent enzyme [34]. Therefore, its over-activation decreases both the NAD^+ pool and glycolytic rate and electron transport and ATP synthesis. Besides negatively affecting insulin secretion, this situation may lead to pancreatic β-cell death [35].

Oxidative Stress

Whereas low ROS levels exert a beneficial effect on β-cells [9], their overproduction causes oxidative damage to proteins, lipids, and nucleic acids, and it induces oxidative stress. In hyperglycemia conditions, ROS are mainly generated by glucose auto-oxidation and also through an increased electron flow in mitochondrial respiratory chain [36]. However, in recent years it has been demonstrated an important participation of the NADH oxidase complex [1], as their components have been identified in rat pancreatic β-cells [37]. An increased mitochondrial pathway initially accelerates NADH production. The latter participates in the mitochondrial respiratory chain, and it represents the first step for $O^{\circ-}_2$ production that also generates other radicals such as hydrogen peroxide (H_2O_2) and the hydroxyl radical ($^{\circ}OH$), one of the most potent oxidants. An increased $O^{\circ-}_2$inhibits glyceraldehyde 3-phosphate dehydrogenase (GAPDH) inducing accumulation of glyceraldehyde 3-phosphate (G3P) within the glycolytic pathway. This leads to the activation of others ROS-producing pathways and to oxidative stress [38, 39] as: advanced glycation end products (AGE), as their precursor (methylglyoxal) is generated from G3P. It also leads to PKC activation as glycerol (its activator) is also produced from G3P [40] (Fig. 12.2).

The alterations induced by oxidative stress range from synthesis modifications and insulin secretion, endoplasmic reticulum stress, and activation of the apoptotic intrinsic pathway [7]. ROS lead to activation mechanisms that reinforce β-cell death and their decreased cell mass. They also induce mitochondrial membrane potential alterations, thus modifying permeability and the release of proapoptotic proteins (cytochrome c, apoptosis-inducing factor, among others) and activating the apoptotic proteolytic cascade [1]. β-Cell susceptibility toward the damage induced by free radicals and their low abundance of *antioxidant* mechanisms have been previously demonstrated [39]. Therefore, it is considered that oxidative stress is greatly responsible for pancreatic β-cell death after being exposed to hyperglycemia. The ROS-induced damage on β-cells has been quantified by the presence of 8-hydroxy-2′-deoxyguanosine (8-OHdG) on subjects affected by T2D, in animal models [30], and in vitro

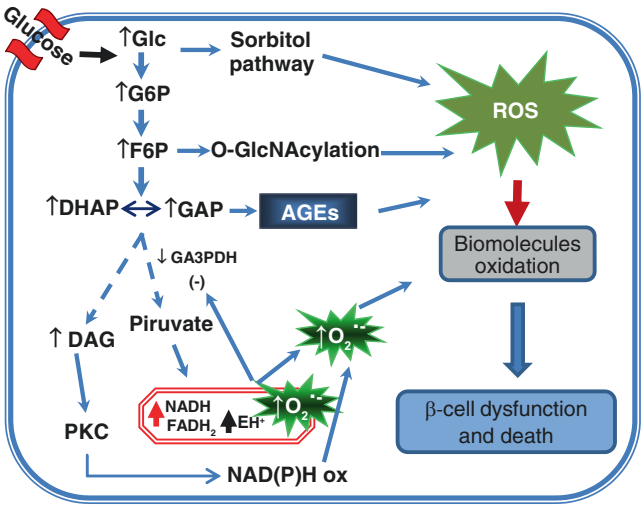

Fig. 12.2 Hyperglycemia induces ROS production and oxidative stress by increasing glycolysis and oxidative phosphorylation pathways. This situation induces biomolecule oxidation and β-cell exhaustion and death. ROS reactive oxygen species, O-GlcNAcylation, AGE advanced glycation end products

on insulin-secreting cells [1, 41]. It has been demonstrated that H_2O_2 addition to rat and mouse β-cells cultures alters mitochondrial membrane potential; it decreases ATP levels as well as glucose-stimulated insulin secretion (GSIS) [42]. This effect is abolished when the expression of antioxidant enzymes is increased. GSIS decrease induced by ROS has been linked to GAPDH and glycolysis, and, as previously mentioned, it consequently decreases ATP levels.

In addition to direct damage induced on biomolecules, oxidative stress favors the activation of other pathways such as O-glycosylation, poly(ADP-ribosylation), and O-linked β -N-acetylglucosaminilation (OGlcNAcylation). All of them may modify or inhibit the function of proteins. Approximately 2–3% of glucose entering β-cells is diverted to the hexosamine biosynthesis pathway in order to synthesize uridine diphosphate N-acetylglucosamine (UDP-GlcNAc); thus O-GlcNAcylation regulates protein function depending on glucose availability. Among the proteins prone to modification by OGT are Pdx1, FoxO1, NeuroD1, IRS2, Akt, and p53; thus it regulates glucotoxicity and β-cell apoptosis [9].

Mitochondrial Alterations

Mitochondrial physiology plays a very important role on the regulation of the insulin secretion mechanism. When exposed to hyperglycemia, β-cell mitochondria exhibit important functional and morphological changes that affect the ATP/ADP ratio required for insulin release. ROS increased due to hyperglycemia modifies mitochondrial permeability and induces apoptosis. ROS oxidizes *cardiolipin*, a phospholipid responsible to preserve mitochondrial architecture and membrane potential maintenance, and it also provides support for proteins involved in mitochondrial bioenergetics. Through hydrophobic and electrostatic interactions, cardiolipin keeps cytochrome c attached to the inner membrane. During early apoptosis, ROS oxidize cardiolipin, and they disrupt its interaction with cytochrome c that becomes detached from inner membrane, and it is released to cytoplasm [43], where it participates for apoptosome formation in order to activate proapoptotic caspases (intrinsic pathway). Cardiolipin is also the target of the proapoptotic protein t-Bid that is activated by caspase-8 (extrinsic pathway). tBid promotes pore formation on the external membrane mediated by Bax and Bak [44]. Thus, cardiolipin is a central regulator to achieve the activation of both apoptotic pathways.

Mitochondrial integrity and abundance are also regulated by *fission* and fusion mechanisms. These processes, although opposite, are coordinated in order to preserve mitochondrial morphology, size, and abundance. Mitochondrial fusion is regulated by *mitofusins* 1 and 2 (Mfn1 and Mfn2) as well as by the Opa1 mitochondrial dynamin like GTPase (Opa1). Mitochondrial fusion allows the exchange and merging of the organelle's content, including membranes, genetic material, and other metabolites. It also contributes for mitochondrial function preservation in metabolic stress conditions and during glucolipotoxicity [45]. Conversely, mitochondrial fission is mediated by several proteins such as the mitochondrial fission 1 protein (Fis1), the mitochondrial fission factor (Mff) on the external membrane, and the GTPase dynamin-related protein 1 (Drp1). Fission is essential in order to segregate damaged or dysfunctional mitochondria [46]. Alterations of mitochondrial dynamics balance mediated by the loss or gain of proteins regulating fusion or fission events impact on mitochondria structure (fragmentation) and their function as well as glucose-dependent insulin secretion [45].

In response to glucose, cell energy and mitochondrial membrane function are also regulated by *uncoupling proteins* (UCPs) located at their external membrane. UCPs are mitochondrial transporters on the inner membrane that regulate the coupling status of the respiratory chain as well as ATP synthesis. Thus, they keep the necessary ATP/ADP needed for glucose-stimulated insulin secretion. They also contribute to the mitochondrial antioxidant defense by inducing physiologic uncoupling that accelerates metabolism and decreases ROS and oxidative stress [27]. Five uncoupling proteins have been identified in humans as important regulators of corporal weight gain, the energy balance, and T2D. The most important are UCP-2 and UCP-3 because of their participation for mitochondrial membrane potential maintenance and ATP production. UCP-2 protects β-cells against oxidative stress. INS1 cells cultured in presence of H2O2 increase UCP-2 expression as well as survival rate; they also decrease ROS and caspase activation. However, hyperglycemia and *hyperlipidemia* increase UCP2 activation; consequently they reduce ATP synthesis and insulin secretion. UCP-2 also promotes mitochondrial membrane potential alterations along with the consequent release of proapoptotic factors and β-cell dysfunction that may lead to apoptosis [47].

Endoplasmic Reticulum Stress

Oxidative stress and endoplasmic reticulum stress (ERS) are interlinked regarding β-cell dysfunction because of their direct effects on insulin biosynthesis and secretion [48]. The endoplasmic reticulum (ER) ensures the appropriate folding and processing of proteins that will be secreted, among them insulin, as well as the degradation of *misfolded proteins* or those exhibiting alterations. Thus, the organelle's overload leads to misfolded protein accumulation and ERS. The latter triggers the unfolded protein response (UPR) in order to restore ER homeostasis and to decrease protein synthesis. It also increases the expression

of genes involved in protein folding and ER-linked protein degradation. UPR is mediated by proteins bound to the ER membrane: PERK (protein kinase-like ER kinase), IRE1α (inositol-requiring enzyme 1α), and ATF6 (activating transcription factor 6) [49]. When stress occurs, PERK autophosphorylation induces eif2α (eukaryotic translation initiation factor 2α) phosphorylation, a factor that inhibits protein synthesis, whereas it promotes ATF-4 transcription. The latter positively regulates the expression of ERS target genes such as the C/EBP homologous protein (CHOP) and the downstream growth arrest and DNA damage-inducible protein (GADD34). These two proteins activate protein phosphatase-1 (PP-1) that in turn dephosphorylates eif2α, thereby restoring transcription. Acute exposition of β-cells to high glucose levels induces an intermediate UPR signaling characterized by IRE1α phosphorylation and activation as well as glucose-stimulated insulin secretion. However, excessive UPR stimulation induces β-cell death and diabetes. In patients displaying insulin resistance and in islets isolated from *ob/ob* mice, it has been demonstrated that a constant and steady demand for insulin represent ER constant stimulation and it eventually leads to stress [49]. Additionally, the increase of FFA also induces ER stress as it affects protein processing and trafficking, Ca^{2+} regulation, and oxidative stress in mouse insulin-producing cells (INS1) and in human cell lines [50]. Palmitate activates the UPR response through phosphorylation of IRE1 and PERK as well as β-cell apoptosis mediated by caspase-12 and caspase-3 activation [51].

Obesity and Inflammation

Currently, obesity stands out as a risk factor to develop T2D. Nevertheless, if obesity actually causes diabetes, most obese individuals sooner or later would develop hyperglycemia and T2D. In spite of this, approximately 20% of all obese individuals are diabetic [52]. This suggests that obesity and resistance toward insulin are factors that increase the risk to develop diabetes, but they are not inductors. Thus, it has been proposed that, in obese individuals, hyperglycemia may be more related to β-cell impaired function and decreased mass [53] and/or their inability to adapt themselves toward the new metabolic demand [54]. Even though some of these studies have demonstrated a decreased β-cell mass in obese humans affected by T2D (postmortem donors) and in those who displayed alterations of fasting glucose levels by 65% and 40%, respectively [10], in obese individuals not affected by T2D, β-cell mass and insulin secretion are increased by 50% in order to cope with resistance to insulin [55]. In obese rodents a physiologic adaptive expansion of β-cells is observed due to increased generation, decreased death, and β-cell hypertrophy [56]. Through this adaptation, β-cells preserve normal glycemia until they become exhausted and eventually die, thus leading to T2D development. Cell expansion is a complex process involving the activation of several pathways that converge to regulate proliferation, survival, cell size, and insulin secretion. Apparently, proliferation and hypertrophy are most important during the β-cell expansion phase, whereas apoptosis may participate in the final phases, during β-cell failure caused by hyperglycemia. Some evidence shows that, in animals displaying resistance toward insulin, the IGF1/PI3k/Akt/mTOR pathway participates during β-cell adaptation induced by a high-fat diet. mTOR (mammalian target of rapamycin) mediates protein synthesis in response to nutrients and growth factors, and it stimulates the phosphorylation of some components of the protein synthesis machinery such as p70S6K (ribosomal S6 kinase protein) and 4E-BP (IF4E binding protein). Akt also participates in cell cycle regulation by inducing phosphorylation and degradation of the cyclin-dependent kinases inhibitors such as p21 and p27. Apparently, the increased β-cell mass in obese individuals may be a reversible event, similarly to pregnancy. Some studies have reported that insulin secretion decreases concomitantly with weight loss or caloric restriction, whereas sensibility toward insulin is regained as well as β-cell function. Furthermore, caloric restriction enhances mitochondrial biogenesis and respiratory efficiency, and it decreases ROS production and promotes metabolic homeostasis [57].

Additionally, because of FFA increase, obesity predetermines a chronic inflammation state in adipose tissue that is characterized by increased proinflammatory *adipokines* and cytokines. These attract B cells, T cells, and macrophages toward the pancreas and adipose tissue where they secrete even more proinflammatory cytokines and chemokines, thereby contributing to inflammatory reaction and to autoimmune elimination of β-cells. The presence of reactive T cells in islets is observed in patients affected by T2D exhibiting severe β-cells lesions and low insulin secretion [58]. Obesity implies an increased amount of adipocytes and also of their fat content, a vascularization decrease, hypoxia, and cell necrosis. Signal molecules derived from cell elimination may bind to Toll-like receptors (TLRs) and to nucleotide-binding oligomerization domains (NOD) in order to induce a local or generalized immune response. The latter consists on the assembly of cytosolic protein complexes comprised by bound nucleotides, leucine-rich repeats sequences (NLRs) and caspase-1. Once active, they initiate IL-1β production [59]. Hyperglycemia increases the production of the NLRP3 *inflammasome*, whereas FFA activate TLR2 and TLR4, thus promoting macrophage recruitment and β-cell stress [58].

Plenty of evidence exists on the importance of proinflammatory cytokines (IL-1β, TNFα, and interferon-γ (IFNγ)) to activate signaling cascades in β-cells, such as NF-κB, the

mitogen-activated protein kinase (MAPK), and the Janus kinase/signal transducer and activator of transcription (JAK/STAT). β-Cell elimination by the proinflammatory cytokines IL-1β, TNFα, and IFNγ begins by their binding to specific receptor in β-cells and to the endoplasmic reticulum [59]. The consequences of increased ROS were previously mentioned. Conversely, in the presence of cytokines, the 12/15-lipoxygenase (12/15-LO) induces the cleavage of arachidonic acid to produce highly reactive metabolic such as 12-hydroxyeicosatetraenoic that may induce oxidative stress and mitochondrial dysfunction [30]. It has been also demonstrated that thioredoxin-interacting protein (TXNIP) interacts with NLRP3 and contributes to IL-1β production induced by hyperglycemia [60]. The latter contributes to β-cell dysfunction and apoptosis in T2D. TNFα negatively regulates the insulin receptor substrate-2 (IRS-2) in β-cells by inducing its phosphorylation and modifying insulin signaling. In obesity leptin secretion by adipose tissue also predominates. Leptin inhibits glucose-stimulated insulin secretion in β-cell lines and normal mice [61], and it also contributes to intolerance toward glucose in diabetes.

β-Islet Amyloid Polypeptide (IAPP)

Amylin is synthesized by pancreatic islets and it is secreted along with insulin. Amylin is comprised by 37 amino acids, although it may produce polypeptides and be accumulated in islets in response to stress. IAPP effects initiate after binding to its receptors. Only three of them are known. They contain the calcitonin receptor in their inner structure and one of the following three receptor activity-modifying proteins: RAMP1, RAMP2, or RAMP3. The accumulation of intracellular amylin has been linked to both oxidative and endoplasmic reticulum stresses. β-Amyloid plates are a common feature in patients affected by T2D. During hyperglycemia/hyperlipidemia, IAPP synthesis also increases in β-cells along with proinsulin, and they reach enough levels in order to allow for oligomer formation [18]. They also stimulate IL-1β, islet inflammation, and β-cell apoptosis. IAPP soluble peptides have been detected, they represent early intermediates for fibril formation and they are also responsible for cell death. In peripheral tissues, IAPP modifies glucose metabolism [62], it suppresses glucose uptake induced by insulin in muscle cells [63] and digestive secretion (gastric acid, pancreatic enzymes), and it delays gastric emptying. IAP administration to rats decreases food intake [64], but when an IAPP antagonist is provided, food intake increases as well as body weight [65].

β-Cell Apoptosis and p53

β-Cell apoptotic death after being exposed to high glucose levels has been associated with p53 protein translocation toward mitochondria [1]. Furthermore, β-cell population recovery and the rescue from the diabetic phenotype was demonstrated in p53-knockout mice, thus highlighting the importance of this protein for diabetes establishment [2].

p53 protein is a transcription factor engaged in DNA damage monitoring. Depending on the severity of the damage, p53 triggers apoptosis or arrests the cell cycle until the DNA repairing mechanisms are activated. p53 activation occurs in response to several types of stress, mainly those damaging DNA, and this leads to its stabilization and accumulation in cells submitted to stress conditions. p53 is also involved in apoptosis triggering by interacting and forming complexes with Bcl-2 and Bcl-XL through its DNA-binding domain, thus allowing Bax-Bax oligomerization and the release of cytochrome c [66].

Apoptosis onset induced by p53 at mitochondria level is associated with oxidative stress. In insulin-producing cells (RINm5F) cultured on glucose 30 mM, p53 translocation to mitochondria, cytochrome c release, and apoptosis were induced because of oxidative stress [1]. Taking this into account, it was proposed that glucose increase modifies intracellular p53 distribution and it promotes its mitochondrial localization besides inducing p53 phosphorylation, impairing its degradation, and increasing its biologic activity [67]. The presence of p53 in mitochondria is correlated with a decreased Bcl-2/Bax ratio, a decreased mitochondrial membrane potential [1], p53 activation, and increases of p21, Bax, and apoptosis [68]. This emphasizes p53 participation during the decrease of β-cell mass induced by hyperglycemia.

Hyperglycemia regulates p53 stability and function by inducing posttranslational modifications such as phosphorylation, poly(ADP-ribosylation), and N-acetylglucosamination [69].

p53 Phosphorylation

Hyperglycemia promotes p53 mitochondrial localization and its phosphorylation at serine 392 (homologous to Ser289 in mouse). This correlates with a Bcl-2 decrease, Bax increase, and β-cell apoptosis. The inhibition of the p38 MAPK hampered p53 phosphorylation, and it curtailed β-cell apoptosis induced by hyperglycemia, thereby suggesting its participation during the decrease of pancreatic β-cell mass. As in mitochondria p53 is engaged in complex formation with other antiapoptotic and/or proapoptotic proteins and as it triggers the mitochondrial permeation process, it is likely that its phosphorylation is a requirement that may

enable its interaction with such proteins and to induce cell death. Additionally this process stimulates the interaction between p53 and the p300/CBP and P/CAF coactivators that promote its acetylation, thereby inhibiting its ubiquitination and degradation [70]. These results indicate the importance of p53 phosphorylation as one of the factors contributing to β-cell elimination as consequence of hyperglycemia through mitochondria (Fig. 12.3). Hyperglycemia also leads to ATM activation in cytosol, which in turn phosphorylates p53 at serine 15, thus avoiding its recognition by Mdm2, its ubiquitination, and nuclear degradation and also contributing to apoptosis triggering in response to hyperglycemia in β-cells [71].

p53 O-N-Acetylglucosamination

Hyperglycemia promotes O-GlcNAcylation of several proteins, including p53. This consists on the addition of an N-acetylglucosamine moiety in serine or threonine residues. O-GlcNAcylation is analogue to phosphorylation, and it regulates the stability, activity, or subcellular localization of target proteins. This modification depends on glucose availability, and it represents a cellular regulation mechanism according to nutritional environment. In a glucose-rich environment, the O-N-acetylglucosamination of p53 has been observed and it is liked to its stability and it prevents its degradation. O-GlcNAc in p53 at Ser149 enhances its stability by interfering with phosphorylation

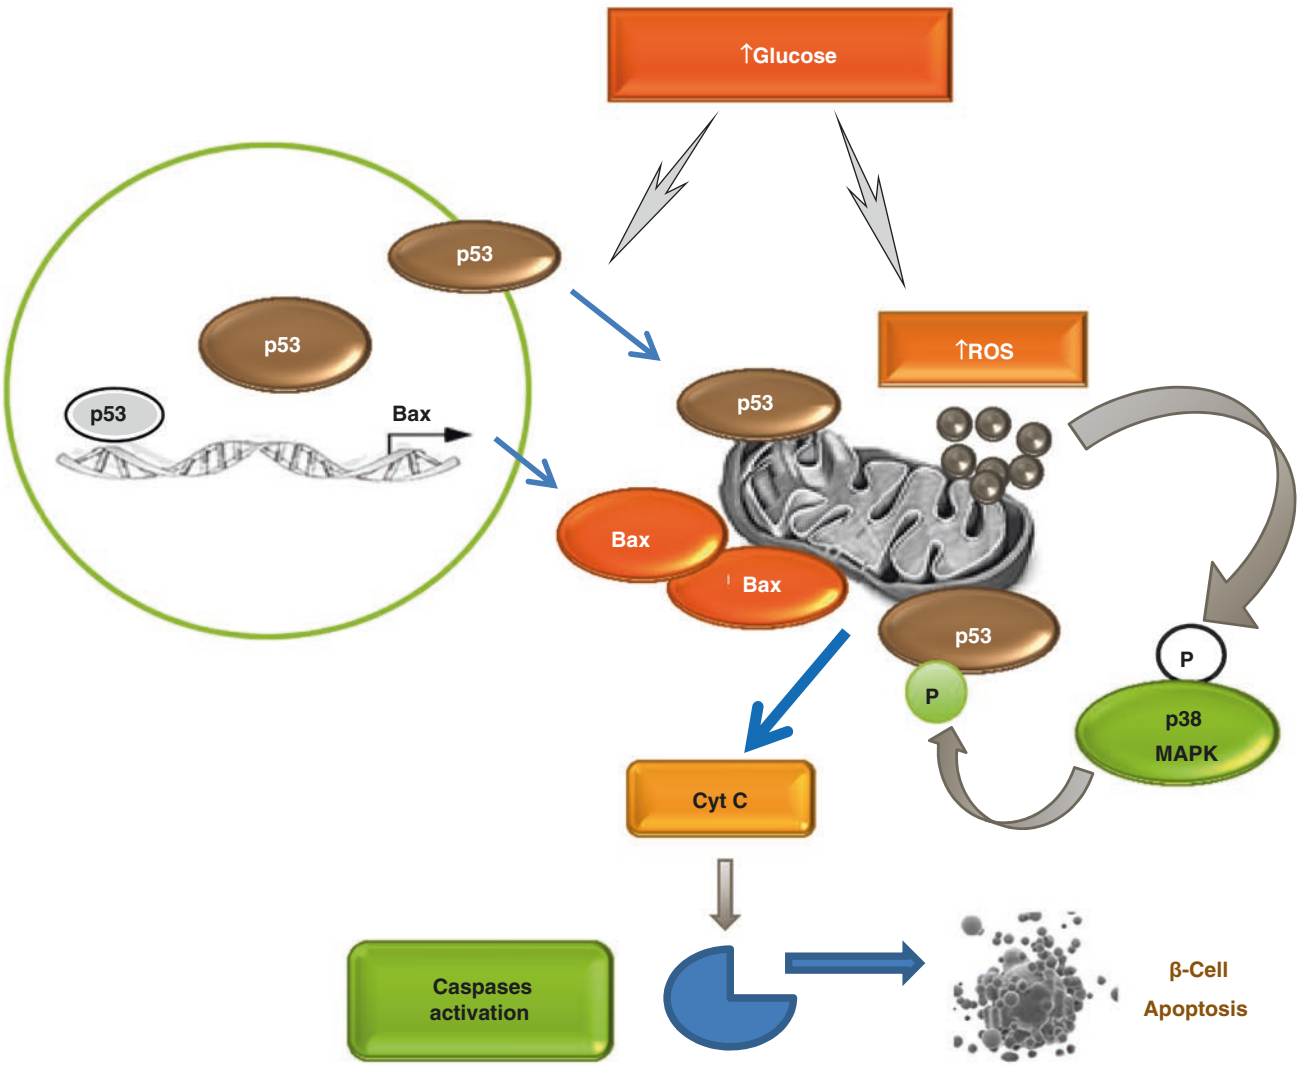

Fig. 12.3 Hyperglycemia promotes p53 translocation to mitochondria and its phosphorylation. There, p53 contributes to mitochondrial permeability, cytochrome c release, and β-cell apoptosis. P: phosphorylation, ROS: reactive oxygen species, Cyt c: cytochrome c

at Thr155, by overcoming its interaction with Mdm2 and its ubiquitination and its subsequent proteolysis. All of this results in higher p53 stability [72]. Thus, it has been proposed that O-GlcNAc stabilizes p53 and may represent a signal for its translocation to mitochondria [71], where it may contribute to the release of proapoptotic factors [73].

p53 Poly(ADP-Ribosylation)

Another protein that becomes active when DNA suffers damage is poly (ADP-ribose) polymerase (PARP). This enzyme catalyzes the transfer of ADP-ribose units from NAD^+, an essential cofactor for ATP synthesis and redox potential balance, to the carboxylic residues glutamic and aspartic acids of several nuclear proteins. Poly(ADP-ribosylation) is important for DNA replication and repair, transcription, inflammatory response, and cell death mainly caused by genotoxic agents, infection, and stress. PARP fragmentation is concomitant with β-cell apoptosis triggering induced by hyperglycemia. These results are in agreement with previous reports showing that hyperglycemia triggers apoptosis in β-cells and pancreatic cell lines such as RINm5F. Poly(ADP-ribosylation) of p53 in presence of high glucose levels is an early response that may contribute for protein stabilization and probably to its translocation to mitochondria as well as to the increased apoptotic rate of RINm5F cells caused by high glucose levels [73].

p53 Regulation by Mdm2

Cell survival depends in great extent on the balance between synthesis and degradation of p53. Among the mechanisms regulating p53, the expression and activation of Mdm2 (murine double minute 2) is of great importance. Mdm2 is an E3 ubiquitin ligase that binds p53 and it transfers *ubiquitin* to the latter residues, thereby enabling its recognition by *proteasome*s for targeted degradation. Depending on the amount of ubiquitin residues attached to p53, this protein will be degraded or exported to the cytosol. Mono- and/or poly-ubiquitination of p52 is defined by the concentration and activation status of Mdm2.

As previously mentioned, the interaction between p53 and Mdm2 depends on intracellular environment impacting on those posttranslational modifications displayed by these proteins. In the case of Mdm2, ubiquitination, *sumoylation*, and phosphorylation disrupt the formation of the p53-Mdm2 diene, and they stabilize p53 levels. It has been demonstrated that Mdm2 phosphorylation on Ser395 mediated by ATM decrease its ability to target p53 for degradation. Previously it was demonstrated that p53 phosphorylation by Akt participates in its regulation as it attenuated transactivation and increased p53 ubiquitination [74]. High glucose concentration decreases the expression of Mdm2 mRNA and its protein levels on both nucleus and cytosol [75]. Mdm2 expression is regulated by p53. Although we previously demonstrated its stabilization in presence of high glucose levels, this protein is not targeted toward nucleus, but it translocates to other organelles such as mitochondria; thus it cannot stimulate Mdm2 expression. Additionally, DNA fragmentation induced by hyperglycemia also may affect the expression of Mdm2 mRNA [1].

Formation of the p53-Mdm2 complex increased in presence of high glucose, although its ubiquitination was not observed. The latter demonstrates that glucose increased levels induce Mdm2 activation in cytosol and its interaction with p53 is also promoted, whereas its ubiquitination is inhibited [71]. It is known that the E3 ubiquitin ligase activity of Mdm2 depends on other domains comprising this protein. The latter activity is located within the *RING finger domain* at the C-terminal. This region also contains the substrate lysine acceptor and its main function is to label p53 for degradation. The central acid domain of Mdm2 binds to the RING finger domain and it stimulates catalytic activity, thereby promoting ubiquitin release from the E3 enzyme. The interaction between the acid domain and the RING finger domain depends on its phosphorylation by ATM [76]. An increase of ATM-mediated phosphorylation has been also observed in hyperglycemia. Thus, it is not excluded that stress and the phosphorylation cascade induced by high glucose levels may phosphorylate some residues on the RING finger domain and/or on nearby regions and on the acid central domain in Mdm2 leading to the inhibition of p53 polyubiquitination and degradation.

Conversely, p53 ubiquitination also depends on ATP levels. In hyperglycemia conditions, ATP decreases due to increased ROS and mitochondrial uncoupling. Therefore, if ATP decreased levels occur, ubiquitin ligases are unable to condensate the glycine residues on their C-terminal region with the lysine residues on p53. Thus, it is necessary to analyze these factors in hyperglycemia conditions in order to know about its participation for p53 ubiquitination in RINm5F cells.

Alterations in the Cell Cycle

Cell Proliferation Rate

In obese subjects, β-cell failure to compensate for insulin resistance has been related to either an inappropriate cell mass expansion or the inability of preexisting cells to respond toward glucose. This may be generated from defects of insulin signaling or the absence of insulin receptors and IGF-I in these cells [62]. For instance, *knockout* mice for these receptors exhibit a decreased cell mass and develop diabetes from an early age. It has been pointed out that progression through the cell cycle is also altered. It has been observed that cyclin

inhibitor p27kip1 is progressively accumulated inside β-cell nucleus in mice lacking the insulin receptor substrate-2 (IRS-2) and also in *db/db* mice. p27kip1 accumulation in oxidative stress and hyperglycemia conditions may be another pathway by which ROS decrease β-cell mass as the deletion of its gene hampers hyperglycemia effects and induce β-cell proliferation [77]. Another important regulator of β-cell replication is the cell cycle inhibitor p21, which is expressed at high levels in adult β-cells, and it has been linked to proliferation decrease during senescence. It is known that β-cell replication potential is lost with age and it is correlated with the loss of expression of genes such as EZH2 (enhancer of zeste homologue 2), a histone methyl transferase that represses the transcription of cell cycle inhibitors when histone 3 is trimethylated in its lysine 27 residue (H3K27me3). EZH2 decreases H3K27me3 and increases p16 and p19 expression and it inhibits β-cell proliferation [78].

β-Cell Dedifferentiation

During recent years it has been observed that pancreatic β-cells undergo a *dedifferentiation process* when metabolic demand increases and also during hyperglycemia and inflammation. In mouse, hyperglycemia modifies the expression of transcription factors and insulin secretion. For instance, the loss of FOXO1 leads to β-cell dedifferentiation, decreases insulin content, and reverts its phenotype toward progenitor-like cells, characterized by the expression of Ngn3. Although changes in transcriptional factors have been observed on humans and primates affected by diet-induced prediabetes, a dedifferentiation process has not been demonstrated. β-cell dedifferentiation induced by hyperglycemia is reverted when blood glucose values are restored. Insulin immunostaining loss correlates with an increased glucagon staining in several diabetic mouse models. In one of these, it was observed that small β-cells begin to express glucagon, although it is not known if these cells will transform into α-cells or if they represent an intermediate cell type expressing glucagon [54, 79]. The Pax4 gene also participates in β-cell dedifferentiation. The latter is an embryonic development regulator of pancreatic islets, and its presence on adult β-cells from animals confers protection against stress-induced apoptosis, and it stimulates cell proliferation. However, the sustained Pax4 expression promotes β-cell dedifferentiation and hyperglycemia. Pax4 overexpression is concomitant with Ngn3 expression. This suggests that an acute Pax4 increase protects cells, but its steady or chronic expression induces β-cell dedifferentiation into progenitor cells apparently as a protective mechanism against deleterious environmental effects [80].

Conclusions

Obesity, insulin resistance, and glucose intolerance affect pancreatic β-cell functional status. Particularly, generation of new cells (*neogenesis*, replication) is decreased, whereas the apoptotic death rate increases. Among the mechanisms leading to β-cell alterations, it has been observed the participation of several proteins synthesized by the cell itself, such as amyloid polypeptide and the type 2 uncoupling protein, the molecules expressed and released by adipose tissue (free fatty acids and cytokines), the presence of high glucose levels, and the reactive oxygen species produced by glucolipotoxicity. It was recently proposed that high ROS appearing levels during hyperglycemia promote phosphorylation, poly(ADP-ribosylation), and/or O-GlcNAcylation, and they may interfere with p53 degradation by inhibiting the Mdm2 E2 ubiquitin ligase. Therefore, p53 degradation is avoided, and its recruitment to mitochondria and the apoptotic mechanisms are promoted along with β-cell dysfunction.

Loss of β-cell mass may reach a critical point in which the deleterious effects mediated by the aforementioned molecules might not be reverted, thus decreasing insulin production and release and contributing to diabetes development. Several treatments exist in order to attenuate β-cell deterioration. Changes of dietary routine and increased physical activity are among them. The objective is to promote weight loss and specially to decrease abdominal fat and insulin resistance. Thus, eventually β-cell mass may be regained.

Concluding Remarks

- Activating hyperglycemia metabolic pathways induces β-cells apoptosis.
- Free fatty acids are more toxic when hyperglycemia is present.
- Oxidative and endoplasmic reticulum stress, mitochondrial alterations, inflammatory cytokines, islet amyloid polypeptide, together or separate, can decrease pancreatic β-cell mass.
- Hyperglycemia induces posttranslational changes in p53 that inhibits its degradation and promotes mitochondrial location.
- Many factors trigger the death of pancreatic β-cells and decrease β-cell mass. However, most appear to have their origin in hyperglycemia, so control of glucose levels is of great importance in preserving the mass and function of pancreatic β-cells.

Multiple-Choice Questions

1. At what stage of embryonic life is β-cell mass set?
   (a) Before birth
   (b) At 2 years old
   (c) While breastfeeding
   (d) Between 5 and 10 years old
   (e) At 5 years old
2. A decrease of β-cell mass was observed in persons without diabetes but with:
   (a) Chronic hyperglycemia
   (b) Metabolic syndrome
   (c) Impaired glucose tolerance
   (d) Obesity
   (e) Type 2 diabetes
3. All are apoptotic cellular death characteristics, except:
   (a) DNA oligonucleosomal fragmentation
   (b) Phosphatidylserine exposition
   (c) Death cell phagocytosis
   (d) Intracellular content release
   (e) Formation of apoptotic bodies
4. Increased production of reactive oxygen species in hyperglycemic conditions is due to
   (a) Microsomes
   (b) Oxidative phosphorylation
   (c) Macrophages
   (d) Endoplasmic reticulum
   (e) NADPH oxidase
5. Endoplasmic reticulum stress is characterized by:
   (a) DNA oligonucleosomal fragmentation
   (b) Increased insulin demand
   (c) Unfolded protein response
   (d) Oxidative stress
   (e) Changes in mitochondrial permeability
6. In hyperglycemic conditions, p53-induced apoptotic β-cell pathway:
   (a) Releases intracellular content
   (b) Changes mitochondrial permeability
   (c) Activates death receptors
   (d) Expresses proapoptotic proteins
   (e) Inhibits cell cycles
7. Hyperglycemia induces the activation of metabolic pathways related to β-cell death as:
   (a) An increase in reactive oxygen species
   (b) Accumulation of amyloid polypeptide
   (c) Stress of the endoplasmic reticulum
   (d) A hexosamine pathway
   (e) All of the above
8. What mitochondrial alterations contribute to the dysfunction of β-cells in diabetes?
   (a) Fission and fusion events
   (b) Loss of glucose sensitivity
   (c) Changes in ATP/ADP rate
   (d) Increased proinflammatory cytokines
   (e) Modification of NAD/NADH+ rate
9. Chronic hyperglycemia affects the survival of β-cells by:
   (a) Decreasing beta-cell mass in diabetes by apoptosis
   (b) Causing β-cell hyperplasia and exhaustion
   (c) Causing cell dedifferentiation
   (d) Creating a loss of glucose sensitivity
   (e) All of the above

Correct Answers

1. (d) Between 5 and 10 years old
   At this stage of development, the rate of cell replication is reduced and the pancreas reaches its full size
2. (c) Impaired glucose tolerance
   Postmortem studies in humans showed a decrease in pancreatic cell mass of up to 50% in people with impaired fasting glucose
3. (d) Intracellular content release
   An important characteristic of apoptosis is the formation of apoptotic bodies, which consists of the invagination of the plasma membrane that surrounds the subcellular remains and prevents the release of intracellular material
4. (b) Oxidative phosphorylation
   Mitochondria are the main sources of endogenous ROS in hyperglycemic conditions. Of the oxygen consumed by mitochondria, ∼1–5% is converted to ROS as by-products of the flow of electrons in the respiratory chain
5. (c) Unfolded protein response
   Constant requirements of insulin during glucose intolerance and insulin resistance lead to alterations in the processing of proteins in the RE. This situation stimulates an ER response known as unfolded protein response and ER stress
6. (b) Changes mitochondrial permeability
   P53 in the mitochondria releases Bax from Bcl-2, allowing Bax oligomerization and pore formation to release proapoptotic factors as cyt c
7. (e) All of the above
   During hyperglycemia, the activation of all these metabolic pathways was observed, which concluded with the activation of the intrinsic pathway of apoptosis
8. (a) Fission and fusion events
   Hyperglycemia alters the expression of the proteins that regulate mitochondrial fusion/fission events, which modifies the $\Delta\Psi m$ and allows the output of proapoptotic factors
9. (e) All of the above
   Chronic hyperglycemia decreases pancreatic β-cell mass by activating apoptosis and inhibiting the cell cycle, in addition to inducing the dedifferentiation of β-cells and the sensitivity to glucose is lost

Glossary

Adipokines Cytokines (cell signaling proteins) secreted by adipose tissue.

Amylin A 37-amino acid peptide hormone, discovered in 1987, which is co-located and co-secreted with insulin by the pancreatic beta cells in response to nutrient stimuli.

Antioxidant Molecule that inhibits the oxidation of other molecules.

Apoptosis (a-po-toe-sis) Was first used by Kerr, Wyllie, and Currie in 1972 to describe a morphologically distinct form of cell death and energy-dependent biochemical mechanisms.

Apoptosome Molecular complex of two major components – the adapter protein apoptotic protease-activating factor 1 (Apaf1) and the procaspase-9. These are assembled during apoptosis upon Apaf1 interaction with cytochrome c. Apoptosome assembly triggers effector caspase activation.

Cardiolipin Phospholipid important of the inner mitochondrial membrane, where it constitutes about 20% of the total lipid composition.

***Caspase* (cysteine-aspartic proteases, cysteine aspartases or cysteine-dependent aspartate-directed proteases)** Family of protease enzymes playing essential roles in apoptosis and inflammation.

Ceramides Family of waxy lipid molecules. A ceramide is composed of sphingosine and a fatty acid.

Cytochrome c Heme protein serving as electron carrier in respiration. Cytochrome c is also an intermediate of apoptosis.

Cytokines Cell signaling small proteins. Involved in autocrine signaling, paracrine signaling, and endocrine signaling as immunomodulating agents.

Dedifferentiation process Processes by which cell that were specialized for a specific function lose their specialization.

Fission Division of mitochondria into new mitochondria.

Flavoprotein Proteins that contain a nucleic acid derivative of riboflavin: the flavin adenine dinucleotide (FAD) or flavin mononucleotide (FMN).

Fusion Process mediated by several large GTPases whose combined effects lead to the dynamic mitochondrial networks seen in many cell types.

Glucolipotoxicity Combined, deleterious effects of elevated glucose and fatty acid levels on pancreatic beta-cell function and survival.

Hyperlipidemia Elevation of fats or lipids in the blood.

Hyperplasia Enlargement of an organ or tissue caused by an increase in the cell proliferation rate.

Inflammasome A multiprotein cytoplasmic complex which activates one or more caspases, leading to the processing and secretion of proinflammatory cytokines – e.g., IL-1 beta, IL-18, and IL-33. Assembly of inflammasomes depends on the NOD-like receptor family members, such as the NALP protein kinase: enzyme catalyzing phosphorylation of an acceptor molecule by ATP.

Misfolded proteins Are proteins structurally abnormal and thereby disrupt the function of cells, tissues, and organs. Proteins that fail to fold into their normal configuration; in this misfolded state, the proteins can become noxious in some way and can lose their normal function.

Mitofusins Proteins that participate in mitochondrial fusion.

Necrosis Morphological changes in cell death caused by enzymatic degradation.

Neogenesis Generation of new cells.

Oxidative stress Pathological changes in living organisms in response to excessive levels of intracellular free radicals.

Proenzyme Precursor of an enzyme, requiring some change (hydrolysis of an inhibiting fragment that masks an active grouping) to render it active form.

Proteasome An intracellular complex enzymatic that degrades misfolded or damaged proteins (proteolysis), after damaged proteins are tagged by ubiquitin.

Resistance to insulin Pathological condition in which cells fail to respond normally to the hormone insulin.

RING finger domain Really Interesting New Gene finger is a proteins domain that plays a key role in the ubiquitination process.

Stem cells Undifferentiated biological cells that can differentiate into specialized cells and can divide.

Sumoylation Small Ubiquitin-like Modifier (or SUMO) proteins are a family of small proteins that are covalently attached to and detached from other proteins in cells to modify their function. Posttranslational modification involved in various cellular processes.

Triacylglycerol Ester of glycerol with three molecules of fatty acid.

Ubiquitin Small (8.5 kDa) regulatory protein that has been found in almost all tissues (ubiquitously) of eukaryotic organisms and regulated proteolysis.

Ubiquitin ligase Protein that recruits, recognizes a protein substrate, and catalyzes the transfer of ubiquitin from the E2 enzyme to the protein substrate.

Uncoupling proteins Proteins that uncouple phosphorylation of ADP from electron transport.

Brownlee M. The pathobiology of diabetic complications: a unifying mechanism. Diabetes. 2005;54(6):1615–25. The author presents a unified mechanism that links overproduction of superoxide by the mitochondrial electron-transport chain to high glucose-mediated damage and diabetes complications. This paper provides the basis for understanding of the origin of ROS and oxidative stress in diabetes.

Hasnain SZ, et al. Oxidative and endoplasmic reticulum stress in b-cell dysfunction in diabetes. J Mol Endocrinol. 2016;56:R33–54. https://doi.org/10.1530/JME-15-0232. Here, the importance of deleterious

effects of oxidative stress and endoplasmic reticulum stress-induced unfolded protein response is evaluated on β-cell insulin synthesis and secretion as well as on inflammatory signaling and apoptosis. Additionally, the authors describe recent findings on how inflammatory cytokines contribute to β-cell dysfunction and protect interleukin 22.

Kaufman B, et al. Mitochondrial regulation of β-cell function: maintaining the momentum for insulin release. Mol Aspects Med. 2015;42:91–104. https://doi.org/10.1016/j.mam.2015.01.004. Pancreatic β-cell function and insulin release is mitochondria dependent. In this work, the authors review mitochondrial metabolism and control of mitochondrial mass as they relate to pancreatic β-cell function.

Ortega-Camarillo C, et al. The role of p53 in pancreatic β-cell apoptosis. Immunoendocrinology. 2015;2:e1075. https://doi.org/10.14800/ie.1075; © 2015. This paper examines p53 mobilization to a mitochondrion and its phosphorylation, as well as the activation of the intrinsic route of β-cell apoptosis by hyperglycemia. They also describe how hyperglycemia affects the p53 degradation pathways.

Sharma RB, Alonso LC. Lipotoxicity in the pancreatic beta cell: not just survival and function, but proliferation as well? Curr Diab Rep. 2014;14(6):492. https://doi.org/10.1007/s11892-014-0492-2. This paper reviews free fatty acids' (FFAs) positive and negative effects on beta cell survival and insulin secretion. It also examines strong new findings that lipids may also impair compensatory beta cell proliferation.

Strycharz J, et al. Is p53 involved in tissue-specific insulin resistance formation? Oxid Med Cell Longev 2017; Article ID 9270549, 23 p. https://doi.org/10.1155/2017/9270549. The protein p53 is connected with metabolic defects underlying cellular aging, obesity, inflammation and β-cells apoptosis. Additionally, the authors discuss p53 regulation of multiple biochemical processes such as glycolysis, oxidative phosphorylation, lipolysis, lipogenesis, *β*-oxidation, gluconeogenesis, and glycogen synthesis.

Obesity in the Pathophysiology of Diabetes

13

Juan Antonio Paniagua González and Antonio Vidal-Puig

Obesity as a Public Health Problem

Obesity and overweight states are characterized by an excessive accumulation of body fat. Depending on the amount of fat accumulated, but also on the individual's genetic and exposure to specific environmental factors, the obese patient can develop several health problems. The increase in the prevalence of obesity and associated complications is considered a major public health issue that affects all demographic groups, irrespective of age, sex, race, education, or economic level [1]. The World Health Organization (WHO) estimates that more than 1.9 billion adults (≥18 years old) were overweight, and of these over 600 million were obese, according to worldwide data registered in 2014 [2]. In the United States, obesity rates have been rising in both, adults and children in recent years [3–5]. The maintenance of a healthy weight, usually achieved between 18 and 25 years of age, requires a life-long sustained energy equilibrium between energy intake and energy expended, which is affected not only by diet but also age, stage of development, genetic makeup as well as epigenetic, level of nutritional education, as well as physical and psychosocial interactions [6, 7].

A useful tool to define a person as obese or underweight is the body mass index (BMI), estimated by the relationship between weight and height. The age-standardized death rate, from any reason, was generally lowest in subjects with a BMI of 22.5–24.9 kg/m^2 [8–10]. Moreover, deaths associated with high BMI are ranked fourth, behind deaths from hypertension, smoking, and unhealthy diets and ahead of deaths related to hyperglycemia, sedentary lifestyle, high salt intake, alcoholism, and high blood cholesterol levels [11]. Lastly, it is also of relevance that the association between nutrient intake and diseases, such as cancer, diabetes, cardiovascular disease (CVD) [12, 13], obesity, body fat distribution, hypertension, insulin resistance, and hyperglycemia, is well established [14–16].

Deaths from CVD, cancer, and diabetes account for approximately 65% of all deaths, and obesity, mainly abdominal adiposity, increases the risk of all these disorders. BMIs higher than 25 kg/m^2 have a direct relationship with mortality due to CVD [6, 17–21]. CVD accounts for about 38.5% of all deaths in United States. Of relevance, this figure has declined since the 1940s and 1960s [8], associated with several primary prevention activities, improved treatment for acute ischemic phase, and secondary intervention [22, 23].

Deaths from all cancers accounted for about 23% of the total [8]. As high BMI increases mortality from cancer in most specific sites [10, 24, 25], compared to people with normal weight, obesity could increase cancer incidence about 14% in men and 20% in women. People with BMI ≥ 40 kg/m^2 could increase risk of death from cancer up to 52% in men and 62% in women [26]. Higher circulating glucose levels, low-grade inflammatory state, increased oxidative stress, and an altered bioavailability of hormones, mainly insulin, estrogens, and androgens, could be implicated in the rise in current cancer rates obesity-related. Finally, during the 1990s, in the United States, there was an increase of diabetes prevalence to 61%, and of this ≈90% were type 2 diabetes (T2D), in parallel with increase in the obesity rates [27]. Diabetic patients have 2–4 times higher risk of incidents of CVD [28]. Recently, global mortality directly related to diabetes was observed to be 2.9 million, about 5.2% of all deaths. Of this 2–3% was observed in the poorest countries, and over 8% was in the United States, Canada, and the Middle East. In people aged 35–64, this rates increased from 6% to 27% [29].

In the United States, approximately 70% of T2D patients are overweight and obese, and over a period of 10 years, the risk of diabetes rose to 27% in people who gained 5 kg or

more [30]. Specifically, central obesity is strongly related with metabolic disorders associated with insulin resistance and diabetes [31, 32]. The current advice to prevent and treat T2D includes maintaining an ideal body weight (BMI < 27–30 kg/m^2), physical activity, limiting the intake of sugar and saturated fat, and increasing the consumption of mono- and PUFA, as well as whole grains and fiber [33–35].

Obesity: Measurements and Assessment

Measuring body weight provides a sense of the degree of obesity; however, a more accurate and comparable measure of obesity is obtained by relating body weight to height [36]. The BMI is calculated as the ratio between weight and height squared ratio and expressed as kg/m^2. Based on the BMI measurement, it can be discriminated low, normal weight, overweight, and obese states in adults. The WHO has standardized BMI as (1) lower than 18 kg/m^2 as low weight; (2) between 18 and 25 kg/m^2 is normal weight; (3) between 25 and 29.9 kg/m^2 is overweight; and (4) greater than or equal to 30 kg/m^2 is obese [37, 38]. However, the BMI does not provide information about body composition (fat-free muscle mass/fat mass) nor about the pattern of body fat distribution. Thus, a better measure of obesity that overcomes these limitations is the measurement of percentage of body fat (BF%), which relates total weight to the weight of the fat mass. Of course, this is more difficult to measure than the BMI limiting its daily clinical use, but several accurate methods exist [39]. Body composition can be estimated from anthropometric measurements of skinfold thicknesses in several anatomical regions [40]. In research, BF% is determined by hydrostatic weighing (body weight by immersion) as the gold standard [41]. Alternatively, the bioelectrical impedance analysis technique can directly estimates the amount of the fat-free mass (FFM) and indirectly the body fat by subtracting from total body weight [42]. Individuals with normal weight or overweight, but that also have a high BF%, exhibit a cardiovascular risk which is comparable to those with obesity estimated by BMI. Of note, it is observed that at the age of 20, a BMI equal to 30 kg/m^2 implies a 30% of BF%. However at the age of 60, the same BMI represents a 40% BF% in men and up to 40–50% BF% in older women [43].

BMI informs neither the location nor distribution of the excess body fat. Central obesity occurs when the excess of fat accumulates in the intra-abdominal area, even at the expense of a decreased fat accumulation in the peripheral adipose tissue. Several parameters can be used to measure central obesity. The most widely used requires measuring the waist circumference (WC) and hip ratio (HR) to create the waist-HR (WHR). Subjects having a large WC have increased mortality [44] despite having a BMI < 30. Thus, high-risk individuals are better identified by incorporating WC and WHR measurements to BMI [45]. The WC measurement of central obesity varies with race and is currently accepted as >88 cm in women and >102 cm in men in the United States [46]. Finally, the relationship of waist circumference to height (WHtR) can also be used to identify adults at high cardiometabolic risk [47–49]. All these parameters help also to predict the risk of metabolic diseases such as T2D [50].

In research intensive settings, more complex and accurate techniques are available, such as dual-energy X-ray absorptiometry (DEXA), computed tomography (CT), and magnetic resonance imaging (MRI). DEXA estimates body fat distribution by scanning arms, legs, and trunk [51, 52]. Differentiation between abdominal subcutaneous fat and intra-abdominal fat, which is composed of visceral adipose tissue (VAT) and intraperitoneal and retroperitoneal fat, is better seen by MRI and CT [53, 54]. Finally, single-voxel magnetic resonance spectroscopy is the gold standard for measuring ectopic fat, outside anatomically defined fat depots. Ectopic fat can be estimated after separating water and fat signals within each voxel (using software such as jMRUI) [55, 56].

Adipocyte and Adiposity Development

Types of Adipocytes and Differentiation

When describing fat depots, it is important to differentiate two types of well-differentiated adipose tissues, which have specific distribution and function and are referred to as white adipose tissue (WAT) and brown adipose tissue (BAT) (Fig. 13.1). The WAT main function is the deposit of surplus energy as triacylglycerol (fat), which could be mobilized and offered to other metabolically relevant organs through hormonal signaling. The WAT is designed to be plastic and expand. In fact, WAT accounts from 5% to 50% of human body weight. However, WAT is also a main source of endocrine signaling [57]. One of the key hormones is adiponectin, typically associated with metabolically "healthy" expansion of adipose tissue facilitating adipocyte lipid storage and consequently preventing ectopic lipid accumulation. Conversely, leptin prevents lipogenesis while facilitating lipolysis and fatty acid oxidation. These actions may be mediated centrally by activation of sympathetic efferent signals to both brown adipose tissue and WAT to induce lipolysis. Leptin has recently been suggested as therapy for individuals with generalized lipodystrophy, who frequently develop severe metabolic syndrome characterized by hepatic steatosis, insulin resistance, and diabetes mellitus.

Physiological expansion of WAT involves different degrees of hypertrophy and/or hyperplasia of adipocytes and active remodeling of vascular and mesenchymal stromal cells.

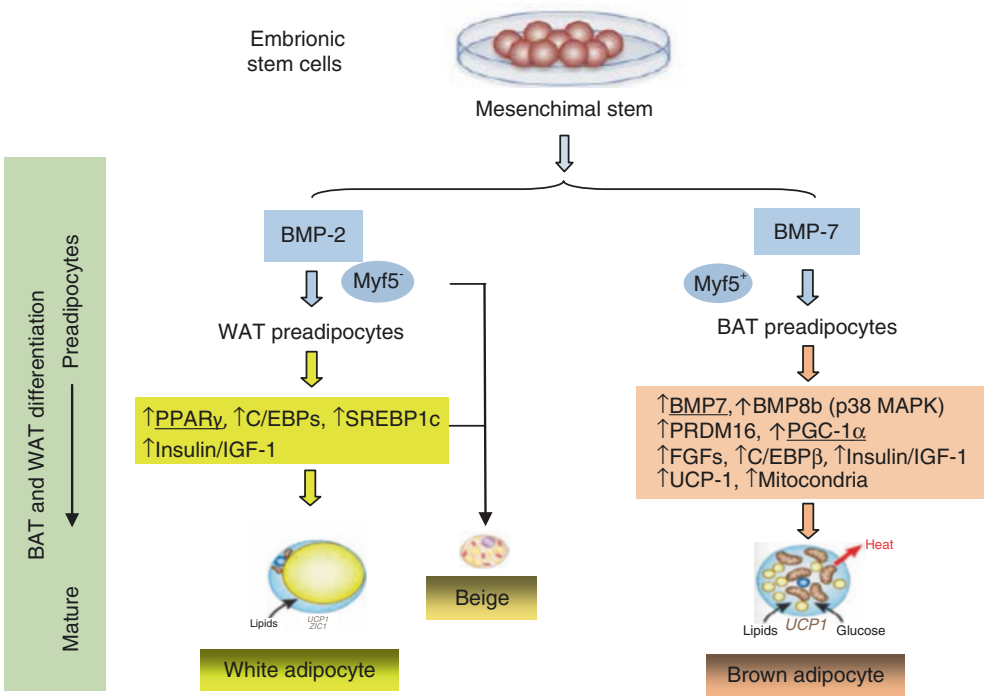

Fig. 13.1 Adipose tissue expands to store excess energy as fat and regulates fuel needs to other tissues. In WAT growth transcriptional factors such as the binding proteins CCAAT/enhancer-binding protein (C/EBP) and PPAR-γ are fundamental. Sterol regulatory element-binding transcription protein-1c (SREBP-1c) activates PPAR-γ expression [256] and mediates lipid biosynthesis by insulin [257]. Mature WAT is characterized by the expression of glucose transporter 4 (GLUT4) sensitive to insulin and enzymes like fatty acid synthase (FAS) and glycerol-2-phosphate dehydrogenase [258, 259]. During adipose tissue expansion, inappropriate vascular tissue development results in hypoxia, and death of adipocytes and macrophage infiltration is induced [260]. On the other hand, BAT derived from Myf5⁺ mesoderm progenitors shares a common origin with skeletal myoblasts [261]. The development of BAT requires that PRDM16 activates PPAR-γ coactivator (PGC-1α/β) or CtBPs and inhibits transcriptional factors that induce WAT [262, 263]. In addition, bone morphogenetic protein 7 (BMP-7) turns on a full program of brown adipogenesis involving induction of PRDM16 and PGC-1α and expression of UCP-1 which is a feature of brown cells [264]. Last, beige fat cells adapt functions, either like "WAT" when energy balance is exceeded or like "BAT" in response to stimuli similar to BAT activation. Today, research in identifying the main genes that control differentiation, development, and activation of BAT is highly active. (This work is licensed under a Creative Commons Attribution-NonCommercial (CC BY-NC 4.0) International License [231])

Also immune cells, endothelial cells, and undifferentiated or adipocyte precursor (AP) cells must also be coordinately developed [58]. Storage of excessive fat in WAT causes mechanical overload and contributes to increased risk of metabolic disorders. The repertoire of molecules secreted by adipocytes is not exhausted. Recently asprosin was described to be abundantly expressed in mature white adipocytes, accumulated in excess in the blood of humans with obesity and proportional to insulin levels, which has suggested asprosin levels may be associated with insulin resistance [59].

The role of BAT is thermogenesis contributing to energy expenditure and body weight regulation (Fig. 13.2) [60, 61]. In mammals, BAT is the primary site of thermogenesis in the absence of muscle contraction. BAT thermogenic function is mediated by the activation of a specific mitochondrial uncoupling protein 1 (UCP1) (Fig. 13.2). In humans, BAT function is particularly important for the control of body temperature after birth and in early childhood [62]. However, data from adipose tissue samples together with evidence provided by positron emission tomography coupled with computed tomography have established the existence of functionally active brown adipose tissue in adult humans [63–66]. Furthermore, some of these studies also relate the degree of activation of these sites with BAT and lower BMI, increased basal energy expenditure, and decreased onset of diabetes [67]. BAT in adult humans can be found in the cervical and supraclavicular [68] regions, depots identified as canonical BAT exhibiting similarities with the BAT in rodents. Lastly, recent studies have reported on secretory molecules from BAT, so-called batokines, which include fibroblast growth factor 21 (FGF21), neuregulin 4 (NRG4), vascular endothelial growth factor A (VEGFA), and bone morphogenetic protein 8B (BMP8B). These studies indicate that similarly to WAT, the BAT may also play a physiological role as an endocrine organ [69].

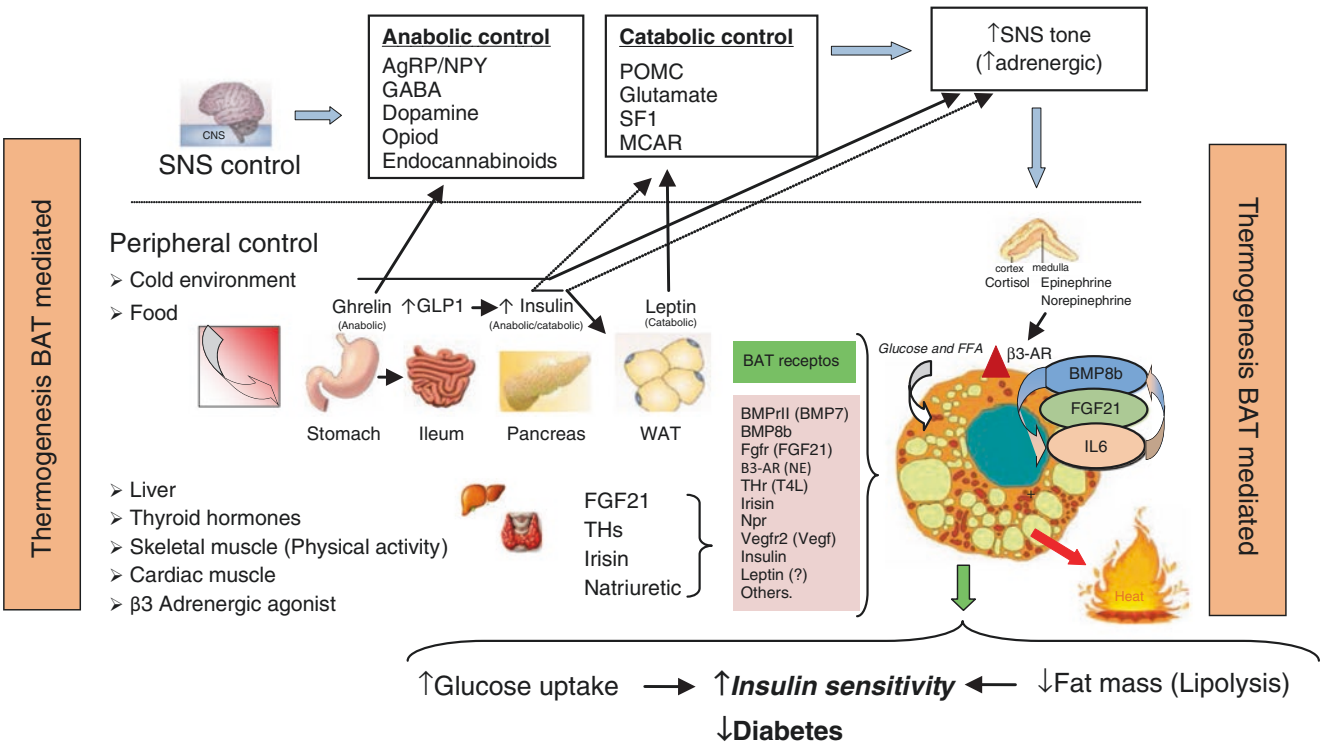

Fig. 13.2 *By contrast to WAT, brown adipose tissue* (BAT) was developed especially for energy expenditure (thermogenesis) mainly controlled by the SNS, which highly innervates brown fat cells. BAT is regulated in response to cold temperatures, hormones, and diet. BAT abundance and activation is highest in children and decreases with age. BAT activity decreases with BMI, body fat, and visceral obesity. Of note, BAT activity is lower in diabetics than nondiabetic subjects. Thyroid hormones play a key role in controlling BAT activation, such as the cold-induced deiodinates thyroxine (T4) to the more active T3. Norepinephrine binds to β-ARs inducing PGC1α and expression of UCP1. Whereas β1-AR mediates precursors of BAT proliferation, β3-AR plays a key role in the thermogenic function of BAT. Another signal, irisin hormone, released from muscle to fat tissue, mediates the beneficial effects of exercise reducing diet-induced obesity and improving insulin resistance. In addition, FGF21 is secreted by adipose tissue, liver, and skeletal muscle, through regulating lipolysis in WAT as well as increasing substrate utilization by increasing fatty acid oxidation in the liver. This actions may be mediated increasing activity of adiponectin. WAT white adipose tissue, BAT brown adipose tissue, PRDM16 PR domain containing 16, PPAR-γ peroxisome proliferator-activated receptor-γ, PGC-1α peroxisome proliferator-activated receptor γ coactivator 1α, SNS sympathetic nervous system, BMI body mass index, FGF21 fibroblast growth factor 21. (This work is licensed under a Creative Commons Attribution-NonCommercial 4.0 International License [231])

On top of white and brown adipocytes, a third fat cell named beige/brite, which shares similarities with brown adipocytes, are found infiltrating skeletal muscle as well as in diverse areas of WAT [70]. Of note, beige cells are Myf5-positive cells, a classical feature of BAT, and appear dispersed in WAT [71]. The term "beige" describes their similar morphology with white adipocytes but the inducibility of features similar to brown adipocytes including UCP1 activity with β-adrenergic stimulation [72, 73]. There is also evidence that beige mature adipocytes can be interconvert between typical white and brown adipocytes, without the need for "de novo" cell differentiation from precursor cells [73]. A priori, this could mean that the rate of lipid storage or lipid oxidation could be adapted and adjusted in response to external stimuli such as a decrease or increase in temperature. Results from mice indicate that activated beige cells may contribute to improve carbohydrate metabolism and prevent/reverse fatty liver [74]. In any case, the physiological relevance of these cells in humans is far from being confirmed.

Effects of Hormones and Adipokines on Adipogenesis and Glucose Metabolism

Adipose tissue development and function are modulated by hormones, growth factors, secreted molecules by adipose tissue cells, nutritional factors, and pharmacological drugs (Fig. 13.2).

Hormones and Growth Factors

Insulin is key anabolic hormone that contributes to adipocyte differentiation and lipogenesis [75]. Brown preadipocyte determination is also regulated by insulin through a necdin-

E2F4 interaction that represses peroxisome proliferator-activated receptor-γ (PPAR-γ) transcription [76]. When in excess, hyperinsulinemia, either exogenously or endogenously, is a major enabler of adipose tissue expansion contributing to weight gain. Several molecules produced by cells from the adipose tissue, such as tumor necrosis factor alfa (TNF-α), leptin, and resistin, interact and inhibit insulin signaling on adipocytes.

Glucocorticoids and sexual hormones also affect the functionality and development of the adipose. For instance, the infusion of hydrocortisone increases levels of circulating free fatty acids (FFAs) by activating the mechanisms of lipolysis [77, 78]. Glucocorticoids promote adipogenesis by increasing the expression of both PPAR-γ transcription factors and C/EBPδ and decreasing the expression of pref-1 [79]. The adipocyte also has a complete arsenal of enzymes that regulate the metabolism of steroid sex hormones [80]. Glucocorticoids control activity of 11-β-hydroxysteroid dehydrogenase 1 and 2 (11 βHSD1 and 2) that can change the active form cortisol to inactive cortisone and vice versa [81]. Of note this enzyme is highly expressed in visceral adipose tissue which may contribute to regional redistribution of fat [82, 83]. Another key aspect related to adipose tissue distribution is in sex steroids. Body fat distribution is different in men and women, and adipose tissue has activity of either cytochrome P450-dependent aromatase or 17-β-hydroxysteroid dehydrogenase (17βHSD) enzymes that can modify the repertoire of steroids. Aromatase mainly regulate the rate of transformation of androgens into estrogens, while 17βHSD regulate the formation of a more active form of androgens. Of note, the ratio 17βHSD/aromatase in adipose tissue correlates directly with central obesity [80, 84].

Thyroid hormones are main contributors to global growth and development [85] by exerting an important role controlling energy metabolism and the function of the main metabolic organs such as the adipose tissue, liver, heart, skin tissue, or muscle [86, 87].

Growth hormone and insulin like growth factor 1 Growth hormone (GH) is critical for somatic growth but also has enormous influence of the regulation of body fat composition and distribution, through its lipolytic and anabolic effects [88].

Major Adipokines

Adipose tissue contributes to the metabolic control of energy substrates such as glucose and lipids and interacts with several hormonal systems. The molecules produced by adipose tissue (adipokines) act in many organs including adipose, muscle, and CNS. In obese and insulin-resistant patients, there are qualitative and quantitative changes in the repertoire of adipokines. For example, some adipokines increase (e.g., leptin, resistin), while others decrease (e.g., adiponectin) [89] (Figs. 13.2 and 13.3).

Leptin Leptin is secreted by adipocytes, establishing a negative feedback between the amount of adipose tissue and satiety centers in the brain [90, 91]. Leptin also serves as a sensor of energy availability enabling energy demands such as pregnancy and adaptation to starvation [92]. Leptin levels decrease after weight loss, enabling saving energy adaptive response involving low thyroid activity, sympathetic tone, and decreased basal energy expenditure [93]. Thus, treating leptin deficiency with recombinant leptin not only reduces food intake and body weight [94] but also reverses infertility, prevents lipodystrophy-associated metabolic complications, and reverses impaired glucose metabolism [95–98]. The leptin action appears to be facilitated by insulin, glucocorticoids, TNF-α, estrogens, and C/EBPα and is decreased by androgens, β3-adrenergic activity, GH, FFAs, and PPAR-γ agonist [99].

Leptin also plays an essential role in energy metabolism, by facilitating lipid mobilization and preventing ectopic fat accumulation (lipotoxicity syndrome) [100, 101]. Leptin facilitates lipid oxidation and by doing so can reduce excessive fatty acid accumulation in the liver, pancreas, heart, kidney, and muscle tissue (Figs. 13.2 and 13.3).

Adiponectin Adiponectin is produced in mature adipocytes and is more abundant in peripheral subcutaneous than visceral adipose tissue [102]. Adiponectin receptors are G protein-coupled highly expressed in the muscle (AdipoR1) and liver (AdipoR2) [103]. Through them adiponectin promotes lipid oxidation in skeletal muscle and the liver and reduces hepatic glucose production and postprandial hyperglycemia [104, 105] contributing to maintain metabolic homeostasis.

Adiponectin deficiency, as observed in obesity, plays a role in the development of insulin resistance and type 2 diabetes as suggested by the following: (a) Adiponectin levels have an inverse relationship with degree of obesity, insulin resistance, and T2D [106, 107], which is reversed by adiponectin treatment which results in improvement of IR [108]. (b) Adiponectin reduces FFA levels and is associated with improved lipid profile, glycemic control, and reduced inflammation in T2D patients [109]. (c) TNF-α plasma levels and its hepatic production are decreased by adiponectin treatment, which also improved hepatomegaly, steatosis, and ALT levels related with nonalcoholic fatty liver disease (NAFLD) [105] (Fig. 13.3). (d) The PPAR-γ agonists (thiazolidinediones, TZDs) redistribute lipids from central

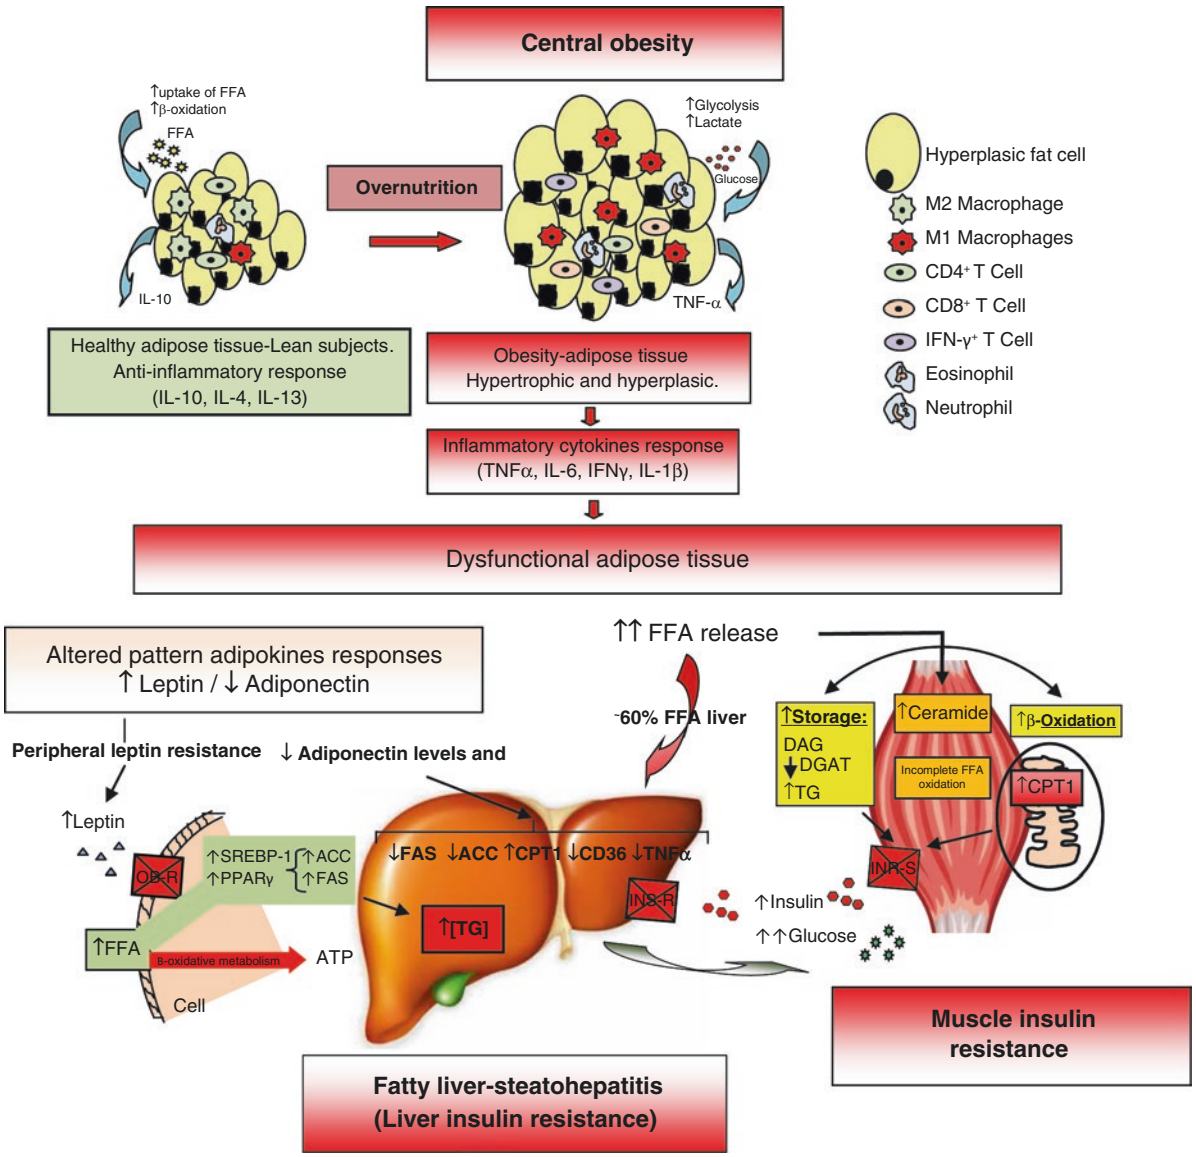

Fig. 13.3 Dysfunctional adipose tissue. When adipose tissue expands, it is slowly infiltrated by macrophages, and a low-grade chronic inflammatory state is developed [193, 265]. Several macrophage subtypes can be seen, which can be divided into pro-inflammatory M1 or alternatively activated M2 [266]. Adipocytes, macrophages, and immune T cells contribute to the production of inflammatory cytokines [127, 174, 193, 267]. The M1 macrophages are induced from precursor M0 macrophages by stimulation of type 1 T-helper (Th1) inflammatory cytokines like IFN-γ and TNF-α and lipopolysaccharide, whereas the M2 macrophages are induced by type 2 T-helper (Th2) cytokines such as IL-4 and IL-13. While adipose tissue of obese subjects shows mainly M1 macrophages, lean subjects have high levels of M2 macrophages. M2 macrophages are involved in remodeling and tissue repair through the action of IL-10, IL-1 receptor antagonist, and arginase-1, which result in better insulin sensitivity. Whereas M1 macrophages use glucose for energy, M2 macrophages activate the β-oxidation of fatty acids [266, 268]. Finally, M1 macrophages are a principal source of TNF-α which, by activating Wnt signaling and suppressing expression of PPAR-γ, interferes with the development and function of adipocyte and reduces the capacity to store triglycerides [269, 270]. Peripheral adipose tissue will expand to an equilibrium point, and when exceeded (inflexibility), glucose and lipid uptake decline, while insulin levels rise in order to maintain serum glucose within the normal range [271]. In addition, inflexibility is associated with early insulin resistance which increases lipolysis in adipose tissue, generating a redistribution of fats with systemic lipotoxic effects in the muscle, liver, β-cell, etc. (lipotoxicity). Furthermore, increased TNF-α and IL-6 levels are inversely related with peripheral and hepatic insulin-mediated glucose uptake [180]. The liver takes up excess released of FFA in serum to capacity by storing with triacylglycerol (TAG) and slowly fatty liver could be developed (NAFLD). Peripheral FFAs contribute ~60% of total TAG stored in the liver, whereas the de novo lipogenesis is ~26%, and ~15% is from food [230]. On the other hand, leptin levels rise with adipose expansion, while adiponectin levels tend to decrease. The elevated leptin levels should increase β-oxidation in non-adipose tissues, decreasing excess fatty acids in these cells. However, this action may be partially blocked by the anabolic effect of hyperinsulinemia, inducing a leptin system dysfunction (peripheral leptin resistance) [89]. In addition, adiponectin action improving peripheral glucose uptake and adiponectin protective action on liver fat accumulation are decreased [105]. Finally, both leptin and adiponectin seem to regulate the deposition of fat in insulin-sensitive tissues by increasing β-oxidation. IFN-γ interferon-γ, TNF-α tumor necrosis factor-α, IL interleukin, PPAR-γ peroxisome proliferator-activated receptor-γ, WAT white adipose tissue, FFA free fatty acids, NAFLD nonalcoholic fatty liver disease, CPT-1 carnitine palmitoyltransferase-1, FAS fatty acid synthase, ACC Acetyl-CoA carboxylase.

to peripheral depots and also increase adiponectin levels and improve lipid profile and insulin sensitivity while improving diabetes and NAFLD [110]. This suggests that maintaining normal levels of adiponectin may help in the treatment of early-stage diabetes. However, the relationship between adiponectin levels and cardiovascular disease is not well established [111].

Others Adipokines

Resistin has also been related to obesity, insulin resistance, and development of T2D. Blocking the action of resistin improves insulin sensitivity [112]; however, the significance of resistin in glucose metabolism in human still is inconclusive.

Visfatin is produced predominantly by abdominal adipose tissue and has been suggested to have insulin-mimetic actions [113, 114]. However, the importance of visfatin in glucose metabolism is still unclear [115].

Omentin-1 Obesity decreases both omentin plasma levels and omentin gene expression in visceral adiposity [116]. In obese women with polycystic ovary syndrome (PCOS), glucose and insulin levels were negatively related with omentin-1 levels, whereas metformin treatment increased serum omentin levels in parallel with improvements in insulin sensitivity and glycemic control [117, 118].

Obestatin is a hormone that opposes the effects of orexigenic effect of ghrelin. Obestatin decreases in subjects with diabetes and impaired glucose tolerance [119], and its receptors are downregulated in obesity-associated T2D [120].

Retinol-binding protein 4 Retinol-binding protein 4 (RBP4) is released from adipocytes and correlates with the degree of insulin resistance in obesity, T2D, and relatives of T2D patients [121–123]. The specific role of RBP4 in insulin resistance has not been determined.

Asprosin Is a 140-amino-acid polypeptide, recently described, abundantly secreted, and expressed in WAT. Levels of asprosin are increased in fasting situations in healthy humans. Asprosin acts on the liver stimulating hepatic glucose production. Asprosin administration induces a quick increase in plasma levels of glucose and insulin. Blocking asprosin actions might be beneficial for the treatment of type 2 diabetes mellitus [59].

Inflammatory Adipokines

TNF-α is a transmembrane protein released mostly by activated macrophages and also by other cell types including endothelial cells, adipocytes, etc. [124–126] (Fig. 13.3). Both TNF-α gene and its receptors are present in adipocytes and are expressed at higher levels in WAT [102]. TNF-α contributes to local and systemic inflammation, which limits the proliferation and differentiation of mature adipocytes. Increased release of TNF-α from adipose tissue contributes to the impairment of insulin action [127–129] and treatment with anti-TNF-α antibody led to improvement in glucose utilization in obese rats [127] at least. Similarly, obese mice genetically modified to ablate TNF-α had close to normal insulin sensitivity [129]. Moreover, weight reduction is associated with both improved insulin activity and decreased TNF-α gene expression [130]. The mechanism how TNF-α promotes insulin resistance may involve the decrease in the expression of PPAR-γ and target genes involved in lipid and glucose uptake [131, 132]. A link between fatty acid binding protein 4 (aP2), FFAs, and increased expression of TNF-α in obesity has been suggested [128]. Not only TNF-α but also interleukin-6 (IL-6) were both increased after nutritional fatty acid activation of Toll-like receptor 4 (TLR4) [133].

IL-6 is secreted by adipose tissue, T cells, and macrophages (Fig. 13.3). Adipocytes can produce IL-6, which is associated with C-reactive protein (CRP) levels and inflammatory states typically found in obese patients [134]. About 1/3 of the total concentration of IL-6 is produced in adipose tissue, mainly by visceral adipose tissue compared with peripheral adipose tissue [102]. It has been suggested that IL-6 levels are directly linked to obesity and insulin resistance [135] and to the inhibition of the activity of lipoprotein lipase (LPL) [136].

Chemokine molecules are potent chemoattractants of leucocytes and modulate the formation of reactive oxygen and cytokines. The chemokine molecule 5 (CXC ligand 5, CXCL5) is expressed at high levels by the macrophage of white adipose tissue [137]. Serum levels of CXCL5 are elevated in obese patients independently of their degree of insulin resistance above the levels observed in normal-weight subjects [137]. Furthermore CXCL5 serum levels are reduced after weight loss.

Fatty Acid Metabolism Effects on Adipogenesis and Glucose Metabolism

FFAs are energy-rich molecules fundamental regulators of metabolism. Excess calories ingested as fat, protein, and carbohydrates end up stored as triglycerides in white

adipocytes. FFAs are also essential constituents of the cell membrane, influencing its fluidity and the topology of receptors, transporters, and other membrane proteins. In addition, FFAs can have hormone-like actions and serve as ligands of nuclear receptors controlling gene expression [138]. Although food is the main source of essential fatty acids, de novo endogenous biosynthesis could supply nonessential fatty acids [139].

Both linoleic acid (ω-6 series) and linolenic acid (ω-3 series), have been related to decreased insulin resistance and CVD, must be included in the diet [140]. By contrast, excess saturated fatty acids and trans fats in the diet are associated with increased insulin resistance and risk of CVD [140].

LPL activity is increased by insulin and depends on apo CII and apo CIII being released by adipocytes. LPL is essential for FFA uptake from lipoproteins and storage [141]. In addition, cytoplasmic fatty acid-binding proteins (FABPs) facilitate intracellular transport and partition of FFA to specific compartments and functions [142]. FABPs link lipid metabolism, hormone action, and systemic energy homeostasis involving glucose metabolism [128].

De novo biosynthesis of saturated chain fatty acids is carried out mainly in the liver where acetyl-CoA is formed from pyruvate. Most de novo FFA are synthesized from acetyl-CoA and malonyl-CoA through two enzymatic steps, including acetyl-CoA carboxylase (ACC) and fatty acid synthase (FAS). The ACC controls production of short fatty acids which are elongated until 16-carbon palmitic acid is formed by FAS (cytosol). Nearly all fatty acids required can be synthesized from palmitic acid by several steps of oxidation and elongation [143]. Finally, various enzymes which regulate the synthesis of triglycerides are also implicated in glucose metabolism [144]. Overexpression of diacylglycerol acyltransferase 1 (DGAT1) results in increased adipose tissue without affecting IS but increases the secretion of TNF-α [145]. A remaining question is whether de novo lipogenesis originated from fatty acids may have a specific fate or contribute to specific functions different from the pools of FAs generated from dietary nutrients.

Obesity Effects on Pathogenesis of Type 2 Diabetes

Type 2 diabetes mellitus (T2D) is characterized by hyperglycemia, insulin resistance, and inappropriately low secretion of insulin. The prevalence of T2D has increases in parallel with the increased prevalence of obesity [146] and sedentary lifestyle [147]. Pathogenesis of common forms of T2D is complex [148], requiring the combination of different degrees of insulin resistance and insulin deficiency [149]. In addition, insulin resistance and defects in insulin secretion can be determined via genetic and/or varying environmental factors, complexity that makes difficult to isolate a single cause in diabetic patients [150]. However, it is clear that the final development of diabetes requires beta cell failure as suggested by the fact that obese subjects do not necessarily develop T2D.

The potential molecular links between obesity and increased risk of T2D include exacerbated inflammatory response with excessive cytokine secretion (TNF-α and IL-6), insulin resistance, defects in fatty acid metabolism and lipotoxicity, mitochondrial dysfunction, and endoplasmic reticulum stress. However, weight loss is a central intervention working on most forms of prediabetes, because even modest weight loss improves glycemic control and reduces diabetes risk.

The risk of T2D and cardiovascular disease rises with the amount of body fat and more particularly when fat accumulates in central or abdominal depots [151]. Whether subcutaneous fat deposition is less pathogenic than visceral fat is quite likely but requires further investigation. In addition, the contribution of the subtypes of adipose tissue to glucose metabolism is important. For instance, increased level of brown adipose tissue may help to control carbohydrate metabolism and prevent or reverse obesity [63, 152].

Infiltration of immune cells in adipose tissue can alter its metabolic functions. Although the adipose tissue is not the cause of obesity per se, taking advantage of the specific functions of the repertoire of fat cell types and functional characteristics of the depots including the immune cells may help to uncouple obesity from its complications.

The main proposed mechanisms linking obesity to insulin resistance and T2D include (1) increased and altered secretion of adipokines (TNF-α, adiponectin, leptin, etc.) directly to inflammation and insulin resistance; (2) ectopic fat deposition, predominantly in the liver, skeletal muscle, and ß-cell, contribute to altered fat, insulin resistance, and glucose metabolism; and (3) mitochondrial dysfunction causing a bioenergetic cellular defect leading to decreased insulin sensitivity and defective pancreatic ß-cell function.

Effects of Fetal Develop on Adult Glucose Metabolism

The Nurses' Health Study (NHS) of over 69,000 women found an inverse relationship between birth weight and adult diabetes [153]. A meta-analysis with an adjusted odds ratio of diabetes of 0.80, 95% CI 0.72–0.89 for each 1 kg increase in birth weight confirmed this [154]. However, a higher birth weight (>4.0 kg) is also be associated with an increased risk of diabetes [155]. Lastly, a U-shaped relationship between birth weight and the development of T2D was found in a meta-analysis. Thus, high and low birth weight are associated with a similar increased risk of diabetes (ORs 1.36 and 1.47) [156] although not necessarily attributable to the same mechanisms.

Effect of Adult Obesity on Glucose Metabolism

After absorption in the intestine and after synthesis in the liver, triglycerides (TG) are transported in specialized lipoproteins [chylomicron and very low-density lipoprotein (VLDL)] to adipose and other tissues. Intracellular toxic accumulation of diacylglycerol and the input and output flows of FFA and acyl-CoA can be ameliorated by the formation and safe storage as TG [157]. Droplets containing TG are surrounded by a monolayer of phospholipids and proteins, e.g., perilipin (ADRP), which regulates lipid droplet formation, growth, and dissolution [158].

Obesity and Lipotoxicity Syndrome

The main function of the adipose tissue is fat storage. Adipose release of FAs and uptake into non-adipose tissues must be coupled matching demand and supply. For instance, in fasted state or during physical exercise, the lipolysis in adipose tissue is increased, a process that requires the coordination of suppression of plasma insulin and elevation of contrainsulin hormones (glucagon, cortisol, epinephrine, etc.). However, in obesity, it is quite normal to reach a prolonged overfeeding state, where fat load may exceed the functional storage capacity of the adipose tissue determining a state of metabolic inflexibility, where lipid uptake and mobilization is inefficient (inflexibility) (Fig. 13.4).

Another factor contributing to its functional defect is the adipocyte cell size. When adipocytes enlarge in an attempt to increase their capacity, they also become insulin resistant. This makes that the antilipolytic effect of insulin is reduced and that lipolysis of triglycerides from the adipose tissue as a whole increased and the bulk FFA release is increased. This leak of FFA and accumulation in plasma subsequently promotes insulin resistance in the muscle and liver [159] and also inhibits insulin secretion [160], ultimately causing β-cell apoptosis [161].

Among the most important factors controlling adipocyte capacity for storage and functional switch between storage and lipolysis, we identify the nuclear receptor PPAR-γ as a key transcription factor that controls the coupling between lipid storage and adipogenesis and lipolysis [162]. In addition, the direct role of leptin on adipose tissue functionality has been suggested. However, common forms of obesity are typically characterized by leptin resistance predominantly located at central hypothalamic action [163]. Leptin action central and/or peripherally appears to be implicated in processes that prevent lipotoxicity in non-adipose tissues through the regulation of β-oxidation mediated in part by its effects through peroxisome proliferator-activated receptor-α (PPAR-α) activity. This proxidative effect helps to minimize the metabolic burden of ectopic accumulation of lipids. Patients with insulin resistance syndrome have lower mRNA leptin abundance in peripheral adipocytes than IS patients (leptin resistance), even though insulin treatment acutely increases leptin levels [89, 164]. Another factor to consider is that a chronic increase of β-oxidation may contribute to oxidative stress and to generate inflammation, which may be potentially harmful [163].

Adiponectin, another adipose tissue derived hormone, also has a major role in improving insulin sensitivity, anti-inflammatory, anti-apoptotic, and pro-angiogenic effects that enhance whole body and adipose metabolic flexibility. Adiponectin action in adipose tissue improves both, the efficiency of the adipose tissue at regulating the releases of FFAs and increases the rate of FFA reesterification during the postprandial state [165]. However, the low serum adiponectin levels typically observed already in the early stages of insulin resistance are not sufficient to prevent the subsequent derail of adipose tissue function [89]. As part of the natural history toward the development of diabetes, there is progressive failure of the adipose tissue homeostatic mechanisms. When they are overwhelmed, lipids cannot be hold efficiently in the adipose tissue and accumulate in tissues that cannot store excess lipids such as the muscle, β-cells, liver, heart, and kidneys [101] without triggering metabolic toxic responses.

In addition with the leak of FAs, the dysfunctional adipose tissue also produces and releases an abnormal pattern of adipocytokine (e.g., decreased adiponectin and increases leptin, TNF-α and IL-6). This promotes an inflammatory state that further compromises the insulin sensitivity and functionality of the adipose tissue depot. Advancing in the natural history, the development of central obesity further exacerbates hyperinsulinemia and hyperglycemia, initially in the postprandial state and finally to global hyperglycemia. This phenotype is typically associated with hypertriglyceridemia, hypoalphalipoproteinemia, hypertension, and fatty liver (dysfunctional metabolism in the liver), a cluster of pathologies commonly diagnosed as metabolic syndrome (MetS) [166].

Pathogenesis of Obese Type 2 Diabetes

Obese T2D is typically associated with four clinical and metabolic defects: obesity, insulin resistance, dysfunction of β-cells, and increased hepatic endogenous glucose production [167]. However, the mechanisms by which these defects progress, the way they affect each other and contribute to the increase of glucose levels in obese T2D, are not fully elucidated. In a landmark longitudinal

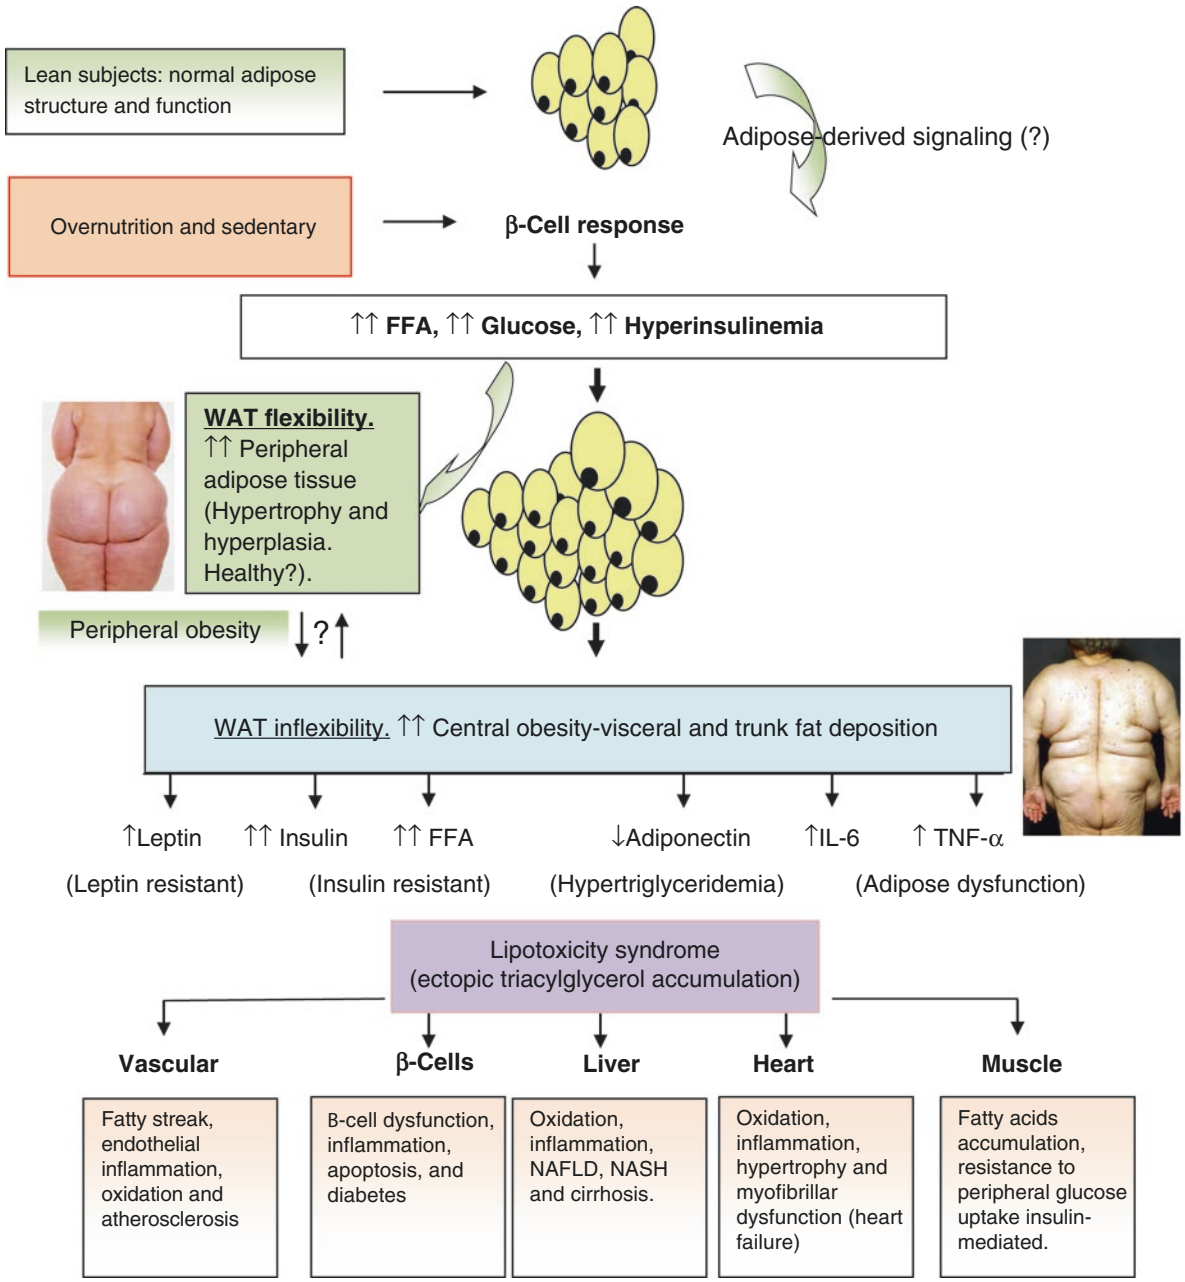

Fig. 13.4 Adipose tissue expandability and metabolic syndrome. After overeating with positive energy balance, adipose tissue increases its storage capacity, which is regulated by several factors. In individuals with a high capacity for storing fat, mainly when WAT is expanded (WAT flexibility), most, despite obesity developing, will remain normal, known as metabolically healthy obese (MHO). However, a low-grade chronic inflammatory response is frequently observed leading to dysfunctional adipose tissue [272]. Therefore, a pro-inflammatory milieu with elevation in IL-6 and mainly TNF-α, an altered adipokines profile with decreased adiponectin and increased leptin levels, will result in a dysfunctional adipose system. Increased release of cytokines and adipokines is related to insulin resistance, hyperglycemia, altered lipid profile, and cardiovascular diseases [89, 273, 274]. Insulin resistance is associated with the accumulation of lipids in non-adipose tissues such as muscle (lipotoxicity), due to increased lipolysis of fatty acids from adipose tissue. On the other hand, when the maximal storage capacity of adipose tissue is achieve, dysfunctional adipose tissue results, and redistribution of fat is initiated. Limitation in fat storage capacity could be necessary and even precedes the development of metabolic factors. Ectopic lipid accumulation in non-adipocyte cells causes lipotoxicity in these organs, including inflammation and apoptosis. Thus, lipotoxicity in β-cells could decrease β-cell mass (β-cell dysfunction) and can cause diabetes. Increased fat in the liver leads to NAFLD and nonalcoholic steatohepatitis (NASH) and could cause hepatic dysfunction, myocardial dysfunction in the heart, the endothelial fatty streak that could be a precursor of generalized arteriosclerosis, etc. The point at which adipose tissue begins to fail is probably influenced by genetic and epigenetic factors. However, the question is: Can storage capacity in WAT be enhanced to meet an increased demand? [275] One answer in humans is treatment with PPAR-γ agonists (TZDs) that transfer fat from central to peripheral deposits, improve lipid profile and insulin sensitivity, and reduce diabetes and NAFLD [110]. WAT white adipose tissue, MHO metabolically healthy obese, IL interleukin, TNF-α tumor necrosis factor-α, NAFLD nonalcoholic fatty liver disease, NASH nonalcoholic steatohepatitis, PPAR-γ peroxisome proliferator-activated receptor-γ, TZD thiazolidinedione. study of obese subjects with high incidence of T2D (Pima Indians of Arizona), peripheral insulin effect (euglycemic clamp), acute insulin response (AIR), and endogenous glucose production, in those whom glucose tolerance deteriorated from normal (NGT) to impaired (IGT) to T2D over 5.1 ± 1.4 years, were measured [167]. Patients who developed IGT typically presented increased body weight, decreased insulin sensitivity, and defective acute insulin secretion. In those who developed an open T2D, a greater increase in body weight, coupled with a more severe insulin resistance and deterioration of insulin secretion, and further increase of hepatic glucose production (HGP), was observed. By contrast, overweight patients who maintained normal glucose tolerance still gained weight associated despite decreased insulin-stimulated glucose disposal; however they maintained a robust insulin secretory response (AIR that was increased).

Another organ that is gaining relevance in metabolic failure associated with diabetes is the gut. The gastrointestinal tract should be considered as a large and specialized endocrine organ that releases two major incretin peptides: the glucagon-like peptide1 (GLP-1) by L-cells (distal small intestine) and glucose-dependent insulinotrophic peptide (GIP) by k-cells (early small intestine). GLP-1 and GIP jointly contribute to rise by 60–70% insulin released in response to a mixed meal [168]. In the context of the obese T2D patients, their β-cells generate resistance to GLP-1 and GIP [169]. Thus, despite their levels being normal or minimally reduced, their signaling in beta cells is dysfunctional. Moreover, GLP-1 also reduces glucagon releases by α-cells on the pancreas and reduces appetite. Finally, in these patients the GLP-1 resistance results in hyperglucagonemia and increased HGP and contributes to weight gain by promoting an orexigenic response [170].

The kidney is another point of metabolic control [171]. The kidney generates about 15–20% of the endogenous glucose production, mainly in fasting period, and is controlled by insulin function. But, the kidney in obese T2D is insulin resistant leading to an increase in its glucose production increases. Furthermore, the glucose filtered is efficiently reabsorbed by sodium glucose transporter 2 (SGLT2) (80–90%) and SGLT1 (10–20%). During early stages of hyperglycemia, this capacity of reabsorption is increased and contributes to maintain elevated glucose levels but also to retain sodium and water which may contribute to increase high blood pressure.

Contributing to the phenotype, it could be argued that as insulin and amylin, which is released together with the insulin, have anorectic signaling properties acting in hypothalamus, in obese T2D this signal of insulin is likely to be dysfunctional so that appetite is not suppressed which may contribute to overweight [172, 173].

Underlining Factors of Obesity-Induced Insulin Resistance

(a) *Inflammation and insulin resistance*

Long-time overfeeding and positive energy balance require adipocytes to increase their number and size. Excessive expansion of adipose tissue is associated with metabolic dysfunction, changes in adipokines, increased hypoxia, immune cell infiltration, and attempts to remodel, cell death, and apoptosis. Inflammation is part of an early homeostatic response aimed to repair of damaged tissues (Figs. 13.3 and 13.4).

Enlargement of adipose tissue is associated with secretion by adipocytes of monocyte chemoattractant protein (MCP)-1, which promotes monocyte infiltration in WAT and differentiation in adipose tissue macrophages (ATM) [174]. Moreover, adipocytes also induce the expression of the adhesion molecules ICAM-1 and platelet and endothelial cell adhesion molecule 1 (PECAM-1) on endothelial cells, which further attract monocytes [175]. The physiological role of this process is to facilitate the physiological remodeling of an expanding tissue. In obesity, failure to maintain the homeostasis of the organ results in uncontrolled inflammatory response generating a chronic low-grade inflammatory state. ATM contributes to the release of inflammatory factors. Of relevance macrophages share many adipocyte genes such as fatty acid-binding protein 4 (FABP4) and PPAR-γ, whereas adipocytes can express numerous macrophage factors such as TNF-α, IL-6, and MMPs [176]. Moreover, ATMs have been artificially classified as M1 pro-inflammatory and M2 anti-inflammatory macrophages on the basis of membrane markers. In obesity typically, there is an enrichment with a greater ratio of activated M1 than M2 macrophages [177, 178]. These pro-inflammatory M1 ATMs secrete pro-inflammatory cytokines such as TNF-α, IL-1β, and IL-6, whereas M2 ATMs secrete anti-inflammatory cytokines including IL-10 and IL-1 receptor antagonist [178]. Of relevance the preferential type of ATM and degree of infiltration are linked with the progression of insulin resistance [179]. Hence, oversecretion of TNF-α from macrophages and to a lesser extent by adipocytes is a major characteristic of obesity and contributes to insulin resistance of obese humans [127, 180] (Fig. 13.3).

Inflammation of adipose tissue in obesity also involves infiltration of different T cells. Regulatory T cells (T_{reg}) represent 5–20% of the $CD4^+$ T cells and play a major role in controlling immune actions [181]. T_{reg} release anti-inflammatory cytokines, preventing macrophage infiltration and promoting a M2 macrophage phenotype [179]. Of relevance, with weight gain, a decrease in T_{regs} is observed [181], whereas there is an infiltration and activation of $CD8^+$ T cells that contribute to attract macrophages in the early stages of obesity [182].

Another relevant type of immune cells are the eosinophils, main contributors to IL-4-secretion, representing about 4–5% of cells in WAT. Macrophages are the main target of IL4 promoting an anti-inflammatory M2 phenotype which can improve glucose metabolism through preservation of M2 macrophages in WAT [183]. Lastly, neutrophils also seem to participate in the immune cell infiltration of the AT, contributing to obesity-induced insulin resistance [184].

Insulin sensitivity is affected by inflammation through various mechanisms. *TNF-α* inhibits insulin action by altering insulin receptor substrate 1 (IRS-1), though the activation of its p55 receptor [185]. In addition, TNF-α, FFA, ROS, and hypoxia activate IκBα kinase β (IKKβ) and c-Jun N-terminal kinase 1 (JNK1) in WAT and the liver inhibiting insulin activity by changing phosphorylation of IRS-1 [186, 187]. Furthermore, TNF-α also inhibits PPAR-γ function, with it impairs lipid synthesis and fat store in WAT. Moreover, inflammation increases plasma FFA levels through stimulation of lipolysis and reduction of TG synthesis, inducing insulin resistance in adipose tissue [188].

IL-1β activity requires two stress response signals. The first, necessary for production of pro-IL-1β, needs the activation of TLR4 (LPS, SFA, etc.) [189]. The second, which converts pro-IL-1β to active IL-1β, is controlled by the NOD-like receptor (NLRP)3-caspase 1 inflammasome complex [190]. Formation of NLRP3 inflammasome is induced by stressors that include FFAs, glucose, adenosine triphosphate (ATP), uric acid, ROS, etc. [191]. Thus, activation of the NLRP3 induces caspase-1 activity that converts pro-IL-1β to mature IL-1β. The major roles of NLRP3 inflammasome and caspase-1 activity in obesity-induced IR have been recently described [192].

Interleukin-6 is secreted by the WAT, skeletal muscle, and liver [193, 194]. Plasma IL-6 levels increase in overweight patients [195] in response to high levels of insulin and TNF-α. IL-6 inhibits insulin action through phosphorylation of IRS-1 [196]. In addition, raised IL-6 plasma levels are also associated with steatohepatitis and liver dysfunction [194]. However, IL-6 appears to stimulate insulin secretion by increasing the number of GLP-1 receptors in β-cells [197]. Thus, increased IL6 may contribute to the early increase of insulin secretion observed in obese patients. In addition, while elevated IL-6 secretion from WAT and the liver appears to have adverse metabolic effects, increased IL-6 secretion by skeletal muscle seems to be metabolically advantageous. In fact, physical inactivity has been shown to reduce skeletal muscle IL-6 expression and secretion [198]. The difference may be that whereas the increase in plasma IL-6 levels induced by exercise results from glycogen/MAPK activation and activation of anti-inflammatory levels of IL-1RA and IL-10 levels [199], the IL6 secretion from adipose and the liver is mediated by NF-κB, thus emphasizing the pleiotropic role of IL-6.

Finally, *interleukin-10* is an anti-inflammatory cytokine produced by monocytes, M2 ATMs, DCs, T cells, and B cells. Thus it is expected to play a favorable role in obesity-induced IR. Of relevance IL-10 is decreased in T2D [200], whereas weight loss increases IL-10 expression in WAT concurrent with diminished pro-inflammatory gene expression [201].

(b) *Mitochondrial dysfunction and obesity-induced insulin resistance*

Mitochondria is the main site for oxidation of fatty acids and glucose; thus its dysfunction may contribute to FFA and lipid accumulation and favor IR [202]. Mitochondrial biogenesis is activated by insulin and diminished in subjects with IR [203, 204]. In humans the existence of mitochondrial dysfunction in obese T2D who display lower NADH:O_2 oxidoreductase activity and reduced mitochondrial size than lean subjects has been observed [205]. Moreover, mitochondrial dysfunction in obese and insulin-resistant patients decreases lipid metabolism in muscle compared with lean control subjects [205–207]. Therefore, when mitochondria is exposed to excess lipids for β-oxidation, the oxidation of glucose may be impaired contributing to a state of insulin resistance. Furthermore, mitochondrial function improves after exercise training increasing uptake and oxidation of glucose in parallel with an improvement in insulin sensitivity [208]. In addition, molecular studies have found a decrease in peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC1α), the key coactivator of mitochondrial biogenesis, and a decrease in phosphorylation pathways in muscle mitochondrial of T2D patients compared with control without diabetes [209, 210]. Thus, these studies have suggested the possibility of a genetic predisposition for mitochondrial dysfunction already observed in the early stages of insulin resistance and diabetes. Although a compensatory attempt to increase mitochondrial oxidative activity that could deal with the increased lipid supply in the short term has been shown [211], a sustained exposure to high-fat diet, prolonged for more than 4–6 weeks, may not be able to be compensated by increasing the mitochondrial activity leading to ectopic lipid accumulation and IR [212, 213]. However these observations are not consistently shown [214, 215]. It still unclear whether the observed defects in mitochondria function could be due primarily to a decrease in their number in muscle or secondary to metabolic defects within the mitochondria. It is known that insulin sensitivity improves after weight loss, an effect that does not require mitochondrial function to improve or even to change. Drugs which inhibit mitochondrial function and ATP production (TZDs, metformin, etc.) improve insulin sensitivity [216]. Lipid infusion-induced insulin resistance also enhances mitochondrial β-oxidation [217]. In nonobese sedentary humans after a period of overfeeding, IR was increased without changes in mitochondrial function [218]. Also muscle mitochondrial function was not distinctively impaired in obese and T2D compared with control subjects [218, 219]. Finally, there is some evidence that decreased mitochondrial function may induce insulin sensitivity, whereas an increase

mitochondria function is associated with insulin resistance in transgenic mice [214, 215]. Thus the relationship between mitochondria and insulin action remains complex and still not well established.

(c) *Oxidative stress and obesity-induced insulin resistance*

Mitochondria are an important source of superoxide generation in cells, having the greatest capacity for production in the electron transport chain (ETC). Under physiological conditions, mitochondrial superoxide contributes to mitochondrial function. Several studies have proposed a relationship between oxidative stress and IR. Lipid infusion increased levels of oxidative damage markers such as plasma thiobarbituric acid reactive substance (TBARS) and was associated with a decrease in insulin sensitivity [220]. A decrease in intracellular reduced glutathione (GSH) is associated with a decreased insulin sensitivity in T2D patients. In addition, infusion of GSH improved oxidative damage and insulin sensitivity [220, 221]. However, the physiological contribution of ROS to insulin sensitivity and metabolic response remains controversial, and several studies have been unable to reproduce consistently these observations [222, 223].

(d) *Endoplasmic reticulum stress and obesity-induced insulin resistance*

Endoplasmic reticulum (ER) is an important biosynthetic organelle that regulates many biological processes required for nutrient storage and metabolization. If the surplus of nutrients is greatly increased, synthesis, processing, and secretion of proteins may need to be increased, generating ER stress and dysfunction. Accumulation of unfolded or misfolded proteins is observed with ER stress [224]. ER stress is also induced by factors such as hyperglycemia, viral infections, hypoxia, and lipid overload or qualitative changes in membrane lipid composition [224]. ER stress has also been linked to the activation of chronic inflammation by activating JNK [225], raised oxidative stress, insulin resistance [226], and leptin resistance in obesity [227]. Moreover, amelioration of ER stress with drugs directly improves insulin sensitivity in obese mice and recently also observed in insulin-resistant obese patients [228]. However, the specific mechanisms and process by which ER stress induces insulin resistance in humans still remain to be fully elucidated.

(e) *Skeletal muscle glucose and lipid metabolism*

Adiponectin exerts direct effects in the skeletal muscle where it promotes fatty acid oxidation, decreases intramuscular lipid accumulation, reduces toxic deposit of ceramides, and results in the improvement of insulin sensitivity [57]. Leptin also may play an insulin sensitizing role in muscle through the CNS or through the leptin receptors which are highly expressed on muscle and participates on its growth. Leptin's effect seem more related to the enhancement in FFA oxidation and amelioration of lipid deposition in muscle mediated by AMPK activation [229].

(f) *Liver insulin resistance and hyperglycemia*

As the key organ regulator of lipid and glucose metabolism, the liver is commonly affected by ectopic lipid accumulation (Fig. 13.4). Fatty acids accumulation in the liver results from imbalance of different sources: dietary fat, increase in lipolysis from adipocytes, and from de novo hepatic lipogenesis, without excluding defects in oxidation and on lipoprotein assembly and secretion. High-fat diets have been shown to produce fatty liver, whereas low-fat/high-carbohydrate diets have been shown to produce hyperinsulinemia in the context of selective insulin resistance and stimulation of de novo lipogenesis via SREBP-1c. Thus, dietary composition can have a major effect by affecting the relative sources of fat in the liver. However, an overproduction of FFAs from adipose tissue in the context of obesity is probably the most likely source of the excess triglyceride accumulating in the liver [230].

When an inflammatory environment is established in the adipose tissue, the whole body lipid metabolism becomes altered, initiating postprandial hypertriglyceridemia, because the liver overproduction of VLDL is not removed in time and remains for longer in plasma (postprandial hyperlipidemia). Further, because lipolysis from peripheral adipose tissue is exacerbated, the interstitial content of FFAs increases, which can be taken up by the adjacent muscle cells (↓ IS) or again transferred into lipoproteins to the plasma and could be taken up by the liver (↑ VLDL production) and other organs (lipotoxicity).

The ectopic accumulation of fat in the liver has been strongly associated with both hepatic and adipose tissue insulin resistance, an almost universal finding in nonalcoholic fatty liver disease (NAFLD) [231, 232]. Thus, whereas insulin sensitivity is reduced by ~45–50% (whole glucose disposal), the ability of insulin to inhibit endogenous hepatic glucose production is also decreased. However, not all obese individuals necessarily develop metabolic complications, as some remain insulin sensitive and do not develop fatty liver [89].

On top of all these factors, the link between obesity and associated metabolic abnormalities seems to be better related to the topography, anatomical distribution, and/or the functional peculiarities of the adipose tissue, a phenomenon which seems to be more relevant in patients with relatively normal weight (Figs. 13.3 and 13.4). The mechanism(s) whereby increased visceral adiposity is associated with insulin resistance is unclear, but circulating hormones secreted from adipose tissue have been implicated in modulating insulin sensitivity. Importantly, adiponectin

receptors (AdipoR1 and AdipoR2) are expressed in the liver. Adiponectin is associated positively with insulin sensitivity and associated negatively with intra-abdominal and hepatic fat. Adiponectin stimulates glucose use and fatty acid oxidation in the liver by activating AMP-activated protein kinase (AMPK) and PPAR-α [57]. Moreover, adiponectin exerts a protective action on liver fat accumulation, favoring lipolysis by promoting the action of CPT-1 and enhancing fatty acid transport into mitochondria to undergo β-oxidation while preventing the action of FAS, ACO, and TNF-α and decreasing the expression and action of CD-36 protein that promotes the transport of fatty acids [105]. Adiponectin induces suppression of Sterol regulatory element-binding protein-1c (SREBP-1c) a key factor regulator of lipogenic gene expression in the liver. In addition, adiponectin lowers toxic hepatic ceramide accumulation by enhancing ceramidase activity. Recently it has emerged that FGF21, released by adipose tissue, liver, and skeletal muscle, increases adiponectin levels. Also treatment of T2D subjects with pioglitazone also increases adiponectin levels, and this has been associated with decreases in hepatic fat and correlated positively with hepatic and peripheral insulin sensitivity both pretreatment and posttreatment [233].

Leptin prevents de novo lipogenesis while activating β-oxidation of fatty acids in the liver and has anti-inflammatory effects on the liver. Leptin increases inclusion of triglycerides into VLDL enabling release of lipid from the liver. Clinical trial is currently ongoing to show the effect of leptin therapy for NAFLD.

With respect to the role of the inflammatory cytokines IL-6 and TNF-α, the plasma levels of these two inflammatory cytokines are increased in subjects with NAFLD and NASH [89]. Moreover, peripheral blood monocyte production of TNF-α and IL-6 is increased in subjects with NASH [234].

β-Cell Dysfunction in Obese T2D Subjects

In obese insulin-resistant subjects, the pancreatic β-cells homeostatically increase insulin secretion to maintain glucose levels. The mechanisms involved in this β-cell compensation are not well known but result in both increased generation of β-cells and enhanced β-cell functional responses (Fig. 13.5) [235, 236]. β-cell mass is increased in obese compared with lean subjects [237]. The signaling for compensatory β-cell mass expansion may include increased glucose and FFAs (probably the most important direct stimulus), insulin, and other growth factors [235]. Glucose is the natural stimulus to release storage granules and to synthesize insulin by β-cells. Glucose must enter β-cell by a special glucose transporter (GLUT2) increasing pyruvate and ATP/ADP ratio (glucose oxidation) which trigger insulin release (first phase) [238]. The maintenance of hyperglycemia stimulates specific β-cell glucokinase (GK) activity which forms glucose 6-P that increases insulin production (second phase) [238]. The expression of GK and GLT2 is directly associated with the differentiation of β-cells, and both are regulated by PDX1 [239].

In addition, FFAs are essential for amplification of glucose-stimulated insulin secretion (GSIS) and other nutrient and non-nutrient stimulus [240]. First, the binding of FFAs to FFAR1/GPR40 receptors increases intracellular Ca2+ necessary for insulin release and, second, through generation of malonyl-CoA (inhibits fatty acid oxidation), which increases intracellular LC-CoA and diacylglycerol levels (DAG), in the malonyl-CoA/LC-CoA pathway [240, 241]. In addition, nutrients stimulate L-cells in ileum, and higher fat content in food raises levels of glucagon-like peptide 1 (GLP-1) [242]. GLP-1 and FFAs can have synergistic actions increasing GSIS [243], which may also stimulate β-cell growth [244, 245]. However, the incretin effect gets progressively impaired during the transition from IGT to diabetes. In addition, obesity and glucose tolerance each attenuate the incretin effect on β-cell function and GLP-1 response [246]. Pancreatic cells are connected with the parasympathetic system increasing insulin secretion, and its hyperactivity may be involved in the growth of β-cells [247]. Histological studies of the pancreas from necropsies and surgery have supplied important data for our knowledge of pathogenesis of islet β-cell dysfunction in T2D [237, 248]. An important research focused on the pancreas obtained from necropsies analyzed the total number of beta cells (β-cell mass), the stage of beta cell in regeneration, and those in apoptosis (Fig. 13.5). One hundred and twenty-four pancreases in total from lean and obese subjects were investigated, both groups having normal glucose tolerance and T2D and the obese group having the addition of impaired fasting glucose (IFG) [237]. In patients with normal glucose tolerance, the study found that relative cell volume was increased in obese versus lean cases ($P = 0.05$) increasing the mechanism of neogenesis ($P < 0.05$). However, a decrease of 40% and 63% in β-cell mass in IFG and T2D obese patients compared with obese normal glucose tolerance subject was also observed. Lean T2D patients compared with lean normal glucose tolerance subjects had a reduction of 59% in β-cell mass. The reduction of β-cell mass is evident in patients with impaired fasting glucose suggesting that the loss of β-cell mass starts in the early stages. Finally, the study of mechanisms implicated in this loss of β-cell mass found no significant effect on β-cell neogenesis, but β-cell death by apoptosis was increased [237].

Underlying Mechanisms Implicated in β-Cell Failure in T2D

(a) *Glucotoxicity and glycation stress.* Insulin secretion is reduced during periods of hyperglycemia, while partial recovery of β-cell function is achieved after control of glucose levels in T2D patients. Glucotoxic mechanisms

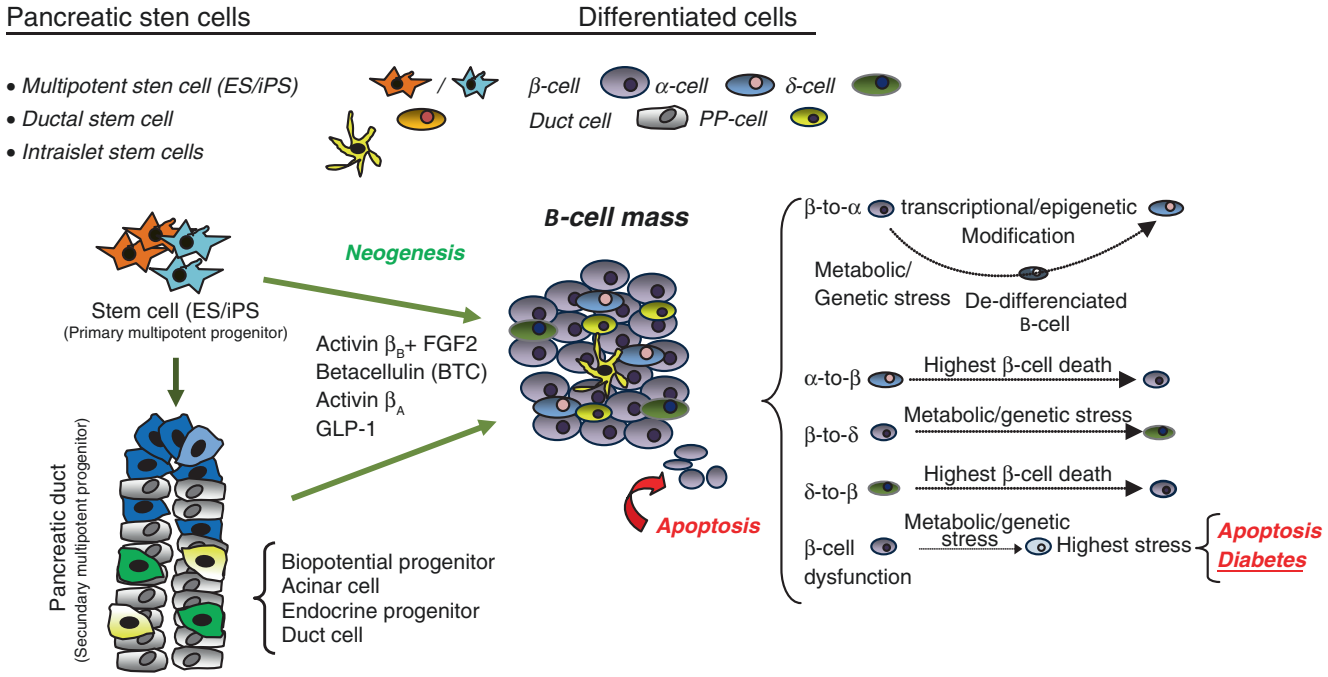

Fig. 13.5 Pancreatic β-cell failure appears as fundamental in the development of hyperglycemia in T2D, although insulin resistance may have been present for many years [276]. Insulin levels increase rapidly in relation with weight gain, probably associated with impaired insulin action; therefore hyperinsulinemia is frequently observed at diagnosis of T2D in obese subjects. However, only ~20% of obese subjects develop diabetes, while the remainder can maintain elevated insulin levels without hyperglycemia for many years. Thus, it appears that β-cell mass could progressively be reduced until it crosses a set point where insulin secretion is no longer sufficient to maintain the normal glycemic range in obese type 2 diabetic patients. Today, an increase in apoptosis of β-cells greater than a decrease in neogenesis is the most accepted cause for the loss of β-cell mass [237] (Fig. 13.5). β-Cell death can be increased by an accumulation of high toxic lipids, a human islet amyloid polypeptide, and finally by the generation of high levels of glucose in the type 2 diabetes with obesity. In addition, in obese individuals a high demand for insulin increases endoplasmic reticulum dysfunction (ER stress) and also hyperglycemia increases reactive oxygen species (oxidative stress) both contributing to apoptosis of β-cells. Thus, if β-cell mass is lower than 50%, the remaining β-cells try to increase their function in order to compensate, which produces chronic β-cell stress. Therefore, proinsulin levels are frequently increased early in developing T2D, probably due to ER stress of β-cells. In addition, proinsulin levels after hemiprancreatectomy determine the risk of developing diabetes, mainly in obese patients. Furthermore, the incretin effect is decreased in type 2 diabetes, affecting insulin secretion rates expressed as a percentage of insulin secretion. The incretin effect on total insulin secretion and β-cell glucose sensitivity and the GLP-1 response to oral glucose were significantly reduced in diabetes compared with NGT or IGT. Glucose tolerance and obesity inhibit the incretin effect independently [246]. In healthy subjects, infusion of physiological levels of GLP-1 increase insulin secretion. However, in patients with type 2 diabetes, physiological levels of GLP-1 had no effect on insulin release, whereas the infusion of GLP-1 at pharmacological levels (1 pmol/kg/min) increased just the "late-phase" (20–120 min) insulin response to levels similar to healthy subjects [277]. Furthermore, inflammatory pathways, such as increased interleukin-1β within islet β-cells, are involved in β-cell apoptosis in type 2 diabetes. Although the half-life and neogenesis rates of β-cells are difficult to establish in humans, it appears that β-cell can take several years to regenerate. However, interventions such as bariatric surgery can improve β-cell function in a few weeks in obese type 2 diabetes patients. In addition, β-cell function improved in obese T2D patients treated with a very-low-calorie diet (VLCD) weeks before insulin sensitivity was changed

implicated in β-cell damage include increased glucosamine pathway activity and glycation stress, raised oxidative stress, increased ER stress, activation of inflammatory, and toxic accumulation of islet amyloid polypeptide (IAPP) [249, 250].

(b) *Mitochondrial dysfunction and reactive oxygen species.* Increased surplus of glucose and FFAs raises its oxidation in mitochondria resulting in increased superoxide generation and production of uncoupling protein 2 (UCP2) in β-cell [251, 252].

(c) *Lipid effects on β-cell function.* An increased surplus of TG/FFA in β-cells induces glucose oxidation by which K+ATP channel pathway can be enhanced [243]. Thus, more than a direct lipotoxicity effect, elevated FFAs and hyperlipidemia can be a major signal for a flexible adaptation of β-cell mass to obese-induced insulin resistance [243]. However, the lipotoxicity effects of increased FFAs on β-cell can be seen more in combination with chronic hyperglycemia (glucolipotoxicity) [100, 241]. During hyperglycemia AMPK/malonyl-CoA signaling is stimulated, which slows down mitochondrial fat oxidation and promotes FFA accumulation in more complex lipids, some of which are lipotoxic [100, 241].

(d) *Islet β-cell exhaustion and ER stress.* The high requirement of insulin synthesis initiates mechanisms for compensating β-cell mass and generates high endoplasmic reticulum (ER) activity for the production of proinsulin. Continuous formation of proteins

including insulin results in stress and dysfunction of ER which affects the normal pattern of insulin secretion, a significant component of β-cell failure in T2D [253].

(e) *Differentiation of undifferentiated cells to pancreatic β-cells*

Hyperplasia, proliferation and neogenesis of pancreatic β-cells, may be adapted in relation to obese-induced insulin resistance and transitory β-cell damage. In humans pancreatic β-cell proliferation in pregnancy and T2D has not been observed. Therefore, similar to factors that induce multipotent stem cells (ES/iPS) to produce β-cells, we may be able to identify factors that inhibit pancreatic β-cell proliferation in various conditions. In humans, hyperglycemia progress is related with β-cell failure associated with a reduction of β-cell mass by increased apoptosis or dedifferentiation of β-cells during metabolic stressors such as is observed with obesity (Fig. 13.5).

Fate change between the different endocrine cells is observed under different conditions of stress. This may occur either directly or through a dedifferentiated state. Continued stress on the β-cell can lead to dedifferentiation that causes diabetes [254]. Future studies of some compounds that regulate endogenous stem-cell differentiation could lead to drugs that stimulate β-cells neogenesis [255].

Multiple Choice Questions

1. Talking about "Obesity: Measurements and Assessment," which one of the following statements is not correct?
   (a) Body mass index (BMI) is currently used to classify from low and normal weight to overweight and obese state in adults and is estimated by the weight/height squared ratio.
   (b) Deaths associated with a high BMI are ranked fourth behind deaths from hypertension, smoking, and unhealthy diets, and ahead of deaths related to hyperglycemia, sedentary lifestyle, high salt intake, alcoholism, and high blood cholesterol level.
   (c) Several clinical parameters can be used to estimate central obesity, with the most widely being waist circumference (WC), hip ratio (HR), and waist-HR (WHR).
   (d) In research, to measure obesity and body fat distribution, more complex and more accurate techniques are used, such as dual-energy X-ray absorptiometry (DEXA), computed tomography (CT), and magnetic resonance imaging (MRI).
   (e) In research the single-voxel magnetic resonance spectroscopy is the gold standard for measuring distribution of body fat.
2. With respect to the "Adipocyte and Adiposity Development," which one of the following statements is not true?
   (a) In humans there are two types of well-differentiated adipose tissues, which have different distributions and functions and are referred to as white adipose tissue (WAT) and brown adipose tissue (BAT).
   (b) The WAT is mainly related to the function of deposit of surplus energy as triacylglycerol, which could be mobilized and offered through hormonal signaling and has a tremendous ability to expand.
   (c) Adiponectin increases adipocyte lipid storage and prevents ectopic lipid accumulation. In addition, leptin decreases lipogenesis and increases lipolysis and fatty acid oxidation.
   (d) Thermogenic function of BAT is mediated by the activation of a specific mitochondrial uncoupling protein 1 (UCP1), where the saturation of the production of ATP is dissipated as heat. Therefore, activation of these sites with BAT decreases basal energy expenditure and increases onset of diabetes.
   (e) A third fat cell similar to brown adipocytes is also found infiltrating skeletal muscle and in different areas of WAT. This could mean that the rate of lipid storage or lipid oxidation could be adapted and adjusted.
3. Which characteristics or pleiotropic effects of hormones and adipokines on adipogenesis and glucose metabolism are not correct?
   (a) Adipocyte differentiation and lipogenesis require insulin receptors and insulin action.
   (b) The infusion of hydrocortisone increases levels of circulating free fatty acids (FFA) associated with the activation mechanisms of lipolysis.
   (c) The PPAR-γ agonists (thiazolidinediones, TZDs) increase fat central depots, also decrease adiponectin levels, worsen lipid profile and insulin sensitivity, and increase liver fat in NAFLD.
   (d) Leptin is secreted by fat cells, establishing a negative feedback between the amount of adipose tissue and satiety centers in the brain.
   (e) Adiponectin is produced in mature adipocytes and is higher in peripheral adipose tissue than visceral adipose tissue.
4. Talking about inflammatory adipokines all is true less one.
   (a) Both TNF-α gene and its receptors are present in adipocytes and at higher levels in WAT. Increased release of TNF-α from adipose tissue may play a role in the impairment of insulin action.
   (b) TNF-α increases the expression of PPAR-γ and increases expression of genes involved in lipid and glucose uptake.

(c) A fatty acid-binding protein (aP2) could be the link between FFA and increased expression of TNF-α in obesity.
(d) About 1/3 of the total concentration of IL-6 is produced in adipose tissue, mainly in visceral adipose tissue compared with peripheral adipose tissue.
(e) IL-6 levels are directly linked to obesity and insulin resistance and inhibit the activity of lipoprotein lipase (LPL).

5. Which of "Obesity Effects on Pathogenesis of Type 2 Diabetes" is not completely true?
(a) Type 2 diabetes mellitus (T2D), at least at the beginning, is characterized by hyperglycemia, insulin resistance, and impairment in insulin secretion. The prevalence has increased related with obesity and sedentary lifestyle but can arise genetic or varying environmental factors, which complicate finding the cause in diabetic patients.
(b) The risk of T2D and cardiovascular disease rises not only with the amount of body fat particularly increases when fat accumulation is in peripheral depots.
(c) Increased and altered secretion of adipokines in obesity (TNF-α, adiponectin, leptin, etc.) contributes to insulin resistance.
(d) Ectopic fat deposition, predominantly in the liver, skeletal muscle, and ß-cell, contributes to altered fat and glucose metabolism.
(e) Mitochondrial dysfunction and endoplasmic reticulum stress could be a link between obesity and diabetes, by decreasing insulin sensitivity and altering ß-cell function.

6. In relation to "Obesity and Lipotoxicity Syndrome," everything is true except one statement:
(a) Adipose tissue is the primary responsible for fat storage. Thus, a correctly functioning adipose tissue is necessary to maintain an adjusted delivery of surplus fuel to other tissues and nontoxic storage of lipids.
(b) When the adipocytes enlarge, it develops insulin resistance, and the antilipolytic effects of insulin is reduced. The increase of FFA in plasma results in more insulin resistance in muscle and liver, inhibits insulin secretion, and induces β-cell apoptosis.
(c) Leptin secretion decreases in parallel with fat accumulation and as a result adipose tissue expands. Leptin action appears to be implicated in processes that increase lipotoxicity in non-adipose tissues.
(d) Leptin regulates and increases β-oxidation through controlling peroxisome proliferator-activated receptor-α (PPAR-α) activity by minimizing ectopic accumulation of lipids.
(e) Adiponectin has a major role in improving insulin sensitivity, anti-inflammatory, anti-apoptotic, and pro-angiogenic effects that enhance the metabolic flexibility of adipose tissue.

7. In relation with "Pathogenesis of Obese Type 2 Diabetes," find out the statement that is not true:
(a) There are overweight subjects who maintain normal glucose tolerance. These can gain weight associated with insulin resistance (IR), but their acute insulin response (AIR) could be adjusted upward.
(b) The gastrointestinal tract is a large endocrine organ that releases two major incretin peptides. The glucagon-like peptide 1 (GLP-1) by L-cells (distal small intestine) and glucose-dependent insulinotrophic peptide (GIP) by k-cells (early small intestine) jointly rise by 60–70% insulin released in response to a mixed meal.
(c) GLP-1 reduces glucagon releases by α-cells on the pancreas and reduces appetite. In T2D patients, the GLP-1 resistance results in hyperglucagonemia and increased HGP and weight gain by eating.
(d) The kidney generates about a 15–20% of the endogenous glucose production, mainly in fasting period, and is controlled by insulin function. But, kidney in obese T2D is insulin resistant, and glucose production is decreased.
(e) The glucose filtered is reabsorbed by sodium glucose transporter 2 (SGLT2) (80–90%) and SGLT1 (10–20%). When hyperglycemia initiates, this capacity of reabsorption is increased and contributes to maintain elevated glucose levels and retention of sodium and water.

8. In relation with "β-Cell Dysfunction in Obese T2D Subjects," all are correct except one:
(a) In obese insulin-resistant subjects, pancreatic β-cells increase insulin secretion to maintain glucose levels. The mechanisms involved in this β-cell compensation are not well known but implicate both increased generation of β-cells and enhanced β-cell responses.
(b) The signaling for compensatory β-cell mass expansion includes increased glucose, while mainly FFAs, GLP-1, and insulin decrease β-cell mass increasing apoptosis.
(c) Glucose is the natural stimulus to release storage granules and to synthesize insulin by β-cells. Glucose must enter β-cell by a special glucose transporter (GLUT2) increasing pyruvate and ATP/ADP ratio (glucose oxidation) which trigger insulin release (first phase of insulin secretion).
(d) The maintenance of hyperglycemia stimulates specific β-cell glucokinase (GK) activity which

forms glucose 6-P that increases insulin production (second phase of insulin secretion).

(e) Pancreatic cells are connected by the parasympathetic system increasing insulin secretion, and its hyperactivity may be involved in the growth of β-cells.

9. Histological studies of the pancreas from necropsies and surgery have supplied important data for our knowledge of pathogenesis of islet β-cell dysfunction in T2D. Which of the following one is not true?
   (a) In patients with normal glucose tolerance has been found that relative cell volume is decreased in obese versus lean cases decreasing the mechanism of neogenesis.
   (b) A decrease of 40% and 63% in β-cell mass in IFG and T2D obese patients compared with obese normal glucose tolerance subject has been also observed.
   (c) Lean T2D patients compared with lean normal glucose tolerance subjects had a reduction of 59% in β-cell mass.
   (d) The reduction of β-cell mass is evident in patients with impaired fasting glucose suggesting that the loss of β-cell mass starts in the early stages.
   (e) The study of mechanisms implicated in this loss of β-cell mass found no significant effect on β-cell neogenesis, but β-cell death by apoptosis was increased.
10. Talking about "the underlying mechanisms involved in the failure of β-cells in T2D," point out the incorrect one:
   (a) Insulin secretion is reduced during periods of hyperglycemia, while partial recovery of β-cell function is achieved after control of glucose levels in T2D patients (glucotoxic mechanisms).
   (b) Glucotoxic mechanisms implicated in β-cell damage include increased glucosamine pathway activity and glycation stress, raised oxidative stress, and increased ER stress, activation of inflammatory, and toxic accumulation of islet amyloid polypeptide (IAPP).
   (c) An increased surplus of TG/FFA in β-cells induces glucose oxidation. Thus, more than a direct lipotoxicity effect, elevated FFAs and hyperlipidemia can be a major signal for a flexible adaptation of β-cell mass to obese-induced insulin resistance.
   (d) The lipotoxicity effects of increased FFAs on β-cell can be seen more in combination with chronic hyperglycemia (glucolipotoxicity).
   (e) Continuous formation of proteins, including insulin, results in stress and dysfunction of endoplasmic reticulum (ER) activity which not affects the normal pattern of insulin secretion in T2D.
11. The differentiation of undifferentiated cells to pancreatic β-cells plays a key role in the maintenance of the β-cell mass. Point out the incorrect of the following;
   (a) Hyperplasia, proliferation, and neogenesis of pancreatic β-cells may be adapted in relation to obese-induced insulin resistance and transitory β-cell damage.
   (b) In humans, hyperglycemia progress related with β-cell failure is associated with a reduction of β-cell mass by increased apoptosis and/or dedifferentiation of β-cells during metabolic stressors such as is observed with obesity.
   (c) Fate change of differentiation from multipotent stem cells (ES/iPS) between the different endocrine cells is observed under different conditions of stress.
   (d) Continued stress on the β-cell could lead to its dedifferentiation in an α-cell, which will not affect the normal pattern of insulin secretion in T2D.
   (e) Future studies of some compounds that regulate endogenous stem-cell differentiation could lead to drugs that stimulate β-cells neogenesis.

Correct Answers

1. (e) In research the single-voxel magnetic resonance spectroscopy is the gold standard for measuring distribution of body fat.
2. (d) Thermogenic function of BAT is mediated by the activation of a specific mitochondrial uncoupling protein 1 (UCP1), where the saturation of the production of ATP is dissipated as heat. Therefore, activation of these sites with BAT decreases basal energy expenditure and increases onset of diabetes.
3. (c) The PPAR-γ agonists (thiazolidinediones, TZDs) increase fat central depots, also decrease adiponectin levels, worsen lipid profile and insulin sensitivity, and increase liver fat in NAFLD.
4. (b) TNF-α increases the expression of PPAR-γ and increases expression of genes involved in lipid and glucose uptake.
5. (b) The risk of T2D and cardiovascular disease rises not only with the amount of body fat particularly increases when fat accumulation is in peripheral depots.
6. (c) Leptin secretion decreases in parallel with fat accumulation and as a result adipose tissue expands. Leptin action appears to be implicated in processes that increase lipotoxicity in non-adipose tissues.
7. (d) The kidney generates about a 15–20% of the endogenous glucose production, mainly in fasting period, and is controlled by insulin function. But, kidney

in obese T2D is insulin resistant, and glucose production is decreased.

8. (b) The signaling for compensatory β-cell mass expansion includes increased glucose, while mainly FFAs, GLP-1, and insulin decrease β-cell mass increasing apoptosis.
9. (a) In patients with normal glucose tolerance has been found that relative cell volume is decreased in obese versus lean cases decreasing the mechanism of neogenesis.
10. (e) Continuous formation of proteins, including insulin, results in stress and dysfunction of endoplasmic reticulum (ER) activity which not affects the normal pattern of insulin secretion in T2D.
11. (d) Continued stress on the β-cell could lead to its dedifferentiation in an α-cell, which will not affect the normal pattern of insulin secretion in T2D.

Pathogenesis of Gestational Diabetes Mellitus

14

Evangelia Kintiraki, Gesthimani Mintziori, and Dimitrios G. Goulis

Introduction

Gestational diabetes mellitus (GDM) constitutes the most common metabolic disease of pregnancy, with a continuously increasing prevalence [1, 2]. It has been associated with several maternal and fetal/neonatal complications [3, 4]. Increased maternal age, increased pre-pregnancy body mass index (BMI), excessive weight gain during pregnancy, Aboriginal Australian, Middle Eastern and Pacific Islander ethnicity, positive family history of GDM, and parity are established risk factors for the development of GDM [5, 6]. GDM, similarly to type 2 diabetes mellitus (T2DM), is a multifactorial disease; its pathogenetic mechanisms are not yet fully understood. Genetic and acquired factors that affect insulin sensitivity and insulin secretion have been implicated to GDM development and determine the disease severity [7]. Hormonal, inflammatory, and immunologic factors contribute to GDM pathogenesis. Suboptimal lifestyle, such as hypercaloric diet, unhealthy nutritional habits, and reduced physical activity, contributes to central obesity, a triggering factor for GDM [8, 9].

Insulin Action and Sensitivity

A major pathogenetic mechanism for GDM is the reduced insulin sensitivity that occurs in normal pregnancy due to placental and maternal hormonal action. Insulin action is impaired at hepatic, muscle, and adipose tissue level [10–12]. Impaired post-receptor insulin signaling is mainly responsible for pregnancy-induced insulin resistance. Experimental studies showed impaired mRNA or protein expression of insulin signaling cascade components, such as insulin receptor substrate (IRS)-1 and (IRS)-2, as well as glucose transporter (GLUT)-1 and (GLUT)-4 in adipose tissue and muscle of women whose pregnancies were complicated by GDM. Decreased IRS-1 tyrosine phosphorylation, decreased GLUT-4 insulin-induced translocation to the cell surface, and decreased glucose transport into the cell were also found in muscle and adipose tissue of women with GDM [13–16]. Similar post-receptor insulin defects have been found in the placenta of GDM-affected pregnancies [17]. Chronic low-grade inflammation that characterizes obesity, which often accompanies GDM pregnancies, contributes to insulin signaling impairment [18], as well as oxidative stress [19].

Placental Hormones

Placental hormones, such as human placental lactogen (HPL) and placental growth hormone (GH), are opposed to insulin action [20]. HPL is produced by syncytiotrophoblast and is gradually increased during pregnancy until about 30th gestational week, when it reaches a plateau. It is correlated to fetal weight and well-being as well as placental function [21]. HPL is the main insulin resistance mediator during pregnancy. It acts as an "anti-insulin" agent in order to ensure adequate glucose supply to the embryo [22, 23]. HPL results in raised maternal blood glucose concentrations by increasing insulin resistance and raised free fatty acids concentrations by increasing lipolysis [24]. A sudden drop to HPL concentrations could indicate fetal distress [25–27]. Growth hormone (GH) is an anabolic hormone, involved in carbohydrate and lipid metabolism, and, when in excess, has diabetogenic properties, opposing insulin action [28]. Human placental GH is the main GH molecule produced during pregnancy, having an effect on maternal insulin sensitivity [29]. It is produced mainly by placental syncytiotrophoblastic cells, and it is gradually increased by midpregnancy to term. Studies in transgenic mice showed severe insulin resistance induction by placental GH [30].

Maternal Hormones

Maternal serum GH, other growth factors, such as insulin like growth factor-1 (IGF-1), their binding proteins, prolactin (PRL), progesterone, and cortisol are altered in women whose pregnancies are complicated by as compared with unaffected pregnant women [31, 32]. PRL is produced, mainly, by anterior pituitary lactotroph cells and, secondary, by the central nervous system, immune cells, nonpregnant uterus, placenta, amnion, decidua, and the mammary gland. The most well-known action of PRL is lactation. Other PRL effects are mammary epithelial proliferation, corpus luteum function, and immune response [33, 34]. Evidence about PRL's effect on insulin sensitivity is contradictory. Hyperprolactinemia, as in patients with a prolactinoma, exacerbates insulin resistance to the nonpregnant state [35, 36]. The latter effect regresses after treatment with dopaminergic receptor agonist [37]. In contrary, studies in nonpregnant healthy women (with normal prolactin concentrations) showed that lower prolactin concentrations were correlated to decreased insulin sensitivity and increased risk for diabetes [38, 39]. During pregnancy, PRL is also produced by decidual cells and fetal pituitary. Maternal PRL is increased gradually by conception to term [40]. In pregnant rats, increased prolactin concentrations have been correlated to a post-receptor insulin defect [20]. In humans, higher concentrations of PRL during the third trimester of pregnancy have been associated with decreased glucose tolerance, implying a causative relationship between hyperprolactinemia and GDM [41]. In contrary, in another study, no difference in PRL concentrations has been found between GDM and controls [42]. Maternal, placental, and fetal adrenal steroids, progesterone, cortisol, estrogen, and androgens, also contribute to pregnancy-induced insulin resistance [43]. Progesterone, produced initially by the corpus luteum and later by the placenta, inhibits insulin action in vivo and in vitro, mainly by inhibiting the PI3-kinase pathway of the insulin signaling cascade in the adipocytes [44]. Cortisol can also induce insulin resistance through post-receptor insulin defect [20]. Androgen receptors are overexpressed in placentas of GDM-affected pregnancies as compared to controls [45]. Although it is known that estrogens regulate carbohydrate metabolism, the underlying mechanisms are not fully understood. In the nonpregnant state, estradiol (E_2) partially affects insulin signaling through modification of mitochondrial function [46]. In GDM-affected pregnancies, estrogen concentrations are lower as compared to unaffected pregnant women [47].

Maternal Adipokines

Maternal adipokines have a significant effect on insulin action. Adiponectin, an adipose tissue-derived plasma protein, has a beneficial effect on carbohydrate metabolism by increasing insulin sensitivity [48, 49]. It is produced mainly by white adipose tissue (WAT). Adiponectin seems to express protective properties for the vascular endothelium and the heart through anti-inflammatory action and suppression of the atherosclerotic processes [50–52]. Higher concentrations of adiponectin have been associated with lower risk of T2DM development in nonpregnant women [53]. In pregnancy, evidence about adiponectin concentrations is not consistent; placental production of adiponectin has not been confirmed by all investigators [54, 55]. Some studies have demonstrated an increase in adiponectin concentrations in early pregnancy and a gradual decrease thereafter compared with the prepregnancy state [56, 57]. Although evidence regarding gestational concentrations of adiponectin and carbohydrate metabolism is less clear, a link between hypoadiponectinemia and insulin resistance exists [57, 58], as pregnant women with GDM have lower adiponectin levels than healthy controls [59].

Another adipokine, leptin, is strongly involved to metabolic issues affecting insulin secretion and action as well as tissue insulin sensitivity [60, 61]. Leptin is produced mainly by WAT adipocytes, proportionally to adipose tissue mass [62]. In a lesser degree, it is produced by brown adipose tissue (BAT), placenta, skeletal muscle cells, ovaries, and gastric cells. Leptin's primary action is the regulation of energy homeostasis [63]. Leptin reduces insulin synthesis and secretion, whereas it increases insulin sensitivity [61, 64]. Obesity is associated with resistance to leptin action [65]. During pregnancy, placenta-derived leptin results in nearly a 100% increase in maternal serum concentrations [66, 67]. Further increased leptin concentrations have been found in GDM-affected women as compared to non-affected pregnant women [68, 69]. Both adiponectin and leptin gene polymorphisms have been correlated to GDM occurrence [70]. Low adiponectin and high leptin concentrations during the first trimester may predict GDM occurrence during later pregnancy [71, 72].

Fetuin B, a recently identified adipokine, impairs insulin action. Women with GDM-affected pregnancies have higher fetuin B concentrations as compared with controls [73]. Data on resistin, visfatin and apelin concentrations, and their association with GDM are not consistent. Other novel adipokines, such as omentin and chemerin, have been associated to GDM development, and a causal effect is implied by some investigators [74].

Immunological Changes and Low-Grade Inflammation

Normal pregnancy is accompanied by immunological changes and a low-grade inflammation that is occurred to the benefit of the fetus [75, 76]. Inflammation is exacerbated by obesity, a common risk factor of GDM, and

affects insulin sensitivity through post-receptor signaling defect. Inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), have a direct adverse effect on insulin action in healthy nonpregnant women, inducing insulin resistance [77]. TNF-α is a transmembrane protein produced mainly by activated macrophages in response to immunological stimulus [78]. In a lesser degree, it is expressed by other cells, such as lymphoid cells, cardiac myocytes, endothelial cells, and adipocytes. It expresses a cytotoxic effect on many cells; simultaneously, it has a regenerative effect on tissues [79, 80]. TNF-α induces phosphorylation of the IRS-1, thus preventing the interaction of insulin with the insulin receptor and impairing insulin action. Interleukin-6 (IL-6) is a pro-inflammatory cytokine and an anti-inflammatory myokine expressed by immune cells, such as T-cells and macrophages, visceral adipocytes, osteoblasts, and vascular smooth muscle cells. It is the main stimulator of the production of many acute-phase proteins. It impairs insulin-induced insulin receptor and IRS-1 phosphorylation, resulting to inhibition of the insulin signaling cascade [81]. C-reactive protein (CRP) is an acute-phase protein of hepatic origin that is increased in response to inflammation and IL-6 secretion. It acts through activation of the complement system, triggering phagocytosis by immune cells. CRP is associated to insulin resistance in healthy individuals; high concentrations of high-sensitivity (hs)-CRP are indicative of higher risk for metabolic, cardiovascular, and cerebrovascular disease [82]. The Generation R Study showed that increased CRP concentrations during early gestation are associated to high risk of neonatal complications [83]. During normal pregnancy, low-grade inflammatory markers, such as CRP, IL-6, TNF-α, and GlycA, have found to be increased, suggesting an upregulation of systemic maternal inflammation [75, 84]. In contrast to this normal maternal adaptation, a further increase of some inflammatory markers is considered a risk factor for adverse pregnancy outcomes, including GDM. Specifically, it has been shown that women with GDM-affected pregnancies have increased IL-6 concentrations as compared to controls [85]. In a recent meta-analysis, TNF-α has been found to be higher in GDM pregnancies compared to controls, independently of BMI [69]. CRP has been associated with GDM; an increase in its concentrations during early pregnancy is predictive of GDM development later in pregnancy [86, 87].

Oxidative Stress

Normal pregnancy is considered a condition of increased oxidative stress. Several pathologic conditions during pregnancy, including GDM, are associated with a further aggravation of oxidative stress. It is believed that oxidative stress is caused either by increased reactive oxygen species (ROS) production or by a reduction of the antioxidant capacity [19]. Both an increase in oxidative stress markers and a decrease in antioxidative factors have been found in GDM-affected pregnancies. ROS induce inflammatory response and inflammatory protein expression, aggravating the normal low-grade inflammation and insulin resistance during pregnancy. Furthermore, increased protein oxidation due to enhanced oxidative stress could be implicated to GDM pathogenesis [87, 88].

β-Cell Dysfunction and Insulin Secretion

β-Cell Dysfunction

During normal pregnancy, pancreatic cell adaptation occurs to compensate for the increased need for insulin. β-cell expansion and hyperfunctioning occur early in pregnancy in order to cope with the decreased insulin sensitivity that occurs after the second half of pregnancy [89]. GDM is characterized by decreased insulin response to oral glucose and protein, sluggish first-phase insulin secretion, and delayed peak insulin secretion [90]. Subclinical pre-existing β-cell dysfunction, rather than a gradual decline of β-cell function during pregnancy, and the effect of maternal hormones and inflammatory mediators (see Sect. 2) on β-cell function constitute main mechanisms for the occurrence of GDM [91, 92]. Pre-existing β-cell dysfunction, due to genetic predisposition, does not allow for compensatory pancreatic β-cell hyperfunction to counter-regulate for the increased insulin resistance of pregnancy (Fig. 14.1) [93]. β-cell dysfunction in pregnancies complicated by GDM persists postpartum as compared to controls. Given the normalization of insulin sensitivity after delivery, only a small percentage of women with GDM remain within diabetic ranges; nevertheless, the risk for developing T2DM in later life remains increased (Fig. 14.2) [94].

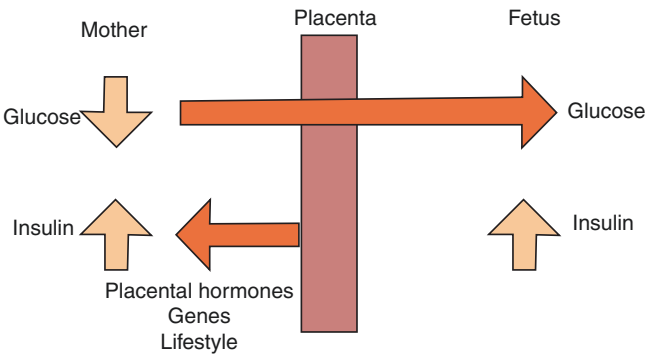

Fig. 14.1 Pathogenesis of GDM: combination of maternal and placental hormonal alteration, genetic predisposition, and suboptimal lifestyle. (Adapted from: Poulakos et al. [93])

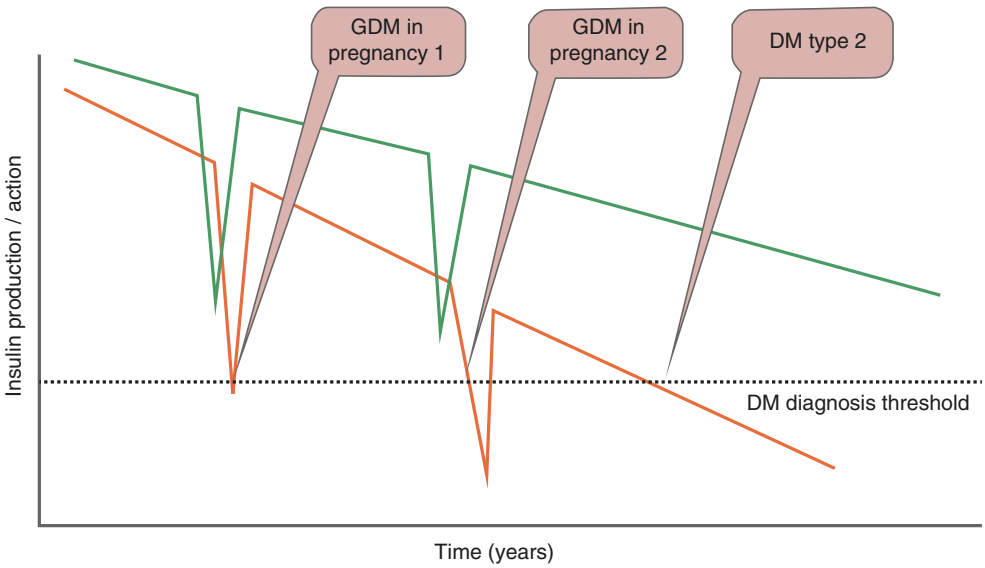

Fig. 14.2 T2DM development in women with prior GDM. Women with a history of GDM have increased probability of developing GDM in later life due to genetic predisposition and suboptimal lifestyle. (Adapted from: Poulakos et al. [93])

Vitamin D Deficiency

Hypovitaminosis D, defined as low serum concentrations of 25-hydroxy- vitamin D_3 [25(OH)D_3], has been correlated to β-cell dysfunction in the nonpregnant state; vitamin D supplementation has been shown to improve insulin secretion in rats [95, 96]. During pregnancy, lower 25(OH)D_3 concentrations have been associated with GDM [97]. Moreover, lower 25(OH)D_3 concentrations postpartum have been associated with impaired β-cell function in women with a history of GDM [98]. Increased parathyroid hormone (PTH) concentrations have been implicated to GDM pathogenesis, partially through insulin secretion impairment [99].

Maternal Hormones

The effect of maternal hormones on β-cell function and proliferation during pregnancy is still not completely understood, and some results are contradictory. Despite that PRL is considered as a major regulator of β-cell expansion and hyperfunction during pregnancy, higher prolactin concentration has been correlated to decreased glucose tolerance during late pregnancy [41, 100]. PRL receptor-null mice have shown β-cell maladaptation during pregnancy [101]. Moreover, PRL has been found to reduce menin concentrations, a known tumor suppression factor that also suppresses β-cell proliferation and may be implicated to GDM development in pregnant mice [102]. 17β-estradiol is seemed to be involved to β-cell adaptation and insulin secretion during pregnancy, specifically β-cell survival [103, 104]. Progesterone receptor-knockout mice have increased insulin secretion probably due to increased β-cell mass [105]. The latter is in accordance with another experimental study that showed an apoptotic action of progesterone to pancreatic β-cells through an oxidative stress-dependent mechanism [106]. HPL stimulates insulin secretion and may have a central role to regulation of islet function during pregnancy [107]. Recent data suggest a leptin-induced decrease of insulin secretion by direct action on β-cells. Moreover, leptin affects β-cell proliferation and apoptosis and inhibits insulin gene expression [108].

Low-Grade Inflammation

As mentioned above, the low-grade inflammation that characterizes GDM affects glucose metabolism through an increase to insulin resistance. Additionally, an impairment on adipokines production, possibly due to this inflammation, has also been correlated to β-cell dysfunction and decreased insulin secretion [69, 109]. Specifically, GDM-affected women have lower adiponectin concentrations as compared with controls [69, 110]. This hypoadiponectinemia of GDM pregnancy has been associated to β-cell dysfunction [111]. As part of the low-grade inflammation, GDM-affected women have increased TNF-α concentrations [69]. Beyond insulin resistance, TNF-α has a pro-apoptotic effect on β-cells [112]. The latter could contribute to the reduced insulin secretion of GDM. As mentioned above, GDM-affected women have lower concentrations of 25(OH)D_3. Vitamin D deficiency has also been associated to increased concentrations of inflammatory markers that could further deteriorate β-cell function [113].

Oxidative Stress

Beyond insulin resistance, oxidative stress per se or as a consequence of inflammation and hyperglycemia has been linked to decreased insulin secretion during the nonpregnant state [114]. GDM is characterized by increased oxidative stress as it is determined by increased concentrations of advanced glycosylated end-products (AGEs) and other markers of oxidative lipid and protein damage [88, 115]. Recently, a furan fatty acid metabolite, 3-carboxy-4-methyl-5-propyl-2-furanpropanoic acid (CMPF), has been recognized as a possible negative regulator of β-cell function, inhibiting insulin synthesis and secretion through oxidative stress and mitochondrial dysfunction in human and mouse islets. Women with GDM have increased concentrations of CMPF as compared with controls [116]. Moreover, in GDM-affected women, CMPF predicted lower β-cell function indices [92].

Autoimmunity

A rare cause of GDM is an autoimmune destruction of pancreatic β-cells, similar to that of type 1 diabetes mellitus (T1DM). Autoimmune GDM consists in less than 10% of cases. GDM-affected women with autoimmune form of diabetes often develop T1DM soon after pregnancy or latent autoimmune diabetes of adulthood (LADA) some years after delivery [117]. In a Swedish population, antibodies implicated in T1DM pathogenesis [glutamic acid decarboxylase antibodies (GADA), islet cell antigen-2 antibodies (ICA)/tyrosine phosphatase antibodies (IA2)] have been detected in 6% of women with GDM [118]. Specifically, the prevalence of GADA in GDM-affected women has been shown to extend between 0% and 11%, of ICAs between 1% and 35%, of insulin autoantibodies (IAA) between 0% and 6%, and that of anti-IA2 between 0% and 6% [119]. Moreover, pancreatic autoantibodies may be developed in some GDM women postpartum [117]. GADA were positively associated with postpartum development of diabetes in women diagnosed with GDM [120]. As a consequence, positive GADA and other pancreatic autoantibodies in GDM-affected women can be predictive of postpartum T1DM development [121]. A recent meta-analysis has shown an association between HLA class II variants, which consists of up to 30–50% of the pathogenesis of T1DM, and GDM. Specifically, DQB1*02 and DRB1*1302 alleles have been significantly associated with increased risk of developing GDM. In contrary, DQB1*0602 seems to be a protective allele against GDM development [122]. HLA-DR6 alleles were also positive correlated to GDM development, whereas other haplotypes, such as HLA-DR2 and HLA-DR51, seem to be protective. Besides HLA-DR3 gene and HLA-DR6/DR9 heterozygote were associated to GDM severity and prognosis [123]. Other studies found no significant differences to the distribution of HLA class II polymorphism between GDM, impaired glucose tolerance (IGT), and unaffected pregnant women [124]. It is obvious that the evidence about the relationship between GDM and autoimmunity is still controversial and more studies are needed to establish it.

Genetic Causes

A rare cause of GDM is maturity-onset diabetes of the young (MODY) gene mutations. Several MODY gene mutations are present in GDM-affected women. MODY is an inherited form of diabetes resulting by a mutation of a single, autosomic, dominant gene that disrupts insulin secretion. It may be inherited to the offspring by both maternal and paternal origin; less frequently, it can be caused by de novo gene mutation. Nowadays, several types of MODY have been recognized. Genes that are implicated to MODY development are hepatocyte nuclear factor-1 homeobox a (HNF1a) gene that is responsible for MODY 3 development, glucokinase (GCK) gene for MODY 2, hepatocyte nuclear factor-4 homeobox a (HNF4a) gene for MODY 1, hepatocyte nuclear factor-1 homeobox b (HNF1b) gene that cause diabetes and renal cysts (MODY 5), insulin promoter factor (HPF1) gene for MODY 4, insulin gene for MODY 10, ABCC8 gene [sulfonylurea receptor-1 (SUR1) subunit] for MODY 12, potassium inwardly rectifying channel subfamily J member 11 (KCNJ11) gene for MODY 13, neurogenic differentiation-1 gene (NEUROD1) for MODY 6, kruppel-like factor 11 (KLF 11) gene for MODY 7, carboxyl ester lipase (CEL) gene for MODY 8, paired box-4 (PAX4) gene for MODY 9, and BLK gene for MODY 11 [125–133]. These monogenic forms of diabetes constitute less than 10% of GDM; MODY 2 has been recognized as the most frequent type associated with GDM [134]. Several other mutations of MODY genes have been detected in GDM women such as HNF1a, IPF1, insulin gene, and KCNJ11 gene [135–139]. However, a causal relationship between MODY and GDM has not been established yet. Further investigation is needed regarding the possible clinical implications of MODY gene mutations on maternal and fetal health [134].

Conclusions

GDM is the most common metabolic complication of pregnancy. Its prevalence has been increasing over the years and parallels the increasing obesity trend. The main pathogenetic mechanism is insulin resistance as a result of maternal and

placental hormone alteration, maternal adipokine alteration, low-grade inflammation, and oxidative stress that accompany both pregnancy and obesity. An additional pathogenetic mechanism is β-cell dysfunction either pre-existing, as a result of occult genetic predisposition, or due to hormonal and inflammatory effect of pregnancy and obesity. Less frequent causes of GDM are autoimmune destruction of pancreatic β-cells (similarly to T1DM) and impaired insulin secretion caused by gene mutations, such as MODY.

Multiple-Choice Questions

1. Gestational diabetes mellitus constitutes:
   (a) A rare disease
   (b) The most common metabolic disease of pregnancy
   (c) A disease that begins when healthy blood cells change and grow uncontrollably
   (d) The onset of Type 2 diabetes in pregnancy
   (e) A monogenic form of diabetes occurring in pregnancy
2. In gestational diabetes mellitus-affected pregnancies, estrogen concentrations are:
   (a) Equal as compared to unaffected pregnant women
   (b) Higher as compared to unaffected pregnant women
   (c) Lower as compared to unaffected pregnant women
   (d) Abolished during pregnancy
   (e) Are highly dependent of insulin concentrations
3. The Generation R Study showed that increased CRP concentrations during early gestation are associated to high risk of:
   (a) Asthma
   (b) Neonatal complications
   (c) Weight loss
   (d) Hypoglycemia
   (e) Maternal cardiovascular disease
4. Which is the main pathogenetic mechanism of gestational diabetes mellitus?
   (a) Insulin resistance as a result of maternal and placental hormone alteration, maternal adipokine alteration, low-grade inflammation, and oxidative stress that accompany both pregnancy and obesity
   (b) Insulin as a result of maternal and placental hormone alteration, maternal adipokine, low-grade inflammation and oxidative stress that accompany the obesity
   (c) Autoimmune destruction of pancreatic β-cells (similarly to T1DM) and impaired insulin secretion caused by gene mutations, such as MODY
   (d) Insulin resistance in skeletal muscle resulting from physical inactivity during pregnancy
   (e) High levels of counter-regulatory hormones
   (f) Maternal overweight and obesity
5. Placental hormones, such as human placental lactogen (HPL) and placental growth hormone (GH) are:
   (a) Opposed to insulin action
   (b) Excellent drugs to treat gestational diabetes mellitus
   (c) Acts as a "pro-insulin" agent
   (d) Opposed to glucagon action
   (e) Supportive to insulin action
6. Inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), have a direct adverse effect on insulin action in healthy nonpregnant women, inducing:
   (a) Insulin resistance
   (b) Gestational diabetes mellitus
   (c) C-reactive protein decrease
   (d) Lower risk for metabolic, cardiovascular, and cerebrovascular disease
   (e) Beta-cell failure
7. Maternal, placental, and fetal adrenal steroids, progesterone, cortisol, estrogen, and androgens, also contribute to pregnancy-induced insulin resistance.
   (a) False
   (b) True
8. An anabolic hormone, involved in carbohydrate and lipid metabolism, when in excess, has diabetogenic properties, opposing insulin action.
   (a) Growth hormone
   (b) Epinephrine
   (c) Estrogens
   (d) Progesterone
   (e) Leptin
9. Inflammation resulting from impaired adipokine synthesis has been correlated to β-cell dysfunction and decreased insulin secretion.
   (a) False
   (b) True
10. In nonpregnant healthy women (with normal prolactin concentrations), lower prolactin concentrations are associated with:
   (a) Decreased insulin sensitivity and lower risk for diabetes.
   (b) Decreased insulin sensitivity and high risk for diabetes.
   (c) Increased insulin sensitivity and low risk for diabetes.
   (d) Increased insulin sensitivity and high risk for diabetes.
   (e) No associations have been documented.

Correct Answers

1. (b) The most common metabolic disease of pregnancy
2. (c) Lower as compared to unaffected pregnant women
3. (b) Neonatal complications

4. (a) Insulin resistance as a result of maternal and placental hormone alteration, maternal adipokine alteration, low-grade inflammation, and oxidative stress that accompany both pregnancy and obesity
5. (a) Opposed to insulin action
6. (a) Insulin resistance
7. (b) True
8. (a) Growth hormone
9. (b) True
10. (b) Decreased insulin sensitivity and high risk for diabetes

Non-alcoholic Fatty Liver in the Pathogenesis of Diabetes

15

Cristiane A. Villela Nogueira and Nathalie Carvalho Leite

Introduction

Non-alcoholic fatty liver disease [1] is prevalent worldwide and is recently one of the leading causes of chronic liver disease in the occident due to obesity-related epidemic and metabolic syndrome [2]. NAFLD presents with different phenotypes and may progress to cirrhosis and hepatocellular carcinoma. Moreover, it may be the leading cause for liver transplant in the next decade [3]. NAFLD was formerly identified in 1980, when Ludwig et al. described a small series of patients with liver histology characterized by fat accumulation, hepatic necroinflammation, and, in most cases, fibrosis, in the absence of a history of excessive alcohol consumption [4].

Definition of NAFLD

Currently, NAFLD is defined as the presence of macrovesicular steatosis in ≥5% of hepatocytes in individuals who consume little or no alcohol. NAFLD is divided into two major subtypes that comprise different phenotypes histologically identified: non-alcoholic fatty liver (NAFL, also termed simple steatosis), the non-progressive form of NAFLD that rarely develops into cirrhosis, and NASH, the progressive form of NAFLD that can lead to cirrhosis and hepatocellular carcinoma [1] and is associated with an increase of liver-related mortality. NASH is characterized by the presence of steatosis, ballooning degeneration, and lobular inflammation, with or without peri-sinusoidal fibrosis on liver histology [5].

Epidemiology

The background for the high prevalence of NAFLD is multifactorial, being related to sedentarism, Western lifestyle worldwide, obesity, as well as to genetic factors. It is present in almost 30% of the general population [6]. The prevalence of NAFLD in Europe and the Middle East ranges from 20% to 30% [7]. In the USA, one-third of the population is now obese, and one-third of American adults are thought to have NAFLD (Centers for Disease Control and Prevention *Overweight and Obesity* [online], http://www.cdc.gov/obesity/data/adult.html (2012). NAFLD prevalence in Japan and China is similar to that in Europe (20–30% in Japan and 15–30% in China, respectively) [8]. In the Indian subcontinent, the prevalence of NAFLD in urban populations ranges from 16% to 32%; however, in rural India, where most people have traditional diets and lifestyles, the prevalence is around 9%, lower than in urban population [9]. In Latin America, the prevalence of NAFLD has been reported to range from 17% to 33% [10]. Data is lacking in the African continent; however, one study from Nigeria, which included patients with and without diabetes mellitus, identified a prevalence of 9.7% [11]. Regarding pediatric population, the prevalence of NAFLD varies from 3% to 10%, rising up to 40–70% among obese children [12].

Patients with NAFLD and metabolic syndrome share the same risk factors: obesity, type 2 diabetes mellitus, dyslipidemia, and insulin resistance. Diabetes has a huge impact not only on its prevalence worldwide but also on NAFLD severity [13]. The prevalence of ultrasonographic NAFLD in diabetic patients may be as high as 70% [13, 14].

Although cardiovascular death is the most common mortality-related factor among NAFDL population, increasing data regarding liver-related death due to liver dysfunction and hepatocellular carcinoma [1] has been increasingly reported. Although HCC is usually diagnosed in patients with NAFLD-related cirrhosis, it has also been detected in non-cirrhotic NAFLD. However, its true incidence and risk is still unknown [1]. Compared to viral

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_15

hepatitis, the progression of liver fibrosis in NAFLD seems to be slower (patients developing cirrhosis 28–57 years) [15]; however, the burden of patients with NAFLD is higher than those with hepatitis C [16]. At present, NASH cirrhosis is the third leading indication for liver transplantation in the USA [17]. In the forthcoming decades, due to a projected increase in HCC incidence, a change in the burden of related cases of HCC is expected, moving from viral hepatitis to NASH-related cirrhosis as the major risk factor for HCC worldwide [7].

Clinical Manifestations

The clinical presentation of NAFLD is insidious. Most patients are generally asymptomatic at diagnosis and are often referred from an internist with an ultrasound that demonstrates liver steatosis. Indeed, abdominal ultrasonography, owing to its non-invasive profile and easy accessibility, is the main screening and diagnostic method for NAFLD [18], although it is limited for patients that have more than 33% steatosis on liver biopsy. Patients who are symptomatic usually have non-specific symptoms like fatigue and a dull pain or heaviness in the right hypochondria. However, a physical exam with signs of insulin resistance like acanthosis nigricans, an enlarged waist circumference (usually over 88 cm in women and 102 cm in men), and overweight should also be a clinical clue to the diagnosis of NAFLD [19]. It's also important to be aware of some clinical conditions that may be associated with insulin resistance like polycystic ovarian syndrome in young women, which usually presents with obesity, hirsutism, acanthosis, and other diseases like hypothyroidism and sleep apnea disease which are closely related to an increased prevalence of NAFLD (Bano, 2016 #990) [20].

Diagnosis

Most patients with NAFLD are diagnosed by incidental elevated liver enzymes or imaging studies suggesting hepatic steatosis [21]. When NAFLD is suspected, the first step to confirm its diagnosis is to exclude other known etiologies of chronic liver diseases like drug-related steatosis [22, 23], viruses [24], and alcohol. As previously described, a careful history of alcohol ingestion and medications that are related to steatosis must be taken. Of note, some NAFLD patients with excessive alcohol intake may have both alcoholic and non-alcoholic fatty liver disease [25]. The average amount of alcohol that is allowed for patients with NAFLD have been under debate, but so far, although small to moderate amounts of alcohol might be related to a decrease in cardiovascular risk, patients with NAFLD should refrain from drinking alcohol [26]. Generally, for the diagnosis of NAFLD, the upper limit for alcohol intake would be a maximum of 30 g alcohol/day.

The different phenotypes of NAFLD are simple steatosis, steatohepatitis, and fibrosis. However, so far, due to the lack of specific and accurate biomarkers, only liver biopsy can accurately identify steatohepatitis. Steatosis is the most prevalent phenotype, and patients with simple steatosis have a benign course of the disease. Although NAFLD is the most common diagnosis in patients with incidental abnormal liver function tests [27], laboratorial tests are of minor value since most of patients with NAFLD including those with more advanced disease may present normal inflammatory liver enzymes [28]. Another drawback in laboratorial diagnosis of NAFLD is that as fibrosis progresses, both inflammatory enzymes such as AST and ALT and steatosis decrease. On the other hand, patients with persistent abnormal liver enzymes are those who usually present NASH on liver biopsy as well as other liver comorbidities like viral or autoimmune hepatitis. In conclusion, routine AST/ALT do not differentiate steatosis, NASH, or the stage of fibrosis [29].

Liver Biopsy and Non-invasive Markers of Fibrosis

As already stated, the only way to accurately diagnose the different phenotypes of NAFLD is through a liver biopsy. This is an invasive method prone to inter-observer and intra-observer disagreement. In addition, it is painful and difficult to be performed in such a high burden and widespread disease. Due to these drawbacks, the search for non-invasive methods to identify different spectrum of the disease is currently under research. So far, steatosis and fibrosis can be identified by non-invasive methods that vary from serological scores to image methods, and since the presence of fibrosis is the most important prognostic marker of the disease, it is reasonable to develop non-invasive methods that correctly identify or exclude liver fibrosis. At present there are a great number of serological scores that can be used to assess patients with NAFLD. They are usually applied as screening tools to identify patients with higher risk to the progressive forms of NAFLD. The most commonly used is the NAFLD fibrosis score ($1.675 + 0.037 \times$ age $+ 0.094 \times$ BMI $+ 1.13 \times$ IFG/Diabetes $+ 0.99 \times$ AST/ALT ratio $- 0.013 \times$ platelets $- 0.66 \times$ albumin), where a score <-1.455 excludes fibrosis (NPV 88–93%) and >0.676 predicts fibrosis (PPV 82–90%) and FIB-4 [[30]/(Platelets* Sqrt (ALT)] which has been defined as a useful score to predict fibrosis in NAFLD patients as well: a result <1.35 excludes fibrosis (NPV 95%) and >3.25 predicts fibrosis (PPV~ 70%). McPherson et al. compared the performance of simple serological tests to predict fibrosis, and the results are shown in Table 15.1 [31].

Table 15.1 Diagnostic performance of serologic scores to evaluate fibrosis in NAFLD

Test	AUC	Cutoff	Sens (%)	Spec (%)	PPV (%)	NPV (%)
NAFLD fibrosis score	0.81 (0.71–0.91)	−1.45 0.676	78 33	58 98	30 79	92 86
FIB-4	0.86 (0.78–0.94)	1.30 3.25	85 26	65 98	36 75	95 85
BARD	0.77 (0.68–0.87)	2	89	44	27	95
APRI	0.67 (0.54–0.8)	1	27	89	37	84
AST/ALT ratio	0.83 (0.74–0.91)	0.8 1	74 52	78 90	44 55	93 89

Legend: *NAFLD* non-alcoholic fatty liver disease, *BMI* body mass index, *IFG* intolerant fasting glucose, *AST* aspartate aminotransferase, *ALT* alanine aminotransferase, *NPV* negative predictive value, *PPV* positive predictive value

NASH is the phenotype of NAFLD that points to a progressive form of the disease, and so far, only liver biopsy is able to make this diagnosis. The histological definition of NASH comprises the triad of steatosis, cell injury [32], or any amount of lobular or portal inflammation. Of note, fibrosis is not required for the diagnosis of NASH. Semiquantitative histological scoring systems have been proposed for NAFLD, but they are not useful in clinical practice, and each has certain limitations. Recently, Bedossa et al. developed a new histological classification for NAFLD: the FLIP algorithm and the SAF (steatosis, activity, fibrosis) which assesses separately the grade of steatosis [32], the grade of activity [32], and the stage of fibrosis [32]. This algorithm and score may improve the agreement between pathologists when describing fibrosis stage [32].

Other non-invasive tools that have been useful as screening methods for the identification of patients with higher risk of fibrosis are transient elastography (TE) [33], two-dimensional shear wave elastography (2D-SWE), acoustic radiation force impulse (ARFI) which is a type of point shear wave elastography, and elastorressonance. Although elastoressonance has been considered the most accurate method for the identification of liver fibrosis, its use is limited as a screening method by cost and accessibility.

TE uses an ultrasound displacement M-mode and A-mode image produced by the system. It has two probes, M and XL. The XL probe was designed for obese patients, which has increased the success rate of the exam in patients with NAFLD since most are obese and, before the development of the XL probe, most exams were unreliable. Currently, all patients with a skin-to-liver capsule distance (SCD) of >25 mm should be assessed with the XL probe. Measures obtained with the XL probe are generally 1.5 kPA lower than those achieved with the M probe [34]. TE results under 7.9 kPa have a high negative predictive value for advanced fibrosis (97%) and should be employed in daily practice to decide about performing a liver biopsy in patients with NAFLD [35].

Two-dimensional shear wave elastography (2D-SWE) evaluation needs to be performed in a well-visualized area of the right liver lobe, without the visualization of large vessels, liver capsule, ligaments, and the gallbladder [36]. Obesity, which is one of the most prevalent findings in NAFLD patients, might limit a successful exam in addition to poor acoustic window or presence of artifacts and inability of the subjects to hold their breath [37].

In a study that compared the diagnostic performances of supersonic shear imaging (SWE) for the diagnosis of liver fibrosis compared to ARFI and TE in chronic liver disease, SWE, TE, and ARFI correlated significantly with histological fibrosis score; AUROCs of SWE, TE, and ARFI were 0.89, 0.86, and 0.84 for the diagnosis of mild fibrosis; 0.88, 0.84, and 0.81 for the diagnosis of significant fibrosis; 0.93, 0.87, and 0.89 for the diagnosis of severe fibrosis; and 0.93, 0.90, and 0.90 for the diagnosis of cirrhosis, respectively. Hence, all methods might be used to assess liver fibrosis in patients with NAFLD, since the reliability criteria are respected as well as its limitations [37]. Additional studies with 2D-SWE and ARFI are needed in order to better establish the best cutoffs for these methods.

NAFLD and T2DM Interplay

In order to better understand the interplay between NAFLD and T2DM, it is important to review epidemiological data and pathogenetic mechanisms accounting for this relationship. As discussed before, T2DM is a risk factor for NAFLD and its progressive form, NASH, and advanced liver fibrosis [38–40]. Interestingly, in addition to T2DM, a family history of diabetes was independently associated with the presence of NASH and fibrosis in NAFLD patients [41].

In our cross-sectional study, no diabetes-related variable (glycemic control, diabetes duration, or the presence of long-term complications) was associated with the more severe stages of NAFLD [40]. In contrast, data are emerging to suggest that the presence and severity of NAFLD may be associated with the occurrence of macro and microvascular complications in diabetic patients [42–45]. Two hypotheses could explain those conflicting epidemiological observations. First, NAFLD and T2DM may represent two distinct outcomes from insulin resistance, and, in this way, no diabetes-related characteristic would be expected to favor NAFLD progression. The second hypothesis is that both NAFLD and degenerative complications may precede the diagnosis of T2DM, running over time the same and progressive course.

It has demonstrated that over 85% of subjects with NAFLD have impaired glucose tolerance or T2DM by standard oral glucose tolerance test (OGTT) [46, 47]. Therefore, another issue to be considered is whether NAFLD is an important precondition for the development of T2DM. In this regard, several studies have shown an increased incidence of T2DM in patients with NAFLD diagnosed by ultrasonography or only by elevated liver enzymes. However, most of them were conducted in Asian countries, and few were properly adjusted for potential confounding variables [48, 49]. In a recent prospective cohort study of 3153 participants from the Multi-Ethnic Study of Atherosclerosis (MESA), high liver fat was independently associated with development of T2DM [50]. Two systematic reviews with different criteria for selecting studies of NAFLD patients obtained similar results. The two independent reviews demonstrated an increased risk for incident diabetes over a period of 4–10 years [51, 52]. Taken together, these observations have implied a role for NAFLD in T2DM pathogenesis.

Pathogenesis

During the course of human evolution, individuals who had more energy stores were more likely to cope with starvation. In modern industrialized societies, with unlimited access to caloric food, this evolutionary adaptation becomes maladaptive. An increased caloric intake exceeding rates of caloric expenditure promotes obesity, dysfunction of white adipose tissue, and accumulation of ectopic lipids. This relationship between the nutritional oversupply and NAFLD is reflected by the high prevalence of NAFLD and insulin resistance (IR) among obese individuals.

Insulin Resistance

There is strong evidence of an association of NAFLD and insulin resistance (IR). Euglycemic hyperinsulinemic clamp studies, coupled with tracer infusion, confirmed that the IR is the rule in main tissues even in non-diabetic and non-obese patients with NAFLD [53]. Insulin is a pleiotropic hormone that regulates different cell functions. Concerning lipid-related metabolism, insulin promotes triglyceride storage and inhibits lipoprotein lipase activity in adipose tissue. Insulin resistance at the level of the adipocyte seems to be the primary defect in NAFLD [54, 55]. Impairment in insulin-mediated suppression of lipolysis leads first to elevated circulating non-esterified fatty acids (NEFAs) and subsequently to a sustained excess delivery of these fatty acids to skeletal muscle and liver. In fact it is the tissue-specific distribution of fat from adipose tissue into ectopic depots that determines liver and muscle insulin resistance, not the whole-body quantity of fat.

As obesity and the deposition of ectopic fat increases, adipose tissue is more likely to be infiltrated with macrophages and undergo inflammation. Thus, the expanded and dysfunctional adipose tissue secretes inflammatory cytokines such as tumor necrosis factor α (TNFα) and interleukin 6 (IL-6), which decrease insulin sensitivity at the level of the adipocyte. TNFα activates pro-inflammatory pathways: the nuclear factor κB (NF-κB) and c-Jun N-terminal kinase (JNK) [56]. TNFα-induced attenuation of insulin signaling is mediated by JNK and occurs via serine phosphorylation of insulin receptor substrate [57]. In addition, serum levels of adiponectin, a hepatoprotective adipokine, are reduced in patients with NAFLD. Adiponectin improves insulin sensitivity and decreases both steatosis and inflammation [58].

Insulin resistance also leads to adverse effects on the metabolism of carbohydrates: increased gluconeogenesis and glycogenolysis in liver as well as reduction in peripheral glucose uptake. Chronic hyperglycemia induces insulin secretion by the pancreatic beta islet cells, leading to compensatory hyperinsulinemia. The mechanisms of beta cell progressive failure are less well defined; however, elevated levels of glucose as well as increased circulating NEFAs may be responsible for pancreatic beta islet cell dysfunction and apoptosis [59]. With time, as hyperglycemia worsens, fasting and total insulin production begins to decline. It is the progressive loss of beta cell insulin secretion in the setting of insulin resistance (IR)/hyperinsulinemia that predisposes to T2DM development.

Compensatory Hyperinsulinemia

Interestingly, it has been argued that many of the adverse effects due to insulin resistance result much more from compensatory hyperinsulinemia in organs that remain sensitive to its action. In fact, there is selective insulin resistance even in different pathways within the same tissue or organ. In the liver, for instance, while insulin fails to suppress gluconeogenesis, it continues to promote FAs synthesis (de novo lipogenesis, DNL). Both hyperglycemia and hyperinsulinemia activate transcription factors sterol regulatory element-binding protein-1c (SREBP-1c) and carbohydrate response element-binding protein (ChREBP), which upregulates most genes involved in DNL [60].

The synthesis of long-chain FAs is determined by the sequential action of various enzymes: acetyl CoA carboxylase (ACC), fatty acid synthase (FAS), fatty acid elongases, and desaturases [61]. In turn, many of these enzymes are directly controlled by the key regulator SREBP-1c and liver

x receptor, which is also an important component of the nuclear receptor superfamily.

Hence, the action of these upregulated lipogenic enzymes and the increased delivery and uptake of FAs (adipose tissue and diet) play a critical role in the induction of NAFLD. Hepatic steatosis develops when the balance between hepatic triglycerides (TAGs) synthesis from free fatty acids (FAs) exceeds the liver capacity to oxidize FAs or export TG in the form of very-low-density lipoprotein (VLDL). FAs may be oxidized in the mitochondria, peroxisomes, and microsomal system. β-oxidation within mitochondria, however, is the most efficient source of energy under normal circumstances. Uptake and oxidation of FAs by mitochondria are both inhibited by a key intermediary of de novo lipogenesis. Decreased disposal of FFA is also the result of reduction in production of apolipoprotein B, leading to a relative impairment of very low-density lipoprotein (VLDL) generation [62].

Hepatic Insulin Resistance

Although hepatic TAGs are thought to be inert or even protective for NAFLD progression, FAs metabolites such as diacylglycerol (DAG) may further contribute to IR and NASH development. The probable causal link between citossolic DAG content and IR is attributed to PKCε activation. Activated PKCε isoform binds and inhibits insulin receptor kinase, leading to reductions in insulin-stimulated tyrosine phosphorylation of insulin receptor substrate IRS-2 and insulin signaling [63]. In contrast to hepatic DAG, other FAs metabolites, such as ceramides, are less important lipid mediators of hepatic IR in NAFLD [64].

Selective insulin resistance (IR) in the liver is a key pathophysiologic event in the development of NAFLD and type 2 diabetes. Differences in insulin receptor (InsR) activation underlie the selective IR of glucose production relative to lipogenesis. Decreased (InsR) activation has been observed in the liver of patients with NAFLD and results from a cell-autonomous downregulation of receptor number and/or activity in response to chronic hyperinsulinemia. It has been shown that a greater degree of intact InsR signaling is required to suppress glucose production than to stimulate lipogenesis, one through forkhead O transcription factor-1 (FOXO1) and the other through SREBP-1c [65]. This "bifurcation" of hepatocyte insulin signaling underlies the mechanisms by which one branch (i.e., glucose metabolism) becomes resistant to the effects of insulin, whereas the other (i.e., lipid metabolism) remains sensitive or even stimulated by hyperinsulinemia. These molecular features of hepatocyte insulin signaling do not rule out the role of excess citossolic DAG in hepatic IR.

Genetics in NAFLD Pathogenesis

During the last years, genome-wide association studies revealed genetic variants associated with NAFLD pathogenesis. Patatin-like phospholipase domain-containing protein 3 (PNPLA3), transmembrane 6 superfamily 2 (TM6SF2), and glucokinase regulator (GCKR) gene polymorphisms were recently validated in large and independent cohorts. The most well-described genetic risk variant is the I148M variant in PNPLA3 gene. The I148M allele leads to a loss of phospholipase lipolytic activity, which predisposes to increased hepatic fat content and progressive liver damage. In the case of TM6SF2, (Lys E167K) T allele has been associated with hepatic retention of TAG and hepatic fibrosis and (Glu E167K) C allele with VLDL secretion and atherogenesis. However, both genetic variants in PNPLA3 and TM6SF2 have not been associated with IR or increased risk of T2DM [66, 67]. The P446L variant in GCKR gene increases glucose uptake and DNL in hepatocytes. In this setting, hepatic lipid accumulation from constant glucose substrate favors liver disease but protects from T2DM development.

Endoplasmic Reticulum Stress and the Innate Immune Response

In normal conditions, the majority of secreted and membrane proteins are folded in the endoplasmic reticulum (ER) and transported to the Golgi apparatus. In circumstances of elevated circulating (NEFAs), unfolded proteins can accumulate in this organelle. The "unfolded protein response" [68] or "the ER stress response" (ER) arises from an increased amount of unfolded proteins and impaired capacity to properly fold these proteins in the ER. Accumulation of unfolded proteins in the ER activates transmembrane signal transducers, regulates lipogenesis, and, ultimately, leads to apoptosis-inducing pathways and cell death. Furthermore, a stress-specific transcription factor named X-Box binding protein 1 (XBP1) can also activate c-Jun N-terminal (JNKs) signaling, contributing to the development of IR.

Toll-like receptors (TLRs) are a family of receptors that plays a critical role in innate immune systems. TLR4 received a particular attention because of its ability to recognize free fatty acids and lipopolysaccharides (LPSs) and activate the pro-inflammatory signaling pathway nuclear factor κB (NFκB). Thus, LPSs have an indirect effect on insulin sensitivity and inflammation [69, 70].

Patients with NAFLD have small intestinal bacterial overgrowth and increased intestinal permeability, allowing LPSs and other products to enter the portal circulation. These observations have implied an important role for gut microbiota-induced inflammation in the development of NAFLD and insulin resistance [71, 72].

Conclusion

NAFLD is present in over 30% of the world population. NASH with fibrosis may progress to cirrhosis and hepatocellular carcinoma. In addition, the recent alarming rise of obesity, T2DM and components of metabolic syndrome are even more concerning. Regarding NAFLD and T2DM interplay, it is important to highlight that T2DM is a risk factor for NAFLD and its progressive form: NASH with fibrosis. This link would explain why NAFLD in diabetic patients presents with a high prevalence of advanced stages of the disease. As discussed before, there are a wide range of non-invasive methods available for the detection of steatosis and fibrosis. In general, NAFLD score and transient elastography are the most routinely used tools to discriminate patients at risk for advanced fibrosis. However, the major challenge is to identify reliable non-invasive methods in the specific population of T2DM patients.

Another issue addressed in this chapter is the independent contribution of NAFLD to new-onset T2DM. In fact, NAFLD is believed to concur to the pathogenesis of T2DM through multiple mechanisms. The practical implication of this close interaction of NAFLD and T2DM is related to its therapeutic potential. New promising drugs in the pipeline are expected to improve NASH with fibrosis. Besides that, these new therapies may end up decreasing the risk of incident T2DM.

Multiple Choice Questions

1. Different phenotypes of non-alcoholic fatty liver disease include:
   (a) Simple steatosis, steatohepatitis, and fibrosis
   (b) Asthma COPD overlap syndrome, frequent exacerbators, and alpha-1 antitrypsin deficiency
   (c) Dominant allele and recessive allele
2. Non-alcoholic fatty liver disease is recently one of the leading causes of:
   (a) Chronic liver disease in the occident due to obesity-related epidemic and metabolic syndrome
   (b) Infections H1n1 flu virus
   (c) Gestational diabetes mellitus
   (d) Autoimmune destruction of pancreatic β cells
3. Selective insulin resistance in the liver is a key pathophysiologic event in the development of:
   (a) Non-alcoholic fatty liver disease and type 2 diabetes mellitus
   (b) Latent autoimmune diabetes in adults
   (c) Chronic obstructive pulmonary disease
   (d) Cardiovascular disease
4. Which is the first step to confirm the diagnosis when non-alcoholic fatty liver disease is suspected?
   (a) Exclude other known etiologies of chronic liver diseases like drug-related steatosis, viruses, and alcohol.
   (b) Receive an injection of a small amount of radioactive material; it flows through bloodstream and collects in certain bones or organs. A machine called a scanner detects and measures the radioactivity.
   (c) An oral glucose tolerance test measures blood sugar after you have gone at least 8 hours without eating and 2 hours after you drink a glucose-containing beverage.
   (d) Measured with a device known as a sphygmomanometer, which consists of a stethoscope, arm cuff, dial, pump, and valve.
5. Non-alcoholic fatty liver disease is defined as:
   (a) The presence of macrovesicular steatosis in ≥5% of hepatocytes in individuals who consume little or no alcohol
   (b) The presence of macrovesicular steatosis in −5% of hepatocytes in individuals who consume little or no alcohol
   (c) The presence of macrovesicular steatosis in ≥50% of hepatocytes in individuals who consume little or no alcohol
   (d) The presence of macrovesicular steatosis in ≤5% of hepatocytes in individuals who consume little or no alcohol
6. Non-alcoholic fatty liver disease is multifactorial, related to sedentarism, Western lifestyle worldwide, obesity, as well as to genetic factors with a frequency of:
   (a) Almost −20% of the general population
   (b) Almost 100% of the general population
   (c) Almost 30% of the general population
   (d) Almost 2% of the general population
7. Insulin resistance at the adipocyte level is the primary defect in non-alcoholic fatty liver disease because:
   (a) Insulin promotes HDL cholesterol storage and promotes lipoprotein lipase activity in adipose tissue.
   (b) Insulin promotes triglyceride storage and inhibits lipoprotein lipase activity in adipose tissue.
   (c) Insulin resistance is a promoter of weight loss.
8. Hyperglycemia and hyperinsulinemia activate transcription factors sterol regulatory element-binding protein-1c (SREBP-1c) and carbohydrate response element-binding protein (ChREBP), which upregulates most genes involved in DNL.
   (a) True
   (b) False
9. Patients with non-alcoholic fatty liver disease have small intestinal bacterial overgrowth and increased intestinal permeability, allowing LPSs and other products to enter the portal circulation.
   (a) True
   (b) False

10. Type 2 diabetes mellitus is a risk factor for non-alcoholic fatty liver disease and its progressive form, NASH, with fibrosis because:
    (a) There is an established link between diabetes and non-alcoholic fatty liver disease.
    (b) Positive family history of gestational diabetes mellitus and higher parity are established risk factors for the development of gestational diabetes mellitus.
    (c) Subjects with normal glucose metabolism (at various ages and at risk for all forms of diabetes) have shown that normal glucose tolerance is characterized by glucose levels within a very narrow range.
    (d) Physical inactivity is also a leading risk factor for the development of non-communicable diseases and is responsible for substantial economic burdens worldwide.

Correct Answers

1. (a) Simple steatosis, steatohepatitis, and fibrosis
2. (a) Chronic liver disease in the occident due to obesity-related epidemic and metabolic syndrome
3. (a) Non-alcoholic fatty liver disease and type 2 diabetes mellitus
4. (a) Exclude other known etiologies of chronic liver diseases like drug-related steatosis, viruses, and alcohol
5. (a) The presence of macrovesicular steatosis in ≥5% of hepatocytes in individuals who consume little or no alcohol
6. (c) Almost 30% of the general population
7. (b) Insulin promotes triglyceride storage and inhibits lipoprotein lipase activity in adipose tissue
8. (a) True
9. (a) True
10. (a) There is an established link between diabetes and non-alcoholic fatty liver disease

Part III

Examples of Global Experiences in Diabetes Care

Diabetes Management in Asia

16

Roopa Shivashankar, Kavita Singh, L. R. Aravind, and Nikhil Tandon

Chapter Objectives

- To provide an insight into current issues in management of diabetes mellitus in Asian countries
- To understand distinctive health systems factors that influence management of diabetes mellitus
- To present examples of best practices in diabetes care in Asia

Introduction

Asia as a continent is diverse and consists of large low- and middle-income countries (LMICs) [1]. Asian populations are racially heterogeneous and have differing demographic, cultural, and socioeconomic characteristics. A few decades earlier, they were more physically active, and most people followed distinctive sociocultural norms and traditional dietary practices [2]. The prevalence of diabetes mellitus (DM) has sharply increased in Asia due to rapid economic, demographic, and lifestyle transitions that have occurred over the past two decades [3, 4]. Conservative estimates based on population growth, aging, and urbanization rate in Asia suggest that India and China will remain the two countries with the highest numbers of people with DM (150.7 million and 123.5 million, respectively) by 2040 [5]. Also, among the top ten countries, three more are in Asia—Indonesia, Pakistan, and Bangladesh [5].

In 2015, 415 million people worldwide had diabetes, with 193 million people, or close to half (46.5%) of them, being undiagnosed. The global prevalence of DM is predicted to reach 642 million by 2040 [5]. The International Diabetes Federation (IDF) Diabetes Atlas, 7th Edition data for 2015, revealed that the DM prevalence in the Middle East, Southeast Asia, and Western Pacific regions was 9.1%, 8.5%, and 9.3%, respectively [5]. Notably, 60% of the world's diabetic population is from Asia [6, 7]. The unique feature of DM in Asian countries is the rapidly increasing prevalence of diabetes in the younger age group [8]. In China, from 1994 to 2000, there was an 88% increase in prevalence in the 35–44-year age group [9, 10]. Data from southern India show that the people younger than 44 years contributed to 25% of all people with DM in 2000 and that proportion rose to 35.7% in 2006 [11]. Factors that have contributed to the epidemic of obesity and diabetes in younger populations are the rapid transition in dietary habits, reduced physical activity, changing pattern in leisure activities, longer working hours, and decreasing sleep hours [12]. Increasing levels of modernization, industrialization, and economic advancements adversely affect biological and environmental risk factors for diabetes [13]. Further, the literature suggests that Asians have higher propensity to develop diabetes at low thresholds of conventional risk factors such as age, body mass index (BMI), upper-body adiposity, and other metabolic features, when compared to other populations [3, 4, 8, 10]. Diabetes develops at least a decade earlier in Asians than in white Caucasians. Both the thrifty genotype and thrifty phenotype might be operative in Asian groups [2, 12, 14]. Asian populations also have high rates of clustering of cardiovascular risk factors even at a young age [2, 15].

Prevalence of Type 1 Diabetes Mellitus (T1DM)

Asia has one of the highest burdens of T1DM in children, with 77,890 affected in 2013. According to the IDF estimates, India has the second largest number of children with type 1 diabetes (67,700) after the United States and the largest proportion of incident cases of T1DM among the Southeast Asia countries [5, 12]. Beta cell autoantibodies are typically present only among 30–40% of patients with T1DM in Asia, compared to the reported prevalence of 70–80% in Western populations [12]. This may reflect differences in underlying pathophysiology. On the other hand, an increasing proportion of patients treated as T2DM is recognized to have evidence of progressive autoimmune destruction of beta cells and latent autoimmune diabetes in adults (LADA) [16, 12].

Prevalence of Young-Onset Diabetes

Population-based and community-based studies of type 2 diabetes in children are few, but several clinic-based studies exist [17]. Increasing prevalence of overweight and obesity in children and adolescents is one of the important causes of young-onset diabetes. The 2002 National Nutrition and Health Survey in China showed that 4.1% of children aged 7–12 years and 5.6% of children aged 12–18 years were overweight, and the obesity prevalence was 2.5% and 1.6%, respectively [12]. In Hong Kong, a community-based survey showed that 8–10% of children aged 12–13 years were obese [18]. A recent study from India reported high prevalence of metabolic syndrome in adolescents aged 10–18 years: 22.3% in girls and 16.6% in boys [19, 20]. Prevalence of overweight (18%) and obesity (5.5%) were also found to be significantly higher among children aged 5–18 years in India [21]. Prevalence of young-onset diabetes is increasing in Asian populations, and their rising trend is linked to epigenetic factors, such as maternal imprinting, and unhealthy lifestyle changes leading to high rates of obesity [14, 22].

Urban and Rural Prevalence of Diabetes

Although the prevalence of diabetes is often higher in urban than in the rural settings, the rates are increasing more rapidly in the rural population. A systematic analysis of long-term trends between 1989 and 2005 showed a 2.2-fold increase in diabetes prevalence in urban populations from 8.3% to 18.6% and a 4.2-fold increase in the rural population from 2.2% to 9.2% [23–25]. In Sri Lanka, between 1990 and 2000, the prevalence of diabetes increased 1.2-fold from 5.3% to 6.5% in the urban population and 3.4-fold from 2.5% to 8.5% in the rural population [26, 27]. In urban Indian adults, diabetes prevalence increased from 3% in 1970 to 12% in 2000, with a narrowing of rural-urban gradient [28]. Furthermore, the prevalence of type 2 diabetes in rural South India was 9.2% and 18.6% in urban area in 2006 [29]. More recently, the ICMR-INDIAB study conducted in 15 states in India reported the overall prevalence of diabetes was 7.3% and higher in urban areas (11.2%) than in rural areas (5.2%) [30]. In rural Bangladesh, prevalence of diabetes increased from 2.3% to 6.8% between 1999 and 2004 [31]. In a national survey in 2001, 8% of Korean adults had diabetes, with little difference between urban and rural areas [32]. Other Asian countries including Japan, Malaysia, Indonesia, Thailand, Nepal, Cambodia, the Philippines, and Vietnam also have experienced a marked increase in prevalence of diabetes [15, 33–38].

Economic Burden of Diabetes Care

Inadequate resources, an insufficient health-care budget, lack of medical reimbursement, and socioeconomic barriers contribute to the sub-optimal management of diabetes, resulting in costly diabetes complications in Asian countries. The cost of diabetes care increases manifold when complications occur or when insulin treatment, admission to hospital, or vascular surgery, or amputation is required [39, 40]. In India, annual mean expenditure by patients on diabetes care is estimated to be $227 in urban areas and $142 in rural areas [41, 42]. Importantly, the low-income group spends nearly 25–35% of their annual income on diabetes care [43]. Annual direct and indirect costs of diabetes care were estimated to be $31.9 billion in 2010 for India [44]. Because of the high economic burden on the patients and their families, people tend to neglect health care, causing severe morbidities and early mortality [40].

Status of Management of Diabetes Mellitus in Asia

Management of diabetes is complex and includes detection, control, and prevention of complications of diabetes [45]. Sufficient evidence is available from research that early detection and appropriate management of diabetes—regular monitoring of cardiac risk factors, screening of complications, and pharmacological treatment of glycemia, blood pressure, and cholesterol and lifestyle modifications including tobacco cessation—reduce complications and deaths and improve quality of life [46–49].

The degree to which diabetes is detected and appropriately managed varies widely not just between countries but

also within different regions within countries. In this section, we will summarize the status of diabetes management in Asia.

Screening/Diagnosis of Diabetes

High prevalence [50], long latent asymptomatic period [51], availability of validated screening tools [52]and effective treatment [47] makes DM a good candidate for screening. Greater than 50% of the persons with diabetes have no symptoms and therefore remain undetected unless actively screened for diabetes [51]. IDF recommends opportunistic screening of high risk individuals in resource poor settings. [53] IDF also suggests that the diagnosis of diabetes should preferably be based on fasting plasma glucose but capillary glucose or even glycosuria may be used for diagnosis if the blood testing facilities are not available [50]. Comprehensive diagnostics including glycated hemoglobin (HbA1c) measurement and classification of type of diabetes can be made if higher resources are available. Asia has the largest number of adults with undetected diabetes [50]. The average lag between onset and diagnosis is seven years for diabetes [54–56]. In most Asian countries, a comprehensive plan for detection and management of diabetes either does not exist or is only partially implemented (Table 16.1). Initiatives in the past decade in countries like India (National Program For Prevention and Control of Cancer, Diabetes, Cardiovascular Disease and Stroke [NPCDCS]) [57], Bangladesh (Primary Prevention of Diabetes Mellitus and Non-Communicable Disease [PPDM and NCD's Program]) [58] and Malaysia (national strategic plan for NCDS [NSPNCD]) [59]have resulted in high risk screening at health facilities and communities. Recently, the National Health Mission, India has decided to implement universal screening of all adults ≥ 30 years every three years in 100 districts in India. [60] These initiatives are yet to be scaled up nationally and yet to be evaluated for their cost-effectiveness, and impact at the population level.

Drug Therapy

The most common diabetes prescription in Asia is use of single drugs [61, 62] with recent trend of higher use of combination therapy [63, 64]. Metformin or first generation sulfonylureas [61, 62] are the most commonly used category of drug in both monotherapy and in combination therapy. Thiazolidinediones and Dipeptidyl peptidase-4 (DPP-4) inhibitors use is common in high income countries such as Japan [64]. Though high cost of drug precludes use in low and middle income countries, [61] the use of DPP-4 inhibitors is becoming common in urban centers of LMICs. Insulin use was varied depending on setting and severity of diabetes. Evaluation of Taiwan's National Health Insurance Research Database found the use of insulin to be 7.3% and 8.3% in mono and combination therapy. [63] A large study involving 20554 diabetes patients from India reported use of insulin to be 18% (either alone or with oral hypoglycemic drugs) [65].

Diabetes Complications and Comorbidities

Diabetes patients in Asia are at higher risk of microvascular diabetic complications, in particular nephropathy, compared to the West [66, 67]. Microalbuminuria Prevalence (MAP) survey [68] had recruited 6801 type 2 diabetes patients with hypertension from 103 centers (both primary specialist centers) in 10 Asian countries during 2005. This study found that prevalence of microalbuminuria and macroalbuminuria were 39.8% and 18.8%, respectively. This is alarmingly high compared to the studies done in Western countries, where the prevalence of microalbuminuria ranged from 17% to 21%. However, the prevalence of albuminuria was highly variable within Asian countries [68]. Additionally, an evaluation of diabetes registry of 28,110 diabetes patients registered between 2007 and 2012 from seven countries in Asia (China, Hong Kong, India, Korea, the Philippines, Vietnam, and Taiwan) found that patients with diabetic kidney disease had poorer control of glycemia and blood pressure. Further, less than half of the patients with kidney disease were prescribed renin-angiotensin system inhibitors [69]. As high blood pressure is an important predictor of both albuminuria and renal failure, the synergism with diabetes may prove detrimental [70].

Asian countries also have high prevalence of diabetic retinopathy. Diabetic retinopathy is one of the leading causes of preventable adult blindness in Asia [71]. The evaluation of Joint Asia Diabetes Evaluation (JADE) Program, an electronic registry of patients with diabetes from several Asian countries including Korea, Thailand, Hong Kong, Singapore, and India, found that 20.4% of type 2 diabetes patients had retinopathy [69]. In a population-based survey from rural China, 33.5% of the newly diagnosed diabetes patients had retinopathy [72]. In addition to inadequate control of glycemia and blood pressure [73], anemia also leads to the progression of diabetic retinopathy by aggravating hypoxia [74]. In South Asian countries, anemia is highly prevalent and may be contributing to higher occurrence of retinopathy [75].

Interestingly, risk of diabetic neuropathy is lower in Asians, specifically South Asians. The prevalence of neuropathy in Asian Indians was 4% compared to 13% in Caucasians in UK Prospective Diabetes Study [76]. Shorter height, low levels of smoking, and better skin microcirculation are possible explanation for this low prevalence [76].

Table 16.1 National policies, infrastructure, and expenditure for diabetes in major Asian countries

Country	20–79 population (in 1000s)	DM prevalence estimates (%) [50]	Undetected/ total DM estimates (%) [50]	National operational policy/strategy/action plan for diabetes or NCDs		Adoption of WHO's global monitoring framework [105]	Availability of medicines in primary care facilities [105]			Availability of basic technologies in primary care facilities [105]							Mean expenditure/ person with diabetes in USD [50]	Cost of diabetes covered by central funding/ national insurance [105]
				Exists? [105]	Implementation? [105]		Insulin	Metformin	Sulfonyl urea	Blood glucose	OGTT	HbA_1c	Dilated fundus exam	FVP	FVS	Urine strips[a]

[a]Urine strips for glucose and ketone measurement

However, screening of neuropathy and its management is sub-optimal in South Asia [77]. The rate of foot examination varied between 1.9 and 64% [73]. Physicians considered diagnosis of and treatment of diabetes neuropathy a low priority [78].

Cardiovascular diseases (CVDs) occur at younger ages and lower BMI among Asians [79] and are accelerated in people with diabetes [80]. Among immigrant South Asians in the United Kingdom, certain characteristics such as an earlier disease onset, higher levels of homocysteine, insulin resistance, and low-grade inflammation were responsible for higher cardiovascular diseases [81]. In addition to higher susceptibility, inadequate management of the cardiac risk factors among persons with diabetes leads to a worsening of the situation. DECODA study conducted among Japanese and Indian cohorts with a follow-up period between 5 and 10 years (mean 5.9 years) estimated a hazard ratio of 3.42 (2.23–5.23) for CVD in screened diabetic individuals [82]. It is also worth noting that 78% of all mortality in people with diabetes in this study was associated with either higher blood pressure or raised lipid profiles or both [82].

The bidirectional relationship between diabetes and tuberculosis [83] is a matter of particular concern in Asia as tuberculosis is still a major public health problem in most Asian countries [84]. Diabetes not only weakens the immune system increasing the tuberculosis risk but also leads to higher risk of poor outcomes in tuberculosis. On the other hand, tuberculosis predisposes individuals to impaired glucose tolerance, and antituberculosis drugs such as rifampicin interfere with glucose control. Depression is an under-recognized comorbidity of diabetes [85]. While diabetes increases the risk of depression [86–89], depression affects self-care, compliance to medication, and overall quality of life in diabetes [90]. Depression in individuals with diabetes varied from 15.2% in Malaysia [89] to 47.5% in Iran [91] in Asia.

The literature on diabetes complications in Asia is scarce except for isolated studies from countries such as Japan, China, and India. This precludes comprehensive understanding of the situation of diabetes complications and the reasons for their high occurrence in this region. Early onset of diabetes, long duration with undiagnosed/untreated disease, and presence of comorbidities such as hypertension are possibly the main reasons for Asian patients with diabetes living longer with complications [92–98].

Quality of Care

A review of quality of diabetes care in low- and middle-income countries in Asia found limited information on processes of care (screening of complications and monitoring of risk factors) and outcomes (risk factor control) in Asian countries [73, 99]. The reports on diabetes care processes and outcomes have increased in recent years but are mostly from single, specialist clinics. However, few countries such as Thailand, China, Malaysia, and the Philippines have assessed diabetes outcomes at national level. Further, available limited information suggested unacceptable levels of diabetes care processes and poor control of diabetes in the region [73].

Diabcare-Asia, a multi-country study, provides better insight into the status of diabetes control in select countries from Asia. These studies used standardized protocols to conduct clinic audits of diabetes care [100, 101]. There were two rounds of Diabcare-Asia studies till date. In the first study [100], during 1998, the study recruited a total of 24,317 participants from 230 clinics in Bangladesh, China, India, Indonesia, Korea, Malaysia, the Philippines, Singapore, Sri Lanka, Taiwan, Thailand, and Vietnam. The clinics were either specialist or referral diabetes clinics except in Singapore where primary health-care clinics were also included. About 95% of recruited participants had type 2 diabetes, average age was 57.7 ± 12.2 years, and duration of diabetes was 9.2 ± 6.8 years. The mean body mass index (BMI) of those who were greater than 18 years of age was 24.4 ± 4.0 kg/m^2. Overall, the study found that the average glycated hemoglobin (HbA1c) was 8.6% (± 2.0), and 55% had poor diabetes control (HbA1c ≥ 8%). Further, diabetes complication rates were also high—39% had urine albumin >20 mg/L, 21% had retinopathy, and 34% had neuropathy. The second wave of Diabcare-Asia [101] was conducted during 2003 in 182 centers in China, Indonesia, Korea, Malaysia, the Philippines, Singapore, Taiwan, Thailand, and Vietnam to measure trends in the diabetes care. The demographic profile was remarkably similar in both studies, and the repeat survey found little difference in the diabetes control and complications compared to the previous one, showing no improvement in diabetes control with time.

In the 2005, International Diabetes Federation management practice study (IDMPS) [102] had collected data on diabetes quality of care in a standardized method from Asia, Eastern Europe, and Latin America. A total of 5888 (Type 1512 and type 25,376) diabetes patients were recruited from Asian countries—Korea, China, Indonesia, India, Hong Kong, Taiwan, Malaysia, and Thailand. The mean HbA1c in Asia was 8.6 ± 2.1% and 7.7 ± 1.7% in type 1 and type 2 diabetes, respectively. These rates were similar across the region. Though IDMPS reported lower HbA1c levels in type 2 diabetes, this needs to be interpreted cautiously as the values were from non-standardized laboratory reports. Further, insulin initiation and its sustained use were below par, and self-management was not optimum in most parts of Asia.

To summarize, there is incomplete reporting of diabetes quality indicators from Asian countries. Available data suggest inadequate risk factor control and lack of monitoring of diabetes and its complications.

Challenges for Diabetes Management in Asia

Being the continent with largest number individuals with diabetes, Asian countries face major challenges in prevention, detection, and management of diabetes. While many constraints are similar to those faced by the rest of the world, Asian countries have unique challenges due to cultural practices, which also vary widely between and within countries [2]. In this section, we will elaborate on some of the challenges.

Health Systems

Table 16.1 summarizes the burden of, and existing policies and infrastructure for, diabetes management in major Asian countries [103–106]. In most Asian countries, a national framework for diabetes or noncommunicable diseases either does not exist or is only partially implemented [104, 105]. The World Health Organization (WHO) has created a global monitoring framework to measure prevention and control of NCDs, consisting of 9 global targets and 25 indicators in 2011. Only six Asian countries have adopted the framework to monitor NCDs in their countries [105].

Most Asian countries consist of mixed health-care system consisting of public-funded (either completely or partly free) and private sector (out-of-pocket expenditures) institutions. As described in Table 16.1, the extent of public funding varies in different countries, and only one country, Thailand, covers >80% expenditure of diabetes [105]. Though most countries are providing diabetes care at primary health-care centers, access to diabetes care is disproportionally available in urban areas compared to rural areas [105]. The primary health-care system lacks human resources (e.g., India, the Philippines) and facilities for basic diabetes monitoring and screening of diabetes complication [104]. Poor availability of insulin has resulted in delayed insulin therapy [104]. Government funds or national insurance covers only fraction of cost of diabetes in most countries, except in Japan, Thailand, Singapore, and China [105].

Physician-Level Factors

Physician adherence to diabetes care processes in Asian countries is sub-optimal [73, 99]. In addition to the system-level factors such as lack of infrastructure and coordinated care and high health-care costs, many physician-level factors contribute to this. Physician inertia, that is, failure to intensify treatment when required, is the most important physician-level barrier across the world [63]. The use of diabetes management guidelines is highly variable and inconsistent in most Asian countries [107, 108]. Most Asian countries have a hierarchical health-care system where physician makes decision for patients and patient engagement in their care is low [109]. Several reasons have been reported in literature for this lack of adherence to guidelines. Firstly, primary care physicians or general practitioners are inadequately trained in diabetes management guidelines [108]. Physicians in Malaysia expressed lack of confidence in starting insulin and were not familiar with various insulin regimens and devices [110]. Secondly, most Asian countries lack country-specific diabetes management guidelines [107]. Physicians showed less interest in international guidelines as they thought these were not applicable or practical in local settings [107]. Thirdly, physicians in Asian countries, such as China and India, have exceptionally high workload, which reduces the time available to spend with their patients [107, 108, 111]. Therefore, physicians are less likely to provide lifestyle advice or support [107]. Fourthly, communication skills are not commonly taught during physicians' training in Asian countries. Therefore, the physician-patient communication depends only on physician's innate ability and/or experiences through their practice [111, 112]. Fifthly, physicians often delayed initiation of insulin due to fear of hypoglycemia and concerns about patient's compliance [112]. Finally, physicians, specifically private practitioners, feared losing patients to another doctor who may convince patient that insulin is not required [110].

Patient-Level Factors (Including Gender and Cultural Issues)

Lack of awareness, limited access, and affordability are the major patient-level barriers for diabetes management in Asia. Family plays very influential role in day-to-day life in Asia and can act both as a barrier and facilitator [113, 114]. In Asia, men are also at an advantage since they receive support from their spouses for managing diabetes, since the cultural dictate is that women should first take care of their husbands and only then look after themselves [115]. Lack of social support may thus result in decreased psychological well-being and higher complication rates in females compared to males [116].

The influence of culture is probably stronger in Asia than elsewhere. Kelleher and Islam report that migrant Bangladeshis who were diabetic were reluctant to make dietary adjustments especially with regard to limiting rice in their diet [117]. In Buddhist Thailand, the idea of moderation favored dietary modification, but preference for rice in diet acted as a hindrance at the same time [118]. Further, strong followers of Buddhist values had better self-care and higher frequency of physician visits [119]. Patients with diabetes from Parsi community find it hard to regulate sugar levels as they frequently took part in ceremonies where sugar- and fat-

rich diets were being served [120]. Honey and dates were perceived as highly beneficial by Muslim community, and their inclusion in diet is known to have a negative impact on sugar levels [121]. In some cultures, people were reluctant to cut down fat and sugar in their diet citing that all happens by the will of God and dietary changes do not have any role in disease management [122]. Fasting for religious and cultural reasons is a real challenge for care providers and subjects [123, 124]. Fasting imposes a need to tweak drug dose to prevent hypoglycemia in diabetic individuals [123, 124].

Low levels of physical activity have been observed in Asian populations which is linked to the societal roles and norms in Asia. Men, being responsible for looking after their family affairs, were working extra hours and consequently were unable to spare time for physical activity [125]. Women on the other hand were confined to household chores with few visits outside home [125]. Women also find it difficult to perform regular exercises due to absence of appropriate amenities [114, 126]. In India, women perceived household activities with physical activity as adequate which however was not the case [127]. Also, walking was the most preferred mode of exercise by women. Physical activity seemed to be better in families where the male members were more supportive of physical activity [128]. Physical activities in females were particularly limited by societal norms in Asia. The limited time spent on leisure and physical activity among Asians has resulted in poor glycemic control.

Additionally, diabetes is viewed as stigmatizing, and this leads to delayed initiation and limited overt use of insulin [129]. As women were more stigmatized, they were less likely to follow self-management practices, finally ending up with poor glycemic regulation [130]. Concerns about the toxicity of drugs were the main reason for non-usage, and multiple drug use was generally abhorred [129]. Patients with diabetes are misguided by friends and relatives not to start insulin as they perceive it to cause weight gain or as a mark of severe form of diabetes [112].

Use of Complementary and Alternate Medicines (CAM)

Asian countries have plethora of traditional medicine with strong linkage to culture [131–133]. These traditional medicines are used either as alternative or complementary to modern methods of diabetes treatment.

Most commonly followed for diabetes management are prayer, massaging, hot tub therapy, biofeedback, yoga, and various herbal therapies [134]. Yoga is widely practiced in Asian countries with Hindu or Buddhist traditions. Studies show that yoga has beneficial effect on the glycemic levels [135, 136]. Yoga along with diet and drugs is suggested to be more effective in diabetes management [136]. Yogic practices have been shown to improve insulin response and lipid profile in several studies [137]. Adjunct Integrated Naturopathy and Yoga (INY) that laid emphasis on the role of diet and physical exercise was associated with a significant beneficial effect on glycemic control and reduced the overall need for antidiabetic medications. In India, other alternative medicines include folk medicines, Ayurveda, Unani, and Siddha for diabetes treatment [138].

Traditional Chinese treatments to manage diabetes include acupuncture, herbal medicine [139], and ginseng [140]. Indigenous medicines generally consist of plant products, minerals, or other biological products [133]. A review identified 86 antidiabetic medicines of indigenous origin, 82 were manufactured from plants, and the rest were obtained from animals or insects in China alone [141]. Spices and vegetables were also part of traditional medicines. In Sri Lanka, both Ayurveda and traditional medicines were used to manage diabetes. In a study from Sri Lanka, 76% diabetes patients used alternative medicine, with bitter gourd, ivy gourd, and crepe ginger being extremely popular [142]. Alternative medicines were also used in diabetes management in hope of obtaining a sense of relief and to counter adverse effects of modern medicine.

The issues mainly seen from studies on alternative medicine use in diabetes were under reporting of use of CAM and low adherence to modern medications [143, 144]. Alternative medicine use was found to negatively affect adherence to diabetic drugs. For instance, an Indonesian study found sixfold reduction in adherence to diabetes medication [145].

Diabetes Care Models

Approach for Diabetes Care Models

To combat the escalating burden of DM requires both successful prevention efforts and better disease management. Robust evidence from systematic reviews and meta-analysis of randomized controlled trials (RCTs) has shown that lifestyle modification or glucose-lowering medications can prevent or delay diabetes in high-risk individuals. And, among those with diabetes, good control of risk factors (glucose, blood pressure, and lipids), avoiding tobacco use, and use of cardioprotective medications (e.g., aspirin, angiotensin-converting enzyme inhibitors) [146–149] can substantially reduce the risk and severity of the main diabetes complications. Further, it is well established that multiple risk factor control has the greatest benefits for patients with type 2 DM [150–152]. However, many people living with diabetes in Asian countries are not receiving the care needed to support optimal risk factor control. Diabetes patients in Asian countries receive recommended care only about 20–30% of the time and achieve the recommended targets for glycemia,

blood pressure, and cholesterol less than 10% of the time [23, 153]. Below, we describe the various approaches/models used to improve diabetes care delivery. Most of these reports support the successful delivery of care models in project mode; however scale-up of these models to programmatic delivery is yet to be demonstrated.

(a) *Training health-care providers*: The step-by-step foot program initiated in India [154, 155] focused on preventing lower limb complications in diabetes patients by intensively training physicians and nurses in the use of an algorithm for management of diabetic feet [156]. Training consisted of lectures, practical demonstrations, problem-solving exercises, and hands-on experiences. Three years after program implementation, the percentage of patients with diabetic foot ulcers/complications fell from 24% to 8%, and the amputation rate fell from 22% to 10% [157]. Large-scale capacity building initiatives [158] have trained a large number of primary care physicians, diabetes counselors, and other care providers in India. Examples include certified courses on evidence-based diabetes management, certificate course on diabetes retinopathy, and others (see www.ccebdm.org). But data is not yet available on impact of program at the patient level.

(b) *Peer for progress model (task shifting)*: Several studies and programs have relied on peers (nonprofessionals familiar with diabetes management), instead of health-care providers, to assist with diabetes case management and long-term self-care of diabetes patients with an aim to reduce cost of care. The short-term impact of these "peers for progress" models on risk factor control has been evaluated across several countries (including Thailand). In these programs, peer supporters received training to address the issues of diet, exercise, coping with stress, and diabetes self-management and were assigned a group of patients [10–20] with whom they met regularly. Participants showed significant reduction in weight and blood pressure and mean glycated hemoglobin (HbA1c) [159].

(c) *Multifactorial intervention (integrated care model)*: Increasingly, programs that combine several care delivery components are being implemented and evaluated to improve diabetes care delivery. For example, the Centre for Cardiometabolic Risk Reduction in South Asia (CARRS) Translation Trial tested the clinical effectiveness of a low-cost multicomponent quality improvement (QI) diabetes care model in South Asia [160]. Poorly controlled, type 2 DM patients ($n = 1146$) were assigned to usual care or a multicomponent QI strategy consisting of non-physician care coordinators (to improve patients' adherence to therapy) and electronic health records with decision support software (to enhance physicians' responsiveness). The intervention focused on improving patient self-care and facilitating better monitoring and treatment intensification by providers. At a median follow-up of 2.5 years, twice as many patients in the intervention arm compared to usual care participants (17.7% vs. 7.5%; $p < 0.001$) achieved the primary outcome of multiple risk factor control (HbA1c < 7% and either blood pressure < 130/80 mmHg or LDLc <100 mg/dl), and intervention participants reported significantly higher quality of life and treatment satisfaction [161].

In another randomized control trial of 150 patients with diabetes in Shanghai, China, an integrated intervention program consisting of in-depth diabetes education focused on frequent clinic visits and blood glucose monitoring, nutrition counseling, and meal plans (intervention group) was compared to basic diabetes education (control group). At 3 months of follow-up, the intervention group had significantly lowered their fasting blood glucose, systolic and diastolic blood pressures, HbA1c, and waist-to-hip ratio relative to the control group [162].

Diabetes prevention and care model in rural India: *The Chunampet Rural Diabetes Prevention Project* was implemented in rural parts of South India to provide comprehensive diabetes care and promote diabetes prevention through the use of telemedicine [163]. This project used a mobile health-care van equipped with a digital retinal camera, electrocardiography (ECG), Doppler, biothesiometry, and a satellite to communicate with an urban diabetes care center to screen for diabetes complications. Village health workers, trained individuals with high school qualifications, screened for diabetes complications. This program screened 86.5% of the adult population in and around the 42 villages of Chunampet and identified 1138 individuals with diabetes and 3410 with prediabetes. The mean HbA1c levels among individuals with diabetes in the community decreased from 9.3 ± 2.6% to 8.5 ± 2.4% within a year of implementing this project [164].

Diabetes Prevention Models

Prevention efforts are essential for curbing the diabetes epidemic. However, models for diabetes prevention in Asian countries are limited or partially implemented. Lifestyle changes have been shown to have significant and sustained benefits for individuals at high risk for diabetes in Western countries. The data on diabetes prevention in Asian countries is limited compared to high-income countries, but there is evidence of some successes. Early efforts in China and India focused on conducting large randomized controlled trials of lifestyle intervention for diabetes prevention among individuals with impaired glucose tolerance (IGT). Results from

both studies demonstrated major reductions in diabetes incidence among lifestyle intervention participants compared to controls (relative risk reduction, exercise alone, 41.1%; diet alone, 43.8%; and diet + exercise, 46% in the Da Qing IGT and Diabetes Study and 28.5% in the Indian Diabetes Prevention Program (IDPP)) [165–169]. These efficacy trials showed that diabetes prevention efforts were possible to implement with benefits in lower-resource settings.

More recent studies evaluated different strategies to overcome barriers to delivering lifestyle interventions, such as cost, access to at-risk individuals, and health provider shortages. For instance, the Indian Diabetes Prevention Program-3 randomized participants at ten worksites in India to receive either standard lifestyle advice (controls) or a lifestyle intervention delivered by mobile phones. This study reported a significant reduction in diabetes incidence among intervention participants compared with controls (hazard ratio 0.64, 95% confidence interval [CI] 0.45–0.92) [170]. These results showed that a lower-cost intervention could be beneficial for diabetes prevention and utilizing mobile phones may be a promising strategy for delivering lifestyle advice to hard-to-reach populations.

Other studies are testing the delivery of diabetes prevention to a broader at-risk population with the goal of preventing diabetes in the largest number of individuals. To date, the vast majority of prevention efforts have targeted adults at high risk for developing diabetes, but this conventional approach may not be sufficient for slowing the diabetes epidemic, particularly in populations (e.g., South Asians) which display a rapid conversion from prediabetes to diabetes. For example, the DIABRISK-SL [171] RCT in Sri Lanka aims to compare an intensive versus a less-intensive lifestyle change advice on the primary composite cardiometabolic endpoint, in at-risk urban residents aged between 5 and 40 years. Early results suggest a 26% (95% CI 7–28%) relative risk reduction in diabetes incidence among participants in the intensive lifestyle intervention compared to the less-intensive intervention [171].

Similarly, the Diabetes Community Lifestyle Improvement Program (D-CLIP) study [172], an RCT of diabetes prevention in individuals with any form of prediabetes (IGT, impaired fasting glucose or both), compared standard of care to a culturally tailored lifestyle education curriculum based on the DPP plus the stepwise addition of metformin when needed. Each lifestyle class was paired with a community volunteer peer educator, and participants were divided into peer support groups to increase social support for a lifestyle change and improve the sustainability of the program. After 3 years of follow-up, the relative risk reduction for diabetes was 32% (95% CI 7–50) comparing lifestyle participants to controls [173].

Other studies have relied on trained peer educators to deliver diabetes prevention messages as a way to lower the cost of diabetes prevention. Studies in Thailand [174, 175] reported improvements in health promotion behaviors, diabetes risk factors (markers of adiposity, blood pressure), and diabetes prevention knowledge among individuals who participated in peer-led prediabetes screening or diabetes prevention programs. These results are consistent with the findings from a meta-analysis of translational trials of the DPP in the United States, which found that lay educators can be as effective as health professionals in delivering healthy lifestyle messages [176].

Finally, there is an urgent need to identify and implement cost-effective ways to screen individuals at risk of developing diabetes and its complications. Existing screening tools like oral glucose tolerance tests or glycated hemoglobin (HbA1c) testing can be expensive or unavailable due to lack of necessary testing equipment or reagents in low-resource settings. Diabetes risk scores (e.g., the Indian Diabetes Risk Score [177]) have been shown to be effective and cost-effective tools for screening. However, much of the evidence only supports the successful delivery of these prevention and care models in project mode, and we need a multi-sectoral approach to scale up the successful prevention and care models to programmatic delivery or adoption of some these care models by national programs or at the state level in Asian countries.

Points to Remember

- Asia has 60% of the world's population with diabetes and the largest number of adults with undetected diabetes.
- Diabetes in Asia occurs at younger ages and lower body mass indices.
- Diabetes management guidelines usage is highly variable and inconsistent in most Asian countries.
- Comprehensive diabetes management in Asia should address number of patient, physician, and health system-level barriers.

Multiple Choice Questions

1. Which of the following diabetes complication is less prevalent in South Asian population?
   (a) Foot ulcers
   (b) Neuropathy
   (c) Nephropathy
   (d) Cardiovascular diseases
   (e) Hearing impairment
2. The source of data for Joint Asia Diabetes Evaluation (JADE) program was
   (a) Risk Factor Survey

(b) Surveillance data
(c) Clinical registry
(d) Household survey
(e) None of the above

3. According to International Diabetes Federation Atlas report (2015), which country is the highest per capita mean spender on diabetes in Asia?
   (a) Singapore
   (b) Saudi Arabia
   (c) China
   (d) Japan
   (e) India
4. The Asian countries that have adopted World Health Organization's NCD monitoring framework at national level are
   (a) Bangladesh
   (b) India
   (c) Iraq
   (d) Japan
   (e) All of the above
5. The greatest challenge of diabetes management during prolonged religious fasting is
   (a) Hypoglycemia
   (b) Hyperglycemia
   (c) Dyslipidemia
   (d) Electrolyte imbalance
   (e) Hypercalcemia
6. The average lag between the onset and detection of diabetes in Asia is
   (a) 5 years
   (b) 12 years
   (c) 15 years
   (d) 7 years
   (e) 2 years
7. The unique feature of diabetes epidemic in Asia
   (a) Occurs in younger age
   (b) Occurs at older age
   (c) Is prevalent in low body mass index individuals
   (d) Both a and c
8. Poor glycemic control observed in Asia is due to
   (a) Low physical activity level
   (b) Delayed insulin initiation and sustained use
   (c) Alternative treatment
   (d) All of the above
   (e) None
9. Which among the following method is an easily usable and cost-effective screening tool in low-resource settings?
   (a) HbA1C
   (b) OGTT
   (c) FPG
   (d) RPG
   (e) Diabetes risk scores
10. The delayed use of insulin in Asian countries is due to
    (a) Poor availability
    (b) Fear of hypoglycemia
    (c) Concern about compliance
    (d) Lack of familiarity with insulin regimens
    (e) All of the above
11. An under-recognized comorbidity of diabetes in Asia is
    (a) Depression
    (b) Tuberculosis
    (c) Alzheimer's disease
    (d) Arthritis

Correct Answers

1. (b) Neuropathy
2. (c) Clinical registry
3. (d) Japan
4. (e) All of the above
5. (a) Hypoglycemia
6. (d) 7 years
7. (d) Both a and c
8. (d) All of the above
9. (e) Diabetes risk scores
10. (e) All of the above
11. (a) Depression

Diabetes Management in the United States

17

Mohammed K. Ali, Megha K. Shah, and Tannaz Moin

Introduction

Prevalence and Cost Burdens

In the United States, diabetes affects approximately 10% of the population, and in 2017, this equated to an estimated 30.3 million Americans with diabetes [1]. Type 2 or insulin-independent diabetes accounts for the majority (~90–95%) of cases in the United States. Furthermore, approximately one-third of US adults have prediabetes, an identifiable precursor phase in which blood glucose levels are above normal but not yet in the diagnostic range for diabetes, and one's risk of developing type 2 diabetes increases five to twelvefold [2].

The diabetes epidemic has evolved considerably over the last quarter century. At every counting, the growth in prevalence and absolute numbers of people with diabetes have far exceeded statistical projections. Further, over time, larger proportions of those affected by diabetes are people of minority race/ethnicities and from lower socioeconomic backgrounds, and onset and first diagnosis appear to be younger than in decades past [3].

Diabetes is associated with billions of dollars in health expenditures and lost productivity [4, 5]. Using a compilation of national data sources, diabetes was identified as the leading cause of annual personal health spending in 2013, accounting for over $100 billion in direct healthcare expenditures that year. As a result, diabetes is now the leading contributor to rising healthcare costs in the United States [5, 6].

Health Impacts

Type 2 diabetes typically develops over many years. The slow progression and lack of symptoms in the early stages of disease often delay requests for a screening test, preventive care, and/or medical attention. Other issues, such as lack of insurance or access to timely preventive care, may compound these delays. As such, even in high-income country settings like the United States, approximately 28% of people with diabetes are not aware of their diagnosis [7]. This is problematic as the pathophysiology of diabetes and its impacts on organs continue unabated despite the individual's awareness (or lack thereof) of their glycemic status.

The health impacts of diabetes vary by the type of disease. Type 1 or insulin-dependent diabetes, which accounts for about 5% of cases in the United States, is more commonly associated with acute fluctuations in blood sugar levels. Episodes of severe acute hyperglycemia (e.g., diabetic ketoacidosis [DKA] [8] and hyperosmolar nonketotic coma) or, conversely, severe hypoglycemia most often require immediate medical management. When treated in a timely and appropriate manner, the mortality from acute hyperglycemic episodes such as DKA is extremely low in the United States [9, 10]. Individual patient (e.g., age, additional comorbidities) and resource (e.g., healthcare facilities, experience of staff) characteristics can influence outcomes and risk of mortality.

Both type 1 and 2 diabetes are associated with chronic, progressive damage of the nerves, eyes, kidneys, and/or vasculature [11–13]. Target organ damage of this nature can be

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_17

life-threatening and/or seriously disabling [14]. In a large proportion of persons with diabetes, other cardio-metabolic risk factors (hypertension, dyslipidemia, proinflammatory, and procoagulant states) often co-occur [15] which increases the risk of end-organ damage [16]. The frequency of these end-organ diseases varies according to the underlying phenotype, pathophysiology, as well as care and control of glycemia and other cardio-metabolic risk factors (i.e., blood pressure, cholesterol, and tobacco) [17].

In this chapter, we provide an overview of diabetes management in the United States from a national perspective and examine several aspects of diabetes care including detection, health maintenance, and achievement of cardio-metabolic care goals. We further describe where and how diabetes have been managed over the past few decades in the United States and examine previous and ongoing disparities. We examine and report what local care delivery, payer, and policy interventions have been evaluated to improve quality of care and their respective impacts.

National Trends

Screening

As the national prevalence and absolute numbers of people with diabetes have grown [18], the proportion with undiagnosed disease has not changed dramatically [3]. This has implications for disease burden as undiagnosed people are less likely to have a usual care provider or seek care [7], further lowering their likelihood of being diagnosed; and the progression toward end-organ damage continues. In some cases, recognition of underlying diabetes is only confirmed when diabetes complications are evident. Indeed, national data show that approximately 40% of adults with previously unrecognized diabetes have some form of chronic kidney disease [19].

Similarly, with regard to prevention of diabetes, it is estimated that only about 1 in 10 of the 86 million adults with prediabetes in the United States is aware [20] that they are at high risk of imminently developing diabetes. This awareness gap is likely a major barrier to engaging people at risk of diabetes in evidence-based lifestyle or pharmacotherapeutic interventions to prevent diabetes [21, 22].

There are well-accepted glucose tests to diagnose prediabetes and diabetes and evidence-based lifestyle and pharmaceutical interventions to prevent and manage diabetes. There is also consensus that universal screening – i.e., offering glucose tests to the whole population – is not cost-effective, but rather, targeted screening of individuals at high risk for diabetes is both appropriate and economically sound [23–25]. To promote appropriate testing, expert committees at the American Diabetes Association (ADA) [26] and US Preventive Services Task Force (USPSTF) [27] have reviewed the evidence and set recommendations for health-care providers regarding whom to test and when.

The ADA [26] recommends glucose testing adults age ≥45 years or at any age with a body mass index (BMI) ≥25 kg/m^2 and one other diabetes risk factor (people who are physically inactive, have a family history of diabetes, are of minority race/ethnicity who did not identify as non-Hispanic white, have history of gestational diabetes or delivering a macrosomic baby, are hypertensive [blood pressure ≥140/90 mmHg or antihypertensive medication use], have dyslipidemia [HDL-cholesterol <35 mg/dL, triglycerides >250 mg/dL, or lipid-lowering medication use], have polycystic ovarian syndrome, have known prediabetes, or have known myocardial infarction, coronary heart disease, or stroke).

The USPSTF previously recommended glucose testing in individuals with blood pressure >135/80 mmHg or antihypertensive medication use [27]. In 2015, the USPSTF changed their guideline and now recommend glucose testing between ages 40 and 70 years in those who are overweight or obese [28]. The USPSTF guidelines also note that clinicians should consider screening earlier in persons with one or more additional risk factors (i.e., family history of diabetes, history of gestational diabetes, members of certain racial/ethnic groups such as African Americans, American Indians or Alaskan Natives, Asian Americans, Hispanics or Latinos, or Native Hawaiians or Pacific Islanders) since they may be at increased risk for diabetes at a younger age or at a lower body mass index.

In terms of the extent to which screening guidelines achieve their intended purpose, a study using national survey data showed that, during the period 2007–2012, only half of all US adults that would be eligible for glucose testing based on either the ADA or the older USPSTF criteria were actually offered a glucose test [29]. There is also a sizeable proportion of people (approximately 15%) that receive glucose tests despite not meeting sufficient criteria. Furthermore, in terms of guideline performance, findings suggest that the ADA and USPSTF guidelines are very different in their ideological focus: the ADA guidelines require a lower threshold for glucose testing with the aim of higher sensitivity, while the USPSTF recommendations are more focused on specificity. Despite this difference, the positive predictive value (or yield of people with dysglycemia of those eligible for screening) associated with each guideline was broadly similar – approximately 54–58% for identifying prediabetes or diabetes and around 5–7% for identifying undiagnosed diabetes.

More recent analyses examining the performance of the newer USPSTF guideline show that only 25% of patients would be eligible for screening. Though the newer guideline is more sensitive (~45%) and less specific (~72%), racial/ethnic minorities are less likely to be eligible for screening,

perhaps due to their higher risk of diabetes at lower weight levels [30].

Management of Cardio-Metabolic Risks

It is encouraging that people with diagnosed diabetes do seek care. Nationally, 95% of adults with diagnosed diabetes report having a healthcare provider, and almost 92% report visiting the care provider twice or more in the past year [7].

Furthermore, over the past four decades, the scientific community has made important advances in clinical research. Large robust randomized controlled trials have shown that comprehensive management of cardio-metabolic risk factors, including glucose, blood pressure, and lipids, and avoiding tobacco, can delay both micro- and macro-vascular diabetes complications [31–36]. It is on the basis of these trials and meta-analyses that diabetes management guidelines are set and revised by professional agencies (e.g., the ADA and the American Association of Clinical Endocrinologists [AACE]). Indeed, these same guidelines are used to benchmark quality of care at local and national levels.

Using clinical care goals as targets, national survey data have been used to develop cross-sectional snapshots of how average adult Americans with diabetes are managing their cardio-metabolic risks. The data from consecutive national reports from the 1988–1994 to 2007–2012 surveys show that the proportion of adults with diabetes achieving glycated hemoglobin (HbA1c) levels < 7.0% grew from 42.9% to 52.2% (Fig. 17.1). The proportion of adults with diagnosed diabetes with BP <140/90 mmHg stayed stable, 65.7% to 62.5%, while the proportion meeting LDL-cholesterol < 100 mg/dl increased dramatically from 11.0% to 56.6%. The proportion of adults with very poorly controlled glycemia (A1c < 9.0%), blood pressure (BP > 160/100 mmHg), and/or cholesterol (LDL > 160 mg/dl) all declined. Of note, however, smoking prevalence among people with diabetes has changed marginally over this period (21.5% [1988–1994] to 19.4% [2007–2012]).

National- and state-level efforts that drew greater attention to diabetes through measurement and action may have been the drivers of these important successes. Movements like the National Committee for Quality Assurance (NCQA) and National Quality Forum have made major impacts through setting quality metrics, encouraging accreditation, and establishing performance measurement for healthcare systems. In turn, these processes may have facilitated [37, 38] better achievement of diabetes care goals. Similarly, individual states have used performance measures effectively – in Minnesota, for example, the Community Measurement initiative has reported on healthcare quality annually for a decade and can demonstrate performance for each of 1247 clinics or provider groups [39], and the state's average for meeting diabetes and cardio-metabolic care goals (38%) is higher than the national average (14%). These same successes are unlikely to be ubiquitous across all states, but no formal state-level analyses have examined this.

Other factors that may have contributed to these gains include newer medications; provider education; changes in physician practice norms; use of information technology and electronic health record data, such as clinician decision support; and use of diabetes registries to track management of diabetes and performance measures and to couple audits with feedback. Payers for healthcare and hospital systems have also tracked and offered financial incentives (and disincentives) for care goal achievement (or lack thereof). On the patient side, there have been sustained efforts to educate patients and promote self-management. Each of these quality improvement efforts is discussed in greater detail later in the chapter.

There are limitations to using guideline treatment targets as performance metrics for health systems, localities, and the country at large. Although they are evidence-based, recommended treatment targets are not always what patients desire, and there can sometimes be a tension between quality of care from the health system and provider perspective and patient desires and satisfaction. Treatment targets are subject to change as new evidence is generated (Table 17.1), and these "moving targets" make it hard to understand whether there is any consistency in the patterns being observed. Furthermore, targets are usually dichotomous and can only convey part of the picture – for example, the mean levels of cardio-metabolic indices may be clustered around the target, but because of the single dichotomous metric, they get counted as "good" or "bad." Indeed, patients may also fare worse on specific aspects of their care, but better on others. As such, more "global" measures of disease risk (e.g., Framingham risk score, hospitalizations, quality of life, patient satisfaction, hypoglycemias) may provide alternative indicators than single dichotomous treatment targets.

Screening for Diabetes Complications

Aside from managing glycemia and cardio-metabolic risk factors to prevent diabetes complications, care guidelines [40–42] also recommend regular screenings to detect and treat diabetes complications. Earlier detection is aimed at identifying risk before irreversible target organ damage is incurred. All the microvascular complications of diabetes have a preclinical latent phase and well-accepted, sensitive, and specific eye, foot, and urine checks.

Diabetic retinopathy is very common and occurs in all people with diabetes, given sufficient duration of disease [43, 44]. Retinal screening [45] followed by photocoagulation therapy has been shown to significantly preserve vision [46, 47].

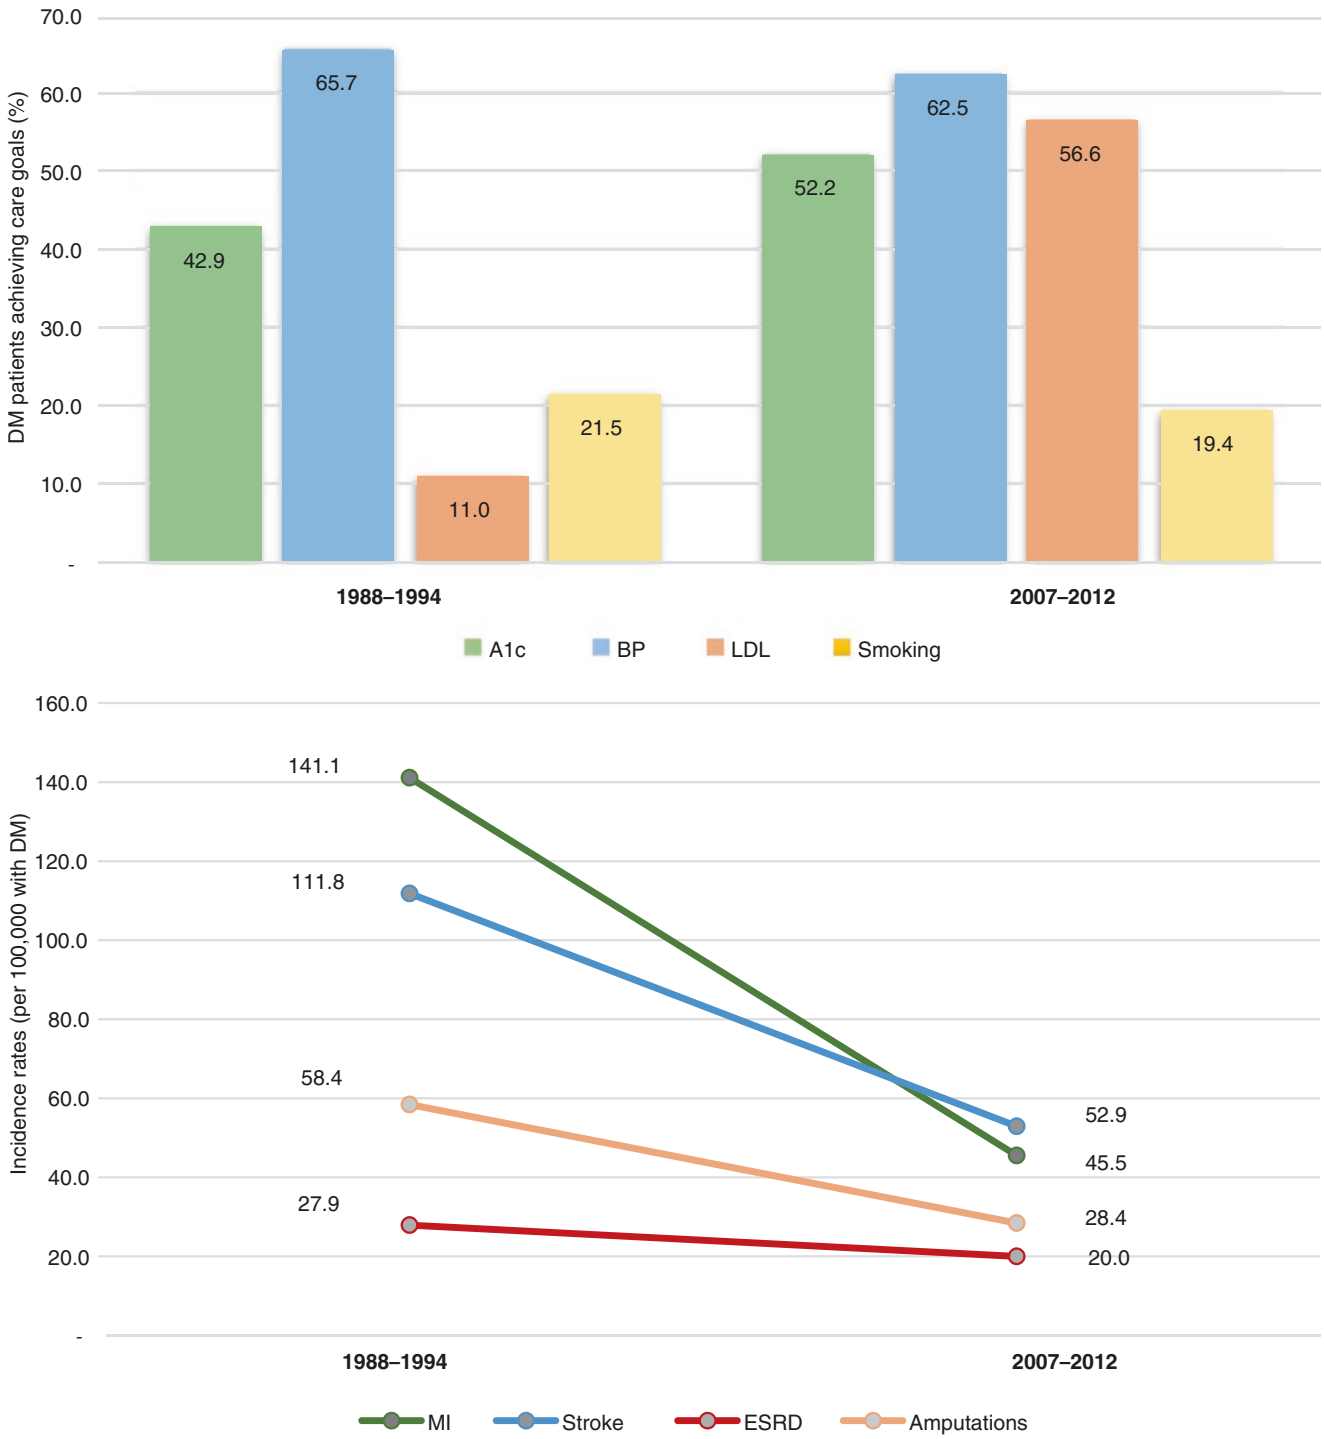

Fig. 17.1 Changes in risk factor control and diabetes complication rates among US adults with diabetes, 1988–1994 to 2007–2012

Neuropathy is also a common consequence of diabetes and, combined with compromised peripheral vascular circulation and poor wound healing [48, 49], ulceration [50], and infections [51, 52], can increase one's risk of gangrene and limb amputation. Regular foot checks and foot care are considered invaluable to prevent foot ulceration and gangrene in people with diabetes [53, 54]. Regarding deterioration of kidney function, annual urine screening and use of ACEi/ARB medications once microalbuminuria sets in are both recommended [54]. Lastly, to lower infections, people with diabetes benefit from annual influenza vaccination and a lifetime pneumococcal vaccination (after age 60) [55–59]. Repeated snapshots of national survey data between 1999 and 2010 show increases

Table 17.1 Evolution of guidelines and care targets

	2010		2016	
	Risk group	2010 target	Risk group	2016 targets[a]
HbA1c (%)	All	<7.0	<45y low risk	<6.5
			45–64y low risk	<7.0
			45–64y med risk	<7.5
			≥65y low risk	<7.5
			≥65y med risk	<8.0
BP (mmHg)	All	<130/80	All	<140/80
LDL (mg/dl)	No CVD	<100	40–75y + DM	Statin
	CVD	<70	High CVD risk	HI statin

CVD cardiovascular disease, *y* years, *HI* high-intensity, *med* medium
[a]Suggested targets by several authors; no formal guideline has endorsed specific targets other than generally supporting individualized glycemic goals [180, 181]

in the proportions of adults with diagnosed diabetes receiving all of these preventive screenings [60].

Incidence of Complications

The limitations of performance metrics notwithstanding, the average 10-year cardiovascular event risk among Americans with diagnosed diabetes has declined over the past three decades, from 16.5% to 11.3%. In keeping with this, between 1990 and 2010, nationally, there were substantial reductions in incidence rates of diabetes complications [61] and increases in life expectancy among people with diabetes [62]. There were marked decreases noted in incidence rates of acute myocardial infarctions (~68% decline), strokes (~53% decline), lower extremity amputations (~51% decline), and hyperglycemic death (~64% decline). The incidence of end-stage renal disease declined more gradually (~28% decline) (Fig. 17.1). Although visual impairment due to cataracts and retinopathy remain an important complication of diabetes, there are no reliable national estimates of trend patterns for these complications to date.

Gaps in Care

The successes described, in quality of care and reductions in incident complications in people with diabetes, should be viewed in context. Over the same period, the absolute number of people with diabetes has grown substantially, nearly threefold [4, 63]. Large numbers of people still do not meet their care goals; the absolute numbers affected by disabling complications have increased; costs of care double every decade; and though excess mortality associated with diabetes has declined, there has been an expansion in the number of years people with diabetes live with disabilities. Many of these concerns are at least partly attributable to gaps in access, suboptimal organization and delivery of healthcare and preventive services, and workforce shortages. We further examine these and other barriers and provide data from program and policy intervention studies as possible future directions for diabetes management to progress toward.

Outpatient Settings in the United States

Over the last 30 years, there has been a shift from hospital-based diabetes management to outpatient primary care. While earlier studies showed that hospital-based care provided better outcomes, health systems began shifting away from hospital-based diabetes management, and several studies showed that diabetes management in primary care setting was as good as hospital-based care and provided greater adherence to guideline-based preventive services [64–66]. Almost all of diabetes management is now in the ambulatory setting by primary care providers, and only 20% of patients with diabetes may be referred to an endocrinologist [67, 68].

Though fewer patients are managed in hospital-based settings for diabetes, admission rates for diabetes-associated complications (such as amputations, cardiovascular disease, and blindness) are still higher in the United States than in comparable countries [69]. Despite the availability and evidence of effective clinical guidelines, wide variation of the treatment of patients with diabetes remains in primary care [70]. Moreover, care gaps remain for many patients with diabetes [71].

Several challenges exist to achieving optimal diabetes care in the outpatient setting, which can be divided in three main areas: the patient, the provider, and the system.

The Patient

Patients must be able to access care, adhere to treatment, afford the care, and have the knowledge and skills to manage their condition on a daily basis. Access to care can often be determined by socioeconomic status and insurance status. Several studies have demonstrated that lower SES is associated with less access to specialist care and to diabetic preventive services and worse control of diabetes [72–74]. Patients with private or public insurance are most likely to have met quality of care measures than those with no insurance [75]. A study using national data over the 1998–2008 period found that an estimated 16% of known patients with diabetes were uninsured and tended to have worse outcomes [76].

Physical access to care continues to be a barrier. Lack of transportation, location in rural areas, and availability of healthcare personnel all play a role in a patient's ability to access care. Rural residents have higher rates of diabetes than urban residents and significantly greater barriers accessing reliable transportation. Moreover, rural residents

can often spend more time trying to access care, thus creating higher cost from missed wages and time spent away from families to have improve quality of care [77].

Treatment adherence continues to be a major challenge in achieving adequate glycemic control. In 1 study of over 160,000 patients in Northern California, over 20% of patients with uncontrolled diabetes had poor medication adherence [78]. While the cause of this can be multifactorial, several challenges exist from the patient's perspective. First, lack of diabetes education can lead to poor understanding of the disease process and empowerment of the patient to play an active role in their care process. While evidence support the efficacy of diabetic education in improving diabetes outcomes, access is still limited. Complex medication regimens and side effects from medications can also lead to poor adherence. Simplifying medication regimens can help address patient barriers to medication adherence [79]. The ADA Standards of Care guidelines recommend that providers address medication factors when reviewing treatment plans with patients to insure that they are simple, affordable, and manageable for the patient [80].

The Provider

Several provider level factors can influence diabetes care. Assessment of adherence can often be overestimated or missed by providers [79]. Patients are often asked to self-report their medication use without any objective assessment of actual medication adherence. In addition, providers are often reluctant to intensify therapy, though it may be clinically indicated; this is known as clinical inertia. Clinical inertia appears to be particularly common with regard to initiating insulin therapy [81, 82].

Though clinical inertia is multifactorial and can be due to system- and patient-level factors, one key area is patient-provider communication. Studies have shown that the quality of provider communication and patient's trust of their providers were associated with better outcomes. Better communication was associated with fewer misconceptions about insulin, thus patients were more likely to begin insulin therapy, and this was associated with improved outcomes [83]. Several studies have also shown that providers who recommend individualized barrier assessment and tailored communication to patients can improve care [84].

The System

Several system-level factors create challenges to optimal diabetes care. First, dissemination of evidence-based practices can be slow. While evidence exists for optimal diabetes care, including processes of care, implementation of these evidence-based guidelines can vary. This can greatly improve through use of guidelines to drive care, structured care management, and performance feedback [83].

Second, coordination of care can greatly improve outcomes. Evidence shows that optimal diabetes management in the outpatient setting requires a coordinated, systematic team-based approach. This strategy can help address several of the processes that create barriers to diabetes management. This is supported by team-based approaches where there are a focus planned visit, education, and appropriate specialty care. Several models have been effective at demonstrating improved care coordination; these are discussed in detail later in this chapter. Many of these system-level factors rely on accurate clinical data; this can also be improved by implementing electronic health records to track diabetes care outcomes and processes of care [83, 85].

Next, addressing financial barriers to patients for medications, health services, and education can greatly improve adherence and outcomes. Studies have consistently found that shifting costs to patients negatively affects outcomes in diabetes care. Increased cost to the patient resulted in lower medication adherence and lower rates of preventive care [86]. Those patients with full cost coverage were more likely to have appropriate diabetes-related care (such as dilated retinal exams), attended diabetes education, and practiced blood glucose monitoring.

Disparities in Diabetes Prevention and Management

Despite considerable evidence for preventing diabetes complications [31–36] and important advances in clinical care, there remain significant gaps in translating this evidence into policy and practice, specifically for vulnerable subpopulations (e.g., some age, race/ethnicity groups, and those with associated comorbid conditions) [7, 62]. Additionally, burdens of diabetes are not uniformly distributed across the United States; the Southeastern United States, for example, is disproportionately affected by diabetes and its complications [4, 87, 88].

Demographic Disparities

With reference to vulnerable populations, African Americans, Hispanics, Native Americans, and Asians/Pacific Islanders all have higher rates of diabetes prevalence as compared to non-Hispanic whites. The prevalence of diabetes among African Americans is around 12% and for Hispanics is around 11%, compared to around 7% for non-Hispanic whites [89]. These disadvantaged groups are less likely to receive diabetes-related preventive care, are less likely to have access to care [7], and have lower health literacy. This lack of care leads to delayed diagnosis, advanced disease, and poor outcomes among these groups [90]. As the US population continues to become more diverse and the number of people with diabetes

increases, addressing disparities in care will be increasingly vital.

While some studies have found no significant difference in most of the processes of care (including periodic hemoglobin A1c, lipid, microalbuminuria testing), those of racial/ethnic minorities and low-income groups tend to have poorer glycemic control [3, 91]. Furthermore, African Americans and Hispanics have higher rates of diabetes-related complications resulting in hospitalizations, end-stage renal disease related to diabetes, and amputation [83, 92, 93].

Disparities also exist in care based on age and gender. Younger adults with diabetes are less likely to receive periodic testing and more likely to have lapses in recommended care [7, 68]. Compared to men, women with diabetes are less likely to be on medication and less likely to receive recommended cardiovascular risk reduction interventions such as aspirin and lipid monitoring [94–97].

Socioeconomic Disparities

Socioeconomic factors contribute greatly to disparities in diabetes. Poverty, low education, and adverse neighborhood characteristics are often interrelated and continue to be concentrated in minority race/ethnic groups [98].

While numerous sources contribute to disparities in diabetes care, there are several potentially modifiable factors. One major contributing factor to poor diabetes outcomes is low health literacy and numeracy among minorities and patients of lower socioeconomic status. Defined as "the degree to which individuals have the capacity to obtain, process, and understand basic information and services needed to make appropriate decisions regarding their health," low health literacy can lead to low self-efficacy and disease knowledge and ultimate low diabetes self-management skills [99, 100]. Inherent to diabetes management is the ability of the patient to comprehend and apply diet and lifestyle instructions, measure and dispense medications, and quantify aspects of their care. Thus low literacy, which is often not assessed, can have major implications for patients' self-efficacy in diabetes management [100].

As mentioned above, access, especially insurance coverage, can greatly affect disparities in care. For example, a national study found that after controlling for demographic and health status characteristics, insurance coverage was more likely to determine whether a patient received diabetes services rather than race/ethnicity or socioeconomic status. It has been argued that expansion of insurance coverage would have the biggest impact of improving the quality of diabetes care and reducing disparities [101]. These studies highlight the implications that health policy can have on addressing disparities [102].

Disparities in Care Delivery

Unconscious bias at the provider and health system level can also contribute to health disparities. Studies have shown that within the same provider panel, white patients had better glycemic control than African American patients, independent of other sociodemographic characteristics, provider performance, or the number of African Americans on their panel [91]. That said, while a majority of providers endorsed that racial disparities exist in diabetes care, only a small percentage of providers acknowledged the presence of racial disparities in their own practice [103]. Thus, unconscious stereotypes may be influencing physician behavior and ultimately the quality of the care provided.

Since the Institute of Medicine's 2002 report, "Unequal treatment: Confronting racial and ethnic disparities in healthcare," the evidence is growing that provider-level and system-level interventions that streamline processes of care and improve cultural competency can improve disparities in care [90]. For example, continuing medical education programs and personal feedback have shown to significantly improve diabetes process measure achievement (e.g., foot exams). Furthermore, assessment of health literacy, provision of culturally competent care, and improved awareness of disparities in care have been shown to be effective strategies improving diabetes care [104]. However, diabetes care disparities persist; further research and work to develop targeted patient-, provider-, and system-level approaches to mitigate disparities in care for vulnerable populations are still needed.

To help address this need, the Centers for Disease Control and Prevention (CDC) created the Racial and Ethnic Approaches to Community Health (REACH) [105] program. The CDC REACH program provides funding to support public and private organizations efforts to address disparities in priority health areas. Between 1999 and 2006, the REACH program supported 40 programs including efforts to improve collaborative relationships between the community and research team [106], diabetes self-management [107], perceptions of body size and shape in a group of black women with diabetes [108], and a comprehensive community diabetes demonstration project in an African American community [109].

Quality Improvement Initiatives in Outpatient Diabetes Care

As mentioned above, there are barriers to achieving diabetes care goals at the patient (e.g., low motivation), provider (e.g., lack of therapy intensification), and/or system level (e.g., fragmented care) [78, 110]. There are a number of patient-, provider-, and practice-level quality improvement (QI) interventions that have been devised to address these barriers [111, 112]. QI interventions include reminders,

audits, and other tools to facilitate better self-management by patients and better care delivery by providers. The literature regarding QI interventions for diabetes management remains dominated by studies testing single interventions, usually focused on patients or providers, but not both. On aggregate, these interventions are associated with incrementally greater clinical benefits than routine care. A meta-analysis of 48 cluster and 94 individual randomized controlled trials [112] showed that, compared to usual care, QI interventions were associated with a 0.37 percentage point larger reductions in HbA1c; 3.1 and 1.6 mmHg larger reductions in systolic and diastolic blood pressures, respectively; and 3.9 mg/dl greater declines in LDL-cholesterol. On aggregate, even control arms experienced benefit, suggesting that more attentive follow-up alone may confer benefit in diabetes care. Similar benefits were noted in a large pragmatic, cluster-randomized, parallel-group trial that assigned European 343 practices to screening and intensive treatment of multiple risk factors (i.e., small group educational meetings with family physicians and nurses to discuss treatment targets, algorithms, and lifestyle advice) versus usual care. Over 5 years of follow-up, the intervention clinic patients experienced greater improvements in cardiovascular risk factors (HbA1c, cholesterol, and blood pressure), but this was not associated with significant reductions in the incidence of cardiovascular events and deaths [113].

Though these single QI interventions are promising, diabetes patients usually face multiple interacting barriers, and sustaining risk factor control is challenging. As such, multicomponent QI interventions or "integrated" care models are recommended [114–120]. Integrated care attempts to address barriers by leveraging existing facilities, infrastructure, and human resources. Integrated clinical care models can be based in primary care or specialist care settings, and some examples of tested models include the chronic care model, collaborative care, and their more formal, contemporary patient-centered medical homes (PCMH) and accountable care organizations.

Clinical Care Models and Practice Redesign

Conceptual Basis

Integrated clinical care models all embody similar principles. For example, collaborative care applies the principles of the chronic care model [114]. Collaborative care interventions have been shown to be of particular benefit in individuals with multi-morbidities like diabetes and depressive symptoms. Key components of the model include (1) focusing on defined patient populations and improving self-care among patients, (2) targeting depressive symptoms with medications and behavioral therapies, and (3) measurement-based treatment ("treating to target," regular review of patient population data, discussion of challenging cases, and recommending treatment modifications until clinical targets are achieved) [121].

A large number of randomized controlled trials have demonstrated that collaborative care is effective in the treatment of depression and anxiety in people with diabetes [122–127]. Collaborative care leads to greater adherence, larger reductions in depressive symptoms, more depression-free days, and better control of cardio-metabolic indicators [122, 127–131]. However, there is a tension in collaborative care models as they have (sometimes conflicting) ideals: that of "treating-to-target" and of being "patient-centered." Very little is known about patient perspectives on these aspects of QI strategies in general – in a review of 554 qualitative research articles related to diabetes over 30 years [132], none used mixed methods to gather patient and provider perspectives on QI.

Regarding the value of multicomponent QI or integrated care models, cost-effectiveness studies have noted that upfront investments are offset by savings for future acute medical care [128, 133]. As such, collaborative care models do incur an upfront cost, but a number of large US health delivery systems and payers view this as a worthy upfront investment [134, 135].

Application of Care Models for Diabetes

The chronic care model [114, 136] and collaborative care [137] concepts have inspired significant practice redesign to enhance diabetes care and outcomes over the past few decades [138]. A notable example has been the growing endorsement of medical homes [139]. Medical homes, also referred to as patient-centered medical homes (PCMHs) [140], were initially used in pediatric practices and later implemented more broadly after the American Academy of Family Physicians (AAFP) and the American College of Physicians (ACP) released position statements in 2004 and 2007 [141]. As mentioned above, the PCMH concept is based on the Chronic Care Model [142] and incorporates several core elements, such as team-based care, information technology, and payment reform, with the goal of providing more patient-centered approaches to the management of chronic health conditions (Table 17.2).

Within the Veterans Administration (VA) Healthcare System, medical homes are referred to as Patient-Aligned Care Teams (PACTs) and have been used to help provide "patient-driven, proactive, personalized, team-based care focused on wellness and disease prevention resulting in improvements in Veteran satisfaction, improved healthcare

Table 17.2 Features of PCMH and applications in diabetes care

PCMH feature	Description	Diabetes example
Team-based care with coordination and continuity	Physician and non-physician providers provide collaborative care Team arranges care with subspecialists and consultants and guides the patient through the health system	Physician refers patient on multiple medications to pharmacist for medication reconciliation and co-management
Information technology and quality tracking	Incorporation of EHR → the use of patient registries and clinical decision support based on updated practice guidelines, quality metrics Checklists to ensure consistency The use of patient registries to review quality and performance data for entire system	Use EHR data to identify patients with poor blood sugar control (i.e., HbA1C > 9.0%) to provide targeted interventions (diabetes education, self-management, etc.) [182]
Enhanced access and comprehensive care	Flexible scheduling system; easy access to the healthcare team Comprehensive care including preventive care, education services, and end-of-life care	Clinic staff contact patient after complicated hospital stay to ensure patient has a follow-up visit within 7 days of hospital discharge
Payment reform	Quality-based payment and fee-for-service reimbursements Sharing of savings from reduced healthcare costs	Payment incentives for meeting specified quality measures for diabetes care

Adapted from [139, 183]

outcomes, and costs" [143]. A typical VA PACT core team consists of a primary provider, a RN care manager, a clinical staff assistant, and an administrative staff member who work with a Veteran patient over time. The core team may also refer the patient to specialists as needed. Previous evaluations have shown that achievement of diabetes care goals in the VA system is as good or even better than in commercially insured programs [144].

In 2008, the NCQA developed a PCMH Recognition Program in collaboration with the AAP, ACP, AOA, and AAFP. An estimated 12,000 practices nationwide have now achieved recognition status [145]. On an annual basis, participating practices use an online platform to submit documentation on their performance in six categories, including (1) patient-centered access, (2) team-based care, (3) population health management, (4) care management, (5) care coordination and care transitions, and (6) performance measurement and quality improvement. The NCQA provides resources, such as training, education, and tools, to groups participating in the program [145].

Evidence

There is now an extensive and growing evidence base to support the PCMH model [146], especially with regard to improving delivery of preventive services, patient satisfaction, and staff experiences, and reductions in emergency room visits [147]. In a study of the Southeast Pennsylvania Multi-Payer Advanced Primary Care Practice Demonstration, which included 25 practices, implementation of the PCMH showed improvements in lipid, blood pressure, and blood sugar control among patients receiving care for cardiovascular disease and diabetes [148]. A 2011 review of medical home demonstration projects also concluded that PCMH have been associated with improvements in quality and cost of diabetes care [139]. For example, the Community Care of North Carolina, one of the first adult care PCMH initiatives beginning in 1998, was associated with improvements NCQA set thresholds for A1C, blood pressure control, and LDL-cholesterol and reductions in emergency room and hospital visits, along with an estimated savings of $161 million dollars [149, 150].

In more recent years, some medical home evaluations have shown less dramatic changes in quality and costs of care. For example, a 2014 study examined changes in the quality, utilization, and costs of care among 32 primary care practices in the Southeastern Pennsylvania Chronic Care Initiative between 2008 and 2011 [151]. Among 11 quality measures, significant differences were only observed in nephropathy screening in diabetes, and there were no significant changes in utilization or costs of care. However, the NCQA notes this study should be interpreted with caution since it was based on the NCQA's "earliest PCMH standards" with "only half of practices achieving the highest recognition level" [146].

Lessons Learned

Demonstration projects have highlighted several important implementation challenges for medical homes [152]. Implementation challenges highlighted in the literature include (1) scheduling issues (i.e., time-limited visits and long wait times), (2) increased staffing needs, and (3) costly investments needed in EHRs [153]. It is worth noting that these challenges are often amplified for smaller practices, where resources may be more limited. A 2010 review also highlighted the "decline of the primary care workforce" (i.e., higher numbers of physicians, physician assistants,

and nurse practitioners pursuing non-primary care specialties) and "lack of full patient engagement" (meaningful participation of patients in their own care) as other important challenges [138].

Policies and Incentives to Address Accountability and Quality in Diabetes Care

Policies and incentives focused on accountability and quality in diabetes care have increased significantly since the late 1990s. In particular, there has been an increased emphasis on the use of standardized performance measures, such as the Health Plan Employer Data and Information Set (HEDIS). HEDIS incorporates 81 measures across 5 domains of care and is used by most healthcare plans to measure performance of care and services [154]. The HEDIS diabetes measures originated from the Diabetes Quality Improvement Project (DQIP), which was a collaboration between the NCQA, the ADA, and the Centers for Medicare and Medicaid Services (CMS) in 1997 [155]. The goal of the DQIP was to develop new QI measures for diabetes care and one of the first examples of the application of disease-specific measures on a national level. The DQIP measures included clinical measures of accountability (i.e., proportion with HbA1c testing annually), quality improvement (i.e., self-management care), and patient survey data that are still used today in national assessments.

The HEDIS measures are now assessed annually including several diabetes-specific measures such as the percentage of patients receiving comprehensive diabetes care (i.e., annual HbA1c testing, glycemic control, retinal screening, LDL screening, etc.). Health plans are incentivized to use HEDIS measures since they are required to collect and submit this information in order to receive reimbursement. For example, the CMS requires health maintenance organizations (HMOs) to submit HEDIS data in order to get reimbursed for services provided to Medicare enrollees under the Medicare Advantage program [156, 157].

Pay-for-Performance Policies

Pay-for-performance programs, which also incentivize the use of quality measures, have been increasingly disseminated. The term pay-for-performance describes the use of financial incentives to encourage health systems or providers to increase quality while decreasing costs (i.e., increase value) of healthcare and service delivery [158]. Quality measures may focus on processes, outcomes, structure, and/or patients' experiences with healthcare delivery. These incentives have been delivered in both the private (i.e., between a specific health plan and provider groups) and public (i.e., the CMS Value-Based Purchasing Program to provide incentives for providers) sectors. Financial penalties (i.e., no payment for service that does meet a specified quality metric) have also been included in some instances.

Studies evaluating the effects of pay-for-performance programs have shown mixed results [159, 160]. For example, a study of 1040 matched hospitals (n = 260 pay-for-performance hospitals and n = 780 control hospitals) found that while performance initially improved in pay-for-performance hospitals compared to control hospitals, there were no significant differences between groups at 5 years of follow-up [161]. A recent review of 49 studies examining the effect of pay-for-performance on physicians, hospitals, and other settings also showed mixed results. Out of the 49 included studies, the only study rated as "good quality" did not find any significant improvements in diabetes outcomes (i.e., proportion with HbA1c and lipid control) [162]. Despite these mixed findings, there has been strong support for the use of pay-for-performance incentives as a means of aligning profits with improvements in patient care and "strengthen[ing] the business case for quality and safety" [163].

Several pay-for-performance programs, including accountable care organizations (ACOs) and Medicare's Hospital Readmissions Reduction Program, were expanded under the Affordable Care Act (ACA). Some of the concerns regarding expansion of pay-for-performance programs include scope (i.e., will payments be large enough for providers to recoup their upfront costs in EHR/information technology to support data collection), unintended effects on the physician-patient visits and relationships (i.e., disruptions in clinical flow or forced disenrollment of noncompliant patients), and the potential impact on safety-net providers and existing race/ethnic and socioeconomic disparities (i.e., will providers avoid higher-risk patients which will further exacerbate of disparities in care) [164–167].

In addition to expanding pay-for-performance programs, the ACA also included several important provisions related to diabetes care [168]. A recent review highlighted several potential improvements in (1) diabetes screening rates, (2) access to diabetes care, and (3) structure of diabetes care resulting from ACA provisions [169]. The authors argue that up to 2.3 million out of 4.6 million adults with undiagnosed diabetes between 2009 and 2010 may have gained access to preventive care under the ACA as a result of provisions requiring health plans to provide free diabetes screening to those at risk and the establishment of the health insurance marketplaces, which makes health insurance more accessible. However, many states with higher prevalence rates of diabetes have not

yet expanded Medicaid as of September 2015, and more studies are needed to fully understand ACA impacts on diabetes care.

Electronic Health Record Policies

Another very important change in federal policy with significant implications for diabetes care was the 2009 Health Information Technology for Economic and Clinical Health (HITECH) Act aiming to expand adoption of electronic health records (EHR) in clinical practice [170, 171]. Specifically, the HITECH Act aimed to expand "meaningful use," where EHRs could be leveraged to help increase quality, safety, and efficiency of care [172]. The use of diabetes registries and clinical decision support tools are two examples of "meaningful use" of EHRs to improve diabetes care and outcomes [171, 173, 174]. Health IT tools designed to support diabetes care are increasingly being studied, and there are growing efforts to engage patients in their care using data from the EHR (i.e., secure messaging, self-management programs). However, important limitations persist including challenges of data security, exchanging data between different EHR platforms, and variability in the support and use of more advanced functions [175].

Research Gaps

Ultimately, success in addressing diabetes and related disparities will be contingent upon how rapidly, efficiently, and effectively existing evidence-based care programs can be translated, adopted, and sustained in clinical and community venues. More and rigorous theory-based translation/implementation research is needed. Implementation sciences involve studying the barriers and processes that lead to effectiveness of interventions (already proven in efficacy trials) in real-life clinical and community settings, as well as investigating the adaptations required to embed these interventions into routine practice. These data can help support communities, clinicians, and decision-makers to become increasingly skilled and comfortable with implementing programs and policies [176–178].

It must also be said that, to truly realize the "triple aim" of better health, better care, and lower cost for the nation with regard to diabetes [179], we cannot ignore the importance of prevention and the health policies needed to support this. The current growth in absolute numbers with diabetes and associated healthcare costs is untenable, and bending the cost curve requires greater adoption of individual-level interventions to prevent diabetes. Similarly, more rigorous evaluation of population-based interventions (e.g., soda taxes) is also needed. Studies assessing the long-term impacts of recent policy changes, under both the HITECH Act and ACA, are also needed. The use of rigorous quasi experiments has increased, and it is hoped that these shed light on appropriate and cost-effective policies and programs for employers, communities, counties, states, and even the federal government to adopt and invest in.

Concluding Remarks

The story of diabetes in the United States over the past quarter century is one of good and bad news. The evidence base for diabetes prevention and management has grown, and with that, there have been improvements in care and control of diabetes [60] and associated comorbidities. However, major gaps persist: (1) The proportion of people with undiagnosed diabetes and prediabetes has not improved, (2) engagement in prevention is exceedingly low, and (3) young adults and disenfranchised populations with diabetes fare poorly in terms of control.

Furthermore, while incidence rates of "classical" diabetes complications like myocardial infarction, stroke, and amputations have dramatically declined in the last 20 years, the overall burden continues to rise due to growing numbers with diabetes and its complications. Again, declines in incidence were less impressive for young adults, minorities, and low socioeconomic populations; and there have been increases in other diabetes complications like cognitive decline, depression, and heart failure. As such, it appears that younger people with diabetes will contend with classical complications earlier in life and older Americans with diabetes will contend with more years of physical and mental disability. This has profound implications for US healthcare in terms of the volume, complexity (i.e., multi-morbidity) of cases, and health system costs related to diabetes.

The changing demographics of people with diabetes in the United States has implications for care in terms of how those affected culturally and psychologically view their illness, if and how they access care, and progression of disease. Equally, the changing nature of how and where diabetes is managed will influence the impacts that this devastating disease places on this nation.

Multiple-Choice Questions

1. Which of the following statements is correct about trends in diabetes in the United States over the period 1990–2015?
   (a) Nearly 90% of people with diabetes remain undiagnosed.

(b) The absolute numbers of people with diabetes complications like heart attacks and strokes have declined.
(c) The proportion of people with diagnosed diabetes achieving individual care goals (like controlling glycemia) has increased.
(d) All of the above are true.

2. Regarding quality of diabetes care in the United States, which of the following statements is false:
   (a) Since the 1990s, there have been concerted state, federal, and nongovernmental efforts to improve diabetes care goals through measurement and action.
   (b) Treatment targets for diabetes are static and do not change as more and newer evidence is uncovered.
   (c) Most of diabetes care is delivered in outpatient settings.
   (d) Comparing outpatient primary vs. specialty care for diabetes, studies have found no major difference in quality of care.
3. True or False: the United States experiences disparities in terms of diabetes-related health outcomes between people of different race/ethnicities, age, gender, and geographies.
4. Regarding the factors related to quality of diabetes care in the United States, which of the following statements is false:
   (a) All gaps in quality are due to patient non-compliance.
   (b) There are reports of unconscious biases that physicians have toward some of their patients which result in some patients doing better than others.
   (c) Clinical inertia is a term to describe how physicians might be reluctant to prescribe certain therapies or intensify certain therapies – for example, insulin.
   (d) System-level barriers to care like limited financial coverage for care have been associated with poorer health outcomes.
5. Which of the following statements best characterizes quality improvement interventions for diabetes?
   (a) Quality improvement interventions have no supporting evidence base and are mostly discovered by trial and error.
   (b) Quality improvement interventions mainly target patients since most of quality gaps are due to patient non-compliance.
   (c) Gaps in diabetes care are usually multifactorial, and so interventions that address several barriers and are "integrated" are more likely to be effective.
   (d) None of the above is correct.
6. Regarding delivering quality improvement interventions for diabetes, which of the following statements is most correct:
   (a) Quality improvement programs are only aimed at specialty care and have no place in primary care.
   (b) Each of the theories (e.g., the chronic care model, collaborative care, etc.) that underpin integrated care delivery is very different and does not have any common features.
   (c) The evidence to support quality improvement interventions for diabetes is weak (i.e., there are no randomized controlled trials or meta-analyses).
   (d) None of the above are true.
7. Patient-centered medical homes (PCMHs) include which of the following features:
   (a) Care coordination using physician and non-physician providers
   (b) Paper-based charting for most patient visits/encounters
   (c) Avoiding costly referrals to subspecialists and consultants
   (d) Enrolling healthier and younger subsets of patients to the practice
8. Challenges for practices considering implementation of patient-centered medical homes (PCMHs) include all of the following except:
   (a) Increased staffing needs
   (b) Costly investment in electronic health records (EHRs)
   (c) Lack of endorsement by professional medical societies and large integrated health systems
   (d) Compliance with accreditation standards to maintain PCMH status
9. Which of the following is false regarding the use of electronic health records (EHRs)?
   (a) EHRs are supported by national policy including the 2009 Health Information Technology for Economic and Clinical Health (HITECH) Act.
   (b) EHRs increase quality of care.
   (c) EHRs decrease efficiency and safety of care.
   (d) EHRs incorporate clinical decision support tools.
10. Regarding pay-for-performance programs, which of the following statements is false:
    (a) Pay-for-performance programs are used to incentivize the use of quality measures.
    (b) Pay-for-performance programs were expanded under the Affordable Care Act (ACA).
    (c) Pay-for-performance programs are used by both private and public insurance programs.
    (d) Pay-for-performance programs have consistently led to improvements in patient care and outcomes.

Correct Answers

1. (c) The proportion of people with diagnosed diabetes achieving individual care goals (like controlling glycemia) has increased.
2. (b) Treatment targets for diabetes are static and do not change as more and newer evidence is uncovered.
3. True
4. (a) All gaps in quality are due to patient non-compliance.
5. (c) Gaps in diabetes care are usually multifactorial, and so interventions that address several barriers and are "integrated" are more likely to be effective.
6. (d) None of the above are true.
7. (a) Care coordination using physician and non-physician providers
8. (c) Lack of endorsement by professional medical societies and large integrated health systems
9. (c) EHRs decrease efficiency and safety of care.
10. (d) Pay-for-performance programs have consistently led to improvements in patient care and outcomes.

Diabetes Management in Africa

18

Simeon Pierre Choukem, Christian Akem Dimala, Camille Maadjhou, and Jean Claude Mbanya

Explanatory Box 18.1: Chapter Objectives

- To discuss the current issues related to diabetes management in Africa
- To review the most frequent treatment strategies and protocols for diabetes in Africa
- To discuss the challenges to the adequate management of diabetes in Africa

Introduction

Beside the fact that Africa is facing the most severe increase in the number of people with diabetes over time as compared with other regions of the world [1], Africans with diabetes face specificities that should be taken into consideration when approaching diabetes management in this area of the world. The most prominent specificities are (1) the absence of global healthcare insurance and coverage and the limited number and distribution of equipped healthcare facilities in most countries, both of which certainly account for the high frequency of acute and chronic complications, and (2) the clinical heterogeneity marked by atypical phenotypes such as ketosis-prone type 2 diabetes [2].

As a chronic disease, the management of diabetes in Africa as in other parts of the world has greatly evolved from the traditional protocols to a more holistic and patient-centered approach. However, the health systems in Africa are often ill-equipped to manage chronic diseases, because these countries still face significant mortality and morbidity from infectious diseases which take priority on most health policy agendas [3, 4]. Nevertheless, there has been significant progress in the types and coverage of diabetes care services.

It is, however, worth noting that despite the aforementioned specificities of diabetes, there are still limited contextualized guidelines, specific to the management of diabetes in Africa, as many countries still rely on guidelines essentially used in developed countries [5, 6]. The integration of diabetes care programs in the health system has been one of the innovative methods adopted by a number of countries in Africa to improve on the management of diabetes. Alongside these programs, associations are being set up in several countries to coordinate actions at national level, all in a bid to control the burden of this disease [4].

Regarding the pharmacological means to treat diabetes, most oral antidiabetic agents are available in Africa, though the newest ones may not be financially accessible to most patients. While traditional formulations of human insulin are more accessible in most countries, insulin analogs in pens, though present in most markets, are still very expensive. Finally, attempts to define the role and include African traditional medicine and phytotherapy in the management strategy of diabetes seem to be of great interest, as these alternatives are often the recourse of many patients, because of their limited financial means and the chronic nature of the disease.

As in other parts of the world, the objectives of management of diabetes in Africa are centered on improving the quality of life of patients, reducing morbidity and mortality through prevention of disease progression and development of complications [7]. Despite the lack of general guidelines for the management of diabetes in Africa as a

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_18

whole due to the specificities of this chronic disease, some countries like South Africa, Tanzania, and Nigeria among others have produced context-specific national guidelines [8–10]. The importance of these guidelines cannot be overemphasized, given the fact that they provide a contextualized framework for rational management decisions and a guide for training healthcare providers on up-to-date evidence-based practices for diabetes management. Overall, these guidelines help to improve on the quality of care delivered to patients and reduce diabetes-related mortality and morbidity [8].

The management of diabetes in Africa can be approached from the following four perspectives:

1. Health beliefs and perceptions relating to diabetes
2. Management of blood glucose
3. Prevention and management of acute metabolic and chronic complications of diabetes
4. Management of comorbidities

Health Beliefs and Perceptions Relating to Diabetes in Africa

For a better approach to the management of diabetes in Africa, it is important to understand the beliefs, knowledge, and perceptions relating to diabetes and related risk factors. In this first section, we shall describe the health-seeking behaviors of people with diabetes in Africa and how this influences the prevention and control of diabetes.

Health-Seeking Behaviors of People with Diabetes in Africa

In Africa, although most patients believe that the ideal place to seek treatment for general healthcare including diabetes is a modern healthcare facility, patients often seek alternative or complementary treatment from folk healers and other sources, mainly because they lack money to pay health service bills. Money is seen as a major determinant of where, when, and which kind of treatment is sought during illness. Patients tend to use traditional therapies because of beliefs about the causes of their ill health and a strong cultural attachment to initial home management and only access modern health services during a crisis. Concerning some of the risk factors for diabetes, some people believe that obesity is a sign of good living and/or good health and that eating healthy is hard to sustain because of practical difficulties. Others consider less strenuous activities such as walking to be a sign of poverty and therefore see this as demeaning.

Figure 18.1 describes the behavioral factors and beliefs associated with the development and progression of diabetes in Africa. This highlights on the relative importance of various health beliefs toward a cultural understanding of diabetes in Africa.

Impact of These Beliefs on the Prevention and Control of Diabetes in Africa

Due to the beliefs described above, many people are not motivated to take action to reduce their risk of diabetes by increasing activity, changing their diet, and losing weight. In addition, home management for symptomatic relief is accepted as essential because patients taken to the hospital are thought to be likely to die. This lack of knowledge, lay beliefs about causation and treatment, and financial barrier increase the likelihood of diabetes and its complications to be managed at home or consultation of traditional healers, thereby delaying presentation to health services. Since the diagnosis of diabetes is late in Africa, most patients already present with complications at the time of diagnosis.

Figure 18.2 illustrates the strong interplay between health beliefs, knowledge, lay perceptions, and health behavior of patients with diabetes in Africa and how this influences its prevention and control. This shows that health outcomes of patients with diabetes in Africa are highly dependent on knowledge and cultural beliefs.

Management of Hyperglycemia

Maintenance of an optimal blood glucose level is fundamental to managing diabetes. This is because the complications of diabetes arise when the chronic hyperglycemia that characterizes diabetes mellitus remains untreated. Normal glycemic control can be achieved using non-pharmacologic and pharmacologic means. Non-pharmacologic means are the first line of treatment, and pharmacologic means are employed in combination. Medical nutrition therapy is the first line of treatment among the non-pharmacologic options [7]. It is worth noting that the therapeutic benefits of pharmacologic therapy are optimal when used alongside medical nutrition therapy.

Explanatory Box 18.2: Objectives of Management of Diabetes Mellitus

- Improve on the early detection of disease in affected individuals.
- Improve the quality of life of patients with diabetes.
- Prevent disease progression to complications.
- Empower patients and encourage self-care practices.

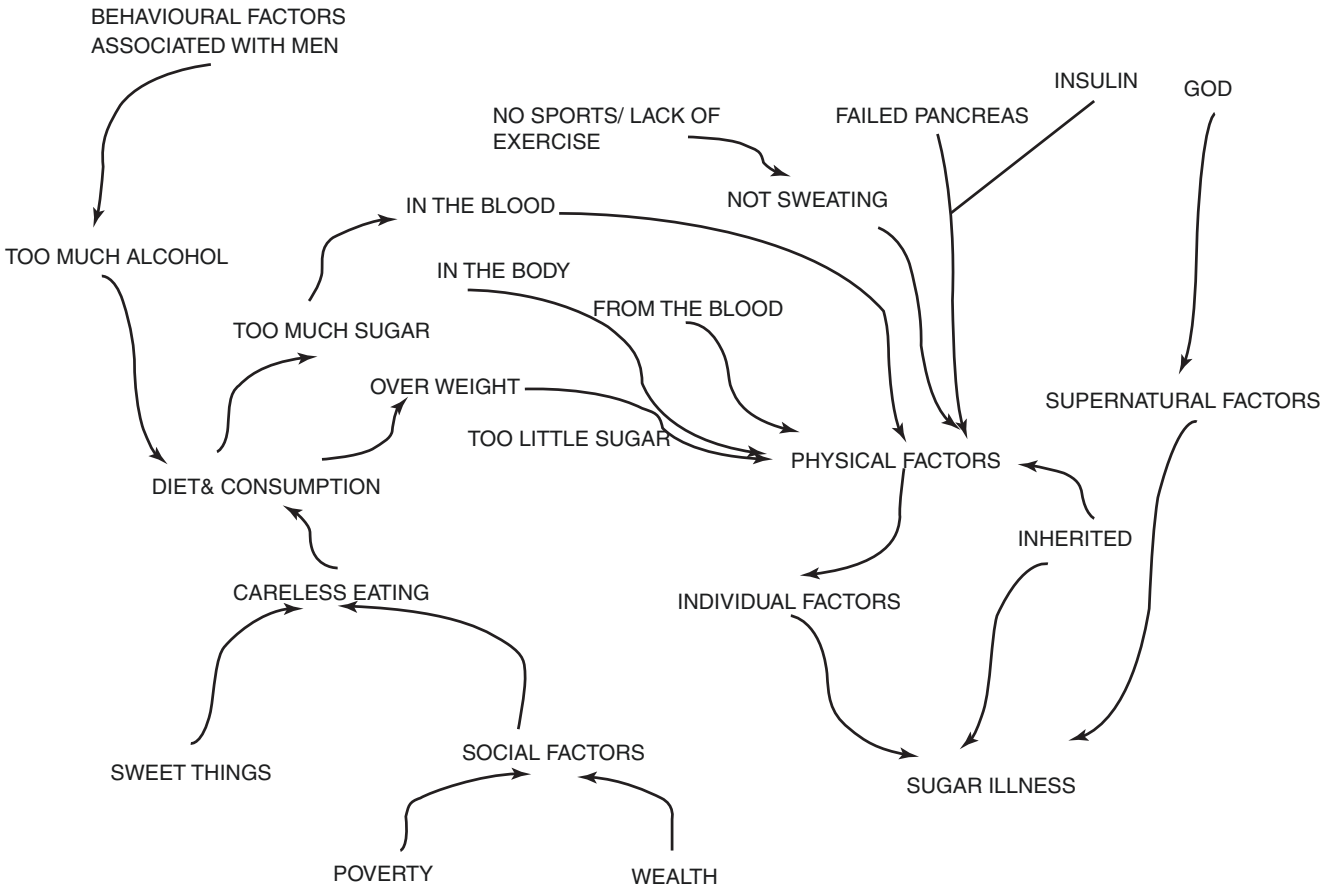

Fig. 18.1 Causal web of diabetes in Africa (Professor Jean Claude Mbanya, personal communications 2014)

Screening and Diagnosis

The asymptomatic presentation of diabetes in its early stages compromises health-seeking behavior, even among susceptible individuals. It has been estimated that a quarter of patients with diabetes at the time they seek medical attention already have complications resulting from the disease [8]. Less than 50% of participants from most studies conducted in sub-Saharan Africa were known to have diabetes with reported within-country variations; the higher percentages were reported in urban areas compared to rural areas [5]. Screening is important in the early detection of disease before the occurrence of complications, thereby reducing disease morbidity and mortality [8]. Even though the Anglo-Danish-Dutch Study of Intensive Treatment in People with Screen-Detected Diabetes in Primary Care (ADDITION)-Cambridge study found that screening for type 2 diabetes is not associated with a reduction in mortality, the careful interpretation of these findings in a resource-limited context as sub-Saharan Africa has been strongly recommended to avoid drawing faulty conclusions and inferences [12]. This is because the socioeconomic context makes Africa the area where screening is most likely to be beneficial.

Nevertheless, the implementation of large-scale population-based screening in the African context is limited by the scarcity of both human and financial resources, since well-organized clinics with suitably trained staff in diabetes screening and care are necessary for an effective screening program. Targeted screening conducted at local healthcare facility level and focused on individuals with increased disease risk is therefore preferred. Logistically less-demanding screening methods, such as risk scoring systems and questionnaires with minimal or no laboratory testing required, have been proposed for identifying people at high risk of developing diabetes [13]. The screening of diabetes is often undertaken alongside other cardiovascular risk factors such as hypertension and hyperlipidemia to ensure a holistic approach to patient care. The Society for Endocrinology, Metabolism and Diabetes of South Africa (SEMDSA) guidelines recommend screening for type 2 diabetes mellitus in all overweight adults at any age so long as they have another risk factor for diabetes and all other adults with no risk factors and aged 45 and above, with rescreening after 3 months to 3 years depending on individual risk [10]. The International Diabetes Federation, however, recommends screening for type 2 diabetes mellitus in individuals aged 40 and above, with familial predisposition, elevated body mass indices, and other cardiovascular risk factors such as high blood pressure and dyslipidemia [14].

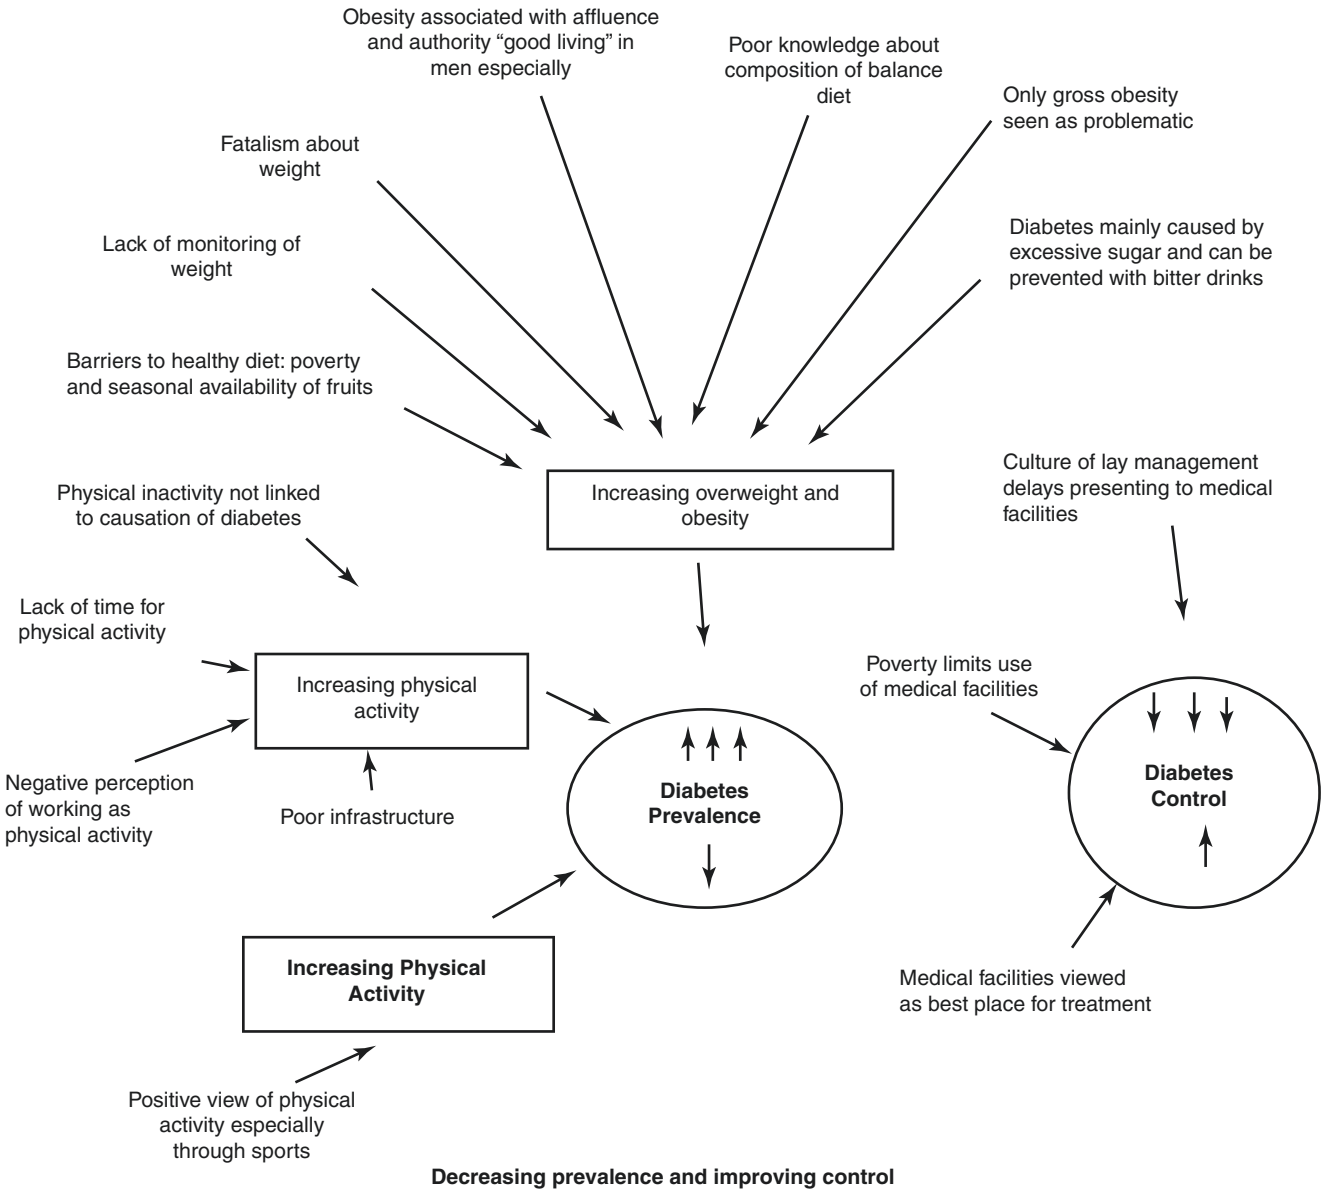

Fig. 18.2 Impact of lay health beliefs on the prevention and control of diabetes in Africa [11]

Explanatory Box 18.3: Screening of Type 2 Diabetes Mellitus

For who?

- Age ≥ 45 if no risk factor
- Any age if overweight or obese with one other risk factor:
  - Family history of diabetes mellitus
  - Hypertension
  - Hyperlipidemia
  - Physical inactivity
  - Pregnancy/gestational diabetes

Methods

- Fasting blood glucose measurement
- Two-hour blood glucose (oral glucose tolerance test)
- HBA1c

Review durations

- Three-yearly in case of negative screening test
- Yearly follow-up in case of positive screening test but negative diagnostic test results

Source: Adapted from the 2017 SEMDSA Guidelines for the Management of Type 2 Diabetes [10]

The criteria for diagnosis of diabetes in Africa are similar to those recommended by the international guidelines [15]. Most patients present with acute hyperglycemia with undoubted clinical manifestations; others are diagnosed through campaigns screening or labor health screening. Oral glucose tolerance test is seldom performed, whereas using HbA1c as a means of diagnosis seems illusive because of the absence of the recommended method (high-pressure liquid chromatography) in most African countries.

Lifestyle Modification

The principal components of lifestyle modification in the African context just as in other parts of the world are diet control, weight control, physical activity, cessation of alcohol consumption, smoking, and other factors known to favor hyperglycemia or to increase the risk of complications.

Explanatory Box 18.4: Components of Lifestyle Modification

Healthy diet:

- Reducing carbohydrate, saturated fat, cholesterol, and salt intake

Weight reduction:

- Target BMI: 18.5–24.9 Kg/m^2

Regular physical activity:

- Aerobic exercises (brisk walking, cycling, swimming, dancing, water aerobics)
- Resistance exercises (free-weight lifting, exercises with weight machines)
- At least three times/week and between 20 and 30 minutes per session
- Reconsider insulin and secretagogues dosing to prevent hypoglycemia
- Consider cardiovascular assessment before and contraindications to physical activity

Reduction of alcohol consumption

Cessation of smoking

Source: Adapted from the 2012 and 2017 SEMDSA Guidelines for the Management of Type 2 Diabetes [8, 10]

Medical Nutrition Therapy

The effects and benefits of medical nutrition therapy are two-pronged: to maintain glycemia within normal limits and also to help reduce body weight which is a modifiable risk factor of diabetes. Adjustments of the diet revolve around a personalized diet based on an assessment of the patient's nutritional status within the context of sociocultural and psychological influences and tailored to the patient's needs based on ongoing monitoring of glycemia and patient support to maintenance of this plan with allowance for flexibility. Even though most patients with diabetes in Africa are aware of the importance of a healthy diet in its management, some are not aware of the specific components of the healthy diet [16].

In addition to this, lack of adherence even when the healthy diet is initiated remains common [10]. Regular medical nutrition therapy contact sessions with dietitians specialized in diabetes management are therefore recommended over the generic nutritional advices and messages often given to patients [10]. Restrictive diets consisting of protein-rich, carbohydrate-free, and fat-free items are not recommended due to no proven long-term benefit [8].

Specific dietary requirements in patients with type 2 diabetes mellitus are as follows:

1. Healthy diet:
   - Increasing daily water intake and having meals at regular times daily
   - Avoiding binge eating
   - Variety of vegetables and fruits excluding fruit juices
   - Low-fat dairy products, meat alternatives, and fish
   - Limiting processed food
2. Carbohydrate:
   - Constitute 45–60% of total energy intake
   - Monitoring carbohydrate intake and limiting sugar alcohols
   - Reasonable sucrose and fructose and artificial sweeteners intakes are acceptable
3. Fats:
   - Should be <35% of the total energy intake
   - Limiting saturated and poly-saturated fats intake
   - Consume monounsaturated fat and omega-3 fatty acids from both plant (flaxseed, walnuts, and canola) and marine (fatty fish) sources instead of saturated fat
4. Proteins:
   - Should make up 15–20% of total energy intake
5. Salt:
   - Reducing dietary salt intake to control blood pressure (<2300 mg/day)
6. Vitamins and minerals:
   - Routine supplementation not required unless in some specific groups such as elderly patients or lactating pregnant women
7. Alcohol:
   - Moderate alcohol consumption for individuals who consume alcohol (one unit per day for women and two units per day for men)

These dietary requirements often difficult to accurately measure have been simplified in the healthy diabetes plate concept (Fig. 18.3a, b).

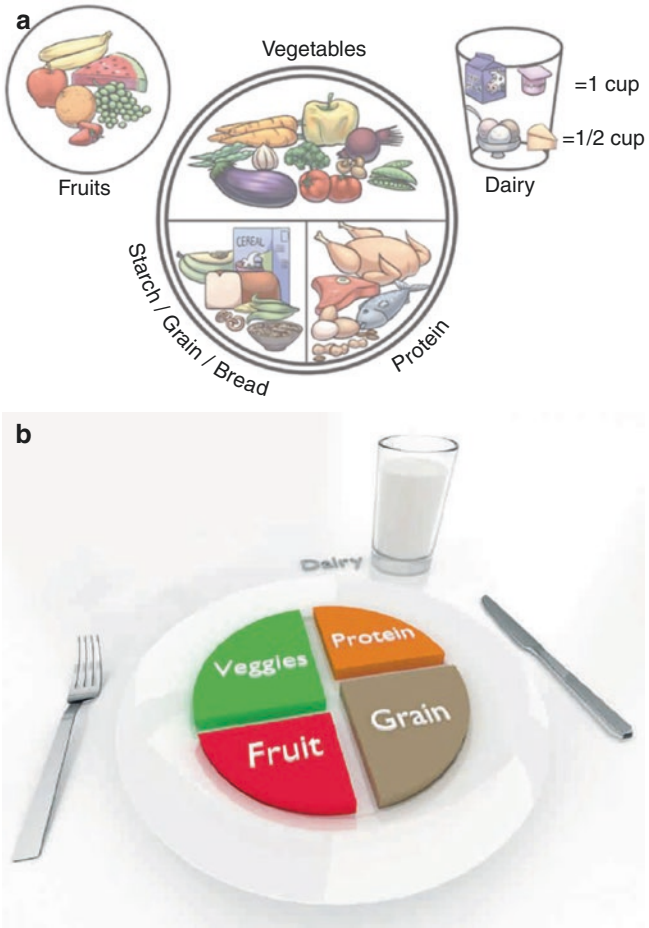

Fig. 18.3 (**a**) The healthy diabetes plate. (Source: The 2012 SEMDSA Guideline for the Management of Type 2 Diabetes [8]). (**b**) The healthy diabetes plate. (Source: Management of Gestational Diabetes in the Community. Training manual for community health workers [17])

Explanatory Box 18.5: The Healthy Diabetes Plate

To constitute the healthy diabetes plate:

- Divide into two equal halves and then divide one of these halves into two equal sections.
- The undivided half section should consist of a variety of non-starchy vegetables, such as spinach, carrots, lettuce and other greens, cabbage, green beans, broccoli, cauliflower, tomatoes, cucumber, beets, mushrooms, and peppers.
- One of the quarters should contain starchy foods, such as whole-grain breads (e.g., whole wheat or rye), whole-grain high-fiber cereal, cooked cereal (e.g., oatmeal), brown or long-grain rice, pasta, baby potatoes, green peas, sweet potatoes, whole-grain crackers, and fat-free popcorn.
- The other quarter section should contain meat and meat substitutes, such as skinless chicken and Turkey portions, fish and other seafood, lean cuts of beef and pork (e.g., sirloin, filet, or pork loin), tofu, soya, eggs, and low-fat cheese. Avoid processed meats (e.g., salami, Vienna sausages, and polony), which are high in fat and salt.
- A glass (240 ml) of nonfat or low-fat milk or 180 ml of light yogurt (at least two servings per day).
- A medium portion of fruit (such as oranges, apples, pears, or small bananas), or two small fruits (such as plums or peaches), or three quarters of a cup of fresh fruit salad. Instead of eating fruit with meals, these are eaten as snacks between meals.

Physical Activity and Other Lifestyle Measures

With obesity and overweight as risk factors for insulin resistance and type 2 diabetes mellitus, weight loss stands out as an important factor to be considered in order to prevent or manage diabetes mellitus. Adjustments in weight should therefore be tailored to match the individual's height to maintain a normal body mass index (18.5 to 24.9 Kg/m^2). The place of patient education on weight loss and its importance in diabetes management cannot be overemphasized, since local perceptions in the African setting consider obesity as an indicator of affluence, status, and good living [11]. Significant reductions in diabetes mellitus-related mortality and morbidity have been reported with regular physical activity [18, 19]. As reported in the findings of a study on a cohort of diabetes mellitus patients in Cameroon, Central Africa, a 12-week aerobic exercise program monitored by a step counter was found to significantly improve the anthropometric and metabolic parameters, alongside the aerobic capacity of patients with diabetes mellitus [19]. The aerobic exercise here consisted of 45-minute sessions holding thrice a week with each session consisting of a warm-up, brisk walking or light running, and a cooldown. Dancing was also introduced at some point during the follow-up period of the aerobic exercise [19]. Despite being aware of the importance of physical activity in preventing or managing diabetes, several patients in sub-Saharan Africa still do not engage into physical activity due to lack of time or access to appropriate infrastructure [11].

Overall, physical activity reduces cardiovascular disease risk; improves insulin sensitivity; controls glycemia, blood pressure, and lipid levels; and reduces the total body weight. It is worth noting that any recommendations to engage in a physical activity regimen should be preceded by an adequate assessment to ensure there are no contraindications to physical activity.

The multicenter Diabcare Africa study conducted in six African countries reported rather low rates of smoking and alcohol consumption among patients with diabetes mellitus in sub-Saharan Africa, with the highest figures detected in Central African regions [20]. Reduction in alcohol consumption to a maximum of one unit per day or less for women and two units per day for men is beneficial in preventing any alcohol-related hyperglycemia [8].

Pharmacologic Therapy

Pharmacologic therapy is considered in addition to lifestyle modifications or when the latter has failed to maintain optimal glycemic levels. In type 1 diabetes, and in any acute metabolic and non-metabolic diabetes presentation, insulin therapy is usually mandatory. As in other parts of the world, the two principal pharmacologic therapies used in Africa are oral antidiabetic medications and insulin therapy, used individually or in combination depending on the type of diabetes and patients' individual circumstances. Over the past decade, however, non-insulin injectable antidiabetic drugs led by glucagon-like peptide-1 (GLP-1) have emerged as an essential part of diabetes management [21]. Many patients in Africa, however, believe that diabetes can be treated using traditional therapy, making compliance to recommended pharmacologic therapy occasionally ineffective [11].

Explanatory Box 18.6: Treatment Targets
Blood glucose

- Fasting plasma glucose (FPG): 4–7 mmol/l
- Two-hour postprandial plasma glucose (2-hour PG) 4–8 mmol/l

Glycated hemoglobin [10]

- Glycated hemoglobin A1c (HbA1c)c ≤ 7%
- HbA1c < 6.5% in newly diagnosed patients in good health

Considerations [10]
Involve patient in discussion on glycemic targets
Three-monthly HbA1c monitoring in patients not at target and six-monthly if target achieved

Oral Antidiabetic Medications (OAD)/Oral Hypoglycemic Agents (OHA)

Majority of patients in Africa on pharmacologic therapy for diabetes are on oral antidiabetic medications [20], since they are generally the first line in type 2 diabetes treatment protocols. Monotherapy or combination therapy with different oral antidiabetic agents is used based on the potential factors underlying the hyperglycemia of the patient, and combination therapy should be based on agents from different classes. The multicenter Diabcare Africa study reported that more than half of patients on pharmacologic therapy were receiving two oral antidiabetic agents for treatment of their diabetes, and very few patients had up to three agents [20]. Nevertheless, treatment should be individualized, based on patient sociodemographic and clinical characteristics as well as economic status. The use of generic medications with proven efficacy is highly encouraged in the African context due to their relative affordability compared to proprietary brand [7]. The biguanide metformin and sulfonylureas agents are often used as first-line agents unless contraindicated. The most commonly used oral antidiabetic agents and their respective characteristics are summarized in Table 18.1.

Insulin Therapy

In general, insulin therapy is used in type 2 diabetes: when oral antidiabetic agents are inadequate to maintain optimal blood glucose levels, in cases of acute hyperglycemia requiring rapid correction, and in pregnancy where most oral antidiabetic agents are contraindicated. In type 1 diabetes, insulin is the compulsory treatment. Africa, however, faces the major problem of limited availability of insulin analogs and even unaffordability when available [5] and frequent run out of human insulin formulation which are more accessible. Nevertheless, insulin therapy should begin as soon as indicated in the management of diabetes, whether in combination with oral antidiabetic agents or as monotherapy.

Explanatory Box 18.7: Insulin Therapy
Indications:

- Type 1 diabetes mellitus
- Poor glycemic control with OAD
- Contraindications of OAD
- Hyperglycemic emergency
- Severe glycemia at initial presentation
- Perioperative glycemic control
- Organ failure (cardiorespiratory, hepatic, renal)
- Pregnancy

Regimens:
Combination therapy:

- NPH (0.2 IU/Kg of body weight/day – administered at bedtime) +
- OAD (metformin and reduced or stopped sulfonylureas dose)

Monotherapy:

- Premixed insulin twice daily, given half an hour before morning and evening meals (0.2 IU/Kg of body weight/day)

OAD oral antidiabetic agents, *NPH* neutral protamine hagedorn
Source: Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Table 18.1 List of antidiabetic drugs available in Africa

Medication	Starting dose	Maximum dose	Adverse effects	Contraindications
Biguanides				
Metformin	500 mg	2550 mg	Abdominal pain Nausea Loose stool Lactic acidosis	Renal failure Hepatic failure Cardiorespiratory failure Pregnancy
Sulfonylureas				
Glibenclamide Gliclazide Glimepiride Glipizide Chlorpropamide Tolbutamide Tolazamide Acetohexamide	2.5 mg 40 mg 1 mg 5 mg 100 mg 500 mg 100 mg 250 mg	20 mg 320 mg 8 mg 40 mg 500 mg 2500 mg 1000 mg 1500 mg	Hypoglycemia Weight gain Skin rashes	Pregnancy Caution with hepatic and renal disease
Thiazolidinediones[a]				
Rosiglitazone Pioglitazone	4 mg 15 mg	8 mg 45 mg	Hepatic impairment Fluid retention Weight gain Dilutional anemia	Renal failure Hepatic failure Cardiorespiratory failure Pregnancy
Meglitinides				
Nateglinide Repaglinide	180 mg 1.5 mg	360 mg 16 mg	Hypoglycemia Weight gain Dyspepsia	Cardiac failure Hepatic failure Pregnancy
Alpha-glucosidase inhibitors				
Acarbose Miglitol	25 mg 25 mg	300 mg 300 mg	Dyspepsia Loose stool	None

Source: Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]
[a]This class is currently absent in most African countries, because of the issues on the cardiovascular safety of rosiglitazone

Table 18.2 Insulin preparations used in Africa

Insulin preparation	Onset of action (minutes)	Peak action (hours)	Duration of action (hours)	Injections per day
Rapid acting	10–20	1–2	3–5	Immediately before meals
Soluble	30–60	2–4	6–8	30 minutes before meals
Intermediate (NPH)	60–120	5–7	13–18	Once or twice
Lente	60–180	4–8	13–20	Once or twice
Biphasic mixture 30/70	30	2–8	Up to 24	Once or twice

Source: Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Insulin preparations most used in the African setting are presented in Table 18.2.

Combination Therapy with Oral Antidiabetic Medications and Insulin

A combination of insulin and oral antidiabetic medications may be necessary to maintain blood glucose levels within optimal ranges. However, this combination therapy is used after failure of monotherapy with OAD, and insulin is required as a supplement to the OAD. An algorithm for the management of type 2 diabetes in Africa is shown below.

Explanatory Box 18.8: Algorithm for Type 2 Diabetes Mellitus Management

Step 1: (Lifestyle modification)

1. Lifestyle changes: diet, physical activity, smoking and alcohol consumption cessation
2. Review in 3 months
   Note: If patient is unwell, with severe symptoms or pregnant, then refer to a tertiary hospital or admit patient and consider insulin therapy

Step 2: (Oral monotherapy)
At follow-up visit after 3 months, if glycemic control is:

3. Adequate: continue monitoring
4. Inadequate and patient is overweight: start metformin at low dose and increase three monthly as required until maximum dose is reached
5. Inadequate and patient is not overweight: start a sulfonylurea at low dose and increase every 3 months as required until maximum dose is reached

Step 3: (Oral combination therapy)
At follow-up visit, if glycemic control is:

6. Adequate: continue monitoring
7. Inadequate: add another class of OAD, start at low dose, and increase every 3 months as required until maximum dose is reached

Step 4: (Oral and insulin combination therapy)
At follow-up visit, if glycemic control is:

8. Adequate: continue monitoring
9. Inadequate: continue OAD and add bedtime intermediate-acting insulin
10. Review in 3 months

Step 5: (Insulin therapy in a secondary or tertiary service)
At follow-up visit in 3 months, if glycemic control is:
11. Adequate: continue monitoring
12. Inadequate: more than once daily insulin is required, so refer to secondary or tertiary care

Specificities of the Management of Ketosis-Prone Type 2 Diabetes

Ketosis-prone type 2 diabetes (KPD) is an atypical form of diabetes that is frequently seen in sub-Saharan Africa. Its management mandates some specific measures because of its dichotomic presentation: acute ketotic onset or relapse that resembles the clinical presentation of type 1 diabetes, further course that is similar to that of type 2 diabetes, and the high probability of near-normoglycemic remissions with risk of hypoglycemia if hypoglycemic agents are maintained in the treatment [22]. Though there is no consensual management strategy, expert opinion suggests the following: [2]

1. During the acute phase (onset or relapse)
   - Manage as any diabetes ketoacidosis
   - Assess autoantibodies to rule out type 1 diabetes
2. Early (first to second week) after the acute phase
   - Educate on hypoglycemia, adjustment of insulin doses, and diet
   - Assess insulin secretion if possible
3. Few weeks after the acute phase
   - Close monitoring including close consultations and phone calls
   - Progressive insulin withdrawal, switch to oral antidiabetic drugs
4. Over months and years
   - Education on diet and physical activity, drug adherence, risk of hyperglycemic relapses
   - Standard follow-up similar to classical type 2 diabetes
   - Inpatient management in case of relapses

Prevention and Management of Acute and Chronic Complications of Diabetes

Prevention and Management of Chronic Complications

Populations of African origin are known to be more likely to develop microvascular complications of diabetes compared to the macrovascular complications of diabetes due to the limited access to adequate diabetes care and partly due to the high rates of hypertension in this population [23]. In most instances, the appearance of complications is the reason for patients seeking medical attention, making early detection of the disease very unlikely [24]. As a result of the higher frequency of microvascular complications of diabetes in patients in Africa, complications such as foot ulcerations, blindness, and renal failure are more frequent in these patients compared to complications resulting from large vessel involvement [25]. The African sociocultural context has a tangible impact on the management of these complications as some procedures such as amputations for chronic limb ulcerations are often unwelcomed [26]. The importance of patient education on the complications of diabetes and their management cannot be overemphasized.

As much as 50% of the patients with diabetes in the multicenter Diabcare study had their serum creatinine levels tested within the last year, with the highest percentages noted in Central Africa compared to East and West Africa. Of these patients tested, 54% had significantly raised serum creatinine levels [20]. Likewise, Central Africa compared to East and West Africa registered the highest proportion of patients tested for proteinuria in the last year [20]. These data show that diabetes complications are rare when adequately investigated for and therefore remain a major concern in the African setting.

With the appearance of complications, the risk of developing cardiovascular disease significantly increases, as well as disease-related mortality. Patients presenting with symptoms suggestive of a potential complication of diabetes should be referred to secondary or tertiary care for a proper assessment of complications. All associated complications of diabetes diagnosed following the full assessment should be promptly managed to prevent major sinister outcomes of diabetes that result in significant impairment such as amputation and blindness [7].

Management of Acute Complications of Diabetes

Poorly controlled diabetes can result in acute metabolic emergencies characterized by significant acute derangement in glycemic levels resulting in altered consciousness and even coma. The reported acute metabolic complications of diabetic ketoacidosis and lactic acidosis, hyperosmolar states, and hypoglycemia are also common in Africa [25]. These life-threatening acute metabolic emergencies that require prompt lifesaving interventions carry high mortality rates in Africa due to a constellation of reasons, among which the late presentation at health facilities, delay in diagnosis, and even lack of insulin [7, 25]. Diabetes-related infections such as foot sepsis and hand infections have been proposed as acute complications of diabetes due to their high frequency and mortality in the African setting [25]. Clinicians should therefore be trained in diagnosing and managing these conditions.

Diabetic ketosis presents with elevated blood glucose levels, heavy and rapid breathing, raised serum and urine ketones, and with or without altered consciousness. Nonketotic hyperosmolar state that has a slower development of the hyperglycemic state presents with marked dehydration and uremia, with minimal or no ketonuria. The cornerstone of management of these conditions is prompt initiation of intravenous fluid resuscitation and gradual lowering of the blood glucose level using intravenous insulin [7]. This requires close monitoring of blood glucose levels, serum electrolytes, and creatinine levels, which is often challenging to implement. A protocol consisting of intramuscular insulin and rehydration was therefore proposed as an alternative to intravenous insulin use in the absence of appropriate monitoring facilities, based on its associated significant reduction in early deaths, simplicity, and inexpensive setup [27]. Hypoglycemia in revenge, characterized by extremely low blood glucose levels, often results from overdosing of diabetes medication and/or insufficient carbohydrate intake to maintain an adequate glucose level. In the African setting, this complication has been especially frequent with sulfonylureas agents [25]. Patients initiated on these agents and insulin should therefore be educated on the potential risks of hypoglycemia and how to prevent and/or manage it.

Explanatory Box 18.9: Management of Acute Diabetic Emergencies

Diabetic ketoacidosis and nonketotic hyperosmolar state

- Intravenous fluids: minimum of 1 L in the first hour (if no contraindication)
- Insulin therapy: short-acting insulin intramuscularly
- Immediate referral to an emergency unit (secondary or tertiary care)

Hypoglycemia

For conscious patient

- Oral glucose

For unconscious patient

- Intravenous fluids: 50% glucose bolus (40–50 ml) or 20% dextrose (100–150 ml) followed by 8–10% glucose if required
- Injectable glucagon
- Long-acting carbohydrate snack on recovery
- Continue intravenous dextrose 5–10% for 12–24 hours as required
- Identify possible cause of hypoglycemia
- Review drug therapy and renal function and adjust antidiabetic treatment accordingly

Source: Adapted from Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Management of Comorbidities

Management of diabetes entails managing associated comorbidities that tend to worsen the prognosis and overall quality of life of patients with diabetes by favoring disease progression to complications and target organ damage. The principal comorbidities often associated with diabetes are cardiovascular risk factors and components of the metabolic syndrome such as hypertension and dyslipidemia. As much as 65% of patients with diabetes were being treated for hypertension and 13% for hyperlipidemia in the Diabcare Africa study, with regional variations in these percentages [20]. Aggressive management of these comorbidities therefore forms an essential component of the management of diabetes in Africa. In individuals without these comorbidities, reducing their risk of developing these comorbidities is important. As with diabetes mellitus, the management of comorbidities is by both non-pharmacologic and pharmacologic means to achieve the desired treatment targets.

The main non-pharmacologic means for managing diabetes consist of lifestyle modifications and diet, also helping in controlling the major comorbidities of diabetes such as hypertension and dyslipidemia. Failure of the non-pharmacologic means should prompt initiation of pharmacotherapy to control blood pressure, hyperlipidemia, and any other known co-comorbidities. Treatment should be individualized and special considerations taken for potential interaction between drug classes, diabetes, and antidiabetic medications. Regular monitoring of lipid profile and renal function of the patient

should be ensured, and prompt referral to a specialist or for secondary/tertiary care should be done in cases of poorly controlled comorbidities or suspicion of target organ damage [7].

Explanatory Box 18.10: Management of Comorbidities

Non-pharmacologic:

- Lifestyle modification
- Reduced salt and saturated fats in diet, regular physical exercise, weight loss

Pharmacologic:

- Antihypertensives (monotherapy, then combination therapy as required)
- Antihyperlipidemics

Treatment targets:

- Blood pressure:
- Systolic blood pressure < 130 mmHg (<125 if persistent proteinuria on dipstick)
- Diastolic blood pressure < 80 mmHg (<75 if persistent proteinuria on dipstick)

Dyslipidemia:

- Total cholesterol <5.2 mmol/L
- LDL cholesterol ≤2.6 mmol/L
- HDL cholesterol >1.1 mmol/L
- Triglycerides <1.7 mmol/L

Interactions to consider:

- High-dose diuretics inhibit insulin release.
- Beta-blockers may accentuate hypoglycemia.
- Alpha-blockers may accentuate autonomic dysfunction.
- Beta-blockers and diuretics may worsen dyslipidemia.
- ACE inhibitors may exacerbate hypoglycemia.

Source: Adapted from Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

Follow-Up of Patients

Regular clinic follow-up is mandatory in the treatment and control of diabetes. The follow-up visits can range from weeks to months depending on the stage of the disease and other clinical and patient related factors such as access to healthcare services. This has been a quite deficient arm of the overall diabetes care in Africa with patients often lost to follow-up due to several known and unknown reasons. Factors assessed at follow-up visits are shown in Table 18.3.

Monitoring of blood glucose control is best done by measuring the standard glycated hemoglobin levels (HbA1c). Unfortunately, the awareness and availability of this standard test is low in most African countries. As reported in the Multicenter Diabcare Africa study, access to HbA1c testing was as low as 47%, despite the variations across study centers [20]. There were, however, remarkable regional differences in the overall HbA1c awareness, being higher in the Central African countries compared to the West African countries. It is worth noting that in settings and centers where the HbA1c testing were available for monitoring of diabetes control, a low proportion of patients achieved their HbA1c targets [20]. An acceptable alternative to the HbA1c in the monitoring glucose

Table 18.3 Factors assessed at follow-up visits

Initial visit	3-month visit	Annual visit
Primary level		
History and diagnosis Physical examination Height and weight BMI Waist and hip circumferences Blood pressure Detailed foot examination Tooth inspection Eye examination Visual acuity Fundoscopy Biochemistry Blood glucose Glycated hemoglobin Lipid profile Creatinine Blood electrolytes Urine glucose Urine ketones Urine proteins Education Nutrition advice Medication if needed	Relevant history Weight Blood pressure Foot inspection Biochemistry Blood glucose Glycosylated hemoglobin Urine protein Education advice Nutritional advice Review therapy	History Physical Examination Biochemistry (As at the initial visit)
Secondary level		
All the above Eye examination ECG Biochemistry Blood glucose Glycosylated hemoglobin Lipid profile Creatinine Blood electrolytes	All the above	As at initial visit
Tertiary level		
All of the above Microalbuminuria	All the above	All the above Microalbuminuria

Source: Adapted from Type 2 diabetes mellitus clinical practice guidelines for sub-Saharan Africa [7]

control in Africa is the laboratory measurement of fasting and postprandial blood glucose levels. The use of urine glucose testing, though might be the only alternative available in some resource-poor settings, is not advised [7].

Current Challenges to Diabetes Management in Africa

Despite the progress made in the management of diabetes in Africa, much still needs to be done on the care of patients with diabetes in Africa. Diabetes is an expensive chronic disease not only for the health systems of countries in Africa but also for individual patients given the organization and financing of healthcare systems and payment of healthcare services by patients [3]. The barriers to adequate management of this chronic disease are:

- The unavailability of logistics for diabetes care
- Population awareness about diabetes and its management and complications due to nontreatment or poor compliance
- Poor glycemic control and late presentation to health facilities especially in type 1 diabetes [28]
- Scarcity of health personnel as a whole and those trained in diabetes care
- Access to medications due to their cost [4]

Africa that was initially plagued solely by the communicable diseases burden now faces a double disease burden, with the increasing number of patients with noncommunicable diseases. As such the healthcare systems of countries in this part of the world are faced with the challenge of resource reallocation from the traditional communicable diseases such as malaria, HIV, and tuberculosis toward the management of chronic noncommunicable diseases such as diabetes [3]. This therefore becomes extremely challenging for healthcare systems of these countries which by default are more adapted to managing acute conditions rather than chronic diseases [29].

As with other chronic conditions, cost stands out as a principal determinant of access and adherence to treatment. Access to antidiabetic medication therefore stands out as one of the major challenges faced by patients in Africa [25]. The lack of universal health coverage in most African countries implies out-of-pocket payments are the main way through which individuals pay for healthcare services, making access to treatment difficult given the high proportion of people living below the poverty threshold. This is particularly the case with insulin-based treatment of diabetes which is not always affordable when available [3]. As such the prognosis of this disease in Africa has not often been satisfactory as in other parts of the world [30, 31]. In 2005, insulin was estimated to cost between $4.30 and $4.60 per 10 ml U100 vial, in Mozambique and Zambia, when bought by the national health systems. Insulin was even more expensive when bought by individuals from private wholesalers [3].

Other more specific problems faced with regard to the management of type 1 diabetes mellitus are the quantification of insulin needs, the storage of insulin under optimal temperature conditions, and timely ordering of medication stocks to ensure permanent availability at all levels of patient care [3].

Population awareness and education about diabetes is a major factor. Many people living with diabetes still resort to unconventional and alternative treatment means such as traditional healers who are generally unlikely to refer patients back to healthcare facilities [4, 32]. There is a need to conduct operational research on such alternatives with a bid to define their potential role in the management strategy of diabetes. Knowledge about diabetes, its complications, and how to manage it is still low [33]. This makes the control of this chronic disease difficult in Africa. This lack of awareness is not limited just to the patients and their caregivers but has been reported to extend to healthcare providers as well [34], with reported instances of coma as a result of diabetes being diagnosed as cerebral malaria or HIV/AIDS, all favored by the lack of appropriate diagnostic facilities [3]. Despite the adoption of the westernized lifestyles that could increase risk of developing diabetes in Africa, the sociocultural practices in this part of the world have not made adequate allowances for the accompanying practices that could reduce disease risk such as adequate physical activity and healthy diet [32]. This is even worsened by local perceptions of the African setting such as the fact that obesity is an indicator of affluence and good living [11]. Despite all the challenges and barriers to the effective management of diabetes in Africa, it is worth noting that there exist considerable within-country differences, with urban regions having more satisfactory systems in place to manage diabetes than the rural areas.

Newer Approaches to Diabetes Management in Africa

Newer approaches to diabetes management are increasingly being implemented in Africa such as the social support and self-management of diabetes that are currently in use in developed countries. Several countries in Africa have now created a national diabetes registry and diabetes associations and are implementing national diabetes programs alongside other primary healthcare programs to cater for patients with this disease. The setting-up of diabetes clinics across countries, through joint efforts from national diabetes associations and ministries of health, is consistently adopted due to their efficiency in disease management [35].

These approaches and programs have been aimed at improving on patient education and awareness about diabetes, patient empowerment with regard to diabetes management, health personnel training, medication supply, diagnostic facilities, and overall improvement in healthcare systems across the continent [3].

Patient education and empowerment aims to educate patients on what diabetes is, how to take care of themselves to reduce their risk of having diabetes, and how to self-monitor their glycemia and adopt healthy lifestyles to reduce the risk of developing complications. The diabetes self-management support provided should be patient-centered and individualized, integrate cognitive-behavioral interventions, and involve the patient as much as possible in the decision-making process [10]. Patients should also be provided with the resources to be able to undertake self-care [7]. The adoption of less costly preventive measures such as physical activity and more precisely aerobic exercise known to improve metabolic and anthropometric parameters of patients with diabetes mellitus should be encouraged.

Points to be covered in a self-assessment education of diabetes patients is covered in the table below [8].

Explanatory Box 18.11: Basic Knowledge of Diabetes

- Basic knowledge of diabetes
- Importance of good comprehensive control and methods to achieve this
- Insulin injection techniques and sites of injection
- Self-monitoring of blood glucose
- Recognition and management of acute and chronic complications
- Foot care
- Smoking cessation and responsible alcohol use
- Preconception care
- Pregnancy: preparing, managing diabetes during pregnancy and appropriate postnatal care
- Psychosocial issues, stress management, and coping skills
- Training of caregivers and family of people with diabetes
- Managing diabetes emergencies
- Importance of an identification disc or bracelet
- Children with type 2 diabetes should be referred for specialist assessment and diabetes education
- Management of elderly patients:
  - Assess knowledge and understanding of diabetes.
  - Evaluate ability to learn and apply new self-care skills.
  - Assess nutrition and physical activity.
  - Address poly-pharmacy and comorbidities.
  - Assess for cognitive dysfunction, depression, and physical disability.
  - Address quality of life versus life expectancy.

Source: Adapted from the 2012 SEMDSA Guideline for the Management of Type 2 Diabetes [8]

Healthcare providers should be trained on diabetes as a chronic disease and its management. They should also be trained on how to disseminate this information to the population that make use of the health facilities and through other means of community engagement and communication [33].

Task shifting in the care and management of patients with diabetes is also gaining grounds in sub-Saharan Africa. There are reports of the successful implementation of nurse-led diabetes care [36, 37]. This has turned out to be cost-effective and has helped in solving the shortage of doctors treating patients with diabetes mellitus [38].

Concerning improving diagnostic facilities and medication supply, standardized means of assessing blood glucose levels should be available at the various levels of patient referral of the health system. Medications for treatment should be made available at all times through improvements in the supply chain dynamics of anti-diabetes medications, and these medications have to be made affordable for patients [3].

Another important component of the newer approaches to diabetes management in Africa is the implementation of a monitoring of care system, whereby the quality of care offered to patients is periodically monitored to identify deficiencies and correct them as appropriate [7].

Above all, the availability of adequate data on disease burden and current level of treatment coverage remain fundamental to assessing the actual progress of the management of this disease and planning on measures to improve diabetes-related mortality and morbidity [28]. Likewise, extensive research should be funded to investigate on the presentation and specificities of this condition in this part of the world [28]. This will demand enormous coordinated actions between key stakeholders, ministries of health, and both government and nongovernmental organizations. A multidisciplinary approach to diabetes prevention and treatment is therefore necessary for effective management of diabetes in Africa, with the involvement of all key stakeholders both at patient and community levels [3, 5, 28].

At the international level, the African regional branch of the International Diabetes Federation, through the African Diabetes Declaration, has summoned governments and agencies involved in diabetes care in Africa to uphold standards of diabetes care with regard to prevention, early detection, and availability and affordability of treatment [3].

The International Insulin Foundation has summarized adequate diabetes management in Africa in 11 key points [3].

Explanatory Box 18.12: Diabetes Management in Africa

- Organization of the health system
- Prevention
- Data collection
- Diagnostic tools and infrastructure

- Drug procurement and supply
- Accessibility and affordability of medicines and care
- Training and availability of healthcare workers
- Adherence issues
- Patient education and empowerment
- Community involvement and diabetes associations
- Positive policy environment

Source: Adapted from Diabetes care in sub-Saharan Africa [3]

Explanatory Box 18.13: Concluding Remarks

- The management of diabetes in Africa has significantly improved over the decades with management taking a more holistic approach.
- There are still limited contextualized guidelines, specific to the management of diabetes in Africa, as many countries still rely on guidelines essentially used in developed countries.
- Treatment cost and medication availability remain major barriers to effective treatment in Africa.
- The role of new drugs such as GLP-1 receptor agonists or sodium-glucose cotransporter 2 (SGLT2) antagonists is worth evaluating.
- A multidisciplinary approach to diabetes prevention and treatment is necessary for effective management of diabetes in Africa.

Multiple-Choice Questions

1. Measures aimed at early detection of disease in affected individuals are known as?
   (a) Primary prevention
   (b) Secondary prevention
   (c) Tertiary prevention
   (d) Treatment
   (e) Management
2. The following are major objectives of the management of diabetes, except which one?
   (a) Bring down HbA1c level below 7% for all.
   (b) Early detection of disease in affected individuals.
   (c) Improve the quality of life of patients with diabetes.
   (d) Prevent disease progression to complications.
   (e) Empower patients and encourage self-care practices.
3. All the following apply to the management of ketosis-prone type 2 diabetes, except which one?
   (a) Patients usually require insulin at onset.
   (b) Patients may be insulin-free for years.
   (c) Patients are insulin-dependent for life.
   (d) Patients may keep an excellent glucose control without any treatment.
   (e) Patients are in high risk of hypoglycemia during the remission period.
4. Management of diabetes is centered on which of the following?
   (a) Early screening and diagnosis of diabetes
   (b) Management of blood glucose
   (c) Management of comorbidities
   (d) Prevention and management of acute and chronic complications of diabetes
   (e) All of the above
5. Which of the following is not a routine pharmacologic management option for diabetes?
   (a) Insulin therapy
   (b) Vitamins and minerals
   (c) Biguanides
   (d) Sulfonylureas
   (e) Meglitinides
6. Medical nutrition therapy recommends one of the following except:
   (a) Increasing daily water intake and having meals at regular times daily
   (b) Variety of vegetables and fruits excluding fruit juices
   (c) Restrictive diets consisting of protein-rich, carbohydrate-free, and fat-free items
   (d) Limiting daily fats consumption to <35% of the total energy intake
   (e) Reducing dietary salt intake to control blood pressure (<2300 mg/day)
7. Which of the following oral antidiabetic class is recommended as the first line for outpatient care of type 2 diabetes?
   (a) Insulin
   (b) Sulfonylureas
   (c) Meglitinides
   (d) Biguanides
   (e) Thiazolidinediones
8. Well-known barriers to the management of diabetes in Africa consist of all of the following except:
   (a) The unavailability of logistics for diabetes care
   (b) Population awareness about diabetes and its management and complications due to nontreatment or poor compliance
   (c) The use of oral antidiabetic agents instead of insulin in patient with diabetes
   (d) Late presentation to health facilities
   (e) Access to medications due to their cost
9. Which of the following side effects of antidiabetic treatment is a major barrier to management?
   (a) Gastrointestinal side effects
   (b) Cardiovascular side effects
   (c) Skin side effects

(d) Hematological side effects
(e) Hypoglycemia

10. The following assessments are part of the annual evaluation of patients with diabetes, except which one?
(a) Blood urea nitrogen
(b) Urine dipstick
(c) Serum creatinine
(d) Electrocardiogram
(e) Lipid profile

Correct Answers

1. (b) Secondary prevention
Secondary prevention consists of methods aimed at identifying patients with disease early before the progression of the disease, as opposed to primary prevention which entails adopting measures to reduce the risk of developing the disease and tertiary prevention which entails treating the disease to reduce mortality and morbidity.
2. (a) Bring down HbA1c level below 7% for all.
This question aims at raising the awareness of physicians taking care of diabetes, on the fact that people living with diabetes should not be restricted to HbA1c level. Targeting HbA1c level below 7% is indeed important, and it is part of the objective "prevent disease progression to complications." Also, HbA1c target should be individualized.
3. (c) Patients are insulin-dependent for life.
Ketosis-prone type 2 diabetes is characterized by an acute ketotic onset that usually requires insulin therapy. This phase is usually followed by a long-term insulin-free remission, during which patients may keep an HbA1c level below 6.5% even without any treatment.
4. (e) All of the above
Management of diabetes entails preventing disease occurrence, managing the blood glucose level, preventing the progression of the disease to complications, and preventing or managing its acute and chronic complications in affected individuals.
5. (b) Vitamins and minerals
Body needs in mineral and vitamins are generally obtained from a regular balanced diet. Mineral and vitamin supplements are not routinely administered to patients with diabetes unless they have other conditions requiring their supplementation such as in lactating pregnant women. An affluence of food supplements – -usually merely made up of vitamins and minerals – in Africa over the past two decades has contributed in disturbing diabetes management. The marketing message conveyed by companies selling these products is that food complements can "cure" diabetes and many other epidemics. These food supplements are not recommended in diabetes management.
6. (c) Restrictive diets consisting of protein-rich, carbohydrate-free, and fat-free items
Medical nutrition therapy which is the first-line treatment of diabetes mellitus consists of all the options mentioned in the question except restrictive diets consisting of protein-rich, carbohydrate-free, and fat-free items which are no more recommended due to no proven long-term benefit. Restrictive diet is not recommended and may be dangerous.
7. (d) Biguanides
Metformin, which is a biguanide, is recommended by most guidelines as the first-line pharmacologic agent in the management of type diabetes.
8. (c) The use of oral antidiabetic agents instead of insulin in patient with diabetes
Even though oral antidiabetic agents are the first-line pharmacologic options to use in patient with diabetes, there are instances in which insulin is preferentially used. Nevertheless, using oral antidiabetic agents instead of insulin is not reported as being one of the reasons for sub-optimal management of diabetes in Africa.
9. (e) Hypoglycemia
Hypoglycemia is the major side effect of antidiabetic treatment. Fear of hypoglycemia by patients or healthcare personnel is a factor for nonadherence to treatment and therapeutic inertia.
10. (a) Blood urea nitrogen
Blood urea nitrogen (BUN) is not part of the routine assessment of diabetes. Routine BUN test is a waste of money. The other tests stated in the question are mandatory as they help identify chronic complications or cardiovascular risk factors associated to diabetes.

Joel Rodriguez-Saldana

The sick suffer enough
We must avoid adding insult to injury by denying them a proper role in determining their future
–Jerome P. Kassirer, M.D.

Introduction

The current model of health care continues to be designed to address every type of health problem from an acute disease perspective, based on episodic face-to-face interactions between health-care providers and patients; this approach does not address the multiple needs of patients with chronic diseases like diabetes [1]. In contrast, participation of patients has become increasingly important; they are assuming new roles as active agents, managers, and producers of their own health; involvement of patients is a new way to understand the relationship between patients, health professionals, and health systems, not only to recognize that they are the main responsible of their health control, but they also have an undeniable influence in policy planning [2]. Health-care providers should ensure to meet the information needs of patients because their perceptions of quality of care and quality of life are associated with the physicians' ability to transfer key information to them [3]. Historically, the professional ideal of the physician-patient relationship held that doctors directed care and made decisions about treatment; the patient's principal role was to comply with "doctor's orders"…the patient supposedly had only a minimal role in making decisions [4]. We have come a long way from the paternalistic view of medicine that excluded patients from discussions about their own health [5]. The enhanced capacity to address patients' needs increases loyalty and persistence, reduces complaints, increases the efficiency, and is also profitable [6]. Improvements in health care can be accelerated and evaluated developing patient-based measurement systems able to provide direct measures of success and failure, strengths and weaknesses, and improvements and declines in the provider's capacity to produce the desired health outcomes [7]. In sharp contrast with these realities, examples of doctors who reject patients not because of time limitations, but on far more questionable grounds, including sexual orientation, ethnicity, or specific health problems such as HIV infection, diabetes, and obesity, have been described and highly publicized as causes of rejection [8]. One of the drivers of the health disparities observed in diabetes is discrimination; discrimination is associated with decreased feeling of patient-centeredness and increased dissatisfaction with care [9]. Discrimination affects health through psychological and physiological stress responses; it is associated with loss of trust, lack of adherence, and poor diabetes management, reduces the use of diagnostic tests including A1c testing and cholesterol checks and clinical services such as eye examinations and immunizations, and produces dissatisfaction with care [9]. The results of a study published by Cykert and colleagues reinforce a need for patient-provider communication that is inclusive, eliminates perceptions of discrimination and bias, increases patient-centeredness, and improves overall clinical care [9]. In patients with diabetes, physician empathy is significantly associated with clinical outcomes, including lower rates of acute metabolic complications. Empathy should be considered an important element in patient care and a significant factor of physician competence [10]. Coverage denial, lack of access, or delayed access to health care is highly prevalent: in the United States, Pearson reported a 7% rate of denial of coverage within a mixed model HMO; in other countries like Mexico, the percentage of out-of-pocket medical expenses, even in recipients of social security, has been estimated to be as high as 75% [11–12]. Denial of coverage is associated with lower ratings of quality of health care and less trust on physicians [11]. A report from a nationally representative sample showed that patients with the highest levels of satisfaction had lower rates of visits to emergency departments, at the expense of higher rates of hospitalization, greater expenditures in medications, and higher risks of

mortality [13]. Patient-centeredness is an important issue in health care; it is highly dependent on values and preferences related to the patient, the expected behavior of professionals, their interactions, and seven key elements including uniqueness, autonomy, compassion, professionalism, responsiveness, partnership, and empowerment [14]. Health beliefs and self-reported capacity to adhere to treatment regimes or to follow general advice are consistently predictive of glycemic control and reduction of cardiovascular risk factors [15]. Understanding the crucial role of patients and their families on the intermediate and long-term outcomes is an essential component of diabetes management. Diabetes has become a representative model of the patient-centered medical home and should be properly addressed in clinical practice.

Milestones of Patient-Centered Care

Western health systems were dominated by a paradigm that considered "diseases" as basic elements of pathology, and since the seventeenth century, diseases were considered as functional or structural abnormalities of cells or body organs, with each abnormality adding in linear fashion, to the extent of illness [16]. Barbara Starfield claimed that "medicine is still practiced this way…in this outdated scheme there is no room to recognize that diseases are not distinct biological entities that exist alone and apart from the person" [16].

The pathological model of disease was challenged in recent decades by a new form of clinical practice that stresses the centrality of the person (not the patient), her or his risk factors and personal priorities, and the need for medical surveillance to understand health and illness. In 1971, DC Taylor brilliantly described three components of sickness: (1) diseases (abnormalities in diagnostic tests), (2) illnesses (the unique combination of symptoms and signs in an individual), and (3) predicaments, the personal, social, and economic consequences of being sick [17]. The paradigm of the pathological model of disease claimed that if mankind could master nature through science, every clinical problem would have a single explanation and solution. Nevertheless, a "whole-patient"-oriented view of disease is more accurate and more equitable than a disease-oriented view [17]. Medical care must evolve to meet the health-care needs of patients in the twenty-first century; clinical decision-making should focus on the attainment of individual (personal) goals and the identification and treatment of all modifiable biological and non-biological factors, instead of solely relying on the diagnosis, treatment, and prevention of individual diseases [18].

Primary Care as the Site of the Medical Home

The new paradigm shift in health care was announced by Freyman in 1989; in this new paradigm, the focus of health care would have shifted to the community [19]. Diagnosis and treatment would be managed in ambulatory settings including homes, and the hospitalized fraction of the population needing medical care would be smaller…primary physicians will be the key personnel in vertically integrated systems, they will become the first contact of all the patients, and they will be responsible to coordinate these services; to provide continuing, comprehensive, and up-to-date medical care; and to refer "the relatively few" who need the services of specialists [19]. These visionary predictions met strong resistance in many countries; reasons include the natural resistance to innovate, the perception of this innovative model as a threat to current interests, particularly economic, of physicians and health organizations, and perceptions of low value by providers of "solutions" of high cost [20]. Although some nomadic patients prefer to navigate through episodic encounters with emergency departments and specialists, most people want a medical home, in which responsibility of care and care coordination resides in the personal medical provider working with a health-care team according to patient's needs and including specialists, midlevel providers, nurses, social workers, care managers, dietitians, pharmacists, physical and occupational therapists, family, and community [21]. Primary care, in which physicians address most of the patients' health-care needs through the lifetime, was developed to serve as the medical home [22]. One of the first descriptions of the attributes and the roles of primary care was made by Scheffler and colleagues in 1978 and included (1) accessibility, (2) comprehensiveness, (3) coordination, and (4) continuity, delivered by accountable providers of personal health services, usually associated with the care of the whole person, rather than a particular illness, and distinguished from other levels of health care by the nature of the services provided, not by the particular training of the provider (i.e., not necessarily provided by physicians [22]). In 1998 Barbara Starfield described the four essential functions or major features of accountability of the primary care medical home [23] (Table 19.1).

Table 19.1 Attributes of primary care

Function	Description
1. Accessibility and first contact: gate-keeping	A point of easy access entry for a health problem; the door to start receiving care from a health professional (nurse or physician)
2. Comprehensiveness	Arrange and provide the full range of patient's health-related needs including preventive, acute, chronic, rehabilitative, and palliative services
3. Sustained, longitudinal care	Dealing with changes in the health status of individuals or groups of personas over years from a regular source of care in one place, by one individual or one team
4. Coordination	Harmonized referral: integration of all types of care, regardless of the provider, including specialists and hospitals

Modified from Ref. [23]

Milestones of Patient-Centered Care

Patient-centered medicine had its roots in 1967, when the American Academy of Pediatrics (AAP), under the leadership of Dr. Calvin Sia, introduced the term "medical home" in the book *Standards of Child Health Care to Describe an Approach to Taking Good Care of Children with Special Care Needs* [24]. The term "patient-centered medicine" was introduced by Balint and colleagues in 1970 in contrast to "illness-centered medicine" [25]. According to Reach and McWhinney, the idea of person- or patient-centered care is a "rediscovery" [26–27]. For example, in 1882 Nothnagel in Vienna said that "medicine is about treating sick people and not diseases," in 1892 Sir William Osler declared that "It is more important to know what sort of patient has a disease than to know what kind of disease has the patient," and in 1926 Crookshank pointed out that "since the origins of the clinical method in ancient Greece, there have been two meanings of diagnosis: to diagnose a disease and to diagnose a patient" [26–28]. Historically, excellence in western medicine was based on the application of anatomy and physiology on the care of patients [29]. The doctor-centered model is the doctor's attempt to interpret the patient's illness in terms of medical explanations, in order to assign the patient's illness to one of the conventional disease categories [27]. From this perspective, success depends on the precise classification of illness, the capacity to link the patient's symptoms and signs with organic pathology and to identify causal agents [27]. These two approaches are clearly different; they represent two ways of thinking, two attitudes to life, two different mental sets, and probably two personality types [27]. Disease-centered recommendations do not address what matters most to patients, who have different health priorities…patient's goals and preferences are rarely translated into actual care decisions [30].

The Link Between Primary Care and Patient-Centered Care

A medical home was defined as the central source of a child's pediatric records and the repository of medical records for chronically ill children, and the definition was expanded to include primary care that is accessible, continuous, comprehensive, coordinated, family centered, and culturally effective [31]. Afterward, the World Health Organization incorporated several concepts currently described as part of the patient-centered medical home (PCMH) as the sixth and seventh declarations of the Primary Care Conference of Alma-Ata in 1978, including access and continuity to care, comprehensiveness and integration of care, patient education and participation, team-based care, and public policies supporting primary care [32]. Primary care probably dates back to the Dawson Report published in the UK in 1920 and introduced the concept of three levels of care – primary and secondary health centers and teaching hospitals – which continues to be the basis of the pyramidal regionalization of health services [33]. In the 1960s and 1970s, primary care found its roots when the vertical approach to health care and the efforts to *transplant* hospital-based health-care systems to developing countries in the absence or lack of emphasis on prevention was critized [34]. At the 1976 World Health Assembly, Halfdan Mahler proposed the goal of "Health for All by the Year 2000," which became crucial in the history of primary care, and that would be confirmed at Alma-Ata in 1978 [34]. Promotion of primary health care since Alma-Ata stressed the need to address the health needs of all people and to recognize family physicians as the primary providers of health care albeit disillusionment about its real contribution to health improvement persists [35]. Achievements have fallen short of expectations, and it is time to launch renewed efforts to strengthen health systems to integrate primary health care [35]. The "missing link" to translate the principles of Alma-Ata from idealism to practical effective public strategies has been the incapacity of health systems to integrate personal and public health, but the challenge continues to be shifting personal health care at the expense of population health [35]. Primary health care contributes to reduce the adverse impact of social inequalities of health and is more effective to achieve better health outcomes, at lower costs, than systems oriented to disease management and specialized care [36]. The turning point in primary care is the inescapable fact that patients with chronic conditions self-manage their illness, and while physicians are experts about diseases, patients are experts about their lives [37]. The literature about the benefits of primary care has shown greater effectiveness, greater efficiency, greater equity, and greater understanding of the mechanisms by which its benefits are achieved [38]. All of the following attributes in combination produce better services: greater first-contact access and use, more continuing person-focused care, greater range of services, and coordination [38]. Primary care is rapidly evolving, but has also become an endangered species: doctor's duties are changing, influenced by advances in medical knowledge and technology, the increasing use of computers, handheld devices and electronic records, and the growing trend to track and measure clinical data [39]. The pressure on physicians to accomplish multiple goals has intensified worldwide; many patients describe their doctors as hurried and unresponsive, and nurse practitioners are perceived more willing to take time, talk to patients, and answer questions; most of the time, physicians' days are spent on administrative tasks, paperwork, and data entry [39]. Overstressed by large patient workloads, many primary care practices are performing poorly: patients are interrupted after 23 seconds trying to explain their problems to a physician, 50% of

patients leave office visits not understanding what the physician has told them, and evidence-based care is provided on a limited basis [40]. Two possible solutions include one very difficult to implement – devoting more time per patient – and one feasible, pioneered by Bodenheimer and colleagues: to reorganize primary care as a team-based endeavor, in which many functions currently in the hands of physicians are provided by other staff members, including nurses or medical assistants [41].

Primary care physicians are central and core components of any high-quality health-care delivery system [42]. According to the Miller-Coulson Academy of Clinical Excellence (MCACE) at Johns Hopkins University, clinical excellence involves achieving distinction in six plus one areas related to patient care [42]:

1. Communication and personal skills to promote successful physician-patient relationships
2. Professionalism and humanism to support the development and maintenance of strong physician-patient relationships
3. Diagnostic acumen, the "science and art" of using information gathered from the history and physical examination to arrive at the correct diagnosis
4. Skillful negotiation within the health-care system, to overcome its increasing fragmentation with many providers, sites of care, and record systems
5. Ability to find, interpret, and apply information to solve clinical problems
6. A scholarly approach to clinical practice to ensure that physicians remain informed about the best practice
   – A passion for patient care

Barriers to Implement the Patient-Centered Medical Home

In the medical home, responsibility for care and care coordination resides in the patient's personal medical provider working with a health-care team needs and including specialists, midlevel providers, nurses, social workers, care managers, dietitians, pharmacists, physical and occupational therapists, family, and community. Patient-centered medical homes and primary care are at crossroads in many countries: family medicine appears to be largely devalued as a professional activity among medical students, who are more interested into specialty care, and primary care physicians are discouraged and even leaving practice [43–44]. In most medical schools, students spend time in the offices of community-based primary care practitioners, where they observe the reality of this type of practice and gain insight into the challenge of caring for patients with a wide range of conditions, including serious chronic diseases [45]. When they observe patients with chronic diseases like diabetes who were hospitalized because of inadequate treatment, medical students cannot help but notice how little attention was devoted to avoid hospitalization through better outpatient management and the scarcity of team-based, patient-centered models of chronic disease management [45]. Time pressures, chaotic work environments, increasing administrative and regulatory demands, an expanding knowledge base, fragmentation of care delivery, and the greater expectations placed on primary care are the multiple contributors to the strain [21]. Burnout is an additional threat to primary care; high levels of emotional exhaustion have been reported by staff and clinicians, resulting in low professional competence, high levels of exhaustion, and cynicism [46]. It has been shown that tight team structure and greater team culture are associated with less clinician stress and burnout [47]. Under the leadership of Thomas Bodenheimer, the Center for Excellence in Primary Care at the University of California in San Francisco has compellingly demonstrated that the current practice model of primary care is unsustainable [48]. They described barriers and limitations to deliver high-quality primary care and have proposed solutions, including (1) expanding the role of health assistants in the delivery of pre-visit and post-visit activities, (2) adding capacity by sharing care with other members of the team, (3) reducing or eliminating time-consuming administrative work, (4) saving time by prescription renewal, (5) returning tasks corresponding to receptionists, pharmacists, and nurses, and (6) improving team communication and functioning through a systems approach redesign [48–49]. The practice of primary care in the future (and already in the present) should provide prompt access to high-quality care that maximizes patient's experiences and minimizes health-care costs and should make primary care more attractive for physicians, while engaging non-physician members in the care process, in the face of growing gap between the supply and demand of primary care [50]. Improvements in the delivery of high-quality primary care result in higher proportions of diabetic patients achieving targets of A1c, triglycerides, and high-density cholesterol, significant reductions in the mean values of A1c, systolic and diastolic blood pressure, LDL cholesterol, triglycerides, and body mass index and decrease in clinical inertia and the incidence of complications [51]. Improving the delivery of high-quality primary care for patients with diabetes is feasible, but requires reinforcements in structure and process that most health systems across the world do not perceive or are unwilling to carry out. Despite all these challenges, primary care is the backbone of many others; for countries aspiring to universal, effective health coverage, a strong primary care system is the essential building block [44].

Transitioning from Primary Care to the PCMH

Patient-centered medical homes represent an updated model of primary care that recognizes and rewards the diverse but necessary activities for a population of patients [44]. Recent steps taken by policy-makers and payers to recognize the essential role of primary care physicians including increased Medicare and Medicaid payments under the Affordable Care Act in the United States have been tempered by continuing divisions between supporters of primary care and specialty care over the relative value of their services and the decreasing interest of medical school graduates for primary care [52]. Most developed nations assure patient access to primary care physicians who are paid based on guidelines and outcomes established by consumers and providers, but in others, a perception that universal access to care is too expensive and unaffordable has been created and nurtured [52]. The results of the National VA Primary Care Survey on Primary Care directors identified 16 moderate to extreme challenges to implement patient-centered medical homes, including access, preventive care screening, chronic disease management, "challenging medical conditions," mental health, special populations, coordination of care, and informatics [44]. A primary care practice that wants to deliver health care effectively must interact with patients where, when, and how they want to be served [53]. According to Berry et al. and Taylor, its building blocks include "physical practice" and "remote practice" components [53]. The former comprise office visits with physicians and health professionals and visits to satellite clinics; remote practice involves at-home visits, telemedicine, and web-based services [53]. Complementing this view, Tayloe identified ten key components of the PCMH: (1) a visionary leadership with an outcome-based approach to health care, (2) a team of providers who are able to provide state-of-the art care, (3) minimization of unnecessary emergency and hospital admissions, (4) integration of hospital and office care, (5) business expertise of physicians and staff, (6) user-friendly electronic medical records, (7) physicians and staff trained and able at implementing quality improvement projects, (8) community-based coordination, (9) support from private and public third-party providers, and (10) a clear understanding of the community needs [54].

The Patient-Centered Care Defined

Table 19.2 summarizes three definitions with complementary components of patient-centered care.

Table 19.2 Evolving definitions of patient-centered care

Year	Author(s)	Definition
2001	Institute of Medicine [55]	Health care that establishes a partnership among practitioners, patients, and their families to ensure that decisions reflect patients' wants, needs, and preferences and that patients have the education and support they need to make decisions and participate in their own care
2010	Epstein et al. [56]	A quality of personal, professional, and organizational relationships; an approach to care perceived as the right thing to do, in order to understand a series of proximal outcomes, including feeling understood, trust, or motivation for change
2012	Valko et al. [57]	A team-based approach to providing comprehensive primary care, involving multiple levels of medical providers, including medical assistants, nurses, physicians, social workers, pharmacists, and behavioral health providers. It is not simply a place, but a model of health care designed to reliably and reproducibly implement the core functions of primary care

Attributes of Patient-Centered Care

Over three decades, several visions about the attributes of centered care have been described, each one with different, enriching patient perspectives (Table 19.3).

The origins of these dimensions are variable; for example, the principles proposed by the Picker Institute Europe were developed from surveys to evaluate patients' experiences with many clinical conditions and in every setting of health care, "with the dream to transform health care systems into a real system that provides effective and compassionate care for everyone" [59]. The American Academy of Family Practice and associated organizations developed their principles based on the chronic care model and the medical home model promoted by the Institute of Medicine [61]; the principles proposed by Battersby and colleagues were organized within the framework of the chronic care model developed by Edward Wagner and colleagues [62]. The Joint Principles of the Patient-Centered Medical Home, formulated and endorsed by the AAFP, the AAP, the ACP, and the AOA in 2007, and integrating behavioral care in 2014, are summarized in Table 19.4 [61, 64].

To be feasible, rewards for change must exceed the cost of change: the American Academy of Family Physicians, the American Academy of Pediatrics, and the American College of Physicians considered a three-component fee consisting of (1) an initial fee for service or visit, (2) a monthly management fee for practices providing medical home services, and (3) an additional bonus for reporting quality performance goals [61].

Table 19.3 Attributes of patient-centered care

Year	1983	1993	2005	2007	2010	2010
Authors	Levenstein et al. [58]	The Picker Institute Europe [59]	Davis et al. [60]	American Academy of Family Physicians [61]	Battersby et al. [62]	Epstein et al. [63]
Attributes or principles	1. Physicians try to enter the patient's world to see the illness through the patients' eyes 2. Invitation and facilitation openness by patients 3. Central objective: allow patients to express all the reasons for the visit 4. Aim: to understand each patient expectations, feelings, and fears 5. The key: to allow as much possible to flow from the patient 6. Crucial skill: to be receptive to verbal and nonverbal cues from the patient	1. Respect for the patient's values, preferences, and expressed needs 2. Coordination and integration of care 3. Information, communication, and education 4. Physical comfort 5. Emotional support and alleviation of fear and anxiety 6. Involvement of family and friends 7. Transition and continuity	11. Superb access to care 12. Patient engagement in care 13. Clinical information systems supporting high quality of care, practice-based learning, and quality improvement 14. Care coordination 15. Integrated, comprehensive care and smooth information transfer 16. Ongoing, routine patient feedback	1. Enhanced access and continuity 2. Identification and management of patient populations 3. Planned and managed care 4. Self-care support and community resources 5. Track and coordinated care 6. Measurement and improved performance	1. Brief targeted assessment 2. Evidence-based information to guide shared decision-making 3. Nonjudgmental approach 4. Collaborative priority and goal setting 5. Collaborative problem-solving 6. Self-management support by diverse providers 7. Self-management interventions by diverse formats 8. Patient self-efficacy 9. Active follow-up 10. Guideline-based case management for select patients 11. Linkages to evidence-based community programs 12. Multifaceted interventions	1. Healing (therapeutic), personal relationships between clinicians, patients, and family members; bridging demographic, social, and economic differences between clinicians and patients. 2. Teamwork from a coordinated community of health-care professionals, including preparations before office visits and eliciting patient's concerns early in the visit 3. Shared tailored information, shared deliberation considering patient's needs and preferences, and shared mind, an approach to care beyond informed consent or treatment

Table 19.4 Joint Principles of the Patient-Centered Medical Home (PCMH) integrating behavioral health care

Principle	Description
Personal physician	To guarantee that each patient has an ongoing relationship with a personal physician trained to provide first-contact, continuous, and comprehensive care, with a whole person orientation
Physician-directed medical practice	Physicians lead the PCMH, supported by a team of health professionals to integrate the physical, emotional, and social aspects of the patient's health needs Facilitative leadership involves shared responsibility, seamless teamwork, honoring the unique abilities of each member, and enabling members to work to their full potential
Orientation to the whole person	Responsibility to provide all the patient's health-care needs and arrange care with other qualified professionals, including care for all the stages of life, acute care, chronic care, preventive services, end-of-life care, psychosocial dimension, and resulting behavior changes in the provision of all the patient's health-care needs
Coordinated and/or integrated care across all the health-care system and the patient's community	Assurance that patients receive the indicated care when and where they need and want it. Avoid fragmentation and separation of primary from behavioral health care Shared registries, medical records, decision-making, revenue streams, and responsibilities. Clarification of real and perceived barriers to communication and regular sharing of information
Quality and safety as hallmarks	Support the attainment of optimal, patient-centered outcomes by care planning processes driven by partnerships between physicians, behavioral health professionals, patients, and their families Support from evidence-based medicine and clinical decision support tools Accountability for continuous quality improvement and performance measurement Active participation of patients in decision-making and feedback to ensure that their expectations are met Appropriate use of information technology to support optimal patient care, performance measurement, patient education, and enhanced communication; incorporate behavioral health, mental health screening, and health outcomes Recognition by nongovernmental entities to document the capacity to provide patient-centered services and behavioral care within the medical home model
Enhanced access	Access to patients, families, and physicians to medical and behavioral care through collaboration, shared problem-solving, flexible team leadership, and enhanced communication
Appropriate payment	Recognition of the added value of behavioral health care; payment in addition, not separate from primary care. Pay per-member and per-month primary care capitation

Modified from Refs. [61, 64]

Effectiveness of the Patient-Centered Medical Home

Evaluations of several patient-centered medical home models have confirmed earlier findings of improved outcomes and satisfaction; patients report very positive experiences with patient-centeredness including being treated with courtesy and respect and communication with providers in a way that is easy to understand [65]. Peer-reviewed literature has documented improvements in quality, reductions in errors, and increased patient satisfaction when they identify with a primary care medical home [66]. Evaluation of peer-reviewed literature has shown that the PCMH improves the quality of health care by reducing and improving care processes and increases satisfaction when patients identify with a medical home, but current evidence is still scarce to determine its effects on clinical and economic outcomes [66–67].

The Patient-Centered Medical Home and Diabetes: The Evidence

Changing the way used to approach patients with diabetes starts with transforming the model of health care [68]. Despite high levels of uncertainty about the effectiveness of the patient-centered medical home, identifying and overcoming the barriers to achieve glycemic targets will become more important, not only to prevent diabetes complications but also to ensure reimbursement for the medical care associated with diabetes management; in this scenario, the role of patients will also change; they will become "health-care consumers" as health systems shift toward a model of value-based care, which seems paramount of the patient-centered medical home [68]. Table 19.5 summarizes the effectiveness of interventions devoted to implement the patient-centered medical home in diabetes management.

Evidence about the effectiveness of the PCMH in diabetes management from meta-analysis and systematic reviews is even more limited. Ackroyd and Wexler selected and described the most effective interventions for diabetes care identified in a meta-analysis of 48 cluster randomized trials and 94 patient-level randomized trials attempting to determine the effect of individual quality improvement strategies for diabetes [79–80]. Albeit the studied strategies were not embedded in PCMH models, they provided some effect about the magnitude of the benefits expected on A1c levels [79]. The study showed larger effects at higher A1c baseline and found that three major components of the PCMH (team changes, case management, and promotion of self-management in addition to clinician education, patient education, facilitated relay of information,

Table 19.5 The patient-centered medical home in diabetes management

Author(s), year, and reference	Intervention	Size	Results
Kinmonth et al. [69]	Parallel group design Randomization between routine care or routine care plus additional training Analysis at 1 year, including practice effects and stratifiers, self-reporting by patients on communication with practitioners, satisfaction with treatment, style of care, and lifestyle	41 practices, 21 in intervention group (250 patients), 20 in comparison group (360 patients)	Patients in the intervention group reported better communication with doctors and greater treatment satisfaction and well-being Differences in lifestyle and glycemic control were not significant
Steiner et al. [70]	Observational study: community health networks organized and operated by community physicians, hospitals, health departments, and departments of social services	1200 primary care practices 750,000 patients Each patient is linked to a medical home: in addition to the usual Medicaid fee, a management fee guarantees ongoing comprehensive primary care, 24-hour on-call coverage, and arrangements with other health professionals	Patients with A1c <7.0%: 47% Patients with A1c >9.0%: 21% Blood pressure control ≥140/90 mm Hg: 34% Blood pressure control <130/80 mm Hg: 37% LDL control ≥130 mg/dl: 19% LDL control <100 mg/dl: 5% Moderate reduction of unnecessary emergency department and specialty care No effect on costs
Paulus RA et al. [71]	Observational study: Analysis of an innovation strategy for care model redesign	55 clinical practices 450 physicians 2.5 million people poorer, older, and sicker than national benchmarks 20,000 diabetic patients Components: Clinical leadership, Dedicated innovation team Electronic record keeping for ambulatory services Financial alignment of incentives	Patients with A1c <7.0%: 34.8% Patients with A1c >9.0%: 21% Blood pressure control <130/80 mm Hg: 43.9% Patients satisfying all nine quality indicators: 6.5% Low applicability
Reid et al. [72]	Observational study Assessment of ambulatory care experiences and chronic illness care	One prototype clinic and two control clinics 6187 adults Quality measures included A1c testing, A1c > 9.0%, retinal examination, LDL-C screening, LDL-C < 100 mg/dl, nephropathy monitoring	Medical home patients reported better care experiences on six scales at 12 and 24 months Quality composite aggregate measures for 22 indicators, including diabetes, showed significant improvements within 2 years Significant lower rates of staff burnout, emergency department visits, and hospitalizations were also observed
Nutting et al. [73]	Observational study Demonstration of the patient-centered medical home through a model with eight categories or domains: access to care and information, practice services, care management, continuity of care, practice-based teams, quality and safety, health information technology, and practice management	From a recruitment of 337 family practices, 36 small independent family practices were selected to become patient-centered medical homes Practices were randomized to two groups: "facilitated intervention" and "self-directed"	Practices adopted more components of the PCMH when using practice coaches A composite score that included A1c, blood pressure, lipoprotein levels, and retinal examination showed improvements in both groups Two years was not enough to implement the entire model and to transform work process Putting discrete model components in place is easier than modifying existing roles and work patterns

Table 19.5 (continued)

Author(s), year, and reference	Intervention	Size	Results
Calman et al. [74]	Observational study Changes in patterns of health-care use throughout a 9-year period of practice transformation including recognition of centers at level 3 PCMH practices	4595 patients with diabetes, including a subsample of 545 patients with A1c improvement	Through the transition to a PCMH, the mean numbers of encounters with outreach, diabetes education, and psychosocial services increased for all patients All patients had visits with a primary care physician Annual levels of A1c decreased steadily during the 9-year period: Patients with A1c ≤9.0% showed increases of outreach services from 59% to 95.3%, diabetes education from 0.0% to 53.3%, psychosocial care from 9.0% to 27.4% and small reductions in primary care from 99.7% to 99.4% Patients with A1c ≥9.0% showed increases of outreach services from 60.2% to 98.5%, diabetes education from 0.0% to 77.8%, psychosocial care from 11.2% to 35.3%, and primary care from 99.4% to 99.5% Patients with A1c ≥9.0% showed decreases from 10.72% to 8.34%
Pagán et al. [75]	Observational study Long-term health and cost outcomes of implementing a PCMH model for adults with poorly controlled diabetes (A1c > 9.0%) based on simulated clinical trial data obtained from the Archimedes model of disease progression and health-care use	Analysis of the cardio-metabolic risk (CMR) data set which includes the results from 19 simulated controlled trials for 100,000 individuals representative of the US population, comparing standard care to interventions targeting diabetes, obesity, and cardiovascular disease	The PCMH model has the potential to not only reduce the proportion of bilateral blindness, foot amputations, myocardial infarction, and death rate, but it is also cost-effective ($7898.00 USD per quality-adjusted life) The PCMH model has potential long-term benefits to both patients with poor diabetes control and health systems and providers
Shah et al. [76]	Retrospective study Comparison of A1c values for patients from clinics with established diabetes registries to patients from clinics without diabetes registries	1038 patients, 713 from clinics with diabetes registries and 325 from clinics without diabetes registries	Patients treated at clinics with diabetes registries did not have greater overall improvement in A1c levels than patients treated without diabetes registries Additional research is needed to determine if diabetes registries are effective tools for the PCMH
Page et al. [77]	Observational study Effectiveness of the PCMH on improving access, quality of care, and changes in compliance for patients with diabetes	10,000 patients treated by a centralized team of nurses and patient navigators who reach out to patients with scheduled appointments, complete motivational reminders and focus on patient encouragement, identification of barriers to keep appointments and communicate patient feedback to care teams	Ten of 11 measures of compliance improved from baseline to 12 month post-implementation, representing a 23.6% increase Significant improvements were observed in the number of patients receiving recommended care Centralized care coordination is effective to improve care for poor and underserved populations with chronic conditions

(continued)

Table 19.5 (continued)

Author(s), year, and reference	Intervention	Size	Results
An [78]	Observational study Associations between PCMH and process measures of diabetes care as well as adherence to oral antidiabetics (OADs)	3334 adult patients with diabetes identified in the Medical Expenditure Panel Survey Patients in the PCMH group were compared with patients without PCMH features Process measures of diabetes care included ≥2 A1c tests, ≥1 cholesterol tests, foot examination, dilated eye examination, and flu vaccination at 1-year follow-up Medication possession rate (MPR) was calculated for patients receiving OADs	11.4% of patients were classified in the PCMH group at baseline, and only 3.6% remained in the PCMH for 2 years Only 26.9% of the patients met all the diabetes care process measures, with a higher proportion in the PCMH (33.8%) versus the non-PCMH group (26.0%) There was no difference in the weighted mean MPR in the two groups The overall adherence rate was 47.7% Patients receiving PCMH had improvements in process measures of diabetes care, but not in adherence to OADs

electronic patient registries, and patient reminders) had significant effects reducing A1c levels [79]. Regarding non-glycemic outcomes, these strategies were associated with increases in aspirin use, use of antihypertensives, lower levels of blood pressure, and LDL cholesterol [79]. A systematic review by Morgan and colleagues analyzed the effect of the use of the seven principles of the PCMH and primary care on A1c levels [81]. Forty three studies were identified, 33 randomized and 10 controlled. The main results per principle are as follows:

- Principle 1 (personal physician): a minimum of two visits to the same physician over 3 years, and continuity of care result in lower A1c levels.
- Principle 2 (physician-directed medical practice): nurse care managers and pharmacist care significantly reduce A1c levels compared to controls.
- Principle 3 (whole person orientation): achieves significant reductions of A1c compared to controls.
- Principle 4 (coordinated and integrated care): (a) two studies using technology enhancements to supplement care coordination showed reductions of A1c from a baseline of 7.35%; two smaller studies had no impact on A1c; (b) two studies providing cognitive behavioral therapy did not reduce A1c; (c) integration of nurse case managers reduced A1c by 2.0% from a baseline level of 10.0%.
- Principle 5 (quality and safety): five studies assessing self-monitoring of blood glucose showed no reductions in A1c.
- Principle 6 (enhanced access): (a) increased frequency of visits (every 2 weeks) achieved fastest control of A1c; (b) each 10% increase in missed appointments increases the odds of poor A1c control.
- Principle 7 (payment): additional payments to physicians reduce A1c levels by 0.55% over 9 years.

This study concludes that applying the PCMH in diabetes management improves glycemic control, and principles 2 and 3 are the most influential [81].

Conclusions

Patient-centered care entered the health policy lexicon until 2001, when it was featured as one of the six aims to improve the quality of health care by the Institute of Medicine of the United States [55]. The IOM described patient-centered care as care that "is respectful to individual patient preferences, needs and values, and ensuring that patient values guide all clinical decisions" [55]. The central role of the PCMH emerges from the growing body of data demonstrating that systems of care based on a strong foundation of primary care outperform systems of care based on specialty practices [57]. Patient-centered care is not simply capitulating to patients' requests, nor is it "throwing information at people and leaving them on their own [56]. Recent advocacy for the patient-centered medical home has arisen worldwide interest, and countless organizations have claimed interest or proposed steps to achieve such type of care, albeit many still do not understand what is the meaning of patient-centered care or are unwilling to accept it and even less implement it. The patient-centered medical home has become a worldwide initiative to reform health care and has moved from pediatrics to involve internal medicine, geriatrics, palliative care, and collaborative disease management in diabetes, cancer, HIV infection, and patients with complex health-care needs. Achieving a 2020 vision of patient-centered care will require champions among primary care leaders, employers, insurers, and politicians [60]. Patient-centered care matters because it

is "the right thing to do," regardless of its contribution to achieve other goals, such as improved quality, patient well-being, or fair distribution of resources [82]. From the perspective of medical ethics, patient-centered care fulfills the obligation of health-care professionals to place the interests of patients above else and to respect their personal autonomy [82]. Leading institutions in the advance of quality of health care such as Virginia Mason Medical Center in Seattle and Planetree, a nonprofit organization devoted to implement a comprehensive, patient-centered model of care with associates in America, Europe, Africa, and Australia, have successfully linked this approach to quality improvement and patient safety and satisfaction [82–83]. In the context of personalized care, patients and physicians work in collaboration to use the available evidence to select between a series of diagnostic and therapeutic options [84]. Shared decision-making implies that patients' preferences and cultural values are influential on clinical decisions; it is demanding and time-consuming and requires the integration of generalists and specialists, who may have competing interests [84]. Elevating the patients' values, preferences, and needs over those of physicians or the health-care organization is absolutely necessary [85]. Patient-centered and person-focused care is important but also different; in contrast with patient-centered care, person-focused care is based on accumulated knowledge of people, to improve the recognition of health problems and needs and facilitate the appropriate care for these needs; it specifically focuses on the whole person [85]. Patient satisfaction is a different concept; it has its roots in consumer marketing, and it is a measure of the capacity of products or services to meet or exceed the anticipated expectations of the customer [84]. The evidence of the effectiveness of the satisfaction-profit chain has stimulated the commercialization of monitoring and measurement of patient satisfaction; if it is accepted as a valid outcome, patient satisfaction should be held in the same standard as any other health intervention [84]. Patient satisfaction should be embraced as a desirable goal, but it must undergo a critical analysis [84]. After more than four decades and despite huge resistance to its principles from the advocates of fragmented, high-cost medical care, the patient-centered medical home has received worldwide recognition, but at the same time, its strengths, weaknesses, opportunities, and threats have been receiving worldwide recognition [86]. Rogers described strengths and weaknesses of the PCMH [86]. Main strengths included (1) commitment to evidence-based medicine, (2) quality improvement, (3) information technology, (4) the efforts to apply them in routine medical care, and (5) understanding the process of change and how to facilitate that process; its main weaknesses lie in the infrastructure principles, including (1) inability to provide universal provision of desired communication skills and shared decision-making, (2) scarcity of health systems to document the personal relationships between physicians and team members, and (3) the absence of formal care planning processes [86]. The PCMH is an opportunity for recognition, increasing compensation and reimbursement to individual physicians that will fund the development of infrastructure; and the perceived threat to family medicine is that programs emphasizing infrastructure focus on cost savings, the emergence of PCMH imposters, and the risk to deviate the focus, a stolen vision in disregard that patient-physician relationships are at the core of the PCMH [86]. In 2013, the Institute of Medicine sponsored a workshop in which it recommended the implementation of "strategies and policies at multiple levels to advance patients, in partnership with providers, as leaders and drivers of care delivery improvement through the protected use of clinical data, informed, shared decisions and value improvement," based on the premise that "prepared, engaged patients are a fundamental precursor to high-quality care, lower costs and better health" [87]. The distinction between patient-centered care and better customer service lies in that it involves actions undertaken in collaboration with patients, not just on their behalf, and requires clinicians to appropriately share power even when sharing feels uncomfortable [88]. According to Millenson, "prepared, engaged patients are not the fundamental precursors to transform health care; patients and providers must change at the same time; a framework that enables a deeper partnership between patients and providers is more important than having 'better patients' [88]. The momentum for widespread adoption of the PCMH has been steadily built, and accumulating empirical evidence has shown that being attentive to the human experience improves quality, empowers patients, lowers costs, and improves health outcomes, and engaging patients and family members as essential partners of the health care team has the potential to reduce costs [89]. Persisting barriers to widespread adoption are based on a relentless demand for solid evidence about the efficacy of the PCHM from the traditional experts who are usually distanced and indifferent from patients and family experiences [89]. The future of the PCMH is uncertain and involves several scenarios: from an increase in patient-centeredness as a function of current trends such as the Joint Principles of the Patient-Centered Medical Home to the extreme where health systems leave behind the PCHM as a result of financial pressures in the pursuit of lowering costs in acceptance of the negative consequences on quality of health care [82]. To become a reality, the PCMH requires adoption of new roles for patients and providers, to achieve balanced levels of collaboration, positive activation, health literacy, and empowerment of patients and their families [90]. Putting patients – our customers – at the center (in our practice, in our use of language, and in our thoughts), the patient-centered medical home accomplishes one of the most legitimate aspects of medical practice and the most important outcomes for patients and their families: from "clinically relevant" to "patient or humanly important [91]." As a moving account of

a dying man by Archie Cochrane, records an act of brotherhood to another person, not medical, just human [92]. Probably above science, this is what patients and their families expect and appreciate the most.

Multiple-Choice Questions

1. Historically, the professional ideal of the physician-patient relationship is:
   (a) That patients have the most important role in making decisions
   (b) That patients have a minimal role in making decisions
   (c) That patients and physicians have equal roles in making decisions
   (d) That patients have very important roles in making decisions
   (e) That patient's relatives are most important in making decisions
2. The enhanced capacity to address patients' needs:
   (a) Is a waste of time
   (b) Increases the economic burden of health systems
   (c) Distracts physicians from their priorities
   (d) Has no effects on the outcomes
   (e) Increases the efficiency and is also profitable
3. Patient discrimination:
   (a) Is unavoidable and necessary in some cases
   (b) Reinforces the patient's compromise to adhere to therapy
   (c) Increases the use of diagnostic tests and services
   (d) Does not affect satisfaction with care
   (e) Reduces the use of A1c measurements
4. The attributes of primary care include all of the following, except:
   (a) Medical expertise
   (b) Accessibility
   (c) Comprehensiveness
   (d) Longitudinal care
   (e) Coordination
5. A medical home was originally defined:
   (a) As the medical setting were patients are more comfortable
   (b) As the repository of the medical record of children with chronic diseases
   (c) As the patient's home with adaptations according to individual needs
   (d) As a "patient-friendly" medical environment
   (e) As the place within clinical settings were physicians organize meetings
6. By comparison to disease management and specialized care, primary care:
   (a) Is less effective than specialized care
   (b) Is less professional
   (c) Is not supported by academic centers
   (d) Is more effective to achieve better health outcomes
   (e) Is exclusively empiric, not evidence-based
7. Clinical excellence involves all of the following, except:
   (a) Expertise in the use of the most recent medications
   (b) Promoting successful physician-patient relationships
   (c) Ability to find and apply information to solve clinical problems
   (d) Skillful negotiation within the health-care system
   (e) Diagnostic acumen
8. In patients with diabetes, improvements in high-quality primary care result in significant reductions of:
   (a) A1c
   (b) Systolic and diastolic blood pressure
   (c) LDL cholesterol and triglycerides
   (d) None of the above
   (e) All of the above
9. The use of the principles of the patient-centered medical home:
   (a) Increases the costs of medical care
   (b) Reduces A1c levels
   (c) Increases physician burnout at unmanageable levels
   (d) Achieves nonsignificant reductions in A1c levels
   (e) Increases the use of diagnostic tests
10. Strengths of the patient-centered medical home include:
    (a) Commitment to evidence-based medicine
    (b) Quality improvement
    (c) Information technology
    (d) All of the above
    (e) None of the above

Correct Answers

1. (b) That patients have a minimal role in making decisions
2. (e) Increases the efficiency and is also profitable
3. (c) Increases the use of diagnostic tests and services
4. (a) Medical expertise
5. (b) As the repository of the medical record of children with chronic diseases
6. (d) Is more effective to achieve better health outcomes
7. (a) Expertise in the use of the most recent medications
8. (e) All of the above
9. (b) Reduces A1c levels
10. (d) All of the above

Outpatient Diabetes Management and the Chronic Care Model

20

Joel Rodriguez-Saldana

Introduction: The Ongoing Story of Diabetes Clinics

In the 1960s, diabetes was considered a common disease, even when being much less common than today; the average practitioner treated 15 or 16 known patients, and hospital clinics admitted approximately 1000 patients each year [1, 2]. The first diabetes clinics were established in North America and Europe in the years following the discovery of insulin with the main objective of teaching patients the technique and principles of its use; only in Britain, 500 had been established in 1973, even in isolated geographical entities [1, 3]. Hospital surveys showed that diabetes was controlled by diet and insulin, early diabetic complications and patient education were overlooked by physicians, and diabetic management by nursing, administrative, and dietetic staff was considered ineffective [4]. Successful clinics prevailing until today were the ones that had the vision, ability, and resources to institute comprehensive diabetic services which coordinated the activities of medical, nursing, and dietetic staffs to deliver multidisciplinary outpatient care, "special services" (dietetic, foot, eye, pregnancy, children, and adolescents), and diabetes education programs as essential components of their services [4–7]. These programs showed marked improvements in all areas of diabetes care, including diagnosis, assessment, hypoglycemia prevention, diet, and referrals [4]. In the majority of hospitals, patients with diabetes admitted to hospitals were seen mostly by specialists, but the sharp rise in the prevalence of type 2 diabetes made this unpractical [8]. Hospital diabetes programs including telephone support for patients, screening by nurses, and a mixture of outpatient and inpatient services showed reductions in emergency room visits, decreases in the incidence of acute complications (ketoacidosis, hypoglycemia) and amputations, lower rates of broken appointments and complaints, and higher levels of patient and professional satisfaction [9, 10]. Most of the other hospitals told a different story: once referred, patients were supposed to be treated for life, doomed to take time out of work and travel, and wait to be seen by a different physician at almost every visit at the diabetes clinic; this approach of fleeting consultations was – and still is – unrewarding from every perspective [1]. Even when the estimated incidence of diabetes was 1.2–1.3% in England, diabetic clinics had such a large load that they became unable to devote sufficient time to difficult cases; medical manpower to deal with the growing workload was (and currently more than ever) met with increasing use of junior staff, resulting in large dropout rates, lack of adherence, high levels of patient dissatisfaction, and abysmal levels of quality of care [1, 2]. Taking into account that the average diabetic required seven to ten clinical visits every year, hospital demands meant establishing huge diabetic clinics with dissatisfaction and depersonalization for patients and staff [1]. In Germany and other countries, hospital diabetes management was paternalistic; patients were admitted to stabilize blood glucose control, and the lack of self-care support had many consequences: glycosuria was preferred to prevent hypoglycemia, the routine therapy was one or two injections of medium-acting insulin per day, self-monitoring and changes in insulin dosage were not allowed, and education was conceived as "obedience training" to follow rigid dietary prescriptions consisting of six to seven meals with fixed amounts of carbohydrates, proteins and fats, and prohibition of sugar [11]. This approach was never assessed, but acute and late complications were evident and frequent [11]. Hospital wards overflowed with patients with diabetes routinely assigned to hospital beds in hallways, timely access to appropriate medical advice was poor, hospital resources were largely devoted to episodic care for acutely and severely ill patients, there was low supervision by specialists, and rates of acute complications were very high [8, 9]. Inpatient hospital care represented >80% of the direct costs of diabetes and was related to higher

risks of cardiovascular complications and renal disease [12]. On the other hand, understaffing and low resources to outpatient facilities were associated with an excess in hospital admissions and direct costs [13]. With the increasing rates of diabetes in recent decades, the amount of patients admitted to hospitals continues to rise [14]. They are more likely to die in the hospital, to occupy more bed days, and to incur in higher costs than people without diabetes [14]. Health systems, unable or unwilling to reinforce multidisciplinary outpatient management, can only expect to see increases in the financial and health burden of preventable hospitalizations [15]. The title of an article by Simmons and Wenzel is accurate: in many cases, diabetes inpatients are a case of lose, lose, lose [14]. The aim of diabetes care should be enabling patients to lead normal lives, with good metabolic control and free from complications. For many patients across the world, such an ideal is still far away [13].

Lessons Learned and Still Unlearned

Failure of clinics established at hospitals, which rapidly became overwhelmed, increased the role of primary healthcare professionals in the shared care of diabetes management. General physicians became increasingly aware of the importance of tailoring management to patient's lifestyles, their expectation to be actively involved in their treatment, and their unwillingness to continue accepting medical advice without questioning [8]. General practitioners in the United Kingdom were among the first to see that they could manage many aspects of diabetes in their own practice. Albeit the pace to provide ambulatory diabetes care was initially slow, many innovative schemes were described and initiated [16]. Combination of need and opportunity prompted the creation of "small clinics of general practice" where groups of general physicians were organized to assist groups of 80 to 100 patients to stop the flow of patient to hospital-based clinics devoted to difficult cases [2, 18, 19]. Pioneering reports from Wilkes, Thorn, Russell, Hill, Singh, and colleagues showed that:

1. Diabetes could be looked after by the family doctor [1].
2. General practice seemed the proper place to look after many diabetics, allowing general practitioners to become increasingly competent in diabetes care [2].
3. Coordinating and sharing "the diabetic workload" with hospital clinics raised community awareness about diabetes, allowing family physicians to deal with problems for which they were trained [17].
4. "Diabetes care delivered by organized general physicians achieved similar levels of metabolic control to the ones reached in hospital clinics" [18].

To summarize, increases in the number of patients with type 2 diabetes, longer life expectancy, and sophistication of treatment produced overcrowding and inadequacies of delivery in hospital-based diabetes care [20, 21]. Increasingly low rates of access to hospital or university clinics and unsuccessful indices of performance occurred, even in countries with large and comparatively smaller populations of patients [20, 21]. Home and Walford reflected that "though some activities required the expertise and resources only available in hospitals, most of them did not require them, as long as general physicians had access to blood glucose monitoring, dietetic, chiropody and nurse educational services [20]." The need to reappraise the role of diabetes clinics was recognized by Thorn and Russell since 1973, but it was also essential to increase the access to effective diabetes management, because only a small proportion of patients attended hospital and outpatient clinics [20, 21]. Since 1986, it was acknowledged that the huge amount of people with diabetes in the community made it unrealistic to treat them in specialist outpatient clinics [21].

Transforming Diabetes Care

Suboptimal diabetes care was associated with high hospital admission rates and poor diagnostic differentiation between patients with mild and severe metabolic problems. Planning of diabetes services needed to be broader beyond those available in most centers, but surveys at facilities demonstrated (and continue to show) large discrepancies with recommended national and international guidelines [22]. A survey carried out by the Medical Advisory Committee (MAC) in Britain showed a scarcity of diabetes clinics or even examination rooms, resulting in lack of referrals; a variety of deficiencies in access to professional services, including obstetricians, ophthalmologists, dietitians, chiropodists, and nurses; a scarcity in the availability of resources to measure glucose and A1c; and absent or inadequate facilities to deliver diabetes education [23]. Nineteen recommendations were endorsed by the MAC; a follow-up report 10 years later showed significant improvements in all the previously described deficiencies, albeit there was still room for improvement [24]. Even when resources were insufficient, reorganization and integration of services produced great improvements in healthcare standards. From its inception in the 1970s, the concept of diabetes centers evolved to a number of "different breeds in the 1990s" [25]. Dunn and colleagues identified four priority areas to be considered for implementation of the Diabetes Control and Complications Trial (DCCT) in Australia: (1) allocation and effective use of resources, (2) standards of care and quality assurance, (3) training and continuing education, and (4) research and evaluation [25].

Effectiveness of Diabetes Outpatient Management: The Evidence

Diabetes centers evolved from traditional hospitalization of new patients; hospital admission to start insulin was occasionally used, but ambulatory care became the norm. The main objective of diabetes management became preventing or delaying the physical and social consequences of the disorder [19]. Early reports showed that transforming traditional to modern management methods was feasible, acceptable, and effective and produced significant improvements in A1c levels without associated increases in the frequency of hypoglycemia [24]. Recent emphasis on issues of cost-effectiveness came to realize that diabetes is a disorder that rarely warrants hospitalization; awareness to these facts reinforced the concept of diabetes ambulatory care [25]. Nevertheless and despite demonstrations of cost-effectiveness of ambulatory management, funding of ambulatory services remained (and continues to be) in huge disadvantage with hospital care [25]. The 1980s witnessed the emergence of multiple initiatives devoted to shift the focus of diabetes management from hospitals to outpatient clinics in Europe, North America, and Australia. Table 20.1 shows examples of outpatient diabetes programs manually collected or identified in a PubMed search from 1980 thru 2018.

Table 20.1 Experiences of outpatient diabetes management across the world

Year, country, and reference	Objectives	Type of study, patients, health professionals, and intervention	Results
1988, United States [26]	Comparative effectiveness of community diabetes care and education on clinical outcomes	Prospective, randomized study 261 patients treated by 61 primary care physicians from 1980 until 1985 from four large and four small communities randomly selected Intervention: four group sessions delivered by paramedical personnel Five-year follow-up	Patients receiving the intervention showed significant changes in healthcare practices, including increases in the use of multiple injections of insulin and self-monitoring of blood glucose Decrease in hospitalizations related to diabetes, probably representing changes in healthcare practices rather than changes in health status A1c levels unchanged
1988, Germany [27]	Efficacy of a structured treatment and education program on the selection of pharmacological therapy, A1c levels, triglycerides, and body weight	Prospective randomized study 114 patients with type 2 diabetes, 65 in the intervention group and 49 in the control group from five general practices Intervention: preparatory course for physicians and assistants; four group monthly education sessions delivered by paramedical personnel	A1c levels remained unchanged in the intervention group; significant decreases in triglycerides and weight loss The percentage of patients receiving sulfonylureas decreased from 68% to 38%
1993, Germany [28]	Feasibility and efficacy of a structured treatment and teaching program in routine primary healthcare	Observational study of a random sample of 17 physicians and their office staffs Intervention: remunerations to physicians and office staff upon completion of a postgraduate training course 179 patients with type 2 diabetes Four 90–120-minute sessions for groups of 4–10 patients, partly based on the Grady Memorial diabetes medical and education program [10] and previously assessed in a controlled trial [27] Program delivered by the office staff	Acceptance by physicians Significant decreases in A1c levels from 8.11% to 7.47%, body weight (mean 2.8 kg), use, and proportion of patients treated with oral antidiabetics
1994, United States [29]	Follow-up of a structured treatment and education program on the selection of pharmacological therapy, A1c levels, triglycerides, and body weight	Prospective, randomized study 440 patients with type 2 diabetes, 61 in the intervention group and 355 in the control group Ten-year follow-up 1981–1991	Positive changes in diabetes care and education Nonsignificant increases in A1c and total cholesterol, significant increases in HDL cholesterol, significant decreases in hospital admissions, and small increases in the proportion of patients receiving formal diabetes education The majority of patients with type 2 diabetes managed on diet alone had never seen a dietitian Nonsignificant changes in ophthalmologic examinations Less patients managed with insulin

(continued)

Table 20.1 (continued)

Year, country, and reference	Objectives	Type of study, patients, health professionals, and intervention	Results
1997, United States [30]	Effectiveness and safety of intensive insulin therapy (IIT) on outpatient, endocrine-based, multidisciplinary practice in patients with type 1 and type 2 diabetes	Longitudinal cohort study, 14-year duration 780 patients, 209 receiving long-term comprehensive treatment including cardiac screening with exercise treadmill tests, noninvasive thallium scan, and cardiology referrals if necessary 571 declined continuing care	Patients with prolonged exposure to comprehensive therapy had significant reductions in overall and cardiac mortality and lower incidence of renal failure Lower comorbidity scores associated with higher survival Two thirds of the patients declined receiving multidisciplinary, intensive care
1998, United Kingdom [31]	Changes in the proportion of patients with diabetes receiving treatment in primary and secondary care over 5 years	Longitudinal study, 1990–1995 Seven general practices, five of them with organized diabetes programs A diabetes review was defined as a contact with a general physician or nurse including examination for at least three potential complications or risk factors	The proportion of patients treated in general practice doubled from 17% in 1990 to 35% in 1995 Patients treated in secondary practice fell from 35% in 1990 to 30% in 1995 Patients treated both in general and secondary practice fell from 6% to 2% Newly diagnosed and treated patients in general practice also increased Albeit theoretically greater activity in primary care would increase the pressure on hospital services, this study showed that this had not occurred
1998, United Kingdom [32]	Effect of training about a patient-centered intervention for general practitioners and nurses on outcomes	Randomized controlled trial 29 general practices receiving training about patient-centered care 252 type 2 diabetic patients Duration: 2 years	High initial levels of professional adoption by professionals Persistence after 2 years: 19% No significant biochemical or functional improvements
1999, Poland [33]	Effect of a disease management program on A1c and fasting blood glucose, the appropriateness of treatment modalities, and timing of therapeutic choices	Pilot prospective study in outpatient clinics, 18-month duration 88 randomly selected patients with type 1 diabetes 132 randomly selected patients with type 2 diabetes 177 pregnant women with type 1 diabetes, 81 receiving the structured program, 74 non-recipients 155 infants from these 2 groups	Patients with type 1 diabetes had significant decreases in A1c, fasting, and postprandial blood glucose, without severe hypoglycemia Body mass changes were nonsignificant Patients with type 2 diabetes had significant decreases in A1c, fasting, and postprandial blood glucose, without severe hypoglycemia Body mass decrease was significant Pregnant women not receiving the structured program had higher rates of hyperglycemia, preeclampsia, ketoacidosis, polyhydramnios, and cesarean sections Higher APGAR scores in infants from recipients of the structured program
2001, United States [34]	Effectiveness of a comprehensive diabetes management program including risk stratification and social marketing on clinical outcomes and patient satisfaction	Prospective trial, 12 months Two outpatient primary care clinics from a managed care organization 370 patients in the intervention group, 193 with available information at 12 months 623 patients in the control group	Significant improvements in glycemic control: Patients at low risk (A1c <7.0%) increased by 51.1% Patients at moderate risk (A1c 7.0–8.0%) increased by 2.5% Patients at high risk (A1c ≥8.0%) decreased by 58.3% and 97.4% had changes in therapy Patients with blood pressure <140/90 mm Hg increased from 38.9% at baseline to 66.8%; 63.0% of patients with blood readings >130/85 mmHg at baseline had changes in medication Patients receiving lipid profile tests increased from 66% at baseline to 100% Patients with LDL >130 mg/dl decreased from 25.4% at baseline to 20.2% 76.7% of patients at the highest risk of nephropathy had a change in medications Patients receiving dilated eye examinations increased from 53.9% to 80.3% Foot examinations increased from 0% to 100.0% 100% of patients and providers were satisfied with the program Patients in the control group remained essentially unchanged

Table 20.1 (continued)

Year, country, and reference	Objectives	Type of study, patients, health professionals, and intervention	Results
2001, Denmark [35]	Effectiveness of a multifaceted intervention for general practitioners on 6-year mortality, morbidity, and risk factors of patients with type 2 diabetes	Open controlled trial randomization of practices to structured personal care or routine care 311 Danish practices, 474 general practitioners 243 in intervention group 231 in comparison group 459 patients randomized to structured care 415 patients randomized to routine care Regular follow-up and individualized goal setting supported by prompting of doctors, clinical guidelines, feedback, and continuing medical education	Equal rates of nonfatal outcomes and mortality in both groups Findings in the intervention group: significantly lower fasting plasma glucose, A1c levels, systolic blood pressure, and cholesterol levels More frequent use of metformin, doctors arranged more follow-up visits, referred fewer patients to hospital clinics, and set more optimistic goals Individualized goals, education, and surveillance in primary care for at least 6 years may bring risk factors of patients with type 2 diabetes to a level that has been shown to reduce diabetic complications without weight gain
2001, Netherlands [36]	Comparative effectiveness of a disease management model to a shared care model for diabetes	Observational non-randomized trial In the traditional care model, patients were seen by endocrinologists at outpatient clinics In the disease management model, patients were seen by nurse specialists delivering direct, organized, and coordinated care with specialists and other providers in general practice 22 general practitioners accepted the shared care model and 29 continued using the traditional model 74 patients agreed to participate in the shared care model and 47 patients continued using the traditional model	No differences were found between groups in quality of life, knowledge of diabetes, patient satisfaction, or consultation with caregivers Glycemic control improved in patients receiving shared care and deteriorated in patients receiving traditional care Factors influencing implementation of the shared care model: project management, commitment, power, and structure
2002, United States [37]	Effectiveness of community-based diabetes care models and use of a diabetes electronic management system (DEMS)	Observational study Three primary care practice sites Implementation of planned care and DEMS with 16 primary care providers	Planned care showed improvements in A1c, cholesterol, microalbuminuria, and tobacco advice DEMS was associated with improvements in all indicators including microalbuminuria, retinal examination, foot examinations, and self-management support The way in which healthcare services are organized and delivered can improve documentation of clinical practice, adherence to performance measures, and metabolic outcomes
2003, United States [38]	Effectiveness of diabetes care directed by nurses and supervised by a diabetologist to meet the American Diabetes Association process and outcome measures versus usual care	Randomized observational trial 504 patients from 2 county clinics: 252 receiving nurse-directed diabetes care 252 patients receiving usual care as controls	Patients under nurse-directed diabetes care received almost all process measures significantly more frequently than control patients A1c levels fell 3.5% by comparison to a 1.5% decrease in patients under usual care After 1 year under nurse-directed care, A1c levels decreased to 7.1%, and the median value fell from 8.3% to 6.6%
2003, United Kingdom [39]	Effectiveness of specialist diabetes clinics receiving patients from primary and secondary care	Observational prospective study, 2-year duration 19 specialist clinics 2415 patients referred to 19 specialist diabetes clinics led by GPs with a special interest in diabetes, to alleviate increasing waiting times for secondary care Training based on 2-day workshops for GPs, follow-up workshops, and case reviews Multidisciplinary support from specialist nurses, podiatrists, dietitians, and retinal screening cameras	Significant increases in overall patient attendance Significant reductions in hospital attendance Main benefits: geographical accessibility, availability in community setting, short waiting times at most clinics, and continuity of staff Reservations included lack of strategic planning in the location of clinics, long waiting times in some of them, and poor communication for referrals Advantages: convenience to patients, acceptability, and increased capacity of physicians

(continued)

Table 20.1 (continued)

Year, country, and reference	Objectives	Type of study, patients, health professionals, and intervention	Results
2004, United States [40]	Effectiveness of community-based, nurse case management and peer education to improve diabetes care, patient knowledge, and satisfaction and reduce health adverse beliefs in undeserved patients	Prospective study, 1-year duration 153 patients from 6 community clinics 76 non-randomized patients from the same clinics with A1c values ≥9.0% as controls	Patients in the intervention group had significant improvements in A1c, total cholesterol, LDL cholesterol, and diastolic blood pressure Nonsignificant changes among patients in the control group
2004, France [41]	Impact of a local adaptation of a structured program on primary care to encourage intensive treatment of diabetes as routine practice	Prospective, randomized, controlled trial in a suburban and semirural area, 12-month Follow-up allocation of all the general physicians from a suburban and semirural area, 35 in the intervention group, 32 in the control group 192 patients in the intervention group 148 patients in the control group Three-day training and follow-up of physicians in the intervention group	Patients in the intervention group were managed more adequately according to guidelines and referrals Significant decreases in A1c in the intervention group (0.86%) No significant differences in other clinical outcomes, incremental costs from the intervention No significant changes in quality of life
2008, South Africa [42]	Effectiveness of a nurse-led protocol and education-based system on diabetes management in a rural setting	Prospective non-comparative intervention 326 patients, 96% with type 2 diabetes Two rural nurses received 12-month training from a diabetes specialist One weekly hospital diabetes clinic and 14 monthly diabetes clinics established in peripheral clinics Cornerstones of the system: patient education, drug dose titration, and clinical outcomes	High levels of acceptance by patients and staff 980 patients enrolled within 9 months Significant decreases of A1c from 11.1 ± 4.2% to 8.7 ± 2.6% at 6 months Patients with baseline A1c >10.0% showed a mean 5.8% fall Diabetes education was associated with significant A1c improvements Rates of hypoglycemia did not increase
2010, United States [43]	Effectiveness of systems-based care in an undeserved population to reduce disparity in care for cultural, ethnic, commercial, and socioeconomic minorities	Implementation of disease registry and management system in four community health centers from a suburban practice network	Community health center patients meeting guidelines showed significant improvements in clinical outcomes except percentage of patients with A1c >9.0% Despite improvements, statistically significant discrepancies persisted between community health clinics and suburban practices in percentage of patients with A1c <7.0%, LDL <100, retinopathy, and microalbuminuria screening Community health centers lagged in all comparisons
2010, United States [44]	Comparative effectiveness of nurse-directed diabetes management between a non-integrated model in which patients were removed from primary care clinics and followed by supervision from an endocrinologist versus an integrated model in which patients were seen by nurses under the supervision of primary care physicians	Observational study, 9–12 months 387 patients randomly assigned to the non-integrated model 178 patients were referred to the integrated model	25% of the patients in the non-integrated model were using insulin (mostly bedtime), and 75% of the patients in the integrated model were using intensified insulin regimes A1c decreased 1.9% in the non-integrated model and 3.9% in the integrated model In the integrated model: 90% of patients met blood pressure goals, 96% met LDL goals, and 47% met the three goals of treatment (A1c, blood pressure, LDL)

Table 20.1 (continued)

Year, country, and reference	Objectives	Type of study, patients, health professionals, and intervention	Results
2010, Mexico [45]	Effectiveness of structured diabetes management on the quality of primary diabetes care	Seven-year statewide diabetes Training, feedback, and reminders to general physicians, nurses, and health professionals to implement 43 outpatient multidisciplinary diabetes clinics at urban and rural health centers Organizational arrangements to reduce waiting times, avoid rotation of staff, and increase time for baseline and follow-up visits Statewide diabetes registry 4393 patients	After five visits, significant increases in the percentage of recorded process indicators were documented in the diabetes registry, including body mass index, blood pressure, A1c, total cholesterol, and foot examination Outcome measures showed significant decreases in A1c and fasting blood glucose Nonsignificant changes in systolic/diastolic blood pressure and lipoprotein levels
2011, Netherlands [46]	Effectiveness of structured diabetes care from the perspective of patients and healthcare professionals in routine practice	Quasi-experimental study, 4-year duration Comparison of structured care (SC) and usual care (UC) SC including organizational components: multidisciplinary cooperation, clear task division, and cooperation between general practitioners, diabetes specialist nurse, and dietitians UC based on clinical guidelines and included three general checks and one extensive check per year, performed by GPs, nurses, or assistants Questionnaires were sent to healthcare professionals and patients in the SC and the UC group	No differences between SC and UC in yearly and three monthly checks More patients in the SC group received diabetes education by diabetes specialist nurses All practices in the SC used the diabetes registry GPs in the SC were significantly more satisfied than GPs in the UC group More patients in the SC group reported contact with GPs, nurses, assistant, and dietitians, received adequate education about diet and foot care, and knew their blood glucose level One year after SC finished, the effects of structured care were still visible
2013, Denmark [47]	Follow-up of study referenced as [34]	Observational study 1381 patients aged ≥40 years and newly diagnosed with type 2 diabetes from national registries 19-year follow-up	Group differences in risk factors from the 6-year follow-up had leveled out Lower rates of microalbuminuria and triglycerides in the intervention group Similar rates in all-cause mortality between the intervention and control group Prompting, feedback, clinical guidelines, continuing medical education, individualization of goal setting, and drug treatment may safely be applied to treat patients with newly diagnosed type 2 diabetes to lower the risk of complications
2013, United Kingdom [48]	Effectiveness of integrated, structured primary diabetes care in partnership with specialists. A challenging vision for two reasons: It challenged the secondary care status quo It would mean a shift of resources within the health economy	Consistent messages tailored and delivered to primary and secondary care providers to persuade them about the need and benefits of change Two phases of implementation: establishment of community diabetes teams changing the secondary care model and establishment of six "super-clinics": pregnancy, renal dialysis, insulin pumps, acute type 1 diabetes, type 1 education, adolescents	Significant improvements of care; 85% of patients discharged from secondary care; estimated savings: £59,940.00 per year 108 patients receiving appropriate treatment in the "super-six" clinic 2996 patients received DESMOND education training 287 clinicians received training Relationships with clinicians and other staff consistently positive Patient feedback overwhelmingly positive

(continued)

Table 20.1 (continued)

Year, country, and reference	Objectives	Type of study, patients, health professionals, and intervention	Results
2013, Australia [49]	Effectiveness on patient outcomes of an integrated primary/specialist model for community care for complex Type 2 diabetes management compared with outcomes for usual care at a tertiary hospital for diabetes outpatients	Prospective, open controlled trial in a primary and tertiary care setting 330 patients with type 2 diabetes ≥18 years old allocated to an intervention (community-based care by general practitioner with advanced skills and endocrinologist partnership) or to usual care in the hospital diabetes outpatient department	Patients in the intervention group showed a 0.8% decrease in A1c, increased from 21% to 42% achieving the A1c target (7.0%), experienced significant improvements in blood pressure and total cholesterol, and achieved significantly higher combined A1c, blood pressure, and LDL cholesterol targets by comparison to the usual care group Community-based, integrated models of complex diabetes care delivered by general practitioners with advanced skills produce clinical and process benefits compared with tertiary diabetes outpatient clinics
2015, United States [50]	Comparative effectiveness of in-clinic health coaching by medical assistants on diabetes and cardiovascular risk factor control versus usual care	Randomized controlled trial 441 patients from 2 primary care clinics Health coaching delivered by three medical assistants who received 40 hours of training and were embedded as part of the care team at the two clinics Patients randomized to usual care had access to any resources available at the clinics except for health coaching Primary outcome: a composite measure of A1c, systolic blood pressure, and LDL cholesterol Secondary outcome: meeting all three goals	Participants in the coaching arm were more likely to achieve goals for one or more uncontrolled conditions at baseline and more likely to achieve control of all conditions Almost twice of the people in the health coaching group achieved the A1c goal and were more likely to achieve LDL cholesterol goals Nonsignificant changes in systolic blood pressure Health coaching by medical assistants has the potential to alleviate nationwide deficiencies in diabetes control in an environment of deepening primary care clinician shortage
2015, Australia [51]	Effectiveness of an integrated model of care for patients with complex type 2 diabetes on potentially preventable hospitalizations	Prospective controlled trial, 36 months duration Multidisciplinary, community-based, integrated primary-secondary diabetes care compared to usual care at a hospital diabetes outpatient clinic 327 patients, 206 of them hospitalized	Compared with the usual care group, patients in the integrated model of care group were nearly half as likely to be hospitalized for a potentially preventable diabetes-related diagnosis after 24 months, even adjusting for age, sex, education, and A1c concentration Integrated diabetes care models reduce hospitalizations
2016, United States [52]	Association between patient-centered care (PCC), diabetes self-care, glycemic control, and quality of life (QOL)	Two adult primary care clinics 615 patients	PCC was significantly associated with QOL, medication adherence, general diet, specific diet, blood sugar testing, and foot care, but was not significantly associated with glycemic control Focusing care around the patient may need to expand throughout the healthcare system before changes in outcomes occur
2017, United Kingdom [53]	Comparative effectiveness of enhanced diabetes primary care with more expensive integrated specialist-community diabetes services	Eight primary care practices and eight matching neighboring practices Enhanced practices had primary care physicians and nurses with an interest in diabetes who attended monthly diabetes education meetings and provided care plans and audits Control practices provided integrated primary-specialist care services	No significant differences were noted between enhanced and primary-specialist services Enhanced primary diabetes care has similar outcomes to that provided by more expensive primary-specialist care
2017, Brazil [54]	Effectiveness of a structured intervention to improve type 2 diabetes management in primary care in a defined region	Comparative observational study 230,448 patients, 124,779 in the intervention group and 105,669 in the control group 61 family strategy team professionals (FHS) from two cities 29 in the intervention group and 32 in the control group One awareness-raising workshop with heads of municipal health departments of the selected cities, with extensive participation of FHS health professionals Constitution of local management teams, reorganization, and local action plans to improve diabetes care Delivery of three training sessions for FHS professionals	Significant differences in staffing the intervention group, including deficiencies in physicians and nurses By comparison with the intervention group, the control group showed better outcomes including: multidisciplinary management, adherence to treatment referrals, diagnostic tests, and educational activities This complex intervention had no detectable impact despite an enormous investment in money and manpower

Outpatient Management of Type 1 Diabetes

Traditional models for type 1 diabetes are organized around a specialist with a multidisciplinary team to deal with education, nutrition, and psychosocial adjustment [55]. A limited number of patients with type 1 diabetes are treated by primary physicians, but even in developed countries, availability and geographical distribution of specialists are real obstacles to refer all these patients to diabetologists [56–58]. Even in the United States, it was estimated that in 2014 the shortage of adult and pediatric endocrinologists was of 1500 and 100, respectively, and that the gap for adult endocrinologists would expand to 2700 [58]. Models of primary care for type 1 diabetes are scarce, but innovative strategies have been conceived and implemented. Based on experiences collected as one of the participating centers in the DCCT, in 1988 the International Diabetes Center organized a team comprising three family physicians, four endocrinologists, a clinical epidemiologist, three nurse specialists, and a dietitian and developed Staged Diabetes Management (SDM), a systematic approach to support clinical decision-making including clinical pathways or DecisionPaths to start, adjust, maintain, or change therapies [55, 59]. Initial experiences with SDM in the United States demonstrated its feasibility and its capacity to standardize clinical practice, reduce clinical inertia, and establish criteria for referral [59]. International dissemination of Staged Diabetes Management has confirmed its feasibility and effectiveness [33, 41, 45].

Challenges of Comorbidity and Multimorbidity in Diabetes Management

Treating chronic diseases like diabetes is often complicated by the coexistence of multiple medical conditions and of social and psychological deterrents; currently, the most common chronic condition among adults is multimorbidity [60, 61], in the words of Kate Lorig, "the Disease of the 21st Century [62]." The contribution of multi-morbidity to the global burden of disease is already huge, but projections are of great concern: it is estimated that during the last 15 years of life, one half of the newborns in industrialized countries will suffer multi-morbidity and its consequences, including poor quality of life, psychological distress, worsening functional capacity, longer hospital stays, higher costs of care, and higher mortality [63–67]. MM also affects processes of care resulting in complex self-care needs; multiple organizational problems; polypharmacy; increased use of emergency facilities; difficulties to apply clinical guidelines; fragmented, costly, and ineffective care; and higher mortality rates [66–71]. Multi-morbidity is important for diabetes management because besides its long-time recognized association with metabolic and cardiovascular risk factors, the frequency of nondiabetes-related (or non-apparently related) comorbidities is starting to be recognized. Negative outcomes associated with multi-morbidity partly result from the fact that healthcare delivery is organized and designed for patients with single diseases [63]. Fortin and colleagues state that "clinical practice is still based on a single disease paradigm which is not appropriate for patients with complex and overlapping health problems [66]". To make matters worse, most clinical trials exclude patients with comorbidity, therefore limiting generalization of research results [71]. Diabetes management clearly applies to these statements: until recently, clinical guidelines failed to recognize the importance of comorbidity, and it has been demonstrated that this is a limiting factor to their implementation [63]. Research about the epidemiology of multi-morbidity, its consequences, and its effects on the process of care is still very limited [71–75].

Definitions and Magnitude

Multi-morbidity (MM) was originally defined by Feinstein in 1970 as "the coexistence of two or more diseases, pathological conditions or clinical entities in the same patient" [76], while comorbidity (CM) is defined as the presence of one index disease and at least one other chronic condition in the same person [77]. MM and CM have become some of the greatest challenges and an additional pressure on healthcare systems. They represent an additional burden on the acute care model which impedes in many cases, even recognizing the main complaint in a hurried visit. Increased effectiveness of healthcare interventions have delayed death by managing (not curing) diseases but have also led to a marked increase in the coexistence of separate diseases in individuals [78]. In less than three decades, the frequency of chronic diseases and associated patterns of comorbidity and multi-morbidity have escalated for several reasons: (1) lowered diagnostic thresholds, (2) new diagnoses, and (3) true increases of some diseases, such as diabetes [78, 79]. Table 20.2 confirms the steady increase in the worldwide prevalence of comorbidity (two or more diseases) in every age group, associated disease patterns, and outcomes.

Table 20.2 Epidemiology of multi-morbidity and comorbidity

Authors, year, and reference	Country	Number	Age group	Prevalence of multi-morbidity (MM) by age groups and additional results
Schellevis et al. [80]	Netherlands	23,534	65 years and older	15% Highest rates of comorbidity for osteoarthritis and diabetes
van den Akker et al. [81]	Netherlands	60,857	Five age groups 0–19 20–39 40–59 60–79 ≥80 years	General prevalence of MM: 29.7%; by age group, males (M) and females (F) 0–19 years: 10.7% and 9.2% 20–39 years: 16% (M) and 18.8% (F) 40–59 years: 33.6% (M) and 35.9 (F) 60–79 years: 60.9% (M) and 64.9% (F) ≥80 years: 74.2% (M) and 79.9% (F) The number of prevalent diseases increased from less than one below 30 years to more than three at 80 years and older
Menotti et al. [82]	Finland (F), Italy (I), Netherlands (N)	F: 716 I: 682 N: 887	65–84 years	10–15%
Westert et al. [83]	Netherlands	13,806	16 years and older	Number of chronic conditions: 1: 80.7% ≥2: 19.3% ≥3: 3.3% Diabetes prevalence: 4.4% Most prevalent comorbid patterns: Lung disease + musculoskeletal disease + neurological disease In addition to being the most common condition, musculoskeletal disease was the most likely to occur in all disease clusters
Woolf et al. [84]	USA	1,217,103	65 years and older	Prevalence of MM: 65% Inpatient admissions for ambulatory care-sensitive conditions and hospitalizations for preventable complications increased with the number of chronic conditions
Beasley et al. [85]	USA	572	Adults	Prevalence of MM: 26% An average of 3.2 problems are managed at each clinical encounter
Fortin et al. [86]	Canada	980	Three age groups 18–44 45–64 65 years and older	Prevalence of MM by age group 18–44 years: 69.3% 45–64 years: 92.8% 65 and older: 98.7% Cumulative index rating scale increases significantly with age
Naughton et al. [87]	Ireland	271,518	70 years and older	2 conditions: 27% 3 conditions: 19% ≥4 conditions: 14% Consistent patterns of disease by age groups
Kadam et al. [88]	UK	9439	50 years and older	1 morbidity: 19% 2–3 morbidities: 36% 4–5 morbidities: 22% ≥6 morbidities: 23% Increasing strength of association between poor physical function and increasing severity of multi-morbidity

Britt et al. [89]	Australia	9156	Five age groups <25 25–44 45–64 65–74 75 years and older	Prevalence of MM <25 years: 2.6% 25–44 years: 14.7% 45–64 years: 46.5% 65–74 years: 74.6% 75 years and older: 83.2% The most common combination was arthritis/chronic back pain + vascular disease
Schramm et al. [90]	Netherlands	Three population studies, two general practitioner registries, one hospital discharge registry, one nursing home registry	55 years and older	Prevalence of MM: Nursing homes: 82% General practice: 72% General population: 56% Hospital setting: 22% Large differences in type of MM between settings
Smith et al. [91]	Ireland	267	45–64 years old	Prevalence of MM: 34.4% Median number of conditions: 4 Mean number of medications: 7.5 Mean number of medical visits per patient: 11.3 in the 12 previous months
Nagel et al. [92]	Germany	13,781	50–75 years old	Prevalence of MM: 67.3% Low educational level was significantly associated with higher prevalence of MM
Marengoni et al. [93, 94]	Sweden	1099	77–100 years old	Prevalence of MM: 55% Median number of diseases among persons with MM: 3 Diabetes was the 12th most prevalent chronic disease occurring independently of CM; when it occurs, it is more frequently associated with hypertension and heart failure Age, gender, and education are independently associated with MM Cardiovascular disease prevalence is not different by age or gender Higher proportion of mental disorders in the oldest old Co-occurrence of diseases exists beyond chance, which clinicians need to take into account in their daily practice; some pathological mechanisms behind identified clusters are well known; others need clarification
Loza et al. [95]	Spain	2192	Adults with MM including rheumatic disease (RhD)	General prevalence of MM: 30% Prevalence of MM including a RhD: 17% MM is associated with impaired daily functioning and lower quality of life Having a RhD worsens the outcomes
Uijen et al. [96]	Netherlands	13,584	Seven age groups, 0 to more than 75 years old	Prevalence of MM, four or more chronic diseases 45–64 years: 7.0% 65–74 years: 30% ≥55% Older age, female sex, and low socioeconomic class associated with higher prevalence of MM

(continued)

Table 20.2 (continued)

Authors, year, and reference	Country	Number	Age group	Prevalence of multi-morbidity (MM) by age groups and additional results
Lee et al. [97]	USA	11,113	65 years and older	Prevalence of MM: 23% Chronic diseases frequently co-occurring: Diabetes: 19.4% Coronary artery disease: 15.9% Congestive heart failure: 4.8% Geriatric syndromes: Falls: 23.2% Urinary incontinence: 25.0% Co-occurrence of chronic diseases and geriatric syndromes is very common
Minas et al. [98]	Greece	20,299	Two age groups: <65 years 65 years and older	Prevalence of MM: <65 years: 7.78% 65 years and older: 11.52%
Glynn et al. [99]	Ireland	3309	50 years and older	Prevalence of MM: 66.2% Healthcare utilization and costs significantly higher in patients with MM Each additional chronic condition is associated with increases in primary care visits, hospital outpatient visits, hospital admissions, and total health costs
Steinman et al. [100]	USA	1.9 million men, 39,000 women	65 years and older	Mean number of chronic conditions: Men: 5.5 ± 2.6 Women: 5.1 ± 2.6 Disease burden increased with advancing age Most common triplet in men: hypertension, hyperlipidemia, and coronary artery disease Most common triplet in women: hypertension, hyperlipidemia, and arthritis Diabetes more frequently associated with hypertension and hyperlipidemia
Barnett et al. [101]	Scotland	1,751,841	Five age groups, 16 years and older	Prevalence of MM: 23.2% The absolute number of people with MM was higher in people younger than 65 years Onset of MM occurred 10–15 years earlier in people living in the most deprived areas and particularly associated with mental health disorders
Paulsen et al. [102]	Denmark	37,651	Patients with hypertension, 25–79 years old	Prevalence of comorbidities: Diabetes: 26.2% Cardiovascular disease: 19.0% Other serious comorbidities, including cancer and mental disorders: 25.7%
Prados-Torres et al. [103]	Spain	275,682	Three age groups 15–44 years 45–64 years ≥65 years	Prevalence of MM 15–44 years: 13% 45–64 years: 43% ≥65 years: 67% Five clinically consistent patterns of MM: Cardio-metabolic Psychiatric Mechanical-obesity-thyroidal Psychogeriatric Depressive

Streit et al. [104]	Switzerland	1002	50–80 years old Assessment of comorbidity with the Charlson index Quality assessment of preventive care and cardiovascular preventive care with 37 indicators from the RAND's Quality Tools	Prevalence of MM: 67.5% Mean Charlson index: 1.8 31.1% of patients had an index of 0 1.4% of patients had an index >8. Quality of care was not associated with higher numbers of comorbidities
Koller et al. [105]	Germany	115,203	65 years and older Five-year follow-up	Prevalence of MM[a]: 57.62% Patients with MM and older than 75 years had higher risk of becoming care dependent than non-multi-morbid people after the first year
van Oostrom et al. [106, 107]	Netherlands	32,583	55 years and older Time trends 2001–2011 in the prevalence of chronic diseases and multi-morbidity	General prevalence of MM: 26% 15% had two diseases 7% had three diseases 3% had four diseases 1% had five or more diseases MM patients received more medical visits, telephone consultations, home visits, diagnostic tests, or minor surgical procedures MM increased from 12.7% to 16.2% in the general practice and from 14.3% to 17.5% on self-reports Aging of population explained part of these trends
Déruaz-Luyet et al. [108]	Switzerland	888	18 years and older; average: 73 years Assessment of clustering of chronic diseases	Four clusters of chronic conditions identified 1 Cardiovascular risk factors and conditions 2 Metabolic and age-related conditions including diabetes, obesity, atherosclerosis, hypertension, neuropathy, osteoarthritis, hearing complaints, and urinary incontinence 3 Alcohol- and tobacco-related conditions 4 Pain, musculoskeletal, and psychological conditions
Nogueira de Carvalho et al. [109]	Brazil	60,202	≥18 years old Prevalence of self-reported MM according to socioeconomic and demographic characteristics	Prevalence of MM: 23.6% Two chronic diseases: 52.8% Three chronic diseases: 25.8% Four chronic diseases: 12.2% Five or more: 9.3% Higher rates in women, people older than 60 years, with low educational level, living in urban areas and unemployed

[a]In the study of Koller et al., multi-morbidity was defined as the coexistence of three or more chronic conditions

Multi-morbidity in Diabetes: The Elephant in the Medical Office

Comorbidity and multi-morbidity are extremely frequent among patients with diabetes; its association with cardiovascular risk factors has been recognized for a long time. From this perspective, Piette and Kerr proposed a framework to consider ways by which associated chronic conditions could influence diabetes medical care, self-management, and outcomes [110]. They classified comorbidities in three groups, (1) clinical dominant conditions, (2) concordant versus discordant chronic conditions, and (3) symptomatic versus asymptomatic chronic conditions, and recognized, in the first place, the preeminence of diseases like cancer, end-stage renal failure, or severe cognitive impairment in the realities of diabetes care and even on life expectancy. Comorbidities in the second group are very common and compete for time in the medical visit and for resources from patients and their families; some of them are inextricably related to the outcomes of diabetes care (hypertension, dyslipidemia), and others are related from their emotional outcomes (depression, stress) or through recently explained pathogenic mechanisms (musculoskeletal diseases). The third group includes chronic conditions which should be managed regardless of being symptoms, worsening, or recurrence [110]. Most reports about diabetes and chronic disease are about associations with single medical disorders or clusters of chronic conditions, in denial of the unifying role of diabetes in the pathogenesis of apparently disparate disorders within the cardiovascular, musculoskeletal, or digestive systems. The study of comorbidity in patients with diabetes is a recent topic and is summarized in Table 20.3.

Table 20.3 Comorbidity in patients with diabetes

Year, author, and reference	Country	Patients	Prevalence of MM and comments
Kerr et al. [111]	United States	1901 diabetes patients who responded to a survey	40% of respondents had at least one microvascular comorbidity 79% had at least one macrovascular comorbidity 61% had at least one nondiabetes comorbidity including arthritis (55%), cancer (14%), and lung disease (10%) Patients with a greater number of comorbidities placed lower priority to diabetes and had worse diabetes self-management scores Type and severity of comorbid conditions, not just the comorbidity count, influence diabetes self-management Patients with comorbidities need additional support to accomplish self-management activities
Ose et al. [112]	Germany	3546 patients with type 2 diabetes	Participation in a diabetes management program, the number of comorbidities, and the interaction between management and comorbidities have a significant impact on quality of life Structured diabetes management may help to counteract the negative effect of comorbidity
Zhang et al. [113]	Australia	17,095 patients with diabetes, 65 years and older	80% of patients had four or more comorbid conditions Only 1.0% had no comorbidity 18.7% were receiving medications for chronic obstructive pulmonary disease or asthma 17.5% were receiving nonsteroidal anti-inflammatory drugs 7.1% had cancer 4.4% were receiving medications for dementia Low utilization of preventive diabetes care services in patients with comorbidity Competing health demands and patients' preferences are very influential in diabetes management
Wermeling et al. [114]	Netherlands	2086 well-controlled patients with type 2 diabetes, including A1c, systolic blood pressure, and total cholesterol	Compared to patients without comorbidities, patients with type 2 diabetes and comorbidities had much lower health status despite good diabetes control Physical limitations and functional impairment are decisive Physicians may take into account patients' health status and integrate the impact of comorbidities into diabetes care
Luijks et al. [115]	Netherlands	712	Prevalence of "any type" of comorbidity: 84.6% 70.6% had one or more discordant comorbid disorders, mostly musculoskeletal and mental, chronic functional somatic symptoms, and deafness 27.2% had three or more comorbid diseases At the date of diabetes diagnosis, patients had between 1.5 and 2.1 comorbidity clusters Diabetes management in general practice is complex in terms of chronic comorbidity "Straightforward" patients without comorbidities are extremely rare" Diabetes management demands management of comorbidities, including discordant diseases Validity of clinical guidelines is questionable if they do not consider comorbidity A patient-centered approach can be of added value

Table 20.3 (continued)

Year, author, and reference	Country	Patients	Prevalence of MM and comments
Pentakota et al. [116]	United States	42,826 patients with new-onset diabetes	Prevalence of comorbidity: 80% Prevalence of discordant illness: 30.1% Prevalence of both concordant and discordant illnesses: 25.5% Prevalence of concordant illness: 13% Prevalence of a dominant illness different to diabetes: 12% Comorbidity from concordant illnesses is associated with increased visit frequency and higher levels of receiving recommended diabetes care Patients with discordant illnesses had decreased diabetes care and patients with dominant illnesses received markedly decreased diabetes care
Teljeur et al. [117]	Ireland	424 patients with type 2 diabetes treated in general practice	Prevalence of comorbidity: 90% 25% of the patients had four or more additional chronic conditions, the most common: Hypertension: 66% Heart disease: 25% Arthritis: 16% Comorbidity significantly increased the number of medical visits and polypharmacy The variety of conditions emphasizes the complexity of diabetes management and the importance of maintaining a generalist and multidisciplinary approach
Alonso-Morán et al. [118]	Spain	126,889 patients with type 2 diabetes	87.6% of men and 92% of women with type 2 diabetes had at least another chronic condition 1.7% of men and 1.9% of women with type 2 diabetes had ten or more chronic conditions By comparison, 54.2% of men and 57% of women without diabetes had at least another chronic condition Ten morbidity clusters were identified in patients with diabetes, the most common related to cardiovascular risk factors and heart disease Patients with diabetes are at higher risk of peripheral vascular disease, heart failure, hypertension, and chronic renal disease
Sancho-Mestre et al. [119]	Spain	491,854 patients with diabetes identified and selected through clinical codes	70% of patients suffered from more than two comorbidities, the most common Hypertension: 68.4% Dyslipidemia: 53.3% Mental disorders: 25.0% Osteoarticular disease: 24.5% Cardiovascular disease: 14.4% Pharmaceutical expenditures increased according to the number of comorbidities
Bralic Lang et al. [120]	Croatia	10,264 patients from 449 primary care practices	77.7% patients had comorbidity The most common Cardiovascular diseases: 69.7% Endocrine and metabolic: 30.1% Musculoskeletal: 14.0% As the number of comorbidities increase, patients were less likely to achieve A1c levels Despite limited time, general physicians are able to deliver proper treatment of patients with type 2 diabetes and comorbidities Comorbidity increases clinical inertia and treatment fragmentation by different physicians, institutions, and therapies
Petrosyan et al. [121]	Canada	861,354 adults with diabetes Compliance with three quality measures according with type of comorbidity	Prevalence of comorbidity: 86% Diabetes-concordant conditions: 20.7% Diabetes discordant: 15.6% Patients with diabetes-concordant and diabetes-discordant conditions: 49.8% Receipt of all recommended monitoring tests in diabetes is higher in patients with diabetes-concordant and diabetes-discordant conditions (30.2%) and lower in patients with diabetes-discordant conditions (19.6%) Hospitalization for diabetes complications is lower in patients with concordant conditions Meeting goals for A1c does not necessarily prevent hospitalizations for diabetes, especially in patients with comorbidities Other factors, including self-monitoring of blood glucose, glycemic control, lifestyle changes, patient education, and drug therapy, are more important

Multi-morbidity in Patients with Diabetes: How Can It Be Explained?

The results of studies described in Tables 20.2 and 20.3 confirm the increasing prevalence of co-morbidity and multimorbidity. In people with diabetes, the prevalence more than doubles the observed rates in people without diabetes, partly explained by the long-time recognized aggregation of cardiovascular risk factors. The concept of multi-morbidity started with a uni-level approach: to the simple counting of co-occurring diseases [122]. Patients are usually managed for each individual disease according to specific guidelines and by different physicians [123]. The logical limitations of this approach have encouraged a shift to integrated, albeit limited, approaches to meet the needs of individual patients [123]. The current view and classification of human disease dates to the late nineteenth century and derive from the observational correlation between pathological analysis and clinical syndromes [124]. Over the years, attention to the interactions of multiple, apparently unrelated diseases occurring at different levels led to a vertical dimension which attempts to clarify the complex interactions of multi-morbidity at the cellular, organizational, and community (even the emotional) levels [117]. In a brilliant essay, Aron addressed the additional burden imposed by multimorbidity on diabetes self-management and the conflicts and potential risks of glycemic control [122]. A new, holistic view suggests that common linked pathophysiological pathways underlie the development of diseases in a non-organ-specific manner and that multiple diseases within one person, regardless of symptoms or organ system, are not necessarily caused by independent mechanisms [123]. Taking into account the highly internal organization of the cell, it would be possible to improve the single gene-one disease approach by developing a conceptual framework to link all genetic disorders with the complete list of disease genes, resulting in a global view of the "diseasome," the combined set of all known disease/gene associations [125]. In the "human disease network," nodes represent diseases, and two diseases are connected if they share at least one gene in which mutations are associated with both diseases [125]. The existence of intricate molecular links between subcellular components and disease genes raises the possibility that diseases may not be as independent of each other as physicians traditionally consider them to be and that diseases form networks in which two of them are connected if they share at least one gene [126]. Diabetes management at one level ignores its complexity, clearly illustrated by its unique aggregation of concordant and discordant conditions… clinicians must think in multiple dimensions! [122].

Addressing Comorbidity in Clinical Practice

Several instruments have been devised to measure comorbidity [127], but the most widely used is the Charlson Comorbidity Index (CCI) [128]. Developed by Mary E. Charlson and colleagues, the CCI assigns a weight of 1 to 10 for a variety of diseases, including diabetes without organ damage [129]. Six diseases have weights of 2, one disease has a weight of 3, and two diseases have weights of 6, in order to calculate the relative risk of 1-year mortality by summing the weights of each condition [129]. Index scores range from 0 to 10, although higher scores are possible for severely ill patients [129]. The CCI has been used to estimate prognosis of comorbidities in a variety of disciplines, from dermatology to oncology, and its power to predict morbidity, mortality, costs, and hospitalizations has been validated and compared with other measures [130]. Its use continues to extend, and it has become available in several versions of online calculators.

Comorbidity is usually managed by different specialists ("as many as necessary"), using independent clinical guidelines. This approach is ineffective and conflicting, increases the demand of professional services and costs, and may even pose risks for the patients. Current disease-oriented guidelines do not account the interactions between different diseases and are designed to manage single chronic conditions [131]. Innovative approaches have been proposed to address the challenge of comorbidity, such as the Adriane principles, a tool to support decision-making during consultations in primary care that involve patients [132, 133]. The Adriane principles were designed as a process aimed to foster an innovative concept in medical decision making for patients with multimorbidity in primary care [132]. This approach establishes realistic goals at the center and three core principles: (1) individualized management, (2) prioritization of patients' preferences, and (3) interactive assessment [132, 133]. The effectiveness of implementing the Adriane principles in comorbidity management remains to be demonstrated.

Challenges of Multi-morbidity in Diabetes Management

Multiple diseases have an additive effect: comorbidity or multi-morbidity has negative effects on mental status and quality of life and increases the frequency of medical visits and the risk of death [67, 134]. Models of integrated, simplified care of comorbidities involving chronic physical disease and mental disorders can decrease disabilities and are associated with significant reductions in total healthcare costs and hospital costs [68, 135]. The challenge to deliver patient-centered care for people with comorbidities is to provide the right care for the right person at the right time, but current medical structures do not support multidimensional care and encourage treating only disease-specific outcomes [136]. The number and type of comorbid diseases have multiple consequences in patients with diabetes, create competing

demands, and promote clinical inertia [137, 138], negatively influencing glycemic and cardiovascular risk control [139, 140]. Comorbidity should be screened at baseline and follow-up visits. The evidence about effective interventions in the management of patients with multi-morbidity is still limited, and remaining uncertainties prevail, despite its high prevalence and impact on patients and healthcare systems [141, 142]. The last two decades have witnessed a steady increase of knowledge about comorbidity in medicine, which has become a challenge for researchers, clinicians, and health policy makers. The current narrow focus on single diseases should be replaced with a holistic view and approach to established patterns of comorbidity and multi-morbidity [143, 144]. Only a radical rethinking of health systems will facilitate the transition and challenges multi-morbidity and its associated disability [145].

The Chronic Care Model and Diabetes

Usual medical care often fails to meet the needs of patients with chronic diseases, even in advanced countries [146]. Meeting the complex needs of patients with chronic illness or disability is the single greatest challenge facing organized medical practice, and usual care is not doing the job [147]. Most of the patients with diabetes either have no access to medical care or receive inadequate treatment [148]. To improve care for patients with chronic diseases, the negative evidence continuing to accumulate about the inefficacy of usual care and the positive evidence about the benefits of innovations in ambulatory care have encouraged new paradigms. Based on their work at Group Health Cooperative of Puget Sound, Washington, literature reviews, and suggestions of an advisory panel, two decades ago, Wagner and colleagues developed a model to improve chronic illness care, a guide to be used to develop effective chronic care by incorporating successful interventions [147]. The chronic care model (CCM) is based on the reality that in chronic diseases, the outcomes are largely dependent on the efforts, resources, and support of patients and their families [149]. The success of treatment requires that patients are well informed about their disease, the place where they can receive treatment, and to have greater control over their treatment [150]. The CCM is not a quick and easy fix or an abstract theory; it is a multidimensional solution to a complex problem, a concrete guide to improve clinical practice [148]. Care for chronic noncommunicable diseases (NCDs) is a global problem; the CCM is a tool to deliver integrated management for NCDs within the context of primary care and provides practical guidance for healthcare program managers, policy makers, and stakeholders to plan and deliver high-quality services for people with NCDs [151].

Taking into account that chronic illness care is largely performed within the primary care setting, the CCM has become a major component [147, 152]. The CCM assumes that medical care is centered in the interaction of patients and practice teams, with support for self-management from the community and organization of healthcare inside and outside the health system [153]. By comparison to usual care, in which isolated physicians give orders to patients, chronic disease management involves collaboration from a group of clinicians from diverse disciplines (nurse case managers, physicians, pharmacists, social workers, dietitians, lay health workers) who communicate regularly and participate in the care of a defined group of patients. Chronic care occurs in three overlapping scenarios: (1) the community, (2) the health system, and (3) the healthcare organization, taking into account that coordination and performance may help or obstruct optimal chronic care. Essential ingredients are research, performance measurement, and quality improvement. The "six pillars of the chronic care edifice" include (1) community resources and policies, (2) healthcare organizations, (3) self-management support, (4) delivery systems design, (5) decision support, and (6) clinical information systems [148, 154, 155]. A systematic review showed that primary care practices are able to implement the CCM and incorporating most or all of its elements is associated with improved quality of care and outcomes in various chronic diseases including diabetes [156].

Glasgow and colleagues developed two scales or surveys to assess the CCM: the Assessment of Chronic Illness Care (ACIC) and the Patient Assessment of Chronic Illness Care [157, 158]. The PACIC and PACIC+ (PACIC extended with six additional multidisciplinary team functioning items to improve content validity) are reliable instruments to measure the chronic care management experiences of patients with diabetes [159, 160]. The PACIC has been translated to other languages [160] and validated in several countries [159, 161, 162] (Fig. 20.1).

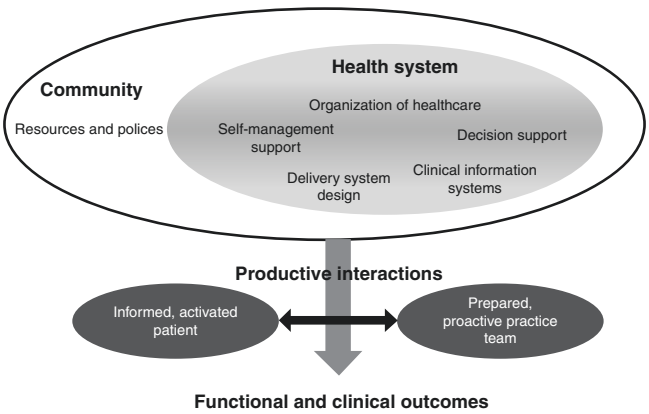

Fig. 20.1 The chronic care model

The CCM in Diabetes

In many ways, diabetes care is the prototype for the CCM and became an emblematic clinical scenario to assess its effectiveness, and increasing evidence shows that the CCM provides a framework for optimal diabetes care [156].Table 20.4 summarizes the results of interventions implementing the CCM since 2001.

To summarize, diabetes represents an ideal clinical setting to implement the CCM. After two decades of being conceived, however, the amount of studies and, most importantly, the number of health organizations and national health systems who have implemented the CCM are still scarce. Beyond endorsement from international agencies [151] and with remarkable exceptions [172], most of the studies and interventions to implement the CCM have occurred in developed countries; adaptations to preexisting models are the rule, instead of studies devoted to implement the CCM "as it is [173]." Most of the studies cited in Table 20.4 continue to appear in systematic reviews, not only because of importance but also because of scarcity of new trials [174, 175]. Available studies show limitations, including non-blinding of participants, brief follow-up, absence of self-report measures for behavior change, small sample size, inadequate training of health professionals, and absence of registries and electronic medical records [176]. Despite these challenges, in less than 20 years, a large amount of experience using the CCM has accumulated worldwide, in every age group and for multiple diseases. More evidence about the effectiveness of the CCM in diabetes management is essential.

Table 20.4 The chronic care model (CCM) in diabetes management

Year, country, and reference	Patients and intervention	Results	Comments
2001, United States [163]	Randomized controlled trial 57 primary care practices serving ≈500,000 people Patients with diabetes ≥30 years attending chronic care clinics at 3–6-month intervals. Components of the CCM: Baseline assessment Individual visits with primary care physicians, nurses, clinical pharmacists, one-group peer support session	Patients receiving the intervention were more likely to receive preventive procedures, foot and retinal examinations, and medication reviews, at no significant differences Rates of participation in diabetes education were significantly higher Nonsignificant differences on physical function, depression measures, days confined in bed, and patient satisfaction Mean A1c levels were equally higher in the two groups, and cholesterol levels were equally lower Chronic care clinic patients visited primary care more frequently; the increase was associated with significant reductions in specialty, emergency room visits, and hospital admissions	Redesign of care including delegation of roles within the practice team, involvement of other disciplines, organization of visits and follow-up, and integration of psychoeducational interventions plays an important role in success
2006, United States [164–166]	Multilevel, cluster design, randomized controlled trial 19 hospitals 166 primary care clinics 1400 academic physicians 90,000 patients with diabetes Implementation of the six elements of the CCM Delivery of diabetes self-management (DSMT) training Stepped approach	Over 4 years, the number of CCM-recognized programs grew from 3 to 21 Significant differences in A1c among patients receiving DSMT in hospital programs versus primary care 2–3 greater proportion of patients received SMDT at primary care offices versus patients referred to hospital-based programs	The CCM is an effective framework to support DSMT With reliable clinical information systems, educators are able to demonstrate the benefits of DSMT on A1c levels Improvements in program and patient outcomes can be sustained, financially self-supporting
2007, United States [167]	Controlled pre- and post-intervention study, 1-year duration 1170 patients with type 2 diabetes 613 assigned to chronic care 557 assigned to usual care	Patients in both groups had improvements in A1c, blood pressure, and lipoprotein levels Participants in the intervention group had a 2.1% greater reduction in cardiovascular risk	Collaborative interventions using the CCM lower cardiovascular risk factors in patients with diabetes

Table 20.4 (continued)

Year, country, and reference	Patients and intervention	Results	Comments
2007, United States [168]	Observational study 30 small, independent primary care practices 90 clinicians, including 60 physicians, 17 nurses, and 13 assistants who completed a questionnaire assessing the use of the CCM 886 patients with diabetes	Use of the CCM was significantly associated with lower A1c levels and ratios of total cholesterol to high-density lipoproteins Every unit increase in the use of the CCM was associated with a 30% A1c reduction and a 0.17% reduction in the lipid ratio	Clinicians in small independent primary care are able to incorporate elements of the CCM in their practice, associated with higher levels of process and intermediate outcomes of diabetes care
2009, 2010, Belgium [169, 170]	Four-year evaluation of a project based on the CCM Implementation based on the ACIC survey Implementation: First stage: 2300 patients with type 2 diabetes Follow-up: 4174 patients	Overall ACIC scores improved from 1.45 at baseline to 5.5 at the end of the study Mean A1c and total cholesterol significantly improved in the intervention group Assessment of long-term complications was insufficient Crucial steps for strengthening primary care included a local steering group, appointment of program managers, and willingness of well-trained and motivated care providers Important barriers include complexity of the intervention, lack of quality data, inadequate information technology, lack of commitment, and unsustainable funding	Adapting the CCM in primary diabetes care has opportunities and bottlenecks Further improvements are required to deliver the CCM components Albeit remarkable improvements were achieved, primary care providers lack the opportunities and resources to take full responsibility for chronic care
2010, United States [171]	Intervention trial 25 practices, 4 physicians per practice Implementation of the CCM measured through staff and clinical management surveys, chart audits, and patient questionnaires	Overall low levels of implementation Sites with higher levels of CCM implementation showed improvements in diabetes assessment and treatment Physical activity counseling for persons with overweight and obesity was associated with CCM implementation, except for people with diabetes	Modest levels of CCM implementation in unsupported primary care is associated with improvements in diabetes care and higher rates of behavioral counseling
2015, Philippines [172]	Observational study Two primary healthcare units in semirural and rural municipalities Adaptation and implementation of the CCM Assessment of chronic illness care (PACIC) and glycemic control	Significant improvements in A1c, glycemic control, and PACIC scores	In resource-limited settings, the CCM improves the quality of primary diabetes care as measured with the PACIC and A1c
2017 Italy [173]	Population-based cohort study 8486 patients exposed to the CCM versus 8486 non-exposed patients Four-year duration	Significant improvements for adherence to clinical guidelines, reduced risk of cardiovascular complications, and protective effects for neurological complications, cardio-cerebrovascular complications, and mortality	Implementation of the CCM-improved diabetes management and reduced cardiovascular outcomes

Diabetes as a Complex Disease

Zimmerman, Lindberg, and Plsek described three kinds of problems in the world: simple, complicated, and complex [177]. Simple problems are clearly defined, with straightforward solutions. Complicated problems don't have straightforward solutions but can be dissected into groups of simple problems. Complex problems have multiple components, commonly not initially perceived and appear during the process of solution. To address complex problems, expertise is important but not sufficient; uncertainty and risk are trademarks. Diabetes management is a complex task. Complexities of diabetic control were recognized five decades ago by Franklin Williams and colleagues, who described the degree in which a variety of continuing intervening factors including (1) biological, (2) psychological, (3) appropriateness

Table 20.5 Main factors affecting outpatient diabetes management

Practice factors	Organizational factors
Partners with interest in diabetes	Diabetes registry
Practice nurses with interest in diabetes	Recall system
Number of practice nurses	Structured diabetes care
Computerized practice	Attachment to diabetes nurses or health visitors
Practice workload	Access to chiropodists
Practice motivation	Access to optometrists
Diabetes education in the general practice	Access to dietitians
Patient factors	Patients self-monitoring
Self-monitoring of patients	Delivery of diabetes education
Frequency of attendance	Diabetes clinical guidelines
Social deprivation	

Modified from Kunthi [179]

(and timeliness referring to clinical inertia) of medical recommendations, (4) adequacy of diabetes education (from a pedagogic to an andragogic approach in adults), (5) patient's resources (cognitive, socioeconomic, motivation, health literacy), and (6) family and social support, converge to achieve the lifetime challenge of day-to-day control [178]. Despite these arguments, reductionist approaches abound and prevail in diabetes management.

To illustrate the complexities of diabetes management, Khunti identified 54 factors associated with effective delivery of care: 23 were practice-related, 14 were patient-related, and 20 were organizational [179]. Table 20.5 summarizes the highest-ranked factors among the 54 original, based on 5 assessment methods: literature review, brainstorming, focus groups, and key informants – general physicians, nurses, and patients.

Countless efforts have failed and continue to fail from denial of this reality. Recognition of complexities of diabetes care starts by identifying the three components of successful diabetes management: (1) patient activation, (2) self-care, (3) support. Each one is essential to achieve the desired outcomes; all of them are directly related to the crucial role and responsibility of people with diabetes and their families. Self-care and support are associated to the capacity to deliver multidisciplinary, patient-centered care, including diabetes self-care education and support. The absence of any one of these components leads to clinical failure, waste of economic resources, and overall dissatisfaction from patients, their families, payers, and providers.

Patient Activation and Its Measurement

Patients unable or unwilling to move in the right direction are very unlikely to achieve the goals of treatment established by evidence-based medicine, even in the best professional environments. Ideally, therefore, it would be desired to explore or assess the level of patient activation. Based on her experience about the unwillingness of health systems to accommodate with her needs as a patient, in 2004 Hibbard and colleagues devised the Patient Activation Measure (PAM), a tool for gauging the capacity of patients to advocate for themselves as they proceed through a medical experience [180]. The original scale had 22 items, which assessed patient self-reported knowledge, skill, and confidence for self-management of one's health or chronic condition [181]. On further analysis, the PAM was reduced to a 13-item measure which has been translated to other languages and validated in the assessment of a variety of chronic conditions [182–185]. Patient activation has been significantly related to health outcomes, in patients with chronic diseases, including diabetes [186, 187]. The PAM has become the gold standard to understand the role of people with chronic conditions in their own health and is likely to be the focus of the next generation of interventions to support informed consumer choices [188].

Self-Care Management

In 1980, Donnell Etzwiler recognized the increased demand of sustained care for chronic disease management, the importance of medical teams, and the main evolution in their development: to include the patients [189]! Don reflected that this had come about not only from the chronic nature of many diseases but also by the number of daily tasks that (patients) are frequently required to carry out. He also stated that to address the health needs of people with diabetes requires developing comprehensive healthcare teams including physicians, health professionals, patients, family members, and involving the community [189]. Self-care was recognized as an essential component of all the pioneering models of diabetes management [5, 6, 10, 11], and a variety of interventions including "teaching machines" (combinations of printed text and still pictures) were proposed since the 1960s [190]. Early efforts were based on prescriptive, pedagogic approaches in which patients were to "be instructed to report" with their physicians; other health professionals were discarded [191]. The consistent failure of traditional diabetes education programs to improve patient self-care, documented since the 1970s, encouraged exploration of innovative approaches [192]. Lorig and Wagner stressed the importance of collaborative relationships between patients and health professionals and the need to share complementary knowledge and authority in the healthcare process, with health services as organizers and financial supporters of these new roles [149, 193]. Many patients are overwhelmed by the multiple, continuous, annoying demands and unpredictable results of diabetes management [194]. Facilitating strategies include asking questions, identifica-

tion of "sticking points" of self-care, goal setting, action planning for change, involvement of family and friends, follow-up, problem-solving, and nourishment of coping skills [194, 195]. Diabetes self-management and support education (DSMSE) has become essential in structured diabetes care and is brilliantly addressed in Chap. 26 of this book. Self-management interventions in people with diabetes receiving self-care management, especially delivered in compact programs with sessions closely grouped together, have shown advantages in glycemic control compared to interventions with an educational approach [196, 197]. Self-management training has higher medium-term efficacy than didactic diabetes education [198]. Self-management is highly dependent from collaborating forces at four levels, according to the ecological model of self-care by Fisher and colleagues: (1) personal factors, reflecting the physical and mental status of patients; (2) immediate relations, with family members and friends, at school and work; (3) health systems; and (4) social determinants of health [199]. After more than three decades, "inclusion of patients" is increasingly recognized but at the same time denied in the real world. The importance of self-care is an undeniable component of success. Integrating DSMSE in routine diabetes care is the essence of person-centered care [200]. "Although the achievement of evidence-based clinical goals reduces the risk of morbidity and mortality in type 2 diabetes, delivery of community practices and referral centers often falls short of these goals [201]." Multiple misconceptions and barriers to integrate self-management support into clinical practice include (1) "we're already doing this"; (2) inability, disinterest, and disdain to address skill deficits; and (3) the need for organizational change [202]. "By comparison to other therapies, DSMSE appears to be the Cinderella of diabetes management...but with greater collaboration, leadership and direction, Cinderella really can become the belle of the ball [200]."

Support

Besides new medicines, main challenges in diabetes outpatient management include (1) recognizing and addressing its complexities; (2) developing, implementing, and sustaining improvements in healthcare systems; and (3) broadening the definition of the "office," reminding that a year has 8760 hours and, in the best possible situation, patients have a very limited amount of time at physician's offices [203]. Essential components of structured diabetes outpatient management include (1) targeting patients at high risk, including intensively reducing A1c levels ≥9.0%, blood pressure ≥160/95 mmHg, and foot care in patients at high risk of foot ulcers [204, 205]; (2) diabetes registries for data collection, reporting, support, and quality improvement [205–209]; (3) local physician champions with specific interest in diabetes and chronic care management, the responsible to coordinate the implementation of the patient-centered medical home [205, 206]; (4) team management involving primary care providers, nurse practitioners, dietitians, and "physician extenders" [210–212]; and (5) health coaching to make sure that patients understand the care plan involving "knowing their numbers," shared decision-making, promoting behavior change, and medication adherence [213]. Health coaching has greatly evolved as an important resource in diabetes self-management and care [214]. Diabetes health coaching improves glycemic control, reduces distress, and increases medication concordance and adherence [215, 216]. Diabetes coaching models comprise (1) personal case management and monitoring; (2) diabetes self-management education and support; (3) behavior modification, goal setting, and reinforcement; and (4) general psychosocial support [214]. Technology has leveraged to facilitate each component of diabetes coaching; its rate of development surpasses advances achieved in other major areas of research [217]. Understanding, development, and implementation of effective interventions for patient support, including diabetes coaching, has become a major challenge and, at the same time, a huge opportunity to link the advances of evidence-based medicine with everyday clinical practice.

Conclusions

> Establishing the best evidence is not the same as implementing the best practice though the former does provide a basis for the latter.
> Philip Davies [218]

Randomized controlled trials, meta-analysis, and systematic reviews have confirmed that unstructured community care is associated with poorer follow-up, worse glycemic control, and greater mortality [176]. This is the case of health systems reluctant and resistant to change the acute care approach in diabetes management like Mexico, where three decades of ill-devised, unstructured, short range, and low resource efforts have not been able to improve clinical outcomes or to reduce diabetes morbidity and mortality [219, 220]. By comparison, worldwide experiences accumulated over three decades have documented the effectiveness of diabetes care in primary practice to reduce risk factors, improve the process of care, decrease referrals to specialized care, and increase the number of consultations when complex, multifaceted interventions and organizational interventions that facilitate structured and regular review of patients are established, in addition to patient education and with support of nurses and health professionals [26–48, 221]. The results of randomized controlled trials have demonstrated that achieving the goals of metabolic control by lowering glucose, blood pressure, and LDL cholesterol reduces the risk of

microvascular and macrovascular diabetes complications [222]. Nevertheless, most diabetic patients do not meet these recommended goals; prevailing and persistent structure and process deficiencies in primary care impede the achievement of outcomes. Studies of the level of diabetes care provided "in the real world" and especially in primary care where the vast majority of patients are seen continue to show that performance levels are highly suboptimal from what is recommended [223]. Challenges of diabetes translation, starting with the urgency to change healthcare systems, were described by Anderson since 1991, but a large proportion of persons with diabetes worldwide continue to be treated "as usual [224]." Establishing effective, sustainable, long-term outpatient diabetes management programs is one of the greatest challenges in this era.

Multiple-Choice Questions

1. Initial experience of hospital diabetes clinics in Europe showed that:
   (a) It was absolutely feasible to treat all patients with diabetes.
   (b) Every patient could receive treatment from highly trained specialists.
   (c) Nurses and dietitians were not required.
   (d) Physicians were the most important elements of success.
   (e) Clinics became overwhelmed, resulting in long waiting times and dissatisfaction.
2. Successful clinics are the ones:
   (a) With the most qualified medical specialists
   (b) Who had the vision and were able to offer comprehensive services
   (c) Charging the highest fees for their services
   (d) In which patients could be admitted to an hospital
   (e) Having access to the newest medications
3. Diabetes management from a paternalistic approach:
   (a) Is essential to make patients follow physicians' orders
   (b) Has been shown to reduce the risk of acute complications
   (c) Reduces the risk of chronic complications
   (d) Has received high levels of satisfaction from patients and their families
   (e) Has never been assessed and is associated with acute and late complications
4. Planning of diabetes services:
   (a) Needs to be broader beyond those available in most centers
   (b) Requires procuring for new medications
   (c) Must be based on the expertise of specialists
   (d) Occurs exclusively at the medical office
   (e) Is not important, patients may attend whenever they want
5. Implementation of a model based on the DCCT in clinical practice requires all the following except:
   (a) Allocation and effective use of resources
   (b) Standards of care and quality assurance
   (c) Training and continuing education
   (d) Research and evaluation
   (e) Recognition that patients are unable to self-manage
6. Outpatient diabetes management:
   (a) Is feasible, acceptable, and effective
   (b) Produces significant improvements in A1c
   (c) Does not increase the frequency of hypoglycemia
   (d) Is not inferior to management in hospital clinics
   (e) All of the above
7. Comorbidity:
   (a) Should be treated by different specialists
   (b) Is very uncommon
   (c) Has no impact on diabetes management
   (d) Is increasingly frequent, "the disease of the twentieth century"
   (e) Is never been more important than diabetes
8. Compared with people without diabetes, the prevalence of comorbidity in patients with diabetes:
   (a) Is very rare
   (b) Is lower
   (c) Is equal
   (d) Is slightly higher
   (e) Is more than double
9. The chronic care model:
   (a) Recognizes that outcomes are largely dependent on patients and their families
   (b) Depends on the availability of all the necessary medications
   (c) Recognizes the preeminence of physicians in all the decisions of management
   (d) Involves fragmentation of services
   (e) Is important but very expensive and complicated
10. Diabetes management:
    (a) Is simple and straightforward
    (b) Is complex but outcomes are certain
    (c) Is complex and outcomes are uncertain
    (d) Depends exclusively on physicians' expertise
    (e) Is independent of patients' resources

Correct Answers

1. (e) Clinics became overwhelmed, resulting in long waiting times and dissatisfaction.
2. (b) Who had the vision and were able to offer comprehensive services

3. (e) Has never been assessed and is associated with acute and late complications
4. (a) Needs to be broader beyond those available in most centers
5. (e) Recognition that patients are unable to self-manage
6. (e) All of the above
7. (d) Is increasingly frequent, "the disease of the twentieth century"
8. (e) Is more than double
9. (a) Recognizes that outcomes are largely dependent on patients and their families
10. (c) Is complex and outcomes are uncertain

Clinical Practice Guidelines, Evidence-Based Medicine, and Diabetes

21

Joel Rodriguez-Saldana

Box 21.1: General goals of treatment for type 2 diabetes

Organization and year	IDF 2013	CDA 2013	NICE 2015	ADA 2018	AACE 2018	Joslin 2018
A1c	<7.0%	<7.0%	<6.5% <7.0% for patients on drugs associated with hypoglycemia	<7.0%	≤6.5%	<7.0%
Preprandial glucose	<110 mg/dl	70–120 mg/dl	NR	80–130 mg/dl	NR	80–130 mg/dl
Postprandial glucose	<180 mg/dl	90–180 mg/dl	NR	<180 mg/dl	NR	<180 mg/dl
Bedtime glucose	NR	NR	NR	NR	NR	90–150 mg/dl
Blood pressure	<130–140/80 mm Hg	<130/80 mm Hg	<140/80 < 130/80 with kidney, eye, or cerebrovascular damage	<140/90 mm Hg	<130/80 mm Hg	≤140/90 mm Hg
LDL cholesterol	<100 mg/dl	<77.3 mg/dl	NR	<100 mg/dl	Low risk: <160 mg/dl Moderate risk: <130 mg/dl High risk: <100 mg/dl Very high risk: <70 mg/dl Extreme risk: <55 mg/dl	<70 mg/dl for patients with ASCVD[a] <100 mg/dl for patients without ASCVD[a]
Triglycerides	NR	132.8 mg/dl	NR	<150 mg/dl	NR	≤150 mg/dl
HDL cholesterol	NR	NR	NR	>40 mg/dl in men >50 mg/dl in women	NR	≥40 mg/dl

[a]*ASCVD* atherosclerotic cardiovascular disease

The Unwarranted Variation in Health Care and Its Consequences

In 1938, Glover reported high variations in the rates of tonsillectomy in small areas of Britain; the probability of undergoing the operation was 20 times higher in children living 7 miles apart [1]. Despite the amount of similar evidence col-

lected for almost four decades, when John Wennberg published his first article on unwarranted variations in the delivery of health care in 1973, he was largely ignored [2]. Over the next four decades, he and his colleagues collected compelling research against the traditional view of quality of health care as "the best in the world" but at the expense of high variability in costs. Wennberg showed that a large part of the medical services delivered in the United States and other countries is not only unnecessary, but it also inflicts a large burden in costs and is potentially harmful [3]. In 1967, Wennberg and Gittelsohn developed a database to identify and compare the underuse of care among neighboring hospital service areas assuming that lack of access and undertreatment were the most important problems in health care [3]. Surprisingly, they found large unjustified variations in the delivery and use of services among neighboring communities: instead of underservice and undertreatment, they found vast variations in the availability of resources and the use of services in neighboring communities without scientific basis [4–5]. Despite huge variations in health-care delivery, people were homogeneous in health, socioeconomic status, education, and insurance [2]. Wennberg came to the conclusion that medicine had wrapped itself in the mantle of science, yet much of what doctors were doing was based more on hunches than good research [2]. Variations were more linked to professional uncertainty about the best way to practice medicine and physician supply: people living in areas with more surgeons per 10,000 inhabitants had more surgery, and residents in areas with more internists received more diagnostic tests [6]. These landmark studies were not warmly received: the first two reports had to be published in *Science* and *Scientific American* [6–7], because journals with wide clinical readerships rejected them arguing that patient demand was the only explanation for variations in health-care delivery, and those studies would be of no interest to the readers [5]. Despite initial and persistent resistance to accept them, similar variations in hospital admissions, length of stay, and specific surgical procedures had been reported in other countries [8–9]. Differences were too large to be ignored, interpreting results was difficult and at times not in favor of the medical profession; unless they were understood at a clinical level, the risk of policy decisions with adverse effects on health was high [8]. Wennberg's studies led to health-care reforms at the federal and state levels in the United States, but in most places in the world, these proposals are still unacceptable [2]. A patient's odds of undergoing surgery, diagnostic, and therapeutic procedures frequently is more dependent on where he or she lives than on clinical circumstances. Despite substantial advances in medical science, regional variations in surgery have not decreased; the rates of ten common surgical procedures have remained stable worldwide [10–13]. Clinical inertia, personal beliefs, and economic interests are still relevant barriers to standardize medical practice. Instead of "evidence-based," "eminence-based medicine" prevails and rules. "What you get depends on where you live and who you see [14]."

Three main reasons have been advocated to explain substantial variations in diagnostic, medical, and surgical procedures: (1) differences in health systems, (2) practice styles of physicians, and (3) characteristics and preferences of patients [15]. Beyond structural differences and recognizing the role of patients to pursuit and select health care, physicians' beliefs about the effectiveness of clinical interventions and their personal interpretation to what constitutes evidence are main contributing factors; patients in high-intensity areas with high availability of services do not experience better health outcomes [16]. To address this problem, the use of clinical guidelines to apply scientific evidence has become increasingly important.

The Ascent of Clinical Practice Guidelines

One of the most important factors influencing physicians is the collection of clinical policies to guide their actions [17]. In 1989, Robert Brook announced the emergence of the movement leading to practice guidelines when the need for careful evaluation of medical practice became a priority based on (1) high rates of unexplained variation in clinical practice; (2) high rates of inappropriate care, adverse events, and medical errors; (3) escalating financial pressures and cost-containment efforts; (4) rapid introduction of technology; and (5) unprecedented questioning and scrutiny of medical care [18–20]. These deficiencies created a demand to obtain clinical evidence about efficiency, cost-effectiveness, and the impact of medical interventions on quality of life [20]. Failure to identify the best services, the appropriate circumstances, and the indicated patients is a threat to patient safety, contributes to the increasing costs, and impedes the improvement of health care [20]. Attention shifted to development of methods providing valid and reliable guidelines about the best interventions "for the real world," based on high-quality, understandable, and practical evidence-based information, not simply anecdotal, consensus-based, opinionated, nihilistic, or with limited scope [21–22].

Albeit articles about guidelines started to be published in the 1960s and the title "clinical guidelines" was mentioned since the 1970s, 1990 was the emblematic year to their advance. Brooke was accurate in his prediction: the vision and efforts of a distinguished group of leaders, including David Eddy, Stephen H. Woolf, Scott Weingarten, Marilyn Field, and Kathleen Lohr in the United States; Richard Grol in the Netherlands; and Jeremy Grimshaw, Ian Russell, and Martin Eccles in the United Kingdom, and the pioneering work of the Agency for Health-Care Policy and Research (AHCPR), the Institute of Medicine (IOM), the American College of Physicians, the Veterans Health Administration in the United

States, and the National Institute of Clinical Excellence in England (NICE, UK) led to an explosion in the development of clinical guidelines and a worldwide discussion about their methodology, implementation, impact, and quality of health care [23–28]. They understood the roles required to improve an organization and to attain its professional goals to advance from [1] the art of craft stage in which skills are passed from practitioner to apprentice [2] to a stage where experience is collected and systematized to form principles leading to the emergence of an integrated structure of thought [23].

Critical pathways were first used in industry; the critical pathway method was developed in the 1950s to coordinate multiple contractors or people to identify the key sequence of events and the critical path that would drive the timeline of a project and started to be applied to health care in the 1970s to define the optimal sequencing and timing of interventions by physicians, nurses, and other staff for particular diagnosis or procedures [24]. Critical pathways are devoted to (1) improve the health status of significant amounts of individuals; (2) reduce unwarranted variations in patient care; (3) minimize delays and resource utilization; (4) enhance communication; (5) decrease costs; (6) reduce significant variations in outcomes; and (7) maximize the quality of health care [24]. Clinical algorithms are criteria maps in flowchart format initially designed by Greenfield and colleagues to perform chart audits of clinical conditions or management, and they became a preferred method to illustrate management pathways [24–25].

Different definitions of clinical guidelines have been proposed. According to the IOM, clinical guidelines are "all the information relevant to approach the diagnostic and therapeutic management of a clinical problem," whereas the AHCPR declared that clinical guidelines are "systematically developed statements developed to assist practitioners and patient decisions about health care to be provided for specific clinical circumstances," and Margolis defined them as "all the relevant information to approach the diagnostic and therapeutic management of a clinical problem, logically driven by a clinical algorithm" [26–29]. Clinical guidelines evolved from pathways to direct the diagnosis or management of symptoms or signs to graphical descriptions of quality improvement. The primary goals of clinical guidelines are [30]:

1. To improve the quality of care, enforcing professionalism, accountability, and efficiency as part of professional activities.
2. To support systems in decision making for clinicians and patients.

Over the next decades, clinical practice guidelines (CPG) became the preferred methods to influence medical decisions and develop practice policies beyond the traditional approach in which practice policies evolve through collection of "standard and accepted" practices, which are not to be changed [31–32]. Main issues of the traditional approach include (1) the obligation to comply with them (policies and norms) and the expectative that people must perform them without deviation. In this approach, the former defines the latter and creates two problems: (1) it is not anchored on reality; policies are not explicitly described or analyzed and (2) outcomes are subjective [31]. In a series of articles, Eddy proposed substituting global subjective judgment for an evidence-based approach, in which clinical decisions were supported by evidence. The steps that he described to identify the tasks to design practice policies are still valid [31–36]:

1. Formulate the problem to be assessed.
2. Identify and interpret the evidence.
3. Synthesize the evidence, the magnitude of its benefits, and harms.
4. Direct comparison of benefits and risks.
5. Estimate costs.
6. Compare health outcomes and costs.
7. Setting priorities.
8. Design a practice policy.

Clinical guidelines have to be flexible, taking into account that outcomes must be assessed by an appreciable but not uniform audience, including providers, payers, and users [36]. The clinical practice guideline movement is consolidated through the common interest of leaders and institutions from the United States and Europe. Several reviews were published until the 28th Bethesda Conference analyzed their association with quality of care, the methodology of development, and implementation [36–42].

Development of Clinical Guidelines

Clinicians need simple, patient-specific, user-friendly guidelines which included three basic components: (1) identification of the decisions which have to be made and their possible consequences; (2) collection of valid evidence to make informed decisions at key decision points; and (3) presentation of evidence and recommendations in a concise, accessible format [43]. The process starts developing the pathway of the clinical guideline, and recognizing the need to abandon the consensus approach, a method of subjective judgment in which participants "simply decide what to recommend" and privilege the biases of traditional, empirical medical practice. Consensus evolved from collective personal experiences, they are sanctioned by selected, frequently biased groups of experts, in the abscence of explicit criteria to select the evidence supporting specific recommendations, they are open to misuse and reluctant to meet quality standards [20, 44–49]. Approaches to develop clinical guidelines are shown in Table 21.1 [50–69].

Table 21.1 Stages in the development of clinical practice guidelines [20, 29–30, 50–69]

Stage	Description
1	Identifying and refining the subject including clinicians, patients, and potential users or evaluators of the guideline.
	Definition of topics in precise terms including condition or disease, interventions, patient population, scientific evidence, and outcomes to define effectiveness.
	Selection criteria:
	1. Disease prevalence
	2. Burden of illness: avoidable morbidity, premature mortality
	3. Costs of treatment
	4. Guidelines about quality of health care include process measures and evidence about effective interventions
	5. Current evidence about practice variability or inaccurateness
	6. Evidence about potential to improve clinical outcomes and reduce costs
	7. Specific needs of people who will implement the guideline
	8. Cost implications
	9. Time or technology required
	10. Competing demands of other health problems
2	Cost analysis and hidden costs in implementation, which could be detrimental to the patient's interests. Health interventions are not free, people are not infinitely rich, and budgets are limited.
	Information about cost implications of alternative preventive, diagnostic, and management strategies for each clinical situation
3	Target audience and clinical setting:
	1. Scope of the guideline
	2. Evidence to be considered
	3. Panel composition
4	Three groups responsible to develop the guideline: (a) development, (b) continuing medical education, (c) implementation. Types of groups:
	(a) Internal: composed entirely by physicians and health professionals who will use them
	(b) Intermediate: including some clinicians who will use them
	(c) External: none of the clinicians will use them
5	Panel of 10–20 members balancing scientific, practical, and political concerns, including:
	1. Primary care professionals with specific interest
	2. Health authorities
	3. Medical specialists with expertise in the guideline topic
	4. One epidemiologist
	5. Health economist
6	Five alternative methods to develop the guideline:
	1. Informal consensus conference or working party ("global subjective judgment"): expert panel making recommendations from subjective evidence; little description of specific evidence or processes. Contributors present preferences and use scientific evidence to support their statements. Agreement without discussing formal analytical methods. Advantages: simple and flexible. Major problems: easily influenced by dynamics of experts, very limited validity of opinions. Problems to establish validity of conclusions
	2. Formal consensus: expert panel in compliance with appropriateness ratings, two-step Delphi technique. Includes methodologists, clinicians and public representatives, excludes persons with strong advocacy positions regarding the topic. Major limitation: consensus-based, evidence-based medicine not required
	3. Evidence-based: recommendations linked to the quality of scientific evidence, eliminating studies non-rigorous studies. Major problems: absence or scarcity of scientific evidence, disregard of clinical experience and patient's preferences.
	4. Explicit method: built on the evidence-based approach. Systematic estimate of the effects of interventions on health outcomes. Combination of scientific evidence and formal analytic methods, including benefits, dangers, and costs of interventions, probability of outcomes and patient's preferences. Thorough review of published literature including scientific validity, health economic analysis, and ranking of options to choose the preferred one. If there is not a clear winner, patient's preferences are taken into account.
	5. Synthetic method: draft prepared by one specialist and one general practitioner, refined by editorial panel to ensure consistency, understandability, and adequacy by nonspecialists and representative of a broad range of opinions. Circulation of the draft for comments by local doctors to create a refined version to be printed and implemented
7	Causal pathway of the guideline
	1. Algorithmization: standard formats for flowcharts or algorithms to make explicit, logic guidelines.
	2. Explicit method describing the use of indirect evidence to establish effectiveness, positive health outcomes, potential adverse consequences of interventions
8	Analytical framework to define questions to be answered to reach recommendations, types of evidence, and relevant information for analysis, including:
	1. Evidence-based
	2. Expert opinion
	3. Clinical experience
	4. Patient's experiences and preferences

Table 21.1 (continued)

Stage	Description
9	Literature retrieval and review
	Evidence-based assessment of clinical questions or conditions Consult sources of evidence-based medicine (Table 21.3)
	Quality of individual studies, internal and external validity
10	Trade-offs to balance benefits and harms of recommendations:
	1. Discrete and measurable outcomes or benefits for patients:
	Intermediate: leading to clinical outcomes
	Surrogate: equivalent to health outcomes
	Health outcomes: efficacy, morbidity, emotional well-being, mortality
	2. Potential risks and harms, adverse events, fatal and nonfatal complications
	3. Quality-adjusted life years
11	Wording recommendations
	Clarity and precision
	Behavioral, direct, specific terms. "Actionable," clear, and concise statements, in active voice
	Avoid using vague, nonspecific words and passive voice
12	Translate evidence into recommendations
	Based on established hierarchies by the Canadian Task Force of the Periodic Health Examination (CTF-PHE), the US Agency for Health Care Policy and Research (AHCPR), or the US Preventive Services Task Force (USPSTF):
	1. Levels of evidence
	I: Evidence from "one well-designed" randomized controlled trial
	II: Evidence from "less well-designed" randomized controlled trials or one well-designed case control study
	III: Evidence from observational studies or case reports
	IV: No evidence – expert opinions, consensus conferences
	2. Categories of evidence
	Ia – Meta-analysis of randomized controlled trials
	Ib – At least one randomized controlled trial
	IIa – At least one controlled study without randomization
	IIb – At least one other type of quasi-experimental study
	III – Descriptive studies: comparative, case-control
	IV – Expert committee reports, opinions of clinical experience or both
	3. Levels of certainty
	High
	Moderate
	Low
	4. Strength of recommendations
	A: Strongly recommended – based on evidence category I
	B: Recommended – based on evidence category II or extrapolated from category I
	C: No recommendation – based on evidence category III or extrapolated from categories I or II
	D: Not recommended – based on evidence category IV or extrapolated from categories I, II, or III
	E: Insufficient evidence to make a recommendation
13	Disclosure of uncertainties in the wording of recommendations and the design of algorithms including:
	1. Lack of scientific evidence
	2. Expert opinion
	3. Special clinical circumstances
14	Physicians' confidence in the correctness of guidelines. Local tailoring or customization to suit local conditions without tinkering with evidence-based recommendations
15	Strategies of implementation
	1. Patients to be covered by the guideline
	2. General reminders for physicians and patients
	3. Quality improvement strategies to reduce clinical and managerial discordances; systematic framework and tools to define, analyze, and improve processes
	4. Specific actions for the majority of the patients
	5. Specific feedback from previous care
	6. Changes in medical records: what was actually done
	7. Monitor patient outcomes
16	Dissemination and learning
	Ascertainment that the guideline reaches the users, learn the guideline, and practice according with it. Learning without transference is a waste of time and resources

(continued)

Table 21.1 (continued)

Stage	Description
17	Internal and external evaluation:
	1. Experts, professional societies, government organizations, consumer groups, health management organizations, insurers, practicing clinicians
	2. Monitoring if the guideline is used
	3. Clinical outcomes
	Intermediate: closely related to the process
	Long term: patient health and function
	4. Quality indicators
18	Effects on quality of health
	1. Percent of patients receiving process measures
	2. Percent of patients achieving outcome measures
	3. Cost-effectiveness
	4. Patient satisfaction
19	Review and updating because of changes in evidence:
	1. Benefits and harms of interventions
	2. Changes in current practice
	3. Outcomes and estimated value
	4. Available interventions
	5. Available resources
20	Feasibility and sustainability: long-term likelihood to operate "in the real world." Take into account that:
	1. Guidelines might be ignored because of non-compliance; most of them are not incorporated into clinical practice
	2. Guidelines may be inadequate to the clinical environment
	3. Unawareness or disregard that using them depends as much on administrative factors as on clinical validity and efficacy
	4. Patient preferences, costs, competing health priorities, magnitude of benefit
	5. When compared with current practice, it is discovered that the guideline did not improve care
	6. Misapplication in clinical practice
	7. Narrow inclusion or exclusion criteria
	8. Unintended effects: Increased costs, adverse events of new interventions
	9. Inefficiencies of health care systems competing with implementation
	10. Inappropriateness for some patients
	1. Acceptance
	2. Institutional and political support
	3. Resources
	4. Continuing leadership
	5. Professional commitment
21	Emerging issues
	1. Strategies to enhance implementation:
	Identification of barriers; anticipative solutions
	Behaviorally specific language
	Multiple formats and channels for dissemination
	Adaptation of educational resources
	Resource implications, to ensure availability
	Data collection tools
	2. The increasing importance of comorbidity

Challenges of Implementation

Despite all the efforts, serious deficiencies persist in the adoption of clinical guidelines as a result of perceived conflicts with clinical freedom; divisive, individualistic personalities; poor planning; lack of resources; and the absence of strategies to change practitioners and patients' behavior [21, 70–77]. Guidelines do not implement by themselves [70]! Publishing a guideline is not enough to produce sustained changes in clinical management [77]. Weingarten stated that "a well-intentioned society puts together a wonderful guideline…they publish it in a journal, and that's where it ends [77]". Implementation requires time, enthusiasm, and resources. Since there is no single effective way to ensure their use in practice, dissemination and implementation require multifaceted interventions [71].

The low rates of adoption of internationally praised guidelines for chronic diseases like diabetes illustrate the complex-

Table 21.2 Approaches to changing clinical practice

Approach	Theories	Focus	Interventions, strategy
Internal processes	Adult learning	Intrinsic professional motivation	Local consensus Interactive learning in small groups Problem-based learning
Epidemiology	Cognitive	Information seeking, decision making	Evidence-based guideline development Disseminating research findings through courses, mailing, journals
Marketing	Health promotion, innovation, social marketing	Adapt to the needs of target audience	Needs assessment, adapt change proposals to local needs Stepwise approach Dissemination through diverse channels (mass media, personal)
Behavioral	Learning	Control by external stimuli	Audit and feedback Reminders, monitoring Economic incentives, sanctions
Social interaction	Social learning and innovation, based on social influence/power	Influence of significant peers/role models	Peer review in local networks Outreach visits, individual instruction Opinion leaders Key people in social networks Patient-mediated interventions
Organizational	Management and system	Structural and organizational conditions to improve care	Reengineering the process of care Total quality management/continuous quality improvement Team building Enhancing leadership Change structures, tasks
Coercive	Economic power and learning	Control and pressure, external motivation	Regulations, laws Budgeting, contracting Licensing, accreditation Complaints/legal procedures

Adapted from Grol [90]

ities of implementation. Profiling (identifying the right person willing to implement a clinical guideline) and detailing (training, support, and follow-up) are still essential. In 1992, Grol described a series of views to change behavior [70]:

- Awareness about the existence of the clinical guideline, interest, and commitment
- Understanding its purpose and contents, recognition of personal gaps or deficiencies, the need to change and improve
- A positive attitude; confidence in performance and success
- Initial and sustained implementation "in the real world", identification and addressing barriers and obstacles [70]

An extensive review about implementation of clinical guidelines in pulmonary medicine addressed the complexities of physician's behavior and the influence of background, ethics, beliefs, and exposure to countless formal and informal guidelines as part of professional training [78–89]. One of these articles stated that (1) education in small doses is ineffective, because it pales in comparison with previous years or decades of education received by physicians; (2) usual methods of passive dissemination are unsuccessful to effect behavior change; (3) multiple strategies are more effective than isolated interventions; (4) implementation "by decree" doesn't work; (5) reminders have shown to be effective; and (6) disregard of situational and environmental factors, pre-existing structure and process deficiencies in health care and the delusion that guidelines by themselves "will improve the situation" are very prevalent [80]."

Grol and colleagues published a classical report about professional barriers to implement clinical guidelines and proposed approaches to change physician behavior (Table 21.2) [90].

In their conclusions, they stated that "when people are planning changes they often adopt a naïve and opportunistic attitude…a strategy is usually chosen quickly and often does not produce the expected results…our understanding of the crucial processes determining whether change will be achieved is still limited [90]."

Clinical Guidelines and Implementation Science

Despite the limited impact of multiple efforts including national standards, norms and regulations, traditional continuing medical education, consensus conferences to influence clinical practice, and waste of time and resources from uncoordinated, decentralized development of guidelines, all these faulty strategies are still preferred and supported [91]. Development, implementation, and evaluation of national

clinical guidelines are very difficult. Local adaptation and effective implementation strategies are keys to success [92]. Gagliardi and colleagues developed and implemented a format that would influence the use of clinical guidelines and examine their contents and dissemination [93]. They found that encouraging their use involves:

1. Easy access
2. Authorship familiarity and trustworthy
3. Short and concise recommendations
4. Additional tools such as checklists, standard orders, summaries, algorithms, diagrams, color-coded tabs, and pocket cards
5. Printed and electronic formats
6. Strong supporting evidence
7. Flexibility of recommendations to the local context
8. Suitability to patient's needs and preferences; auxiliary documents for patients such as leaflets
9. Clinical vignettes describing patient needs and preferences
10. Explicit resource implications
11. Tools to collect evaluative data

In 2013 Grol, Wensing, Eccles, and Davis published a review about the elements of implementation and their effects on quality of health care [94]. In the basic principles of their landmark book, they stated that changes in the organization of institutions or practices can be very important, but improvement of agents of change, including doctors and health professionals, is essential to optimize patient care in terms of quality, safety, and quality improvement [94].

Crossing the Professional Abyss

Despite the current enthusiasm driving the creation of countless clinical guidelines, a large level of unwarranted variation in clinical practice persists even when guidelines based on reputable evidence are available [95]. Clinical guidelines frequently do not affect clinical practice or health outcomes. A national survey of a random sample of members of the American College of Physicians showed that although physicians recognized their potential benefits, many were concerned about the possible effects on clinical autonomy, health-care costs, and satisfaction with clinical practice [96]. Many physicians argue that clinical guidelines are being used for cost containment, instead to improve the quality of care [92, 97]. The potential inability of guidelines to be translated to clinical practice undermines their role as strategies for quality improvement, cost containment, and health system reform [98].

Multiple studies have confirmed the lack of adherence to clinical guidelines by physicians and failure to change clinical practice. Frolkis and colleagues showed that physicians are poorly compliant with clinical guidelines for cholesterol control even in patients at high risk of coronary heart disease. Only 50% of the time they request LDL cholesterol measurements, screening for additional risk factors (hypertension, smoking, diabetes) is suboptimal, and many patients remain untreated [99]. A systematic review by Choudry and associates showed an inverse relationship between the number of years in clinical practice and quality of care: more experience is not associated with better clinical outcomes [100]. Despite the efforts to develop non-biased, evidence-based guidelines, implementation is low, professional compliance is inadequate, and long-term follow-up is limited [101–103]. If patients will benefit from the results of clinical trials, all the steps between research and clinical practice must be effectively delivered. Unfortunately, multiple weaknesses occur at all these steps [104]. Medical factors or barriers reducing adoption or compliance with clinical guidelines include [105–108]:

1. Disregard by physicians and health professionals expected to implement them, lack of familiarity or awareness
2. Factors related to the conservative nature of physicians, including the innovation itself, communication channels, length of time, and characteristics of members of the social environment [108]
3. Individualistic physician judgment resulting in:
   (a) Lack of agreement with specific guidelines
   (b) Lack of agreement with guidelines in general
   (c) Lack of outcome expectancy
   (d) Lack of self-efficacy
   (e) Lack of motivation, clinical inertia
4. Autonomous groups reluctant to introduce innovations or improvements
5. Wandering teams, loss or absence of leadership
6. Overemphasis on the guideline and failure to consider implementation
7. Deficiencies in implementation, poor planning, communication
8. Deficiencies in health-care systems
9. Fragmented information from fragmented groups or institutions
10. Lack of time, poor allocation of resources, and lack of resources
11. Patient factors
    (a) Changes in clinical status
    (b) Patient preferences
12. Plain refusal, "loose cannons"
13. Undetermined reasons

Adoption of clinical guidelines depends on (1) awareness and knowledge about their existence, (2) agreement and self-

efficacy, (3) complexity of structure and sequence, (4) frequency of reminders, (5) self-reported effect in personal versus actual performance and outcomes and measurable improvements in quality of health care, (6) incentives, and (7) removal of disincentives [96, 109–112]. To succeed, physicians, health professionals, and institutions must participate actively in the development of guidelines and commit to their use, and patients should be aware and willing to follow their recommendations [111]. Expectations about their impact on patient care differ and depend on the people involved: physicians and health professionals, payers, administrators, or politicians. The main potential benefit of clinical guidelines is their capacity to improve the outcomes of medical care through intermediate steps of changing knowledge, attitudes, and behavior. As a methodology for process management, adherence to clinical guidelines is the result of a dynamic process influenced by multiple contextual factors, including the barriers and facilitators previously discussed [111].

The development of clinical guidelines has become crucial. They have become a familiar part of clinical practice, but they also have potential benefits and harms [112–113]. Rigorously developed, evidence-based guidelines minimize potential harms and improve the quality of health care [113]. The worldwide interest in clinical guidelines is based on a series of challenges to health-care systems: (1) increasing demand and costs of technologies and treatment; (2) lack of applicability to address relevant issues of clinical practice, associated chronic diseases, safety and risk management, multidisciplinary collaboration, effect on costs or compliance, and patient self-care; (3) persistence of unwarranted variations in clinical practice; (4) the fact that even when evidence is available, final recommendations often reflect personal opinions, local culture, or vested interests of developers or sponsors; and (5) the intrinsic desire to offer the best possible care [113, 114]. Expectations about their impact depend on the people involved in their implementation: clinicians, patients, payers, administrators, and politicians, but their main goal is still to improve the quality of care [115]. Their main potential risk is to be wrong or erroneous, with resulting harms to patients and everyone [113]. Clinical guidelines are criticized when they become "cookbook recipes" in disregard of the variability of clinical situations [113, 116–117]. In addition of their use to assess clinical effectiveness, clinical guidelines also have ethical consequences: either as instruments to direct medical ethics or because their coercive enforcement for other reasons than the patients' benefit [118–119]. Beyond their increase, clinical guidelines have not eclipsed traditional paradigms based on individual expertise [120–121]. Guidelines are important to improve patient care, but innovations are essential to make them relevant and effective [120]. "Without these changes, they will be seen as expensive but unhelpful and ineffective toys for a happy few [114]."

Evidence-Based Medicine and Clinical Guidelines

> Evidence from modern research has a lot to say about the management of diabetes mellitus.
> R. Brian Haynes and Hertzel C. Gerstein [122]

The origins of evidence-based medicine (EBM) date back to the nineteenth century with the development of the numerical method by Pierre Luis in France but are rooted in the history of medicine 2500 years ago, when Hippocrates declared that physicians "need to rely on actual evidence rather than on conclusions resulting solely from reasoning, because arguments in the form of idle words are erroneous and can easily be refuted [123]." In the 1800s Florence Nightingale used evidence from careful record keeping, observation, and statistical measurement to encourage health-care reform, and Ernest A. Codman advocated data collection, patient follow-up and analysis, and interpretation of patient outcomes to improve care and treatment methods [124]. During the Spanish Civil War and the Second World War, a young British physician named Archie Cochrane worried that his advice to colleagues about treating tuberculosis might not be appropriate and feared that some procedures could be harmful [124]. In 1972, he published an influential book in which he suggested that because resources would always be limited, they should be used to provide the type of health care which had been shown to be effective in properly designed evaluations [125–126]. Cochrane championed using randomized controlled trials because they were likely to provide more reliable information than other sources, and he sparked the interest of those who would continue to put them at the top of the research hierarchy [126]. Randomized trials are not always required, available, or feasible to assess the outcomes of health care, but trials with enough numbers of patients are essential to distinguish between the effects of care and the effects of biases or chance [127–128].

EBM gained momentum in the last century, through collaborative efforts of clinical epidemiologists from Canada, the United States, and Europe. The term EBM was coined in the 1990s to label a clinical learning strategy which the staff of the Faculty of Health Sciences at McMaster University in Canada had been developing for over a decade and that was announced in the first edition of their book about clinical epidemiology in 1985 [129]. Its founding fathers, Guyatt, Sackett, Haynes, Tugwell, and Neufeld, were concerned by the reliance of physicians in "their experience," the use of outdated information to resolve clinical problems, and the absence of evidence about medical paradigms of universal acceptance [129]. In 1992 evidence-based medicine was defined "as a shift paradigm, the conscientious, explicit and judicious use of the best evidence in making decisions about the care of individual patients to integrate individual clinical expertise with clinically relevant research, especially patient-

centered" [130–131]. Evidence-based medicine (EBM) is devoted to replace "expert-based" health care, through translation of controlled clinical trials into everyday practice. EBM practitioners must be able to:

1. Understand the patient's circumstances.
2. Identify knowledge gaps and frame questions to fill those gaps.
3. Conduct efficient literature searches.
4. Critically appraise the research evidence.
5. Apply the evidence in patient care [131].

EBM became a watershed in the practice of medicine and has gained increasing acceptance, despite persisting barriers to its implementation and applicability in every clinical setting. EBM was meant to replace intuitive (medical mythology) and authoritarian (opinion-based) attitudes for an authoritative (evidence-based) approach [132]. Incorporating EBM requires training in the skills of finding and applying evidence to patient care within the medical structures [133]. Barriers to use EBM in practice are multiple, including (1) physician's preferences and expertise; (2) clinical inertia and skepticism about the credibility of the evidence; (3) lack of awareness, familiarity with clinical guidelines, or access to information; (4) the clinical setting, including time constraints and pressures to accomplish more tasks during patient visits; (5) a sense of interference with the doctor-patient relationship; (6) lack of education about its principles and techniques; (7) insufficient resources to integrate it in clinical practice; and (8) clinical status and personal preferences of patients [133–134]. Keeping up with advances in medicine has become extremely difficult for most practitioners; finding the best and most valid evidence for a specific clinical question is frequently impossible [133]. On the other hand, a large part of the evidence for medical science has come under scrutiny for its high rate of inaccuracy and bias [135]. In order to change their practice, physicians require a positive attitude toward EBM and to learn and practice its five steps: (1) ask, (2) access, (3) appraise, (4) apply, and (5) audit [134]. Barriers related to the use of EBM arise from the evidence itself, including absence of useful evidence, excessive, contradictory, or outdated information [134]. EBM needs to evolve from the assumption that all clinicians will adopt the best evidence as soon as it appears in clinical guidelines which they will totally follow, to feasible strategies to achieve optimal, streamlined delivery systems.

In EBM, traditional methods to obtain evidence have been discarded [136]. Evidence needs to be relevant and reliable, but science needs to balance the complexities of clinical knowledge, patient's preferences, and health systems. Main empirical sources of evidence come from observations collected in clinical practice, commonly leading to inaccurate associations and surrogate outcomes not representative of true clinical outcomes. Lohr quoted Millenson and Williamson's statement that "more than half of all medical interventions, and probably as many as 85%, have never been validated by clinical trials [136]". Objective sources of evidence include systematic reviews and randomized controlled trials and international collaborations devoted to develop and implement CPG (Table 21.3).

Evidence-based medical practice has a long history reaching back to the seventeenth century, but it has only been systematically applied in the last 40 years; medical practice and health care in disagreement with EBM remains worldwide ubiquitous, even in diabetes management [155].

Table 21.3 Leading sources to rate evidence

Date	Initials, name, and reference	Description
1979	Canadian Task Force (CTF) on the Periodic Health Examination, Canada [137]	Lifetime program to prevent specific diseases and health promotion. Rate of recommendations: A: Good evidence supporting the recommendation B: Fair evidence supporting the recommendation C: Poor evidence to include the recommendation D: Fair evidence to exclude the recommendation E: Good evidence to exclude the recommendation
1992	The Cochrane Collaboration [138–139]	More than 31,000 contributors from 120 countries, more than 5000 systematic reviews to facilitate and extend the creation of systematic reviews of randomized controlled trials (RCT)
1993	Agency for Health-care Research and Quality (AHRQ), USA [140]	Grading system to reply questions about effectiveness
1996	CONSORT (Consolidated Standards of Reporting Trials) statement [141]	Unified statement of requirements to report results of randomized controlled trials. The last version is the 2010 checklist, with 25 items and subitems Six items: Title and abstract Methods Randomization Results Discussion Additional information

Table 21.3 (continued)

Date	Initials, name, and reference	Description
2003	AGREE (Appraisal of Guidelines for Research and Evaluation) collaboration [142–144]	International standard for assessment of CPG Valid and reliable; 23 items, 6 quality domains: Scope and purpose Stakeholder involvement Rigor of development Clarity of presentation Applicability Editorial independence Overall guideline assessment Last update December 2017
2003	STARD (Standards for Reporting of Diagnostic Accuracy) initiative [145]	An initiative to improve accuracy and completeness to report studies about diagnostic tests, potential biases, and generalization 25 items and a flow diagram with information about methods of: Patient recruitment Order of tests Number of patients undergoing the test under evaluation Standard of reference
2004	GRADE (Grading of Recommendations Assessment, Development, and Evaluation) working group [146–148]	Appraisal of six prominent systems for grading levels of evidence and strength of recommendations including American College of Chest Physicians (ACCP), Australian National Health and Medical Research Council (ANHMRC), Oxford Centre for Evidence-Based Medicine (OCEBM), Scottish Intercollegiate Guidelines Network (SIGN), US Preventive Services Task Force (USPSTF), and US Task Force on Community Preventive Services (USTFCPS)
2007	ORION (Outbreak Reports and Interventions on Nosocomial Infection statement) [149]	22-item checklist to raise the standards of quality on research and publication about hospital epidemiology and infection control. A work in progress for successful promotion and dissemination.
2011	OCEBM (Oxford Centre for Evidence-Based Medicine) levels of evidence [150]	Six questions about (1) probability, (2) diagnosis, (3) prognosis, (4) treatment benefits, (5) treatment harms,and (6) screening, with four steps based on quality, imprecision, indirectness, inconsistency, or absolute effect
2011	Clinical Practice Guidelines We Can Trust, by The Institute of Medicine [151]	Eight standards of trustworthiness: Transparency Clear statement of conflicts of interest; chair and co-chair should not have conflict, financial ties creating conflicts should be eliminated Multidisciplinary composition of the guideline development group, including methodology experts, clinicians, stakeholders, and patients Systematic reviews Quality and strength of recommendations Articulating recommendations: actions recommended, when it should be used External review Regular updating
2011	RAMESES (Realist and Meta-Review Evidence Synthesis) statement) [152]	Alternative, extended, and supplementary method to Cochrane-style reviews. Principles of good practice in realist and meta-narrative systematic reviews
2012	WHO Handbook for Guideline Development [153]	Technical aspects to develop a WHO guideline. A methodology to provide a clear path and ensure that guidelines have scientific credibility and meet the WHO criteria for content, methods, and presentation remains accessible and useful
2014	CEPI (Center for Evidence and Practice Improvement), depending on the Agency for Health-care Research and Quality (AHRQ) [154]	A new organization within the AHRQ, consisting of five divisions, one of them the evidence-based practice center devoted to produce evidence synthesis by conducting systematic evidence research and advances in the methods of evidence synthesis to ensure scientific rigor and unbiased view

Clinical Guidelines for Chronic Disease

One decade before the first clinical guidelines for diabetes were published, the challenge to develop recommendations for chronic disease management was addressed by the Joint National Committee (JNC) on Detection, Evaluation, and Treatment of High Blood Pressure [156]. The first report was consensus-based, established very high blood pressure targets of control (i.e., diastolic 120 or higher), and claimed that "for patients with lower pressures, there are no hard data on the benefits of therapy [156]." On the bright side, this landmark guideline included a stepped-care approach and addressed the need to facilitate long-term control and to adapt treatment patterns according to type of facility. In an

era of limited choices of antihypertensive medications, the authors of the JNC-1 report recognized the importance of patient adherence as a cause of failure, the need to persuade patients to tolerate untoward effects of medications, and the advantages of combined therapy [156]. After 40 years, the JNC reports became a benchmark for hypertension management worldwide. Subsequent reports evolved along with emerging resources and needs of their time and included new targets of therapy, treatment at different age groups, patient education to maintain adherence, non-pharmacologic interventions, using new drugs, greater patient involvement, quality of life, costs, and management in "special groups," including diabetes [157–163]. An important addition to the JNC reports since 1993 were the rates of awareness, treatment, and control reported by the National Health and Nutrition Examination Surveys (NHANES) [160]. Awareness, medication, and blood pressure measures started to be reported in the 1960s in the United States at the community level and were adopted to measure the quality of hypertension management in multiple countries worldwide [164]. Improvements in these rates are consistent with the decline in disability caused by hypertension and have important implications for reducing health-care costs [166]. Starting in 1997 in the sixth JNC report, the authors used an adapted classification of categories of evidence to support the recommendations [161]. This evidence-based approach was maintained in the seventh and eighth JNC reports and in hypertension guidelines developed in other countries [162–163]. The last chapter in the story of hypertension guidelines was the 2017 American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines Guideline for Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults [165]. The ACC/AHA hypertension guideline is an outstanding effort to translate evidence-based medicine in clinical practice. Its supplement contains an updated, comprehensive collection of all the randomized clinical trials, meta-analysis, and observational studies addressing diagnosis, treatment, lifestyle changes, monitoring, and prevention of hypertension in every age group [166]. Clinical practice guidelines for other diseases could probably benefit from these examples.

Evolution of Diabetes Clinical Guidelines

Two pathways converge in the ascent of clinical practice guidelines for diabetes management: the surge of the movement of clinical guidelines in the 1980s and the consolidation of evidence-based medicine with the first randomized clinical trials and afterward with the mega-trials on secondary prevention. In 1989, the American Diabetes Association (ADA) published the first version of its "Standards of Medical Care for Patients with Diabetes Mellitus" [167]. Basic medical care included the initial visit, continuing care, intercurrent illness, and special considerations like hyperglycemic crises, hypoglycemia, pregnancy, hypertension, chronic complications, and foot care, a brief comment devoted to children and adolescents; management in pregnancy and in the elderly was not included [167]. Three years later, the Expert Committee of the Canadian Diabetes Advisory Board published its clinical practice guidelines for the treatment of diabetes [168]. This document was more extensive and included definition and classification and a list of patient-centered goals of care [168]. Beyond glycemic targets, the 1992 Canadian diabetes guidelines proposed the following goals: (1) relieve symptoms, (2) prevent and treat acute and long-term complications, (3) promote self-care, (4) treat accompanying disorders, (5) improve the quality of life, and (6) reduce the morbidity and mortality associated with diabetes [168]. The Canadian guideline emphasized the responsibilities of primary care physicians to diagnose and help patients to attain goals, educate and motivate them, and coordinate care and referrals [168]. The Canadian guideline included explanations about diagnosis and management in adults, children and adolescents, the elderly, native Canadians, and pregnant women [168]. This was probably the first effort to present a standardized approach to diabetes care.

Evidence-Based Medicine and Diabetes Guidelines

Starting in 2002, the American Diabetes Association Standards of Medical Care included a grading system developed by the ADA and modeled "after existing methods [169]. The existing methods are not referred in the text, but the grading system originally appeared in the first report of the Canadian Task Force (CTF) on the Periodic Health Examination in 1979 [170]. With the natural chronological evolution in its components, the grading system became a benchmark to establish three major categories of evidence to assess the effectiveness of interventions:

- I or A: Evidence obtained from randomized controlled trials
- II or B: Evidence obtained from cohort studies
- III or D: Opinions of respected authorities, clinical experiences, descriptive studies, or expert consensus

in which I, II, and III refers to the CTF, whereas ABD represent the ADA grading systems. The ADA included a C level for evidence obtained from poorly controlled or uncontrolled studies [169].

Evolution of Diabetes Guidelines

After three decades, diabetes guidelines expanded their scope and aligned in methodology. Management of hyperglycemia continues to be a priority, as reflected in a highly referenced algorithm published by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) in 2006 [171]. The ADA/EASD algorithm established a "general" glycemic goal <7.0% according to the results of several controlled clinical trials, including the Diabetes Control and Complications Trial (DCCT), the Stockholm Diabetes Intervention Study, the UK Prospective Diabetes Study (UKPDS), and the Kumamoto Study, which demonstrated that decreasing glycemia effectively reduced microvascular and neuropathic complications [171]. The ADA/EASD algorithm included a brief discussion about lifestyle interventions and a detailed review of the antidiabetic drugs available in the United States, Canada, and Europe, one algorithm to initiate and adjust insulin regimens and another "for metabolic management" with focus on pharmacologic alternatives to achieve A1c goals [171]. The 2009 version of the ADA/EASD algorithm and recent guidelines from other countries maintain glycemic control as the main goal. Table 21.4 summarizes glycemic targets for adults with type 2 diabetes established by institutions or medical societies worldwide.

Table 21.4 Glycemic targets for adults with type 2 diabetes

Year	Organization and reference	A1c	Fasting blood glucose	Postprandial blood glucose
2006	American Diabetes Association [171–173]	<7.0%	<130 mg/dl	<180 mg/dl
2013	Canadian Diabetes Association [174]	<7.0%; to reduce risk of microvascular disease <6.5% to further lower the risk of nephropathy and retinopathy, at the expense of higher risk of hypoglycemia 7.1%–8.5% in patients with limited life expectancy, functional dependency, coronary artery disease, comorbidities, severe, recurrent hypoglycemia, hypoglycemia unawareness, long-standing diabetes in which control has not been feasible	4.0–7.0 mmol/L	5.0–10.0 mmol/L
2015	National Institute of Clinical Excellence, NICE, UK [175]	Agreed, individualized A1c target based on the person's needs and circumstances Pharmacologic treatment if A1c rises to 6.5% on lifestyle interventions	Limited evidence to establish optimal targets	Limited evidence to establish optimal targets
2016	22 Institutes and Academic Centers from China [176]	<7.0%	80–126 mg/dl, 4.4–7.0 mmol/L	<180 mg/dl, <10 mmol/L
2017	International Diabetes Federation [177]	<7.0%; a target between 7.5% and 8.0% may be appropriate: in patients using multiple medications, with reduced life expectancy, cognitive impairment, chronic kidney disease, severe cardiovascular disease, or multiple comorbidities; values above 8.0% are unacceptable		
2016–2018	Royal Australian College of General Practitioners, Diabetes Australia [178]	Individualized according to patient circumstances. General: ≤7.0%	6–8 mmol/l	8–10 mmol/l
2018	American Association of Clinical Endocrinologists, American College of Endocrinology [179]	<6.5% for patients without serious concurrent illness and low risk of hypoglycemia >6.5% for patients with serious concurrent illness and at risk of hypoglycemia		
2018	American College of Physicians: Clinical Guidelines Committee [180]	Clinicians should: 1. Personalize goals for glycemic control based on benefits and harms of pharmacotherapy, patients preferences, general health, life expectancy, treatment burden, and costs of care 1. Aim to achieve an A1c level between 7.0% and 8.0% in most patients with type 2 diabetes 2. Consider de-intensifying pharmacologic therapy in patients achieving A1c levels <6.5% 3. Minimize symptoms of hyperglycemia, avoid targeting an A1c level in patients with life expectancy less than 7 years, living in nursing homes, or with severe chronic conditions; harms outweigh benefits in this persons		
2018	Joslin Diabetes Center [181]	<7.0% Alternative A1c goals based upon presence or absence of complications, hypoglycemia unawareness, cognitive status, and life expectancy	80–130 mg/dl	<180 mg/dl

Patients at the Center of Clinical Guidelines

In 2012, the ADA and the EASD updated their position statement recognizing that glycemic control needs to be pursued within a multifactorial reduction framework and that aggressive management of cardiovascular risk factors is likely to have more benefits [182]. Based on the results of three cardiovascular trials, the Action to Control Cardiovascular Risk in Diabetes (ACCORD) [183], the Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) [184], and the Veterans Affairs Diabetes Trial (VADT) [185] showing that not everyone benefits from aggressive glucose management, the authors of the 2012 ADA/EASD position statement stressed the importance of individualizing treatment targets. From this perspective, glycemic targets could be more stringent in newly diagnosed, highly motivated, resourceful adherent patients with excellent self-care capabilities, low risk of hypoglycemia, long life expectancy, absence of comorbidities, and vascular complications, while less stringent efforts should be applied to less motivated, non-adherent patients with poor self-care capabilities, high risk of hypoglycemia, long-standing disease, short life expectancy, severe comorbidities and vascular complications, and limited resources [182]. Clinical decisions should also take into account the patients' values and desires [182]. In the following year, the American Diabetes Association convened an expert forum to discuss the concept of personalized medicine in the wake of the 2012 ADA/EASD position statement [186]. The authors recognized that patients' preferences, life expectancy, disease duration, comorbidities, socioeconomic status, and cognitive abilities play a role in the selection of therapeutic options and targets. They concluded that "one size does not fit all," that patient-centered care and standardized algorithmic management are conflicting approaches, but that they can be made more compatible by recognizing instances in which personalized A1c targets and clinical circumstances requiring co-management by primary care and specialty clinicians are warranted [186]. In this approach, A1c targets range from <7.0% in healthy, motivated, and resourceful patients to 7.5–8.5% in patients with social and educational issues, comorbidities, and complications [186]. Trends to recognize the preeminence of persons with diabetes are changing a paradigm that until recently was focused on glycemic targets that even the best candidates are unable or unwilling to pursue or to achieve.

Diabetes Guidelines at the Crossroads: The Evidence Behind the Evidence

During the last three decades, the importance to address all the components of clinical guidelines, including validity, reliability, reproducibility, clinical applicability, clarity, multidisciplinary process, review, and documentation has been emphasized [187]. Guidelines must adhere to increasingly tougher standards of transparency and objectivity and adopt consistent format to make them accessible for clinicians and patients [188]. These requirements are essential to guarantee that clinical guidelines are trustworthy because they set the standard for medical practice, influencing clinical decisions about patients, practice measures, coverage, and reimbursement [189]. Two pathways currently converge to establish the reliability of clinical guidelines: the AGREE II instrument [142–144] and the Institute of Medicine standards for trustworthiness of clinical practice guidelines [151]. As in other clinical disciplines, diabetes guidelines have been carefully reviewed and appraised [187, 190–191]. Two reviews published by Mülhauser and Meyer [187] and Vigersky [190] showed that:

1. Diabetes guidelines have lower scores compared with guidelines on other chronic diseases.
2. Diabetes guidelines show substantial variations in methodological quality.
3. The role of evidence versus expert opinion remains obscure in most diabetes guidelines.
4. Multiple algorithm complexities including a) lack of evidence about selected A1c cutoff points; b) lack of evidence about the effectiveness of starting triple therapy, in disregard of the risk of drug interactions: c) underestimation of the effectiveness of lifestyle interventions: d) rapid obsolescence: and e) disregard of out-of-pocket costs and the near equivalent effectiveness of most classes of therapeutic agents.
5. Absence of peer review. According to the ADA, "once written by the panel, a consensus statement is not subject to subsequent review and does not represent official Association opinion."
6. The most reputed diabetes guidelines fall short of the ideal in key respects including grading of evidence, complexity of algorithms, stratification of patients, disregard of costs, inflexible glucose targets, absence of peer review, and conflicts of interest.

Quality of Evidence of Diabetes Guidelines and Its Consequences

In 2015 the ADA stated that 51% of the recommendations supporting their standards of medical care were based on higher-level evidence and nearly half of recommendations were still of lower level [191]. Two recent systematic reviews confirm this statement [192–193]. Bouchonville and colleagues reviewed all clinical trials with hard cardiovascular (CVD) endpoints cited in the 2016 ADA guidelines and additional studies analyzing CVD endpoints that were omitted in the ADA guidelines [192]. Analysis of 42 studies showed limitations to interpreting the available evidence regarding

the impact of glycemic control on CVD and mortality [192]. The authors state (1) that it is difficult to ascertain to what extent the reported benefits of glycemic control might be attributable to specific lowering agents or to additional reductions in blood pressure and body composition; (2) observation time of many of these studies is insufficient to draw conclusions about CVD events and mortality; and (3) current multifaceted standards for CVD reduction introduce confounding to control groups when endpoints are affected by other factors independent of glycemic control [192]. In their recommendations, the authors state that "while treatment of individual risk factors in isolation is not associated with proven benefits…treatment of multiple risk factors improves CVD outcomes in people with diabetes [192]." Kruse and Vassar performed a systematic review to analyze their fragility index (FI) and the fragility quotient (FQ) of all the randomized controlled trials referenced in the 2017 ADA Standards of Medical Care [193]. Results of 35 out of 172 analyzed studies showed low risks of bias, overall low robustness, and modest FI and FQ levels; this means that only 16 events were required to reverse the significance of a given result [193]. Loss of follow-up is also important: lost participants may have provided enough data to sway the statistical significance of the trials, rendering the result nonsignificant [193]. Their conclusion is compelling: simply collecting the data on participants who were lost to follow-up could alter not only the results of the study but ultimately *the recommendations that guide treatment* [193]. "If we truly aspire to bring evidence based rather than authority-based medicine to clinical decisions, clinical guidelines must be the product of explicit, rigorous, scientific processes; few are [194]." Most statements including recommendations intended to optimize diabetes care are developed by consensus-based panels that move us back toward authority-based medicine [194].

Conflict of Interest, Magnitude, and Consequences

Of all these issues, probably conflict of interest is the most common. In a review of disclosures, 100% of members of the AACE guideline group had conflicts of interest in 2011, compared with 83% in 2010. A similar review showed that 100% of the ADA/EASD had conflicts of interest in 2011 compared with 83% in the previous year [190]. To address this situation, Bennett and colleagues published a systematic review to assess whether guidelines about oral antidiabetics are consistent with current evidence and if consistency of guidelines depends on the quality of guideline development [195]. Two reviewers screened citations to identify English-language guidelines on oral medications for type 2 diabetes in the United States, Canada, and the United Kingdom [195]. The authors assessed if diabetes guidelines addressed and agreed with seven evidence-based conclusions and independently rated guideline quality using the AGREE instrument (Box 21.2) [196]. The results showed that (1) 11 out of 1118

Box 21.2 Items of the AGREE II instrument

Domain	Item or question
Scope and purpose	1 The objectives of the guideline are specifically described 2 Health questions specifically described 3 The population to whom the guideline is meant to be applied specifically described
Stakeholder involvement	4 The guideline development group includes persons from all the relevant professional groups 5 Views and preferences of target population have been pursued 6 Target users of the guideline clearly defined
Rigor of development	7 Evidence obtained by systematic methods 8 Criteria for selecting evidence clearly described 9 Strength and limitations of evidence clearly described 10 Methods for formulating recommendations clearly described 11 Health benefits, side effects, and risks considered in the recommendations 12 Explicit link between recommendations and supporting evidence 13 External peer review before publication 14 Updating procedure
Clarity of presentation	15 Specific, nonambiguous recommendations 16 Management options clearly described 17 Key recommendations easily identifiable
Applicability	18 Facilitators and barriers to implementation 19 Advice and/or tools to put into practice the recommendations 20 Potential resource implications 21 Monitoring or auditing criteria
Editorial independence	22 The guideline is not influenced by the views of the funding source 23 Competing interests of guideline group members recorded and addressed
Guideline assessment	24 Overall quality rating 25 I would recommend it

Modified from [196]

guidelines met the inclusion criteria, (2) only 3 were peer reviewed, (3) most of them made recommendations based on combinations of expert opinion and literature review, (4) the rigor of development summary scores using the AGREE instrument ranged from 0% to 100%, (5) the risk of bias using the independence domain items of the AGREE instrument showed summary scores ranging from 8.3% to 100.0%, (6) 6 of the 11 guidelines reported conflicts of interest among guideline development members, and (7) guidelines with lower editorial independence scores had also lower rigor of development scores, whereas those with higher quality scores scored higher in both domains [195].

The Quest for Quality in Diabetes Guidelines

The AGREE instrument has become the tool to appraise the quality of clinical practice guidelines for many disciplines, including type 2 diabetes [196]. A recent review from Anwer and colleagues assessed the quality of type 2 diabetes guidelines using the AGREE II instrument [197]. The final analysis included seven guidelines and showed that the two domains with highest scores were 1, scope and purpose, and 4, clarity of presentation. Dominion 3, rigor of development, scored high in three guidelines; dominion 3, applicability (implementation), scored high in three guidelines, and six guidelines declared editorial independence. In overall assessment, one guideline was recommended without changes, while six were recommended as long as they were modified according to the health-care context in which they would be implemented [197]. The study addressed the need of clinicians to recognize high-quality, trustworthy diabetes guidelines among the huge amount of available guidelines and the importance of the AGREE II instrument in their design to assess their quality [197]. The methodological quality of diabetes guidelines continues to be disappointingly low and needs to be improved for the benefit of all involved: clinicians, stakeholders, and patients [198].

Challenges and Opportunities Implementing Diabetes Guidelines

Developing high-quality diabetes guidelines and evidence-based medicine is not a guarantee to improve clinical practice. Adherence rates to diabetes guidelines and clinical inertia among physicians are still very low 20 years after it was addressed by El-Kebbi and colleagues [199]. Less than 50% of patients treated by general physicians receive eye examinations, electrocardiograms, A1c measurements, and screening for microalbuminuria [200]; despite favorable attitudes toward guidelines, their use is limited, with only one third report using them often or very often [201]; even at teaching hospitals, treatment targets for A1c, blood pressure, and LDL cholesterol are not met [202]. Non-compliance with clinical guidelines is as high as 70% and occurs across most disciplines and countries [203]. Even in countries with long-standing traditions of using clinical guidelines like the Netherlands, 35% of primary care physicians reported difficulties in changing personal routines, and 6% admitted to being resistant to adhering with clinical guidelines [203]. Multiple arguments to explain physician non-compliance with clinical guidelines have been presented including awareness, complexity, disagreement with contents, overconfidence, time pressures, difficulties in changing clinical practice, and fragmentation of care [203]. Strategies used to implement and improve adherence to diabetes guidelines involve multifaceted interventions directed to practitioners, health professionals, and patients such as audit, feedback, training, and problem-based learning [204–206]. All these interventions combined have shown significant improvements in adherence to diabetes guidelines and the process of diabetes care. Advances in the implementation of diabetes guidelines continue to be reported, mostly in Australia, the United States, and Europe [207]. The challenge resides in the need to receive long-term funding and support to achieve intermediate and long-term clinical outcomes.

New Approaches Beyond Glycemic Targets

Diabetes outpatient management is complex and goes beyond glycemic targets. The analysis of the Steno-2 study demonstrated that intensified multifactorial intervention was more effective to slow progression of retinopathy, nephropathy and neuropathy, macro- and microvascular events, and cardiovascular and overall mortality; increases median life length over 21 years follow-up; and is more cost-effective than conventional treatment [208–212]. Resources for self-monitoring of blood glucose and communication technologies for patient coaching and support have created alternatives to intensify and adjust diabetes management. By comparison, type 2 diabetes management algorithms establish rational sequences for introducing, adjusting, or intensifying pharmacologic alternatives from lifestyle changes to multiple insulin doses every 3 months, reinforcing the need to wait and contributing to clinical inertia [213]. A key barrier to treatment intensification is lack of communication between patients and physicians that would allow patients to understand the consequences of their diagnosis and become engaged in treatment [214]. Despite the universally agreed influence of patients in the outcomes, patient involvement in guidelines is poor, information about lifestyle changes, and diabetes education and nutrition counseling is scarce or absent in type 2 diabetes guidelines [215–216]. Patient and public involvement is highlighted in

multiple guidelines. The third standard of the Institutes of Health emphasizes that guideline development groups should include populations impacted by the guideline and states that "patient and public involvement should be facilitated by including a current or former patient and a patient advocate or patient/consumer organization representative on the guideline development group [215].

Conclusions

The challenges of diabetes management are increased by the complexities of the life of persons with diabetes. Glucose, blood pressure, and lipoproteins are essential targets of therapy, but competing health, social, and economic priorities also have to be addressed. Comorbidity rates in the general population and in persons with diabetes are increasingly higher; some, like cancer, heart failure, or arthritis, are clearly dominant and influential over every aspect of diabetes care and life expectancy [217]. The importance of comorbidities has been recognized and recently addressed in diabetes guidelines [218–219]. Current guidelines focus on individual diseases in isolation; in caring for people with comorbidities, it would be more helpful to develop guidelines that summarized and cross-referenced all the possible recommendations to a particular patient [218]. Assessment of comorbidities has been included as part of the medical evaluation in the 2018 edition of the ADA Standards of Medical Care in Diabetes [220]. Comorbidity is already prevalent and will become more frequent as the population ages and survival from acute disease improves [218]. Developing diabetes guidelines has become increasingly challenging: treatment algorithms need to be personalized and comprehensive at the same time; the individual approach is disconnected with the realities and demands of clinical practice. Although seemingly impossible, new approaches have shown that it is feasible to create personalized, down-to-earth clinical guidelines for type 2 diabetes [220]. The Clinical Guidelines Committee of the American College of Physicians (ACP) and the US Department of Defense recently presented two innovative approaches: instead of glycemic targets, the first statement of the ACP guidance recommends that "clinicians should personalize goals for glycemic control on the basis of a discussion of benefits and harms of pharmacotherapy, patients' preferences, patients' general health and life expectancy, treatment burden and costs of care [180]." Addressing these usually "invisible" factors is decisive to at least explore the possibility to accept and adhere to clinical recommendations. The clinical guideline of the US Department of Veterans provides a detailed algorithm in which before deciding the first pharmacologic alternative, glycemic control should take into consideration the patient's age, reproductive status, comorbidities (including an extensive list of the most important), adverse effects and contraindications of medications, history of severe hyper- or hypoglycemia, social determinants of health, and providing understandable diabetes education [221].

Traditional ABCs of management (A1c, blood pressure, cholesterol) have been expanded and should also include other elements of management: D, diabetes education; E, eye examinations; F, foot examination; G, glucose monitoring; H, health maintenance; and I, indications for special care [222]. Traditional diabetes guidelines stress that patients should receive health care from interdisciplinary teams including physicians, nurse practitioners, physician assistants, nurses, dietitians, exercise specialists, pharmacists, dentists, podiatrists, and mental health professionals, and patients must assume an active role in their care. Fulfilling these recommendations escapes the realities of everyday diabetes care, even in developed, more resourceful countries like Switzerland, where 32% of patients with type 1 diabetes and 44% achieve A1c levels below 7.0% and also low levels of LDL cholesterol [223]. Support for continuing implementation of diabetes guidelines among primary care practitioners is essential to improve the perspectives and reduce the suffering of the increasingly large number of persons with diabetes across the world. Even in good-performing health systems, room for improvement is huge [224].

Multiple Choice Questions

1. According to the American Diabetes Association guideline, the goal for A1c levels in patients with type 2 diabetes is:
   (a) <6.0%
   (b) <6.5%
   (c) <7.0%
   (d) <7.5%
   (e) <8.0%
2. According to the American Association of Clinical Endocrinologists guideline, the goal for blood pressure in patients with diabetes is:
   (a) ≤140/90 mm Hg
   (b) <140/80 mm Hg
   (c) <130/90 mm Hg
   (d) <130/80 mm Hg
   (e) <120/80 mm Hg
3. According to the Joslin Guideline, the goal for LDL cholesterol in patients with type 2 diabetes and atherosclerotic cardiovascular disease is:
   (a) < 70 mg/dl
   (b) <100 mg/dl
   (c) <130 mg/dl
   (d) <160 mg/dl
   (e) <200 mg/dl

4. One of the primary goals of clinical guidelines is:
   (a) To promote the use of new medications.
   (b) To establish medical consensus.
   (c) To increase medical knowledge.
   (d) Create norms to be followed.
   (e) To improve the quality of health care.
5. In order to improve the quality of care, clinical guidelines pursue:
   (a) Reducing the unjustified variation of medical care.
   (b) Guarantee obtaining the necessary resources.
   (c) Treating all patients in tertiary care facilities.
   (d) Total patients' compliance.
   (e) Reinforce the role of physicians in chronic care management.
6. One major challenge of clinical guidelines is:
   (a) Adoption and implementation
   (b) Compliance of patients
   (c) Obtaining the required resources
   (d) All of the above
   (e) None of the above
7. Implementation of clinical guidelines is associated with all of the following, except:
   (a) Awareness about its existence
   (b) Understanding its purpose and contents
   (c) Recognition of personal gaps and deficiencies
   (d) Publication in a leading medical journal
   (e) Confidence in performance and success
8. Encouraging the use of clinical guidelines involves:
   (a) Easy access
   (b) Additional tools including checklists or algorithms
   (c) Strong supporting evidence
   (d) Flexibility of recommendations to the local context
   (e) All of the above
9. Medical factors or barriers reducing adoption of clinical guidelines include:
   (a) Disregard of physicians expected to implement them
   (b) The conservative nature of physicians
   (c) Autonomy and reluctance to innovate or improve
   (d) Absence of leadership
   (e) All of the above
10. Currently, most diabetes guidelines:
    (a) Are high-quality, evidenced-based
    (b) Are high-quality, consensus-based
    (c) Are medium-quality, evidence-based
    (d) Are low-quality, evidence-based
    (e) Are low-quality, consensus-based

Correct Answers

1. (c) <7.0%
2. (d) <130/80 mm Hg
3. (a) <70 mg/dl
4. (e) To improve the quality of health care.
5. (a) Reducing the unjustified variation of medical care.
6. (a) Adoption and implementation
7. (d) Publication in a leading medical journal
8. (e) All of the above
9. (e) All of the above
10. (e) Are low-quality, consensus-based

Measuring Diabetes Quality of Care: Clinical Outcomes, Cost-Effectiveness, and Patient Experience of Care

22

Patrick J. O'Connor, Jo Ann M. Sperl-Hillen, and Todd P. Gilmer

Chapter Objectives

- To discuss advantages and challenges of measuring quality of outpatient diabetes care
- To identify and discuss key measures of clinical quality of outpatient diabetes care including glucose, BP, lipid, and tobacco control and appropriate aspirin use
- To identify emerging opportunities and challenges related to measurement of patient experience of diabetes care, shared decision-making, and burden of treatment
- To discuss factors that influence the cost-effectiveness of diabetes care and to discuss the cost-effectiveness of diabetes case management and diabetes-related clinical decision support

Introduction

It is widely recognized worldwide that the quality of care provided to those with diabetes mellitus is far from optimal. In order to improve care in an intentional way, it is of paramount importance to identify key aspects of diabetes care quality to target, develop valid measures of care quality to track changes over time, and use these measures to identify specific types of actions and interventions that are most likely to effectively impact diabetes quality and performance measures. Here we will discuss the strength and weaknesses of current measures of diabetes quality of care and comment on current challenges that face those engaged in this effort, either as developers of quality measures or as users of such measures in care delivery settings or in accountability organizations. For the sake of brevity, we will focus on outpatient care of adults with type 2 diabetes and limit our attention in this chapter to measures of selected clinical outcomes, cost of care, and patient experience of care.

Measuring Clinical Outcomes in Outpatient Diabetes Care

Data from the United States suggest that diabetes leads to about a 5-year loss of life expectancy and a 10-year loss of disability-free life expectancy [1, 2]. A key question for both clinicians and public health leaders is to identify effective prevention or treatment strategies that mitigate these losses both at the population level and for each patient we see.

One very effective way to mitigate the loss of life expectancy and disability-free life expectancy from diabetes is to prevent or delay the onset of type 2 diabetes. This is the topic of several chapters in this book, and it is clear from large randomized trials such as the Diabetes Prevention Program and similar programs in Scandinavia and China that both lifestyle interventions and certain pharmacologic agents such as metformin and others are effective in this regard [3, 4]. It is clear that primary prevention of type 2 diabetes is a very high priority for both clinicians and public health policy makers.

Once a patient develops type 2 diabetes, the question becomes how to prevent or delay downstream diabetes complications. Microvascular complications such as retinopathy, nephropathy, and neuropathy with associated pain and amputations affect a high proportion of adults with type 2 diabetes, and the prevalence of these microvascular complications typically increases with duration of diabetes and is exacerbated by inadequate glucose, blood pressure, and tobacco control.

However, while trials of intensive glucose and BP control have shown some benefit on onset and progression of these microvascular complications, there is little hard evidence to show an impact on rates of the end-stage microvascular complications such as blindness, end-stage renal disease (ESRD), or amputation [5–7]. Moreover, lifetime occurrence of these end-stage microvascular complications is much lower than is the lifetime risk of a fatal or nonfatal myocardial infarction or stroke in adults with type 2 diabetes [1, 2].

The occurrence of myocardial infarction and stroke in those with diabetes is about twice as high as in those without diabetes, and these major cardiovascular events account for the majority of excess deaths and excess costs attributable to type 2 diabetes [8, 9]. Thus, in measuring quality of diabetes care, it is control of risk factors for microvascular but especially macrovascular complications that should be the focus of attention. In recent years, a composite quality measure often used to assess care of adults with diabetes consists of the proportion of diabetes patients who simultaneously meet all five of these clinical measures: adequate BP control, smoking control, lipid management, glucose control, and appropriate aspirin use. Many experts argue for combining these five measures into a single "composite" measure of diabetes care quality, calculated as the proportion of diabetes patients seen at least once in 12 months in a given care system who meet all five measures (on most recent measure available): non-smoker, A1c <8%, BP <140/90 mm Hg, on a statin unless contraindications or allowed exceptions are present, and aspirin or antiplatelet use if tolerated in diabetes patients with atherosclerotic cardiovascular disease [10]. The box below describes how this composite measure can be implemented.

Explanatory Box: Implementing a Diabetes Composite Quality of Care Measure

Step I: Identify all adult patients with a diagnosis of diabetes and with two or more visits to the clinic in the last 12 months. This is the denominator.

Step II: (a) Classify each patient in the denominator as meeting or not meeting each of these five clinical goals in the past 12 months. (b) If the patient is excluded (criteria for exclusion noted below), they get credit for that clinical goal. (c) If there is no BP measure, A1c test, documentation of aspirin use, or documentation of smoking status within 12 months, they are classified as not meeting that clinical goal.

1. Most recent glycated hemoglobin (A1c) measure done within 12 months is <8%.
2. Most recent systolic BP measure within 12 months is <140 mm Hg.
3. Patient is currently prescribed a moderate- or high-dose statin. (Exclude those with documented statin intolerance and women of child-bearing age.)
4. The patient is on daily aspirin. (Exclude those with no current diagnosis of cardiovascular disease or a documented aspirin allergy or high risk of gastrointestinal bleed or on other anticoagulant.)
5. Patient is currently a non-smoker.

Step III: The patient is counted in the numerator only if they meet all five clinical goals as specified.

Step IV: Divide the numerator by the denominator to calculate the percentage of diabetes patients at the composite diabetes goal.

When this diabetes composite measure was first introduced in 2003 in Minnesota, less than 5% of adults with diabetes in the United States and other regions had all five components at goal. Since then, the proportion of diabetes patients who have all five components at goal has steadily risen to about 40% in the United States, with major variation from less than 10% to about 65% across care delivery systems, individual clinicians, and subgroups of patients.

There are several factors to consider when comparing clinicians, clinics, or delivery system performance using diabetes or other clinical quality measures. First, if the goal is to incent clinicians to improve care, it may be important to adjust the rates of control for socioeconomic or clinical characteristics of patients, if the patient mix varies greatly by care system or across clinicians, as it often does. Otherwise, clinicians who take care of low-income or less educated patients, who may be more difficult to get to clinical goals for a variety of reasons, will be penalized unfairly by the quality measures. This issue is especially important if quality measures are publicly reported or if performance on the quality measures is linked to financial compensation. The counterargument is that adjusting may lead to or reinforce a double standard of care, where lower quality of care for more challenging patient populations is implicitly accepted.

Another consideration related to the use of a composite measure of care is whether to weight the components of the composite measure equally or unequally. Are they all equally important? In the UKPDS study, more intensive glucose control over a 20-year period only extended quality-adjusted life by 90–180 days. In ACCORD and ADVANCE and the VADT trials, intensive glucose control did not extend life at all and in ACCORD led to higher mortality rates [11, 12]. On the other hand, the impact of BP control, lipid control, and tobacco control on life expectancy and major CV events is usually much greater than the impact of glucose control on these outcomes, unless glucose control is especially poor.

Thus, the relative benefit of A1C, BP, lipid, and smoking control varies across patients, and the further from goal a patient is on a given measure (such as A1c, BP, LDL, or heavy tobacco use), the greater the potential benefit will be if effective control is achieved. These considerations would favor a weighted approach to quality measures, with the weight of each component of the composite measure proportional to the potential benefit of that component. In this scenario, one must consider whether the weights should be fixed based on population data (BP, lipid, and smoking control usually confer the greatest potential benefit) or should vary based on the clinical circumstances of an individual patient (in some patients control of very high A1c may confer the most benefit). Technology to enable prioritization of treatment options for individual patients with and without diabetes has recently become available. However, the use of individualized quality of care measures, although logical and potentially useful, is complex to operationalize and therefore has not yet been widely used.

Just as there is wide variation across clinicians, medical groups, and care delivery system in composite measures of diabetes care quality, so too there is wide variation in quality of specific components of the composite measure, such as glucose, BP, lipid, tobacco control, and appropriate sue of aspirin. For example, some clinicians do a good job with glucose control than BP control. Others clinicians may do well with lipids and BP but do poorly with glucose control. There are few studies that investigate in detail at *why* some clinicians do very poorly with glucose or BP control. Variation in the health literacy, numeracy, or overall educational or poverty level of patients can certainly explain some variation in quality of diabetes care across different groups of patients. In assessing variation in quality of diabetes care across clinicians and delivery systems, credibility requires that the analysis be adjusted for differences in patient characteristics.

Another factor linked to variation in quality of diabetes care is a long delay in provider recognition or management of changing levels of glucose, BP, lipids, or other clinical parameters. Deterioration in glucose control, for example, may be due to progression of diabetes, nonadherence to medications, lapses in dietary practices, stress, occult infections, or other factors. When patients well controlled on glucose, BP, or lipids deteriorate, providers who delay investigation of the situation and fail to address underlying reasons and adjust pharmacotherapy in a timely way will, on average, have lower proportions of their diabetes patients at goal [13]. Delayed changes in treatment, often referred to as "clinical inertia," is clearly linked to poor provider performance on key measures of diabetes quality of care.

Some experts refer to measures of the proportion of a provider's diabetes patients who are at a composite goal, or in good control of glucose, BP, lipids, tobacco, weight, and use aspirin appropriately as "accountability measures," because they are often publicly reported on social media. If a provider is doing poorly on these high-level accountability measures, it may be helpful to consider a set of "diagnostic measures" related to key care processes needed to reach glucose, BP, lipid, or other clinical goals. Table 23.1 lists some selected "diagnostic measures" that can shed light not only on why a particular provider may have suboptimal "accountability" measures but also may identify provider-specific improvement strategies or learning inter-

Table 23.1 Examples of variation in percentages of PCP-specific CIOs in study-eligible patients from a larger algorithmically defined set

CIO topic	CIO description	10th	25th	50th	75th	90th	Ratio
Thiazide diuretic underuse	% of patients with uncontrolled BP and adequate renal function not on a thiazide	16.3	18.9	23.1	27.6	30.3	1.9
ACEI/ARB underuse	% of patients with uncontrolled BP who are not on ACEI/ARB use	13.7	15.5	20.0	24.7	27.9	2.0
Use of three or more BP medications	% of patients with uncontrolled BP on three or more medications	1.0	1.9	3.0	4.3	6.0	6.1
Hypertension recognition	% of patients meeting BP criteria without a problem list diagnosis	9.6	12.6	16.0	19.4	23.9	2.5
Use of moderate or high-intensity statins when indicated	% of patients meeting ACC/AHA criteria for statin use with ASCVD risk > = 10% on less than moderate intensity statin	12.6	16.3	23.7	32.3	42.9	3.4
Statin initiation when indicated	% of patients meeting ACC/AHA criteria for statin use but not on a statin	17.1	21.2	27.8	37.3	47.5	2.8
Aspirin underuse	% of patients meeting primary or secondary criteria for aspirin use but not on aspirin	7.5	9.5	13.0	18.2	22.3	3.0
Aspirin overuse	% of patients not meeting primary or secondary criteria for aspirin but on aspirin	5.0	6.3	9.5	12.3	15.9	3.2
Screening for diabetes when indicated	% of patients meeting USPSTF criteria for diabetes screening without tests in 3 years	6.5	9.2	12.6	17.0	20.3	3.1

Columns represent the percentage of patients with each CIO within PCP percentiles and a ratio of CIOs in 90th to 10th percentile PCPs

ventions to address provider-specific problems in some very specific aspects of care.

In prior work, we have observed a great deal of provider-specific variation in these "diagnostic" measures. This observed variation in patterns of care across providers suggests the potential usefulness of tailoring improvement or learning strategies to provider-specific diagnostic measures that are lower than observed in peer providers. In settings where electronic health records or other sophisticated health information technology is available, collecting such detailed data on specific patterns of care at the provider level is increasingly feasible.

When diagnostic measures can be assessed, it is important to consider the best way to use such information. Many strategies might be considered to provide feedback of this valuable information to providers or to clinic leaders, medical groups, or health-care systems. Several characteristics of such feedback are known to increase its effectiveness, such as timely feedback, providing ongoing feedback over time, including positive feedback with feedback on suboptimal performance, providing feedback to a supervisor as well as the frontline provider, providing feedback in both verbal and written forms, providing feedback that is actionable, and setting specific goals for improvement with repeat measurement to assess progress [14]. Table 23.2 provides one simple format that might be considered when giving provider's feedback on the quality of their patient care.

It is noteworthy that in the United States, quality of care as measured by A1c, BP, lipid, or tobacco control is not usually any better at endocrinology clinics or diabetes centers than it is in primary care settings. One reason for this is that difficult-to-control patients are often referred by primary care providers to specialty centers. But it is also possible that some specialty centers focus so much on glucose control that other key aspects of diabetes care, such as tobacco, BP, and lipid control, may not be addressed.

There are hundreds of "evidence-based" components of diabetes care, but not all are of equal benefit, and the strength of the supporting evidence form randomized trials varies. Thus all evidence-based aspects of diabetes care are *not* suitable for selection as quality measures. It is best to focus attention on clinical domains that have a major direct impact on important health outcomes, have affordable and available management strategies, and can be easily measured. Some readers may feel that including measures of screening for retinopathy, neuropathy, foot ulcer, or nephropathy or referral for diabetes patient education should be prominent diabetes quality measures. But in primary care, there are many diseases, and it may be wasteful of time and resources to assess too many quality measures for a single disease. Don't forget that primary care providers also may be measured on dozens of things besides diabetes care, and too high measurement burden and cost will erode the effectiveness of quality measurement as a strategy to improve care.

It is important to keep in mind that once a clinical measure is adopted as a measure of quality of diabetes care, health-care systems and accreditation organizations tend to focus on measuring and improving that particular aspect of care. In the 1990s in the United States, the first publicly reported diabetes quality measure was retinopathy screening—because in the pre-electronic medical record era, it could be accurate and inexpensively measured from insurance claim data. Delivery systems devoted resources to improving eye exam rates, rather than to improving glucose or BP control—the clinical factors that fundamentally drive retinopathy. The impact of that early quality measure was not to prevent retinopathy but to *detect* it early and treat it with lasers. Available resources were diverted away from better control of glucose and BP—two ways to *prevent* retinopathy. Thus, selection of quality measures may have unfortunate unintended consequences.

Diabetes patient education is an important component of diabetes care and should be offered to all patients periodically but has minimal impact on glucose, BP, lipid, or tobacco control in randomized trials [15]. Thus, although it is important and can decrease distress related to having diabetes, measuring diabetes patient education as a key quality measure is ill-advised. It is better to focus diabetes quality of care measures on control of clinical risk factors that directly drive adverse outcomes, such as BP, glucose, lipid, and tobacco control.

Table 23.2 Prototype content of PPF feedback to PCP and their supervisor, updated every 2 months

Selected care improvement opportunity (CIO) from a set of 30	You're doing better than this % of PCP peers	Number of patients evaluated in past 2 months	% of your patients with opportunity to improve care	
			You now	Your goal[a]
Use thiazide diuretics	8	50	38%	23%
Initiate statin treatment when indicated	11	24	35%	28%
Refer smokers to cessation programs	23	14	24%	16%
Hypertension recognition	71	61	12%	☺ Great job!
Screening for diabetes when indicated	83	33	9%	☺ Great job!
Aspirin underuse	94	17	8%	☺ Great job!

Measuring Patient Experience of Care

Diabetes is a complex chronic disease, and clinicians and public health policy makers are faced with the daunting challenge of dealing with a myriad of effects that diabetes may have on many dimensions of a person's life. In addition to its direct biological, psychological, and financial impact on patients, diabetes also may significantly impact the family, friends, employers, and health-care providers of those with diabetes. The social and economic impact of diabetes on direct medical care costs, indirect costs, and workforce productivity is substantial. A fundamental question related to measurement of diabetes quality of care is this: how wide a net do we want to cast? Can we hold the care delivery system accountable for the myriad impact of diabetes on a person's life? Should governments, employers, schools, or nursing homes be held accountable for accommodating the needs of those with diabetes?

There is increasing attention to integration of health care with social services for vulnerable persons or families, which in some cases would include individuals or families who are vulnerable due to diabetes. Diabetes may be associated with increased work absenteeism or presenteeism, decreased income, high medication costs, high health-care costs, and decreases in physical, emotional, and social function. In many communities, social services are available to provide necessary assistance with income, housing, food, safety, or health-care costs. However, integration of social services with primary health-care services is often incomplete, and better coordination of services is often needed. Creative integration of health-care services with government-sponsored or community-based services such as those available through churches or other community-based membership organizations might benefit many patients. Although integration of health-care services and social services may be beneficial for many patients with diabetes, holding clinicians or clinics responsible for delivery of integrated services may not be well accepted by clinicians, and quality measures to measure such aspects of care are yet to be developed.

On the other hand, quality measures that focus on the "patient's experience of care" are increasingly being used in some care delivery systems. The patient's experience of care can be defined to include a number of important factors such as the patient's ability to access necessary health-care services in a timely way, receive clear and comprehensible communication from providers of care, and be satisfied with the clinical care provided.

Some thought leaders have recently proposed that minimizing the burden of care imposed on the patient by their diabetes treatment is a neglected but important aspect of care. For example, treatment with insulin imposes burdens related to blood glucose monitoring, disruption of daily routines, risks of hypoglycemia, and (in some care systems) high out-of-pocket costs for insulin and its delivery equipment. Minimizing the patient's burden of care may improve treatment adherence, participation in timely follow-up care, and perhaps psychological adjustment to diabetes, as well as reduce patient stress [16, 17]. For these reasons, some experts suggest that measuring burden of care is justified and that development of strategies to reduce burden may improve care and adherence and lead to better long-term clinical outcomes [18].

Other important aspects of patient experience of care include patient-centered care and shared decision-making [19]. It is clear that not all evidence-based recommendations are of equal benefit to a given patient at a given point in time. There is strong evidence, for example, that glucose goals should be individualized based on clinical considerations such as risk of hypoglycemia, comorbidity, and age [20–22]. However, quality measurement is complicated by the need to assess patient-specific clinical goals. One possible solution to this problem is to set clinical goals on quality measure that are more generalizable, such as an A1c goal of <8% rather than A1c <7%, to accommodate patient-specific variation in clinical goals.

Shared decision-making is an intrinsic and necessary part of primary care but is too often neglected. One study found that primary care clinicians provided basic information on newly prescribed medications—the name of the medication, its purpose, frequency of dosing, duration of use, and benefits and side effects—only about 20% of the time [23]. This lack of basic information can lead to low adherence to important medications and has been linked to higher mortality rates in some studies [24]. Shared decision-making, however, goes beyond providing such basic information. Shared decision-making involves eliciting a patient's interest in a particular clinical action and co-selection of specific treatments from a menu of available evidence-based choices [25]. When a change in treatment is indicated, the patient should be informed in an honest and comprehensible way of both the benefits and the risks, costs, and burden of the various treatment options.

It is of particular concern that many clinicians (and patients) overestimate, often by an order of magnitude, what the benefits of treatment are. This may be especially true when estimating the benefits of intensive glucose control. For example, in the UKPDS, intensive glucose treatment for about 18 years led to an additional 90–180 days of quality-adjusted life [26]. In the ACCORD randomized trial, intensive glucose control actually increased death rates 18–20% [11, 27]. How many patients, with this information in mind, would opt for intensive glucose treatment? Moreover, depending on their clinical state, many diabetes patients might benefit much more from smoking cessation, BP control, or lipid control, compared to modest improvements in glucose control, especially when A1c is already <8%. The

use of Web-based decision support algorithms and risk equations can be used to accurately estimate and compare the benefits of various evidence-based treatment options [28]. Observing and understanding the treatment preferences of well-informed patients can, in turn, improve our understanding of what factors influence patient treatment preferences, to improve approaches to shared decision-making.

The resources required to systematically assess patients' experience of care are typically much greater than the resources required to measure control of glucose, BP, lipids, and tobacco. Collecting patient-reported information on experience of care, patient-centered care, or shared decision-making may require surveys, conversations, electronic communication, and analysis of verbal or questionnaire data. This can be quite time-consuming and expensive. Although representative random sampling of patients may reduce the resources required for such measures, accuracy may be compromised if sampling is done in a biased way, the response rates are too low, or the sample size is insufficient to draw reliable conclusions.

Nonetheless, there are a number of survey instruments that have been reasonably well validated to measure patients' experience of care, diabetes distress (Problem Areas in Diabetes/PAID), patient-centered care, shared decision-making, and self-efficacy (Diabetes Empowerment Scale/DES); some of these are available in validated Spanish versions [15, 29, 30].

Measuring Affordability and Cost-Effectiveness of Diabetes Care

There are several studies that document that health-care costs of those with diabetes are at least double what the health-care costs are of age- and sex-matched patients without diabetes [8]. The higher costs are driven by several factors, including higher pharmaceutical and equipment costs, more outpatient visits, and more frequent and longer hospitalizations [31]. The length of hospitalization of a wide range of admitting diagnoses is longer in those with diabetes. From the clinical point of view, the major driver of excess, potentially avoidable costs include myocardial infarction, stroke, peripheral arterial disease, end-stage renal disease, and amputation.

Although cost of care is generally higher for those with diabetes, a number of studies indicate that there is wide variation in costs of care not only across nations but also across care delivery systems. This has led many experts to speculate that more attention should be devoted to identifying optimal "care pathways" that combine clinical success with low costs. For example, suppose a patient requires two glucose-lowering agents to achieve their evidence-based glucose goal. The cost to the care delivery system (insurer) for various combinations of effective glucose-lowering medications may vary as much as tenfold depending what medications are selected. Moreover, the out-of-pocket cost to the patient may range from nothing in some systems to substantial in other scenarios. There would seem to be little reason to use more expensive medications, yet clinical guideline recommendations are often authored by clinicians or professional organizations with financial ties to pharmaceutical or device manufacturing corporations that attempt to influence the content of clinical guidelines. In the United States, a recent report emphasizes that these obvious conflicts of interest undermine the credibility of many clinical guidelines. Authors of clinical guidelines are now often required to declare or divest certain financial ties with industry as a condition of guideline authorship [32].

Insulin acquisition costs are another example of variability in cost to the delivery system and in some cases to patients. Recent analysis indicates a 6-fold to 10-fold variation in insulin costs in the United States based on type of insulin (human versus analog) and delivery system (vial versus cartridges). Thus, judicious use of analog insulins, perhaps reserving them for patients at high risk of serious hypoglycemia, could be a policy that substantially lowers costs [33].

The analysis of cost-effectiveness in diabetes care is even more complicated. The threshold of costs per quality-adjusted life year (QALY) that purchasers are willing to pay varies substantially by country, by payer, and by year. The cost of complications such as an amputation or myocardial infarction also varies greatly across nations and across delivery systems within nations. Moreover, pharmaceutical corporations may agree to very different acquisition costs for a given medication in different countries, and within some countries, in different delivery systems. All these factors complicate efforts to accurately estimate cost-effectiveness of diabetes care across time, nations, and delivery systems.

Despite challenges, it is instructive for delivery systems to estimate cost per QALY gained, for various treatment pathways (human versus analog insulin, vials versus per insulin delivery systems, expensive versus less expensive non-insulin glucose-lowering drugs, various scenarios for lipid-lowering treatment strategies, optimal visit intervals, etc.). Doing so, and using these data to identify optimal treatment pathways for various groups of diabetes patients, and to aggressively negotiate drug acquisition costs with suppliers, may well reduce the cost and improve the cost-effectiveness of diabetes care in defined groups of patients.

The recent demonstration that, in addition to metformin, both GLP-1 agonists and SGLT-9 inhibitors may significantly reduce major CV events, CV mortality, and overall mortality will complicate efforts to assess optimal treatment pathways from the cost and cost-effectiveness point of view. The cost-effectiveness of these new medication classes will be driven both by their clinical benefits and by their acquisi-

tion costs. Also important to consider are cost-sharing arrangements with patients, whose ability to bear various levels of out-of-pocket costs typically varies widely by income.

An additional consideration for cost-effectiveness is whether adequate glycemic control can be achieved at the population level with usual care pathways or whether more intensive interventions are needed to achieve glycemic control and control of other clinical risk factors including BP and LDL for a substantive fraction of patients. Intensive interventions that can be implemented at the population level can range from intensive, individual level interventions such as nurse case management combined with peer-led, collaborative diabetes education and self-management training, to Web-based clinical decision support delivered through the electronic health record. Diabetes case management is more expensive at the individual level but has been shown to produce more significant improvements in clinical risk factors including A1c [34]. Clinical decision support requires a substantial initial investment but that can be spread over a large population resulting in low individual level costs, although with smaller clinical effects [35]. These two interventions have been shown to be similarly cost-effective and can be used in a coordinated way.

Finally, it is important to note that the cost-effectiveness of type 2 diabetes prevention has been thoroughly studied, and in most scenarios is cost-saving, whether accomplished via lifestyle change programs or by using medications such as metformin [36]. Very few things in health care are cost-saving, so investments in type 2 diabetes prevention programs are increasingly recognized as a good investment by various private and public care delivery systems.

Summary

Measurement of quality of diabetes care can identify important gaps in clinical care, enable mapping of variation in quality of care across clinicians and delivery systems, and provide useful information needed to guide effective and efficient efforts to improve care. A wide range of measures of diabetes quality of care are available for consideration. Selection of a parsimonious set of measures that are causally related to key clinical outcomes, patient's experience of care, and cost of care may be considered. However, the resources needed for quality measures can be considerable and may vary from relatively low cost for measures that can be extracted from electronic clinical databases to relatively high cost for patient-reported data. Technical issues related to measuring quality of care, public reporting of quality measures, and strategic use of cost and cost-effectiveness measures to help optimize delivery of care to patients and improve clinical outcomes are important considerations.

Concluding Remarks

- Providing measures of diabetes quality of care to clinicians and to the public has been linked to improved quality of diabetes care in many settings.
- Clinicians and care systems often direct available resources to improve what is measured, so selecting measures of care that are directly and strongly linked to major outcomes is imperative.
- Recent data indicate wide variation in quality of care across clinicians after adjustment for patient factors. This information can be used to guide clinician-specific learning interventions.
- In settings with high-quality diabetes care, there is as much as 300% variation in costs. Thus, identifying maximally cost-effective treatment pathways is a topic of interest.
- Improving patient experience of care and minimizing treatment burden may improve adherence, continuity of care, and clinical outcomes.

Multiple-Choice Questions

1. Clinical measures that are causally related to major microvascular and macrovascular diabetes complications are often selected for clinical quality of care measures. Such clinical measures might include all of the following except:
   (a) Aspirin use
   (b) Cholesterol control
   (c) Blood pressure control
   (d) Annual diabetes patient education
   (e) Glucose control
   (f) Nonuse of tobacco

   Comment: Diabetes patient education is important but has only a marginal impact on glucose, BP, lipid, or tobacco control and is not casually related to lower rates of major diabetes complications. Thus, the other aspects of care are more suitable for diabetes clinical quality measures.
2. Regarding the cost-effectiveness of electronic health record (EHR)-linked clinical decision support and diabetes case management, which of the following statements is false:
   (a) Case management is much more expensive on a per-patient basis.
   (b) Over the long run, clinical decision support may be cost-saving.
   (c) They are about equally cost-effective.
   (d) Most patients resist active case management as an invasion of privacy.

(e) Clinical decision support has high initial implementation costs.

Comment: In many studies of diabetes case management, about 2/3 of patients engage in the case management process.

3. Reasons to measure quality of diabetes care at the clinician level include all of the following except:
   (a) There is significant variation in patterns of care at the clinician level.
   (b) It is often difficult to link individual patients to a single responsible clinician.
   (c) Many clinicians like to know how they are doing compared to their peers.
   (d) Such information can guide clinician-specific learning interventions.
   (e) Electronic data make this easier to do than in the past.

   Comment: Well over 90% of patients can be linked to a usual primary care clinician in most health-care systems, based on frequency of visits with various clinicians and/or patient designation of a usual primary care clinician in electronic health record systems.
4. Which one of the following statements about the relationship of outpatient cost of diabetes care to outpatient quality of diabetes care is false:
   (a) Quality of care is not related to cost of care at the clinic level.
   (b) High-quality care costs more.
   (c) Low-quality care can be as expensive as high-quality care.
   (d) Cost of care is important both to the patient and the care delivery system.
   (e) Costs of care vary widely across patients with diabetes.

   Comment: There is abundant evidence that there is not a strong association of outpatient costs of diabetes care and quality of outpatient diabetes care.

Correct Answers

1. (d) Annual diabetes patient education
2. (d) Most patients resist active case management as an invasion of privacy
3. (b) It is often difficult to link individual patients to a single responsible clinician
4. (b) High-quality care costs more

Clinical Inertia: The Role of Physicians in Diabetes Outcomes

23

Joel Rodriguez-Saldana

Introduction

Healthcare delivery is not the only possible influence on diabetes control [1]. Patients and physicians factors and organization and process of care interact by need and determine the outcomes. Clinical inertia and patient adherence are two main deterrents of the effectiveness in patient-provider encounters. Awareness, prevention, and tailored interventions to reduce their impact are essential to achieve the goals and improve the quality of diabetes management.

Clinical Inertia

Resistance to accept and implement effective innovations has always been characteristic of every human endeavor, and the history of medicine provides many illustrative examples of evidence-based interventions that had to wait years or decades before acceptance by practitioners. A major challenge of healthcare is to increase the uptake of evidence-based medicine in "the real world," i.e., knowledge translation, "the process of taking evidence from research and applying it in clinical practice [2]." Unfortunately, the history of medicine is plagued by multiple examples about the difficulties and delays to introduce evidence into this "real world" [2]. One of the main goals of clinical practice guidelines (CPG) is to accelerate the introduction of medical innovations, but implementation and compliance by physicians are still limited, disregarded, and challenged, and clinical inertia is one of the main causes.

Definitions and Evolution

Clinical inertia as an entity was recently described, albeit examples of noncompliance with clinical guidelines or failure to intensify medical treatment have been recognized many years ago. In 1998, for example, Frolkis and colleagues published the results of a chart review of 225 patients admitted to a coronary care unit, in which they showed that despite the wide availability of guidelines for the detection, evaluation, and treatment of hyperlipidemia and the results of major clinical trials of primary and secondary prevention of coronary heart disease, physicians were poorly compliant, even in patients at high risk [3]. Implementation of clinical guidelines, putting evidence-based medicine at work, is still far from accomplished [3–5], and its challenges are addressed in Chap. 26.

Origins and Definition

The term clinical inertia was coined by Cook and colleagues in 1999 to describe the effectiveness of a structured program to improve glycemic control and the importance of self-examination of performance to overcome clinical inertia in 698 African-American patients with type 2 diabetes [6]. Recognizing the importance of clinical inertia, the authors of this study established and measured a quality improvement program with increased emphasis on intensification of therapy, along with perceived barriers to advance treatment [6]. Two years later, this group of physicians authored the landmark review about clinical inertia, which they defined as the inability of physicians to achieve the goals of treatment after repeated visits, or as "the recognition of the problem but failure to act" or, more specifically, as the "failure of healthcare providers to initiate or intensify therapy when indicated" [7]. Recent definitions describe clinical inertia as "an office visit at which no therapeutic move was made (to achieve the goals of treatment) [8]" or as "failure to treat to target or prescribing that is not concordant with clinical

J. Rodriguez-Saldana (ed.), *The Diabetes Textbook*, https://doi.org/10.1007/978-3-030-11815-0_23

guidelines [9]," with the additional claim that clinical inertia could be "a clinical safeguard for the drug-intensive style of medicine fueled by current medical literature and pharmaceutical companies [9]," in the best benefit of patients to adopt less aggressive and also less risky and costly approaches [9]. Conversely, Fraenkel et al. defined clinical inertia as "the preference to maintain the status quo, a barrier to implement treat to target protocols in patients with chronic diseases [10]."

Initially and mostly described in the treatment of diabetes, the influence of clinical inertia on the negative results of patient management is increasingly documented in the treatment of other chronic diseases, including hypertension [11–16], dyslipidemia [17, 18], depression [19], osteoporosis [20], hepatic encephalopathy [21], geriatrics [22, 23], kidney transplantation [24], chronic valvular heart disease [25], dentistry [26], osteoarthritis [27], and chronic obstructive pulmonary disease [28].

Clinical Inertia in Diabetes

Clinical inertia has been described largely in diabetes outpatient management, but in recent years, it has also been reported in hospitalized patients. Table 23.1 presents a summary of studies published from 1999 until 2018 by a PubMed search under the terms clinical inertia and diabetes and additional studies about failure to intensify diabetes therapy.

Table 23.1 Studies about clinical inertia and diabetes

Year	Country and reference	Patients	Type of study	Results
1999	USA [6]	698 African-American patients with type 2 diabetes	Self-evaluation, proportion of patients in whom therapy was intensified and perceived provided barriers to advance treatment	Average reduction in HbA1c of 1.4%; progressive improvement in the percentage of patients achieving HbA1c targets; 57% at goal in 5 years
2000	USA [29]	4523 patients with HbA1c results, 2892 with at least one follow-up test	Assessment of diabetes care using pharmacy and laboratory data between nine medical groups to determine dispensing patterns and changes of therapy based on HbA1c results	Despite having HbA1c levels above 8.0%, most patients had no changes in therapy Inadequate follow-up was documented in more than 60% of patients The effect of changes in therapy on subsequent HbA1c results could not be assessed
2003	USA [30]	570 patients with type 2 diabetes receiving metformin as additional therapy to sulfonylureas	Retrospective observational study Pace and patterns of therapeutic failure and clinical responses	HbA1c levels inexorably rise before clinicians respond: patients spent months at HbA1c levels above 8.0%, and glucose lowering actions were only established when HbA1c levels were 9.0% or higher Hyperglycemic peaks preceded changes in therapy
2004	USA [31]	7208 complete courses of non-pharmacologic or oral antidiabetics	Retrospective observational study Mean cumulative glycemic burden: months at HbA1c levels above 8.0% or below 7.0%	The average patient accumulated nearly 5 years of excess glycemic burden above 8.0% from diagnosis until starting insulin and 10 years of excess glycemic burden above 7.0%
2004	USA [32]	598 adults with type 2 diabetes receiving primary care in an academic medical center	Prospective observational study Failure to achieve treatment goals for HbA1c, systolic blood pressure (SBP), or low-density cholesterol (LDL) during 1 year	Delays were documented for every treatment goal: 51% of patients with elevated HbA1c, 30% of patients with high SBP, and 30% of patients with high LDL had increases in regimes After 1 year, a decline in the proportion of patients above goal for LDL was observed, but not for HbA1c or blood pressure
2005	USA [33]	1765 adult patients with type 1 or type 2 diabetes from 27 primary care and 17 diabetes/endocrinology clinics	Retrospective observational study Measurement and control of HbA1c, blood pressure, cholesterol, and corresponding medical regimen changes	Annual testing rates for HbA1c, for blood pressure, and for total cholesterol were high (97.7%, 96.6%, and 87.6%, respectively) Patients at goal for HbA1c were 34.0%, for blood pressure were 33.0% and for lipoprotein profile were 65.1% for total cholesterol and 46.1% for LDL cholesterol Only 10% of the patients met the recommended goals for all three risk factors Lack of intensification was equal for patients with type 1 and type 2 diabetes

Table 23.1 (continued)

Year	Country and reference	Patients	Type of study	Results
2005	Canada [34]	591 patients receiving specialist care and 1911 receiving primary care	Retrospective observational study Differences in clinical inertia between specialists and primary care physicians	45.1% of patients receiving specialist care versus 37.4% of patients primary care had drug intensifications ($P = 0.009$), attributed to more frequent use of insulin among specialists Clinical inertia was highly prevalent in both groups
2005	USA [35]	23,291 patients with diabetes from 13 Department of Veterans Affairs hospitals	Retrospective observational study To develop a valid quality measure to identify clinical inertia and its consequences on glycemic control	Despite 39% of patients having an initial HbA1c level above 8.0%, increases of antidiabetic medications occurred at only 9.8% of visits Patients receiving more intensive therapy had greater improvements in control
2005	USA [36]	438 African-American patients in primary care and 2157 patients from a specialty supervised clinic by endocrinologists	Longitudinal observational study	Average A1c in the medical clinic was 8.6%, in the diabetes clinic 7.7% ($P < 0.0001$) Lower number of drugs and rates of intensification occurred in the medical clinic, but intensification at both sites was associated with improvements in A1c Patients from the medical clinic had worse glycemic control and were less likely to use insulin and to have their therapy intensified if glucose levels were above the target
2006	Australia [37]	531 patients with type 2 diabetes from an urban clinic	Longitudinal observational study who attended a baseline assessment and five annual follow-up visits Assess the effectiveness of management of type 2 diabetes	After a median duration of 4.0 years and 8.1 years, 18% of patients progressed from diet to oral antidiabetics (OAD) 9% progressed from OAD to insulin, respectively Median HbA1c levels to start OAD or insulin were 7.7% and 9.4%
2006	USA [38]	345 residents of internal medicine residents receiving computerized reminders about patient-specific recommendations and/or feedback on performance or participate as controls	Behaviors when glucose was above 150 mg/dl were classified as "did nothing," "did anything," or "did enough" to describe clinical inertia or two levels of intensification	At baseline, residents "did nothing" in 65% of the visits and "did anything" or "did enough" in 35% of visits After 3 years, 52% "did anything" and 30% "did enough" Active interventions were followed by significant increases in trends to intensify therapy during visits Healthcare behavior improved more in the feedback intervention groups than in control groups Improvements were greatest during the first year and then decreased
2006	USA [39]	Random sample of 5% of 1812 hospital records with a discharge diagnosis of hyperglycemia	Magnitude of clinical inertia in the hospital management of diabetes	Albeit a diagnosis of diabetes was recorded in 96% of patients at admission; daily notes mentioned diabetes in 62% of cases and 60% of discharge notes; 20% of discharges included diabetes follow-up 86% of patients had bedside glucose measurements, but only 52% had documented the assessment of glucose severity Despite a high frequency of hyperglycemia (71%), only 34% of patients had changes in therapy
2006	USA [40]	253,238 patients with hypertension, dyslipidemia, and diabetes	Retrospective observational study	64% of patients experienced modifications for poorly controlled systolic blood pressure, 71% for poorly controlled diastolic blood pressure, 56% for poorly controlled LDL cholesterol, and 66% for poorly controlled A1c Intensification included increases in the number of drug classes and increased dosage 3–4% of patients with high A1c values achieved control without therapy modification Patients preferences and adherence were not measured

(continued)

Table 23.1 (continued)

Year	Country and reference	Patients	Type of study	Results
2007	USA [41]	2065 patients with type 2 diabetes newly started on antidiabetics and followed 3 or more years	Prospective observational study Relationship between initial medication adherence and regimen intensification	Baseline medication adherence: 79.8 ± 19.3% By comparison to patients in the highest quartile of adherence, patients in the lowest quartile were significantly less likely to have increases in regime within 1 year of their first elevated A1c Patients in the highest adherence quartile had 53% greatest odd of medication intensification
2007	USA [42]	211 primary care encounters, patients with type 2 diabetes	Cross-sectional observational study Competition of competing demands to changes in antidiabetic medications Return appointment intervals in patients with high HbA1c levels	Each additional patient concern was associated with a 49% reduction in the likelihood of a change in medication, independent of the length of the encounter and the most recent level of HbA1c For each additional increase in HbA1c, the time to the next scheduled appointment decreased 8.6 days The complex of clinical inertia is limited and does not fully characterize the complexity of primary care encounters
2008	USA [43]	254 patients with type 2 diabetes	Prospective observational study Visit-based factors associated with intensification of antihypertensive medications in adults with diabetes	Primary care providers intensified antihypertensive treatment in only 13% of visits at which blood pressure was elevated Higher systolic and diastolic blood pressures were important predictors of intensification Factors associated with failure to intensify treatment include capillary glucose >150 mg/dl, coronary heart disease, or co-management by a cardiologist
2008	USA [44]	105 patients with diabetes hospitalized for cardiothoracic surgery	Retrospective observational study Barriers preventing appropriate glycemic control in an academic center	Only six patients (5.7%) had adequate glucose control, 99 (94.3%) required intervention, 30 barriers to achieve glycemic control were identified, including "therapeutic reluctance," inappropriate titration of medication, lack of basal insulin, lack of weekend staff trained in diabetes management, use of a sliding scale, prescription of inappropriate medications, knowledge deficits of the weekend staff, and omission to restart outpatient diabetes medications
2009	USA [45]	1718 patients discharged from 37 academic medical centers	Retrospective observational study Evaluation of contemporary management of hyperglycemia: assessment of clinical and laboratory data, glucose measurements on 3 consecutive days, glycemic therapy	Wide variations in hospital performance of recommended hospital diabetes care were recorded, including A1c and glucose measurement Median glucose was significantly lower for patients in the intensive care unit compared to other areas On day 3, only 25% of patients had 6:00 AM glucose ≤110 mg/dl 50% of patients had ≥1 glucose measurement ≥180 mg/dl on days 2 and 3 and severe hypoglycemia occurred in 2.8% of all patient days
2009	Netherlands [46]	1283 patients from 30 general practices	Baseline and follow-up data of a randomized controlled trial on the implementation of a locally adapted diabetes guideline	In the intervention and control groups, the percentage of patients with poor diabetes or lipid control who did not receive treatment intensification were 45% and 90%, respectively Clinical inertia was higher in patients above the target in blood pressure (72.7% versus 63.3%) Clinical inertia was less common when nurses participated in the management In both study groups, cholesterol decreased significantly more in patients receiving treatment intensification

Table 23.1 (continued)

Year	Country and reference	Patients	Type of study	Results
2010	Canada [47]	379 type 2 diabetic patients treated with insulin with and without oral antidiabetics	Survey of 109 family physicians including knowledge of the Canadian Diabetes Association HbA1c target levels and perceived barriers to insulin initiation and intensification	Mean time from diagnosis of diabetes to insulin initiation was 9.2 years Mean HbA1c values before insulin initiation were 9.5% and 8.1% at visit 2, and 7.9% at visit 3 At visit 3, 20% of patients continued to have HbA1c above 9.0%
2011	USA [48]	10,743 patients with newly diagnosed type 2 diabetes from an electronic medical record database	Retrospective observational study	Older patients had higher baseline HbA1c values At 2-year follow-up, 59% of younger patients received oral antidiabetics (OAD) compared with 44% in older patients The median time between diagnosis and start treatment with OAD was 350 days for younger patients and more than 2 years for older patients
2012	France [49]	17,493 patients with type 2 diabetes receiving oral antidiabetics	Retrospective observational study Current procedures to intensify hypoglycemic treatment in general practice according with clinical guidelines	18% of patients required treatment intensification Treatment was intensified after the second HbA1c in 39% of patients, immediately in 13%, within 6 months in 39% and within 1 year in 59% Treatment intensification was less likely in older patients and more likely at higher HbA1c levels
2012	USA [50]	1359 patients from a Veterans Affairs hospital	Retrospective observational study Effect of hospital admission on the medical treatment of poorly controlled diabetes	Of 2015 admissions, 454 had some change in diabetes medications at discharge (22.4%) Higher preadmission HbA1c levels, higher mean glucose at admission, inpatient hypoglycemia and use of insulin were associated with greater odds of change in therapy Clinical inertia occurred in 656 admissions (32%), with no change of therapy, no documentation of HbA1c 2 months after discharge, and no follow-up appointment within 1 month of discharge
2012	USA [51]	770 patients with type 2 diabetes	Survey of 508 primary care physicians by Internet Relevant clinical information and reasons about the absence of treatment of older patients	Reasons to omit pharmacologic treatment included the use of diet and exercise (57.5%), mild hyperglycemia (23.8%), patient's concerns (13.4%), specific concerns about antidiabetics (3.0%), comorbidities and polypharmacy (2.3%)
2012	USA [52]	83 primary care physicians	Cross-sectional study Structured interviews Providers perceptions about the importance to initiate insulin therapy, factors, and barriers affecting this decision	Eighty percent of PCPs endorsed glycemic targets 54% individualized targets based on age, life expectancy, comorbidities, self-management capacity, and willingness 64% reported that patients were resistant to new oral or insulin therapies because of fears about them 80% cited patients' nonadherence would dissuade them from initiating insulin 64% cited patients' resistance as a barrier to initiate insulin 43% cited problems of patient self-management
2013	Spain [53]	2783 patients with type 2 diabetes from primary care centers	Cross-sectional observational study	Thirty-five of patients had HbA1c levels above 7.0% Intensification of therapy occurred in 66.8%, including increase in dose (40.5%), addition of oral antidiabetics (45.8%), addition of insulin (3.7%) Clinical inertia was established in 33.2% of patients and diminished along with complexity of therapy and with HbA1c increase For each unit of HbA1c increase, clinical inertia decreased 47%

(continued)

Table 23.1 (continued)

Year	Country and reference	Patients	Type of study	Results
2013	UK [54]	81,573 patients with type 2 diabetes from a national database	Retrospective observational study Time to treatment intensification in patients receiving one, two, or three oral antidiabetics (OADs) and associated levels of glycemic control	Median time from HbA1c above goals (≥7.0, ≥7.5, or ≥8.0%) to intensification with an additional OAD was 2.9, 1.9, or 1.6 years, respectively, for those taking one OAD, and >7.2, >7.2, and >6.9 years for those taking one, two, or three OADs Mean HbA1c at intensification with another OAD or insulin for patients taking one, two, or three OADs was 8.7, 9.1, and 9.7% The probability of intensification in patients with poor glycemic control taking one, two, or three OADs at the end of follow-up with another OAD was 21.1–43.6% and with insulin 5.1–12.0%
2014	UK, Spain, Brazil, India, Japan, USA [55]	652 patients with type 2 diabetes and 337 physicians	Cross-sectional study; 20-minute online survey Opinions related to clinical inertia from patients and physicians perspectives Correlate perceptions and expectations about diagnosis, treatment, diabetes complications, and therapeutic escalation	Important discrepancies were uncovered in terms of patient and physician perceptions Physicians have low expectations for their patients Patients have at best, a rudimentary understanding of the risks of complications and the importance of control Only 25% reported to be worried about developing diabetes complications; the rest were either not concerned or thought the risk was remote A small proportion believe that lifestyle changes are important; only 37% acknowledge that this is a treatment modality The majority do not intend to adhere Impairments in communication are at the heart of clinical inertia
2014	Bahrain [56]	334 patients from a diabetes outpatient clinic	Retrospective observational study Association between clinical inertia with simpler interventions and outcomes	Treatment intensification was greater for raised HbA1c than for high blood pressure or LDL Clinical inertia for hyperglycemia, 29%; hypertension, 68%; high LDL, 80% Omission to increase oral antidiabetics or insulin occurred in 29% of medical visits Omission to increase antihypertensives occurred in 67.5% of medical visits Omission to increase lipid-lowering therapy occurred in 79.7% of medical visits Clinical inertia is greater in blood pressure and lipid management than in control of hyperglycemia
2014	Spain [57]	2971 patients with type 2 diabetes, 1416 controlled (A1c <7.0%) and 1555 not controlled (A1c ≥7.0%)	Retrospective, cross-sectional observational study	Prevalence of partial clinical inertia (PCI) in some medical visits was 52.5% Prevalence of total clinical inertia (TCI), the absence of intensification of therapy in all visits despite A1c ≥7.0% was 12.8% PCI was lower in patients controlled and associated with sedentary lifestyle, hypertension, and a higher prevalence of vascular complications
2015	UK [58]	20 healthcare providers in general practice	Interviews with 20 providers, 19 physicians, and 1 nurse 10 providers worked in general practices with high scores for quality and outcomes framework (QOF) targets and 10 with personnel from lower scoring practices	Most of the interviewed were unaware of the term "clinical inertia" or unclear about its meaning Interviewees from both lower and higher scoring practices were willing to acknowledge limitations in achievements related to glycemic control and a degree of responsibility Participants had inaccurate perceptions about levels of achievement in their primary care centers and sought to lessen their own accountability by highlighting patient and system barriers Addressing clinical inertia was not seen straightforward, as result of a complex and cumulative pattern of barriers at the provider, patient, and system level

Table 23.1 (continued)

Year	Country and reference	Patients	Type of study	Results
2015	Croatia [59]	10,275 patients with diabetes	National, cross-sectional, observational study Rate of clinical inertia to treat diabetes in primary care and association of patient, physician, and health setting factors	Clinical inertia occurred in 57.7% of clinical encounters Mean clinical inertia by practitioner was 55.6%; 9% were clinically inert with all patients Clinical inertia was associated with increases in HbA1c Univariate Patient and physician characteristics associated with clinical inertia: fasting blood glucose, hypertension, high triglycerides, unhealthy dietary habits, chronic comorbidities, number of patients under care, number of daily medical visits, initiation of oral antidiabetics HbA1c levels had the highest association with clinical inertia; patients with worse glycemic control were more likely to experience it
2015	USA [60]	75,000 patients with type 2 diabetes from a managed care claims database (IMPACT©)	Prevalence and predictors of clinical inertia based on personalized goals Three HbA1c targets were used to identify patients who experienced above targets during the index period; clinical inertia was defined as no intensification of treatment during the response period	Regardless of HbA1c target, 70% of the patients experienced clinical inertia over 6 months and remained above 50% up to 3.5 years later Time to intensification by addition of an oral antidiabetic, insulin, or a GLP-1 receptor agonist ranged from 50.5 to 59.0 days at 6 months and from 702 to 738 days at follow-up During the first 6 months, 20% of patients were prescribed an oral antidiabetic, 5.3% received insulin, and 2.0 a GLP-1 analog Predictors of intensification: point of service insurance, mental illness, a visit to an endocrinologist, or higher HbA1c level Intensification was less likely in older patients, patients taking more than one antidiabetic during 6 months or recent HbA1c measurement above target Prevalence of clinical inertia has increased in the managed care setting in the USA
2016	UK [61]	11,696 patients with type 2 diabetes from a clinical practice research database	Retrospective observational study Prevalence of clinical inertia in patients treated with basal insulin	Basal insulin was started in all patients at a mean ± SD HbA1c of 9.7 ± 2.0% 80.3% of patients were receiving ≥2 oral antidiabetics at the start of insulin 36.5% had intensification of treatment Median time to intensification was 3.7 years Delay to intensify was associated with increasing age, duration of diabetes, and use of oral antidiabetics, and Charlson comorbidity index score 32.1% of patients with HbA1c ≥7.5% suspended basal insulin
2016	Finland [62]	1075 adult patients with type 1 diabetes from a regional electronic patient database and medical records	Retrospective observational study To investigate if the targets established in the guidelines for patients with type 1 diabetes are achieved in medical practice	Despite one of the highest worldwide prevalences of type 1 diabetes (0.8%), only 19% of patients reached a HbA1c target of <7.0%, and 45% had LDL levels below 100 mg/dl Overall, 13–16% of patients younger than 60 and 26% of patients older than 60 years achieved targets of glycemic control
2016	Thailand [63]	98 patients with type 2 diabetes and mean HbA1c 10.3%	Retrospective observational study Effects of clinical inertia on glycemic control and diabetes-related complications	Prevalence of clinical inertia: 68.4% Mean decrease in HbA1c in the clinical inertia group was 0.82 ± 1.5% and 3.02 ± 1.8% in the non-inertia group at 6 months and 1.46 ± 1.85% and 3.04 ± 1.76% after 4 years Clinical inertia was associated with a shorter median time to progression and a higher incidence of diabetic retinopathy Adjusted incidence rate ratio of diabetic retinopathy in the clinical inertia group: 4.92

(continued)

Table 23.1 (continued)

Year	Country and reference	Patients	Type of study	Results
2017	Belgium [64]	578 insulin-naive patients with type 2 diabetes	Retrospective cohort study, 8-year analysis, 1.2-year follow-up Clinical inertia defined as equivalent to prolonged inaction (PI): no change in treatment with an A1c level >7.0% for a minimum 12 months	Prevalence of clinical inertia or PI, 59% Associated factors: Moderate to severe chronic kidney disease (CKD) Less frequent A1c measurement Lower A1c values Smaller number of additional medications Physicians lag behind clinical guidelines: the "real trigger for action is not an A1c level of 7.0%; intensification occurs above 7.0% or even at 8.0% Except for CKD, severe comorbidity does not impede adjustment in hypoglycemic treatment Intensive follow-up at the process level is associated with intensive treatment adjustments
2018	France [65]	6045 patients ≥18 years with type 2 diabetes either simultaneously or sequentially treated with two OADs, GLP-1 receptor agonists or basal insulin	Retrospective analysis of a database of commercial claims Clinical and economic outcomes among patients with uncontrolled T2D initiating two OADs, GLP-1 agonists or basal insulin One-year follow-up	Despite A1c lowering following treatment initiation, many patients do not achieve A1c goals <7.0% The percentage of patients with A1c >7.0% 4 years after initiation of a new class of antihyperglycemic medication ranged from 48% with OADs to 74% in patients initiating basal insulin Baseline A1c was highest in patients receiving basal insulin as second drug (10.1%) At the last available follow-up measurement, 47.5% of patients initiatinged OADs, 41.1% of patients initiatinged GLP-1 agonists, and 32.6% of patients initiating basal insulin had A1c levels <7.0%
2018	USA [66]	7389 patients with type 2 diabetes and an A1c value ≥7.0% despite being on a stable regimen of two OADs for at least 6 months	Retrospective analysis of an electronic health record system	62.9% of patients had no evidence of treatment intensification, including 71.7% of patients with A1c 7.0%–7.9%, 53.3% of patients with A1c 8.0–8.9% and 44.4% of patients with A1c ≥9.0% Physicians do not respond quickly enough to evidence of poor glycemic control, even in those with A1c levels far exceeding typical treatment targets

These studies confirm the magnitude, negative consequences, and benefits of interventions to reduce the effect of clinical inertia in diabetes management. The following conclusions can be achieved:

1. The prevalence of clinical inertia for all diabetes goals is very high: 33–70% for HbA1, 30% for hypertension, and 30% for LDL cholesterol.
2. The glucocentric approach prevails: treatment intensification is more likely for high HbA1c than for hypertension or high LDL cholesterol levels.
3. Lack of glycemic control at every clinical setting: outpatient, inpatient, medical and surgical, and low levels of physicians' awareness.
4. Slow response of clinicians to clinical inertia at HbA1c levels of high risk: up to 5 years of excess glycemic burden.
5. Low (less than 10.0%) and slow (up to 5 years) rates of treatment intensification.
6. Low and slow rates of initiation for every therapeutic modality, with insulin at the top (9.2 years).
7. Wide variations in hospital diabetes outcomes: high rates of hyperglycemia (64%) and persistent hyperglycemia in 50% of patients and low rates of diabetes follow-up after hospital discharge (20–22%).
8. Association with low patient adherence, diet and exercise, disregard of glycemia, patient concerns, comorbidity, and polypharmacy.
9. Equally low levels of patients at goal for HbA1c, blood pressure, and lipoprotein levels in type 1 (19%) and type 2 diabetes.
10. Intensification of therapy improves glycemic control and decreases HbA1c, blood pressure, and LDL cholesterol.

Leading Factors Associated with Clinical Inertia

In their classical article, Phillips and colleagues described three groups of factors as main causes of clinical inertia: (1) overestimation of the care provided, physicians consider that patients are improving despite lack of change in clinical results, (2) subjective or soft reasons to avoid intensification of therapy ("the patient is improving"), and (3) lack of train-

Table 23.2 Associated factors with clinical inertia

Authors and references	Description
Phillips et al. [7]	Overestimation of the care provided "Soft reasons" to avoid intensification Lack of training
Fantini et al. [4]	Organization "arrangements": individual versus in-group practice Patient characteristics: older age, comorbidities Location of practice: rural versus urban
Barth et al. [88]	Age of physicians: older clinicians more frequently work in individual practice and rely on experience; younger clinicians more inclined to accept collaborative, team-based medicine, protocols, and clinical guidelines
O'Connor et al. [82]	Physician factors: failure to initiate and titrate treatment until goals are achieved, failure to identify and manage comorbidities, ineffective clinical encounters, insufficient time, reactive, instead of proactive, care Patient factors: denial or belief that the disease is not dangerous, low health literacy, cost and amount of medications, side effects, poor communication or distrust in physicians, depression System factors: absence of clinical guidelines or disease registries, planning deficiencies, absence of outreach, support and team approach, poor communication
Reach [89, 90]	Discrepancy between the technical rationality of evidence-based medicine and the modes of reasoning of physicians "in real life" "Clinical myopia": failure to give preference to the benefits of treatment intensification
Miles [91, 92]	"Fallacious reasoning and cognitive bias": a conscious decision to withhold or omit the use of evidence-based medicine
Safford et al. [93]	Appropriate inaction; potential appropriate decisions resulting from patients' factors: lack of adherence, psychological or physical stress, lack of resources
Aujoulat et al. [94]	Providers' knowledge of and attitudes toward evidence-based guidelines: insufficient knowledge, disagreement or distrust, lack of applicability Providers' clinical judgment and experience within specific situations Sociodemographic characteristics and medical history of patients, values, comorbidities, polypharmacy, concerns, and reluctance Providers' awareness of patients' attitudes, behaviors, preferences, adherence, literacy, and empowerment Providers' ability to make the appropriate decision within a given clinical and organizational context: reluctance or difficulty to change, clinical uncertainty, limited time, absence of multidisciplinary or team-based care
Strain et al. [84]	Physician factors: overrating the quality of care provided, underestimating the number of patients who are not in target, use of soft excuses to avoid intensification, lack of time, blaming patients' noncompliance, paternalistic approach, knowledge or training to manage multiple chronic diseases, lack of clarity of clinical guidelines Systemic contributors: traditional clinical guidelines focused on goal-setting pathology management disregarding the importance of communication between patient, physicians, and multidisciplinary teams (if available); physicians working in isolation within the health system; time constraints, delays Patient factors: nonadherence, socioeconomic factors, lack of understanding and engagement with the treatment
Kunthi et al. [95]	Clinician-level barriers: limited awareness of clinical inertia, clinicians' overestimation of their quality of care and adherence with guidelines Patient-level barriers: lack of health education, disbelief in the efficacy of therapy, concerns about effects of therapy on quality of life, fear of side effects, lack of confidence to adhere to complex regimes

ing and practice limitations to focus on therapeutic goals and deficiencies in clinical practice to perform and deliver the expected results [7]. These factors have been repeatedly documented, and others have been described (Table 23.2).

Clinical Inertia as a Resource in Defense of Patients

Clinical inertia has also been claimed to be a clinical safeguard, based on results of clinical trials showing that tight glycemic control would not achieve the expected effects on prevention of cardiovascular outcomes in patients with type 2 diabetes, whereas aggressive lowering of blood glucose has been associated with an increase in all-cause mortality, hypoglycemia, and weight gain. In addition, comorbidities and competing health and personal and social factors are very frequent in persons with diabetes from every age group, and interventions to correct them are essential components of diabetes care [42, 43, 51]. A retrospective analysis to examine physician and patient characteristics associated with clinical inertia showed that nearly all the physicians have practiced clinical inertia, but patient characteristics are stronger predictors, and physicians frequently have to devote their limited time to focus on other medical problems and to take into account priorities and patient's preferences [67]. On the other hand, the concept of quaternary prevention, action taken to identify patients at risk of excessive medical treatment and to protect them from medical interference, is rarely taken into account [68]. The principles of hastening to

help and doing no harm have to be considered when establishing the relative risks of clinical inertia versus overtreatment in patients with diabetes [68].

Contribution of Clinical Guidelines to Clinical Inertia

One of the main goals of clinical guidelines is to overcome clinical inertia to achieve the benefits of therapy, but reluctance to comply with them is highly prevalent among physicians [69]. Clinical practice guidelines may also contribute to clinical inertia, when they focus on limited aspects, in disregard of other components of successful treatment, including patient education and self-monitoring of blood glucose [70]. The four guidance statements recently issued by the American College of Physicians for glycemic targets in adults with type 2 diabetes have reinforced these arguments [71]. They were reported as four guidance statements with the first being the personalization of goals for glycemic control, the second statement suggests an A1c target between 7.0% and 8.0% in most patients, the third statement recommends de-intensifying treatment in patients achieving A1c below 6.5%, and the fourth statement recommends liberalizing control in patients with life expectancy less than years because of advancing age or severe comorbidities [72]. While the message conveyed by the revised ACP guidelines is about safety, it has arisen criticism and concern from experts and academia [72, 73]. One of the main sources of criticism is that newer available antidiabetics facilitate glycemic control at lower risk of hypoglycemia and the concern that the revised ACP statements may stimulate and validate it [72]. Treatment algorithms cannot be truly evidence-based because they are unable to present all the available treatment options [74], but recent guidelines have stressed the importance and, increasingly more frequently, the influence and preeminence of comorbidities and social determinants of health in the selection and intensification of therapies [75]. Awareness and measurement of clinical inertia are increasing, and it has been shown that it is more important than poor adherence to therapy by patients [76, 77]. It has been also shown that educating physicians is less fruitful than educating patients [78]: Roumie and colleagues published a study in which 182 providers were randomly assigned to receive several alternatives of education, including online access to the JNC 7 guidelines on Prevention, Evaluation, and Treatment of High Blood Pressure, and 1341 patients with hypertension received computerized alerts, letters advocating drug adherence, and face-to-face education. After 6 months, patients who received education had better hypertension control and lower systolic blood pressure than patients in whom physicians were the ones who received education [78]. Analysis of physicians' responses to computer alerts to comply with the JNC 7 guidelines showed a list of "soft reasons," including lack of agreement with the guidelines (5%), patient-based factors (17%), environmental factors (105), lack of knowledge (2%), and arguments supporting clinical inertia in 66% ("continue the current medications and I will discuss at the next visit") [78].

Addressing Clinical Inertia

The role of clinical inertia in the poor results to achieve the goals of glycemic control, hypertension, and hypercholesterolemia has been clearly established [79]. Accordingly, several strategies have been proposed to address and modify its negative effects:

1. Raise the awareness: more studies about the epidemiology and consequences of clinical inertia are required to measure its worldwide extent, including individual patient, physician and clinic factors, patient-physician relationship factors, and "complex patient" selection effects including competing health problems and nonadherence [79].
2. Measurement: clinical inertia affects the outcomes and the quality of healthcare. Consequently, application of established methods or the development of new measures to quantify its magnitude is essential. Current measures of clinical inertia in diabetes include (1) the proportion of patients having drug therapy intensification at visits above goals of glycemic control [79], (2) the proportion of patients with high A1c levels after drug intensification [29], and (3) a model to predict the probability that an individual visit would result in an increase of antidiabetic medications based on characteristics at that visit including diabetic complications, cardiovascular risk factors, psychiatric or substance abuse disorders, and comorbidities [35]. The complexities and limitations of this method have been addressed by O'Connor, including poor documentation of interventions, the proposed use of a normative instead of a threshold value, placing excessive emphasis on glucose control and diverting attention from other diabetes quality measures [80].
3. Physician education is a key strategy to facilitate intensification of therapy [81]. Targeted interventions to health providers, including (1) enhanced primary care incorporating key features of clinical trials into routine chronic disease care [81–83]; (2) scheduled, frequent, and carefully planned office visits and increased direct contact time with patients [82, 84]; (3) electronic medical records to provide real-time decision support to physicians during office visits and measure opportunities for intensification and variations by practice and patient characteristics [80–83]; (4) monitoring, prompts, feedback, and decision support for healthcare providers to improve systems [80–83]; (5) continued managerial momentum through a five-stage

process: (a) review the process of diabetes care, (b) identify the highest priority goals and treatment strategies, (c) actionable plans to increase clinical encounters in which clinicians take appropriate action, (d) systematically track progress toward achieving goals, and (e) feedback to responsible to make patient care decisions; (6) incorporate performance measures to improve care and control costs, including process (accountability) and intermediate outcome items [80, 81, 83]; and (7) incentives and pay for performance [80, 81, 83].

4. Effective communication with patients: explanation and risk management in the real world, understanding of the progressive nature of diabetes, and the accompanying need to review and adjust treatments [81, 85]. Suitable interventions to promote patient activation and involvement in decision-making and enhance adherence include feedback, education, and support [61, 79–83, 85, 86]; and delivering patient education *that they can understand*, according to personal values and preferences [75, 81].

In conclusion, despite exhaustive efforts to develop evidence-based, non-biased, and feasible clinical practice guidelines, doctors frequently do not follow them. Clinical inertia is the consequence of a discrepancy between the technical rationality of evidence-based medicine and the reasoning of clinical practice in "real life," marked by uncertainty and risk [87]. Like other human complex problems, reducing clinical inertia requires complex solutions, starting at medical schools, and supported by updated, continuing education and assessment of physicians performance and outcomes. Epidemiology, analysis of responsible factors (awareness, attitude, training, organization), and design of interventions about clinical inertia are clearly areas of opportunity to improve one of the crucial aspects in diabetes care.

Multiple-Choice Questions

1. Clinical inertia
   (a) Has been recently described
   (b) Is infrequent
   (c) Is the patient's fault
   (d) Has been described for decades
   (e) Is exclusive of primary care
2. Clinical inertia is defined as:
   (a) Promptness to intensify medical treatment
   (b) The trend to align with medical trends
   (c) Inability to achieve the goals of treatment after repeated visits
   (d) Failure to initiate or intensify treatment when indicated
   (e) Recognition of a problem but failure to act
3. Clinical inertia has been reported:
   (a) Only in diabetes management
   (b) In hypertension
   (c) In diabetes and hypertension
   (d) In acute disease care
   (e) In the management of multiple chronic diseases
4. The reported prevalence of clinical inertia in the management of diabetes, hypertension, and LDL cholesterol is around:
   (a) 10%
   (b) 20%
   (c) 30%
   (d) 40%
   (e) 50%
5. Treatment intensification in patients with diabetes may be delayed up to:
   (a) One month
   (b) Three months
   (c) Six months
   (d) One year
   (e) Five years
6. Introduction of insulin in diabetes treatment may be delayed up to:
   (a) One month
   (b) Three months
   (c) One year
   (d) Five years
   (e) More than 9years
7. In hospital patients with diabetes, clinical inertia:
   (a) Is non-existent
   (b) Is associated with persistent hyperglycemia and low rates of follow-up
   (c) Is minimal with no appreciable effects on outcomes
   (d) Has been overemphasized
   (e) Has not been investigated
8. Leading factors associated with clinical inertia include:
   (a) Overestimation of the care provided
   (b) Subjective reasons to avoid intensification
   (c) Lack of training and practice limitations
   (d) All of the above
   (e) None of the above
9. Clinical inertia may be a resource in defense of patients:
   (a) True
   (b) False
10. Clinical guidelines may contribute to clinical inertia:
    (a) True
    (b) False

Correct Answers

1. (d) Has been described for decades
2. (c–e)
3. (e) In the management of multiple chronic diseases

4. (c) 30%
5. (e) Five years
6. (e) More than 9years
7. (b) Is associated with persistent hyperglycemia and low rates of follow-up
8. (d) All of the above
9. (a) True
10. (a) True

Patient Adherence: Challenges, Myths, and Realities

24

Joel Rodriguez-Saldana

Introduction

To achieve the desired results of medical interventions, patients need to keep appointments, take medications, and make lifestyle changes. Their capacity to accept and carry out these tasks is unpredictable, and the adherence to medical recommendations is highly variable: some people are unable or unwilling to follow all of them, and only a small proportion have high levels of "compliance, adherence, or concordance" [1]. Patient adherence in diabetes is very important because it is associated with clinical outcomes and costs: it is estimated that for every 25% increase in medication, adherence A1c levels decrease 0.34% [2]. Conversely, nonadherent patients are more likely to require hospitalization and to incur in higher healthcare costs [2]. Adherence is a crucial link in the physician-patient interaction in chronic disease management.

Adherence or compliance with a therapeutic regime has been defined as the extent to which patients take medications as prescribed by their healthcare providers [3]. Adherence and concordance are terms increasingly used, because "compliance" implies that patients have to obey and comply with medical orders [3]. This assumption is unrealistic and results in conflicting differences between patients' and physicians' perspectives. Patients' expectations are derived from past experiences of health and illness at a personal level, and as observed in relatives, neighbors, friends, and colleagues, they are influenced by public and professional attitudes and by the media; *no two patients are the same* [4]. Professional beliefs are also influenced by personal experiences as patients, parents, relatives, observers, professional experience, and personality [4]. When patients do not meet the goals and expectations of healthcare providers, they are labeled as "noncompliant," a pejorative term that implies a moral failure to behave appropriately, from the belief that the correct view of diabetes and its management is exclusive of clinicians [5]. The professional concept of compliance is distant from reality, but it is still deeply rooted among physicians all over the world. Adherence rates are even below the goals in clinical trials, especially in persons with chronic diseases [6]. Lack of adherence or persistence with treatment by patients is a major contributor to poor clinical outcomes, regardless of physician's and health providers' efforts.

A Brief Story of Adherence

As far back as Hippocrates, physicians were concerned that patients followed physicians' advice [7]. Association of risk factors with negative health outcomes increased the authority of physicians' recommendations [7, 8]. Infectious diseases became the first focus of patient's compliance, particularly tuberculosis, which was contagious, was very common, affected people from every social and economic status, and, before the advent of antituberculous drugs, had very high mortality; patients who did not follow or obey doctors' orders were stigmatized. Introduction of the first effective antituberculous drugs in the 1940 increased the blaming of patients unwilling to accept hospitalization to receive an extended course of antimicrobials [8]. The emergence of the AIDS epidemic in the 1980s proved that these assumptions continue to be extrapolated for every disease.

Although the importance of drug compliance was initially recognized in tuberculosis, formally measurement occurred in the prophylaxis against streptococcal infection. Mohler and colleagues showed that the frequency and number of doses was inversely proportional to adherence and to the effectiveness of therapy [9, 10]. A controlled clinical trial and follow-up study published in 1957 and 1959 about 405 children with rheumatic fever who were randomly allocated

to compare the effectiveness of three antistreptococcal prophylactic regimens showed that penicillin injections were more effective than oral sulfas or penicillin [11, 12]. Adherence to long-term therapies was started to be measured in patients with tuberculosis when it was found that blood measurements of p-aminosalicylic acid were lower than expected [13, 14], and it was recognized that complexity of the regime reduced completion of therapy [15].

The role of social, cultural, and economic factors with compliance with medical regimes started to be suggested and evaluated. Sociologists, anthropologists, psychologists, and scientists from other disciplines began to study the role of personal, family, and environment on the acceptance, willingness, and adherence to medical recommendations and to explain "illness behaviors" (or "sick roles") beyond the medical perspective [16–18]. Early studies showed that the expectation that patients would always follow "medical orders" was unrealistic. In 1959, Eichorn and colleagues emphasized that patients' decision to accept or reject medical recommendations is the result of multiple determinants, including their attitude toward physicians and health, knowledge about the risks associated with the disease, and the personal approach to life [19].

Additional studies in other therapeutic areas supported these findings: in 1966 Johannsen and associates analyzed the acceptance of patients with heart disease to medical recommendations and predisposing variables to reject them [20]. They showed that education level was associated with disregard of medical advice: 83.3% of the patients followed medical recommendations, 84.1% followed restrictions to return to work, and 66.7% followed psychosocial counseling [20]. Caron and Roth analyzed the adherence of 525 patients receiving antacids, replicating the results of previous reports and the current reality of clinical practice: (1) most of the physicians overestimate patients' real adherence to treatment; (2) their estimates of patients' adherence were subjective, not objective; (3) physicians are unable to distinguish patients who actually adhere to treatment from those who do not; (4) physicians' estimates are highly inaccurate, for some patients too high and, for others, too low; and (5) to make matters worse, this study was carried out in hospitalized patients, in which it is assumed that treatment largely depends on the medical staff [21].

These pioneering studies contributed to raise the awareness of clinicians to recognize, attempt to measure the magnitude of patients' noncompliance, to understand its causes, and to intervene. A review by Porter to collect methods to detect defaulters identified three methods to assess medical compliance, still in use: (1) direct interrogation of patients and their families about frequency, dose, and time in which medications were taken; (2) residual tablet counting; and (3) measurement of drug metabolites or markers in urine [22]. Another study by Davis showed that doctors' perceptions of patient behavior are related to their "social distance" with patients and that reasons for noncompliance include (1) the patient's "personality," (2) the doctor's attitude, (3) the capacity of the patients to understand doctor's advice, (4) personal difficulties in the life of patients, and (5) the economic capacity to follow medical advice [23]. Detailed explanation, reminders, and persuasion were most important to influence noncompliant patients, while authoritarian and threatening attitudes reinforced noncompliance [23]. Afterward Davis described ten categories in doctor-patient interaction, ranging from mutual antagonism, disagreement, and tension to interactions in which mutual tensions are released and patients and physicians are satisfied [24]. Deficiencies in communication between physicians and patients were confirmed as the leading limiting factors reducing the response to medical recommendations. In a study of 800 pediatric outpatient visits to explore the effect of verbal interactions between doctor and patients, Francis and colleagues showed that 24% of the patients were grossly dissatisfied with their relationship to their doctors, 42.1% were highly compliant, 38% moderately compliant, and 11.4% totally noncompliant [25]. Doctor's friendliness, professional attitude, and understanding or concern were associated with high compliance, whereas unmet key factors, lack of warmth in the doctor-patient relation, and failure to receive explanations about diagnosis and cause of the child's illness were associated with noncompliance [25]. The problem of adherence to treatment in children continued to be recognized, and its causes were almost identical to the ones described in adults [26].

Further studies about noncompliance and its causes included taking antacids for peptic ulcer disease [27] and digoxin for congestive heart failure [28]. Gillum and Barsky showed that noncompliance is grossly underestimated and disclosed that leading factors were (1) psychological, (2) environmental and social, (3) complexity of the therapeutic regimen, and (4) physician-patient interaction [29, 30]. It became clear that noncompliance "curtails the benefits of therapeutic regimens, produces inestimable costs, and frustrates physicians." In response to the need to recognize the importance of noncompliance, more accurate and sensitive techniques to predict noncompliance were proposed, because the methods used in those days and even today were inaccurate and impractical or may alienate patients [31]. In 1975, Baekeland and Lundwall recognized (1) the importance of dropping out of treatment and its high frequency in the management of chronic disease; (2) the need to identify patients most likely to drop out; (3) patient factors responsible for dropping out, including personality traits and therapeutic styles; (4) understanding the implications of dropping out as treatment failures; and (5) interventions to

reduce the risk of dropping out, including patient selection and changes in treatment settings and approaches [32]. They also asked a crucial question: Do patients simply abandon treatment, or are they abandoned and/or pushed out of treatment? Rosenstock published one of the first reports in which compliance was associated with behavioral characteristics, including: (1) health motivation "or patients' interest and concern" with their health, (2) perceived susceptibility of the threat posed by disease, (3) perceived benefits of medical interventions, and (4) knowledge of the medical condition and understanding of expected effects of treatment, including schedules and doses of medications [33]. He also acknowledged that in many cases, patients do not receive adequate information about treatment because of organization factors, including long waiting times and distancing attitudes between physicians and patients [33]. In Canada, Stewart and associates made the following questions to a group of patients with chronic diseases treated by family physicians: what factors affect the quality of the relationship? And if the doctor-patient relationship affected the outcomes? [34]. Physicians' factors, including number of health problems and recent visits and allowing the patient to start the dialogue during the visit, were positively associated, while patients' factors were not; he concluded that devoting time and attention to identify comorbidities and continuity in healthcare, physicians would increase their performance [34].

Additional reports confirmed the low accuracy of physicians to predict noncompliance and the need to deal not only with the biomedical aspects of diseases but also with the social and behavioral characteristics of patients; when these factors are not integrated into the process of decision-making, it is unlikely that treatment plans based exclusively on technical considerations will be effective [35, 36]. Noncompliance results from a complex interaction of patients' attributes, including health beliefs, social and behavioral characteristics, the disease or health disorder, complexity of treatment, patient and providers, and organizational strengths and deficiencies. All of them exert strong influences amenable to modification, but less studied [37]. In sharp contrast with the medical opinions about causes of nonadherence prevailing until today, more than 30 years ago, it was confirmed that (1) compliance is not related to income, social class, occupation, or education; (2) physicians are unable to predict patients' willingness or ability to comply; and (3) most of the errors in taking medications are unintentional and related to the complexity and duration of therapy, number of medications, degree and modalities of counseling, and the use of dispensers [37].

New methods to measure compliance were introduced, including pill bottles with microprocessors to record every bottle opening as a presumptive dose, confirming that rates of drug compliance were lower in patients receiving higher doses and that pill counts overestimated the frequency of missed doses and serum concentrations achieved by drugs [38]. Petchey and Murphy noted that "(1) compliance is associated with patients' satisfaction; (2) noncompliance cannot simply be attributed to understanding or memory; (3) instead of being passive recipients of medical advice and treatment, patients participate in (the) monitoring of their health problems and the effects of treatment, its adverse effects, and their impact on their normal lives; (4) the word "compliance" implies that patients are either passively obedient or willfully disobedient in the face of medical expertise; and (5) collaboration in terms of doctor-patient relationships might be more constructive [39]."

Early interventions to improve the adherence to medical regimes included (1) letters, telephone, or physical reminders to reduce the frequency of broken appointments [40–45]; (2) awareness and educating medical students about the importance of compliance by experiencing it themselves [46]; and (3) ascertainment of indirect (self-reports, interviews, pill counting, and computerized monitors) and direct methods (biologic markers, tracer compounds, drug concentrations in the patients' biologic fluids) [41]. Strategies and aids to improve compliance included identifying risk factors of lack of adherence, simplified and individualized treatment plans, patient education, and aids to improve compliance, including labeling and packaging of containers and monitoring by health professionals, patients, and their families [47]. In recent years, the ability of patients to self-monitor capillary blood glucose in patients with diabetes [48], blood pressure in people with hypertension [49], body mass index to achieve sustained reductions in body weight [50], and adjust the dose of anticoagulants [51] has been documented, and stages of parallel cooperative monitoring in chronic disease have been described [52]. Patients are the leaders; adherence largely depends on them.

The Evidence Behind Compliance and Adherence

As a result of the importance of patient compliance on clinical outcomes, robust analysis methods were introduced, including meta-analysis and systematic reviews [53]. R Brian Haynes, a pioneer in this field, published a series of systematic reviews which are periodically updated [54–56]. These studies, and two reviews by van Dulmen et al. [57] and Viswanathan et al. [58], summarize the evidence of interventions to improve patients' adherence (Table 24.1).

Table 24.1 Meta-analysis and review of interventions to improve patients' adherence

Date	Author(s) and reference	Methods	Results
1996	Haynes et al. [54]	Systematic review 1553 citations and abstracts screened, 252 reviewed, 13 randomized controlled trials met all the criteria. Diseases analyzed included asthma, hypertension, streptococcal throat infection, acute infections, epilepsy, schizophrenia	Disparity in clinical problems, interventions, measures, and reporting of adherence Seven showed improvements in adherence, and six led to improvements in outcomes Short-term effectiveness using counseling and written information Long-term effectiveness included combinations of quality of care, information, counseling, reminders, self-monitoring, reinforcement, family support, and supervision Substantial improvements in adherence were not documented
1998	Roter et al. [53]	Meta-analysis 153 studies: 116 randomized controlled trials, 37 nonrandom comparisons Interventions or health problems analyzed: Prevention, immunization or periodic screening Patients discharged from the hospital Hypertension Mental health Diabetes Cancer	Small to large effect sizes for all compliance measures No single strategy or intervention has clear advantages with another Comprehensive interventions combining cognitive, behavioral, and affective components are more effective than single, isolated interventions
1998	Haynes et al. [54]	Systematic review 3133 citations and abstracts screened, 345 full text reviewed, 14 randomized controlled trials met all criteria 16 interventions	Eight studies showed improvements in adherence, and six led to improvements in outcomes Most of the studies were small, introducing the possibility of false-negative error Some interventions are highly complex and unlikely that their effects were mediated by adherence to medication Unclear potential to generalize, replicate, and disseminate the interventions Difficulties to be carried out in non-research settings Most studies did not assess the separate effects of complex interventions involved in chronic disease management None of the studies examined major clinical endpoints, short-term follow-up: less than 6 to 18 months To achieve full benefits of medical therapies, further innovations are required, including involving investigators from different clinical disciplines
2002	Mc Donald et al. [56]	Systematic review 6568 citations and abstracts screened, including 101 review articles, 549 full text reviewed, 33 randomized controlled trials met all criteria 39 interventions Disorders studied: Hypertension Schizophrenia, acute psychosis Asthma Chronic obstructive pulmonary disease Depression Human deficiency virus Diabetes Rheumatoid arthritis Epilepsy Hyperlipidemia Acute infections	Number and type of interventions: 1–6, including behavioral, cognitive, or social Interventions for short-term treatments: Counseling about the importance of adherence reinforced by written instructions Interventions for chronic treatments: Changes in dosing schedules Remaining interventions are complex and multifaceted, including care at worksites, pill containers, counseling, reminders, self-monitoring, support groups, feedback, and reinforcement Higher rates of adherence and improvements in blood pressure and glycemic control achieved with innovative interventions, including telephone-linked computer systems for monitoring and counseling patients with hypertension and automated assessment and self-care education calls with nurse follow-up for patients with diabetes
2007	Van Dulmen et al. [57]	Review of 38 systematic reviews of the effectiveness of adherence interventions published between 1990 and 2005	Effective interventions were found in four theoretical approaches: technical, behavioral, educational, and multifaceted or complex Technical solutions simplifying therapeutic regimes increase adherence rates; in some cases they improve clinical outcomes and reduce costs Effective interventions originate from behavioral theories Theoretical models to explain nonadherence are not effective to improve adherence There is still a scarcity of comparative studies about the effectiveness of theoretical models or their components, which needs to be assessed

Table 24.1 (continued)

Date	Author(s) and reference	Methods	Results
2012	Viswanathan et al. [58]	Systematic review of publications assessing the comparative effectiveness of patient, provider, systems, and policy interventions that improve adherence to medications From 4124 abstracts, 62 trials about patient-provider interactions or system performance, including 19 interventions and 4 observational studies were analyzed Clinical conditions amenable to improvement: Hypertension Heart failure Depression Asthma	Factors that increase medication adherence: Lower out of pocket expenses Case management Patient education with behavioral support Limited evidence about applicability of interventions or long-term effectiveness

Hypertension: An Example of Nonadherence and the Role of Deficiencies in Primary Care

At the same time that the decrease in the mortality by high blood pressure was associated with the appearance of new antihypertensive drugs, low persistence in their use and huge percentages of dropouts resulting in hypertensive crisis and visits to emergency rooms were documented [59, 60]: 50% of the patients were lost at 11 months, 74% dropped out at 5 years, and only 17% remained in treatment [60]. Main reasons to discontinue treatment included feeling well, absence of symptoms, absence of instructions or follow-up, lack of resources, medical advice to suspend, lack of family support, dissatisfaction with health providers, adverse effects from medications, and discouragement [60]. Socioeconomic factors showed differences between patients dropping out of treatment and controls, including education, employment, home ownership, and work status [60]. Leading factors to continue treatment included knowledge about the disease, adverse effects of inadequate treatment and consequences for the family, emotional satisfaction, physical improvement, and family support [60]. Another study showed that nurses under medical supervision were capable to operate a hypertension clinic with very low dropout rates; patients educated to self-monitor their blood pressure had better clinical outcomes and significant reductions in diastolic blood pressure [61].

In addition to its clinical efficacy and its importance to reduce the risk of cardiovascular events, antihypertensive treatment is important because it motivated the design of some of the first clinical trials to examine the effectiveness of interventions to improve patient's compliance. In 1975, Sackett et al. published the results of a clinical trial in which 245 Canadian steelworkers with persistent hypertension were randomly assigned to receive usual treatment and follow-up outside working hours or an educational program explaining "the facts of hypertension," its effects on target organs, health and life expectancy, compliance with use of medications, and reminders for pill taking [62]. The results showed that (1) in order to be effective, the lower limit of drug compliance had to be 80%; (2) patients assigned to the "convenience" strategy failed to increase their compliance; and (3) knowledge about a disease is not important to improve compliance, but patients who received it had become "masters" in health information [62]. Another study of the same group showed that reinforcement by high school graduates with no formal health training who taught patients to measure and record their blood pressure and to chart pill taking resulted in a 21.3% increase in medication compliance, by comparison to a decrease of 1.5% in the control group, with improvements in diastolic blood pressure [63].

In 1973, Finnerty, Mattice, and Finnerty published a groundbreaking analysis of causes of discontinuation of antihypertensive treatment at an outpatient clinic in Washington in which they identified three factors associated with healthcare delivery as the main causes: (1) long waiting times (2 and a half hours), (2) deficiencies in doctor-patient relationships (patients were seen by a different physician on each visit); and (3) brief duration of the visit (7.5 minutes) and, to make matters worse, long waiting times to receive medications at the pharmacy (1.8 hours) [64]. In response to these deficiencies, still encountered worldwide, 25% of patients believed they were able to treat themselves, 61% agreed to be treated by medical students, and 54.4% agreed to be treated by nurses [64]. These organizational deficiencies have been repeatedly documented; they still exist as examples of the management of chronic diseases, including diabetes. Some years later, Finnerty reflected that patients dropped out of treatment not because they were uneducated, not

because they did not care about their health, and not because they could not afford paying for medications [65]. They abandoned the clinic because "they were treated like cattle, herded from one room to another, left waiting for hours, to be examined by different doctors on each visit [65]." Major complaints centered on the amount of time they spent at the clinic and the lack of acceptable, effective relationships with physicians [65].

Hypertension became the prototype disease in which of adherence to medical treatment and its causes were described. Peter Rudd was a pioneer in this field; he recognized that it was very frequent, poorly predicted, and imprecisely measured and described three characteristics associated with failure to achieve blood pressure control: (1) behavioral factors, (2) biologic factors related to the unique manifestations of the disease in an individual, (3) pharmacologic factors including the role of side effects to suspend therapy, and combinations of the three [66]. Despite the publication of clinical practice guidelines since the1970s, a huge gap still exists between the evidence published by controlled clinical trials and what clinicians do in practice and between what clinicians recommend to patients and what patients do at home [67]. This gap and two of its major components (lack of effective physician response to uncontrolled hypertension and deficiencies in patient adherence) are crucial obstacles to deliver and receive adequate quality of care [68]. Problems of low adherence are frequently underestimated and not detected by physicians. Compliance of practitioners with practice guidelines for hypertension is very low, and even worse in patients with diabetes, with the associated increase in cardiovascular risk [69]. Even among patients enrolled in phase IV controlled clinical trials of antihypertensive medications and despite informed consent, all the patients on average omit 10% of the doses, including 42% omissions of a single-day dose, 15% on 1 or 2 consecutive days, and 47% on multiple days; 95% of the patients miss one dose each month, 48% omit taking medications for 78 hours or more at least once a year, and 13% omit every 6 months [70].

Recent methods to measure adherence in essential hypertension include the Morisky Medication Adherence Scale (MMAS), an eight-item structured, self-reported measure of adherence in primarily low income, minority patients [71]. Sensitivity and specificity of the MMAS to identify patients with poor blood pressure control are 93% and 53%, respectively, and a score of adherence in which 8 points were defined as highly adherent, 6–7 points as medium adherent, and less than 6 as low adherent patients is significantly associated with blood pressure control [71]. The MMAS is patient centered and addresses the main causes leading to voluntary and involuntary suspension of treatment including knowledge, social support, satisfaction with care, and complexity of medical regimen [71]. It has been internationally validated [72, 73] and has been applied to measure adherence in patients with diabetes [74].

Adherence and the Complexities of Diabetes Self-Management

The history and evolution of adherence in type 1 and type 2 diabetes has provided relevant contributions to understand the crucial role of patients and their families in the outcomes and the contribution of health delivery factors. Decades ago and still in many places, diabetes was managed with a paternalistic approach: in postwar Germany patients had to be admitted to hospitals to stabilize glucose, in the absence of training or resources for self-care, and were not allowed to change insulin dosages [75]. Mülhauser and Berger claimed that patient education "had degenerated to obedience training" including following diabetes diets based on fixed amounts of carbohydrates, proteins and fats, prohibited sugar intake, and had to be consumed as 6–7 times meals at fixed times, every day ("doctors' orders") [75]. This approach was grossly ineffective; acute and chronic complications were frequent. The emotional consequences of diabetes, recognized for centuries, evolved in the construction of a "diabetic personality," in which the daily challenges to confront the disease, its treatment and consequences, were used to explain and attribute poor treatment outcomes on patients; *it was their fault*. The myth of a diabetic personality ignored the enormous scope of expression of individual personalities in adjusting to the daily demands of a healthy lifestyle. This one-dimensional view implies the adoption of an inflexible model of behavioral adjustment, which is rejected by many people [76]. In one of the first studies to estimate the adherence in home management of 60 adults with diabetes, Watkins and colleagues reported that 75% of patients did not adhere to diet, 66% were making errors in urine testing for glucose, more than 50% made errors in insulin dosage, and only 50% were giving themselves good foot care [77]. Only one patient was deemed "acceptable" – completely adherent – in the five areas of management, and there was a negative association between knowledge and effectiveness of self-care. In other words, *patients in poorer control knew more about diabetes than those under control*. By comparison, a diabetes education program addressing roles of physicians, health providers, and patients and the influence of different attitudes, behaviors, and skills by patients and health professionals showed to improve compliance [78]. Essential features of this program included (1) a team, nonthreatening, nonauthoritarian approach; (2) a group process for support, sharing of experiences, and practice according to individual needs; (3) learning by experience rather than conceptual learning to small groups of patients; (4) regular evaluation for education and to raise awareness: and (5) innovative educational techniques *that induced changes in health behavior* [78].

The multiplicity of self-care activities that patients with diabetes have to carry out every day to "adhere to treatment" confirms the need to distinguish the differential difficulties of "adhering" to medications and to lifestyle changes.

Nevertheless, interventions to improve adherence have been largely inadequate: in 1986, Anderson stated that "diabetes educators lack the time and expertise to become familiar with theories of human behavior…diabetes education reflects an extension of the transference of information found in most schools…based on the idea that lack of knowledge and skills accounts for most of poor self-care behaviors [79]." He also claimed that patients' behavior is strongly influenced by their view of diabetes and stressed the need that diabetes educators become skilled designers of patient education programs that facilitate changes *in the personal meaning of diabetes*. This was a pioneering concept associated with the personal model of disease described shortly afterward by Glasgow and colleagues [80].

Complexities in diabetes management are illustrated by the large variation of adherence to medications, ranging from 36% to 93% [81–84]. Adherence to incorporate lifestyle changes, including diet and exercise, is even lower; multiple factors are influential, including (1) comorbidities, (2) cost of therapy and lack of health insurance, (3) adverse family dynamics and codependency, (3) old age, (4) frequency of doses and number of medications, and (5) poor provider-patient relationships and failure to fulfill the patients' health beliefs [85]. Even when patients are willing to adhere to medical therapy, additional barriers involve (1) cost of medications, (2) remembering doses, (3) reading prescription labels, and (4) obtaining refills [86]. Additional barriers in patients with type 1 and type 2 diabetes demonstrate that adherence to one aspect of the regimen is not related to others and that psychosocial variables and situational factors are also important [87, 88]. Noncompliance with health regimens is by no means unique to diabetes; the problem exists with all chronic dieases [89], but compliance with diabetes regimens may be even poorer than regimens for other conditions, taking into account that the typical diabetes regimen is complex, of lifelong duration, and requires introducing multiple behavior changes [89]. The role and challenges that persons with diabetes have to confront were summarized by Bush [90]:

> Of all chronic diseases, diabetes is foremost in putting the responsibility for ongoing health on patients. Proper diabetes treatment requires not simply that patients take medications and visit the doctor, but that they ultimately make true lifestyle changes….. major and substantial change in behavior is easy to discuss but hard to achieve, and patients may view the treatment of diabetes worse than the disease itself. The inability of patients to do exactly what we want is so rampant that we have made it a diagnosis: non-compliance [90].

Adherence to diabetes treatment has proven to be a conceptual and empirical enigma; studies related to the health belief model, social learning theory, and the psychology of interpersonal relationships to identify determinants of adherence behaviors have great relevance in clinical practice [91, 92]. Over five decades, several models were proposed to explain individual health-related behaviors, including the "health belief model" (HBM) [93–96]. The basic components of the HBM were developed from psychological and behavioral theories derived from the "value expectancy" approach of Levin in 1944 [96], to describe behavior or decision-making under uncertainty. Its major elements included (1) the individual state of readiness to address a particular health problem and the perception of the threat represented by illness, (2) the belief in the efficacy of a person's behavior to reduce the threat and the consequences and perceived barriers involved in the action, and (3) a "cue to action," i.e., external or internal "triggers" that induce the appropriate health behavior, for instance, adherence to take medications [93–95]. Based on this model, a construct was made to explain and predict compliance with health and medical recommendations (Table 24.2).

The HBM showed that to improve patient adherence, it is important to understand why nonadherence occurs, to move beyond the patients' traditional role, and to consider a variety of demographic, psychological, social, physicians', medical system, disease, and treatment factors [93, 94]. In the traditional approach to health behavior change, the healthcare provider is seen as the expert who knows what is best for the patient, based on the assumption that all the patients should change their behavior, that all have the same willingness to change, and that the disease and its treatment are their most important priorities [97]. This assumption is not valid: lack of concordance between patients and providers and divergences in the approach to health status has been clearly documented in persons with diabetes. Despite agreements in the perception of severity, large disparities exist about the impact of adherence on the cost of treatment and its benefits; patient and physician discordance correlates with higher levels of self-care and lower glucose levels [98]. Low levels of agreement between patients and physicians (kappa = 0.23) about adherence to diabetes treatment have been clearly documented, and physicians' recommendations are poorly understood by patients [98, 99]. Despite the existing evidence, patient-provider discrepancies continue to be reported worldwide until today [100].

Table 24.2 Model to predict and explain compliance behavior

Readiness to change and compliance behavior	Barriers and obstacles	Behavior of compliance
Motivation		
Benefits to treat the disease	Age, access to treatment, complexity, side effects,	Likelihood to carry out the expected behavior
Probability that compliance will reduce the threat		

Adapted from Becker and Maiman [94]

> By identifying discrepancies between their assessment of adherence and that of the patients and avoiding the systematic attribution of poor outcomes to poor adherence, physicians could generate more confident and collaborative relationships…..and facilitate self-management [99].

In addition to patient behavior, multiple facilitating and inhibiting factors influence the level of metabolic control including patient-provider relationships, communication, social support, and must be integrated into diabetes care [101]. Application of theoretical constructs such as the health belief model and the locus of control has shown modest improvements in the perceived severity of diabetes, in the ability to carry out recommended behaviors, and on the benefits of training but not on self-reported adherence to treatment [102, 103].

Psychological Issues and Adherence in Persons with Diabetes

The importance of psychological aspects on diabetes was documented as early as the seventeenth century when Willis and Maudsley noted that prolonged depression or anxiety appeared to cause diabetes [104]. Additional reports from the nineteenth century provided a conceptual framework in support that emotional disruptions antedate metabolic decompensation [104]. Studies about psychological aspects of diabetes increased and identified four important topics that continue to be recognized: (1) association of psychological factors with the onset of the disease, (2) the influence of the environment on its course, (3) the immediate response and long-term personal adjustment, and (4) the reaction of the family to the illness and its impact on the family structure [104–106]. The 1970s saw the emergency of behavioral medicine as a new paradigm to understand disease-behavior interactions, an attempt to work backward from physiology to identify relevant behavioral interventions for disease prevention and management, a major difference between a new behavioral model and the old psychosomatic model [107]. Russell Glasgow, a pioneer and leader in the study of behavioral aspects and management of diabetes and chronic disease, described the limitations of applying traditional compliance terms in patients with diabetes, ignoring the complexity of diabetes self-care [108]. "In addition to taking medicines, persons with diabetes have to carry out multiple activities including lifestyle changes and blood glucose monitoring, which are frequently not communicated or measured [108]." He acknowledged that having diabetes, treating diabetes, and developing diabetic complications all have their own psychological impact and that quantitative measurements are essential to account for the complex interactions between personal and environmental factors that facilitate or hinder adjustment and coping, including adherence [109]. Glasgow and colleagues published a series of studies about the relevance of supportive and non-supportive factors related to adherence and glycemic control, including family influences [110], and psychosocial correlates on self-care behaviors [111–113]. Regimen adherence should be considered in the context of other factors, instead of assuming that adherence and control are simply the result of one-to-one interactions between patients and physicians. Analysis of psychosocial factors related to self-management in diabetes resulted in the description of "personal models of disease," including disease-related beliefs, emotions, knowledge, and experiences [114]. Glasgow and associates described the concept of personal models in persons with diabetes and their predictive value to carry out self-care activities related to adherence to treatment and glycemic control [114, 115]. The consistency of personal models of "perceived treatment efficacy (PTE)" as barriers or facilitators to self-management has been consistently confirmed [116]. Patient "noncompliance" may be the result of impaired PTE. If patients do not believe that a recommended action contributes to a positive impact on their health, it is understandable that they might lose their motivation [116].

The Role of Depression on Adherence

The association of diabetes with depression and its importance on clinical outcomes has been recognized for decades [117–120]. The natural course of depression in people with diabetes is more adverse than depression "in the medically well [118]." Screening and treatment for depression in diabetes remains incomplete and is mostly focused on North American and European healthcare systems [119]. Clinical evidence has demonstrated the association between the severity of depression on adherence to diet and medications, functional impairment, and healthcare costs in patients with diabetes [119]. Coexistence of diabetes and depression increases perception of symptoms, disability, and mortality, impairs self-care behaviors, and is "lethal for adherence [120–123]." Ciechanowski coined the term "diapression" to remark the adverse impact of depression on multiple aspects of diabetes including symptoms, self-care, adherence to treatment, life habits, healthcare utilization, and patient trust and satisfaction with care [124]. People with depression amplify and mimic diabetes symptoms and feel worse. Major depression is associated with lower adherence to antidiabetics, antihypertensives, lipid-lowering drugs, and glucose monitoring [124]. Changes in the use of healthcare in patients with diabetes and depression include more calls, appointments, diagnostic tests, more

visits to emergency services, and 4.5 times higher healthcare costs [124, 125]. Conversely, patients with diabetes and depression may use fewer necessary medical services due to missed or cancelled appointments or avoid scheduled appointments because of lack of motivation, isolation, lower concentration, or general disorganization. Patients with diabetes miss more than twice scheduled and same-day primary care appointments than people without depression [126]. Because of the adverse effects of the interaction between depression and diabetes, treatment goals should focus on the improvement of depression as well as improvement on glycemic control [119].

Emotional Distress and Adherence to Treatment

Inconsistencies in the reported prevalence of depression, association with self-management, and glycemic control have led to consider the role of diabetes distress to understand the association between diabetes, the emotional burden of self-management, the threat of complications, and the potential loss of functioning [127]. Diabetes distress refers to a broader affective experience than depression: it captures the worries, concerns, and fears of patients with progressive and demanding chronic diseases such as diabetes [128]. Diabetes distress is not a proxy for clinical depression; instead, it reflects an emotional response to a demanding health-related condition [127]. Baseline diabetes distress is a significant independent predictor of electronically monitored and self-reported adherence at follow-up [129]. Consequently, diabetes distress should be considered one of the components of a core construct among depression symptoms, "subclinical depression," and major depressive disorder [127].

Behavioral Strategies to Improve Adherence and Self-Care

Motivational Interviewing

Motivational interviewing arose from experiences acquired in the management of alcoholism [130], a complex health problem with interrelated social, personal, and behavioral components in which the directive medical approach had been repeatedly unsuccessful. Motivational interviewing has its roots on Bandura's self-efficacy theory, which he defined as "a judgment of one's ability to organize and execute given types of performances [131]." In his classical book, Bandura explained that people have always striven to control the events that affect their lives and that the growth of knowledge over human history enhanced people's ability to predict events and try to control them; the *belief in supernatural systems of control* (in this case, physician's authority over the patient's everyday behaviors) is surpassed by conceptions that acknowledge the people's power to shape their own destiny [131]. Changing threatening health behaviors and following medical advice are important components of almost every medical interaction, but they can be difficult to accomplish; practitioners commonly end up making cursory attempts to satisfy their perception of the problem or avoiding the subject [132]. Telling or threatening people that they will "pay the consequences" if they don't change their lifestyle or take medications is rarely enough to change behavior [132]. People change and follow doctor's orders under the guidance or influence of individual, unique perceptions. Motivational interviewing has been shown to promote behavior change in a wide range of healthcare settings in which lifestyle changes are required, including the "big four" lifestyle habits (smoking, excessive drinking, lack of exercise, and unhealthy diet [133]), adherence to treatment for obesity, diabetes, and infection with the HIV virus [134]. Motivational interviewing is based on the recognition that advising or ordering patients to change is often unrewarding and ineffective [135]. Instead of a vertical approach, a guiding style is required to engage with patients, identify strengths and limitations, encourage motivation for change, and promote the autonomy of decision-making [135].

Diabetes Empowerment

Martha Funnell and Robert Anderson described two approaches to diabetes patient education: one based in compliance, and the second based on empowerment, and they stressed the importance to recognize that adherence and compliance are dysfunctional concepts [136, 137]. Patient empowerment recognizes the unique role and responsibilities of patients in the daily treatment of diabetes, based on the premise that persons have the capacity to make choices and are responsible for their consequences [138, 139]. Diabetes empowerment is intended to enable patients to make informed decisions about *their personal diabetes care* and to be fully responsible members of the healthcare team [138]. Empowerment offers a practical conceptual framework for diabetes education and provides patients with the knowledge, skills, and responsibility to change, promote health, and maximize the use of available resources [140]. Empowerment is defined as "the discovery and development of one's inborn capacity to be responsible for one's own life [141]." It is designed to help patients develop the knowledge, skills, attitudes, and necessary self-awareness to assume the responsibility for their health-related decisions [139]. People

are empowered when they have (1) enough knowledge to make rational decisions, (2) enough control, (3) enough resources to implement their decisions, and (4) enough experience to evaluate the effectiveness of their actions [141]. To identify a measure of diabetes self-related efficacy for adults that focused on psychosocial areas, Funnell and Anderson developed the Diabetes Empowerment Scale (DES), a 37-item questionnaire that showed improvements in psychosocial status and glycemic control [142]. A professional education program based on diabetes empowerment showed significant improvements in counseling skills [138], and the comparison of an empowerment-based Diabetes Self-Management Consultant with mailed metabolic assessments showed modest improvements in diabetes-related quality of life and satisfaction with diabetes care [143]. Unlike the traditional medical approach, empowerment is not something one does to patients: empowerment begins when healthcare professionals acknowledge that patients are the ones who really have the control of their daily diabetes care. "Empowerment occurs when the health professional's goal is to increase the capacity of patients to think critically and make autonomous, informed decisions." [144]

Adherence and Diabetes: A Long Way to Go

Assessment of patient and physicians' disparities has shown that adherence is not dependent of characteristics traditionally perceived by physicians (observable cues) like sex, race, or age. In addition to information and communication problems, prejudice from clinicians reduces their capacity to understand the patients' needs and their resources and willingness to change [145]. The use of "adherence aids," including pill boxes, putting the pills in special places, and associating pill taking with daily events like meals, has shown limited effectiveness [146]. Failure to attend medical visits or to monitor glucose, blood pressure, and lipoprotein levels is associated with higher levels of glycosylated hemoglobin, systolic blood pressure, and LDL cholesterol, but failure of physicians to intensify therapy in patients not achieving the goals (clinical inertia) is also a contributing factor, probably more important than patients' adherence, on the quality of healthcare [147–149]. Adherence to diabetes treatment depends on a variety of interacting factors, with comorbidity and its consequent polypharmacy, as one of increasing importance [150]. Multiple factors affect the patients' capacity to adhere to medical recommendations, including personal capacities, health beliefs, and locus of control. Family and social support provides immediate practical help and contributes to mitigate the stress of living with illness. Several studies have shown positive and significant relationships between social support, and adherence to diabetes treatment albeit the exact mechanism by which social support affects patients' adherence is not completely understood [151]. Emphatic engagement is also important and may even reduce the frequency of acute complications at least [152]. Competence and skills to overcome clinical inertia and assist patients to increase their adherence to treatment, instead of just reiterating what they should be doing and putting the blame on them if they fail, are key components of success in diabetes care [153].

Measuring Adherence in Diabetes and Beyond

Current metrics used to measure adherence in research settings have been recently reviewed [154, 155]. Indirect metrics include the medication possession ratio (MPR), the adjusted medication possession ratio method (AMPRM), the proportion of days covered (PDC), and persistence and daily average consumption; for example, an MPR of 80% is used as the cutoff to define adherence, and PDC represents the number of days supplied during an interval, divided by the total number of days during that interval based on pharmacy or insurance claims [154]. In clinical settings, adherence is indirectly assessed using patient recall, combined with questionnaires to assess barriers, pill counting, and reviewing pill bottles. Methods of direct measurement include direct observation, measuring drug levels, markers, achievement of therapeutic goals, and adherence instruments such as the Morisky Medication Scale, previously mentioned in this Chapter [154, 155]. Adherence rates to self-care modalities in persons with diabetes including diet, exercise, blood glucose monitoring, medication taking, and foot care have been estimated. Recent examples of adherence to medication are shown in Table 24.3.

These studies show that adherence rates are lower than expected in clinical guidelines, even with innovative medications. Taking into account the low rates of persistence documented in these studies "from the real world," it is also intriguing to consider if these medications will achieve the effectiveness that has been documented in long-term clinical trials. For example, the median follow-up of LEADER with a GLP-1 agonist was 3.8 years; median follow-up of EMPA-REG with an SGLT-2 inhibitor was 4 years, whereas the ELIXA trial is considered of short duration because it only lasted 2 years! Giving the short duration of persistence, these innovative medications can only demonstrate, as stated by the experts, "non-inferiority as compared with placebo…but showing no evidence of clinical benefit beyond HbA1c lowering [164, 165]."

Table 24.3 Studies about adherence in diabetes management

Year	Author(s)	Patients and intervention	Results and conclusions
2009	Yeaw et al. [156]	Retrospective analysis of pharmacy claims in a database of more than 64 million members Proportion of days covered and persistence among new users of six commonly used chronic medication categories	Six-month persistence for oral antidiabetics: 66% Odds of discontinuation of oral antidiabetics were significantly lower than for other therapeutic classes
2009	Van Bruggen et al. [150]	Baseline and follow-up data of a randomized controlled trial comparing usual care with care according to a national guideline 30 general practices, 1283 patients Number of prescribed drugs and adherence indices (AI) for oral glucose, antihypertensives, and lipid lowering drugs	Higher drug prescriptions in the intervention group An inverse relationship between the number of drugs prescribed during the last 6 months and patients' adherence to blood pressure medications
2010	Fischer et al. [157]	Compilation of e-prescriptions written in 1 year to identify filled prescriptions to evaluate primary nonadherence and identify predictors of nonadherence	78% of prescriptions were filled Higher adherence rates for prescriptions written by primary care physicians Nonadherence for newly prescribed antidiabetics: 31.4%
2013	Koro et al. [158]	Retrospective analysis of patients with type 2 diabetes from a national database	Persistence at 6 months: GLP-1 agonists, 31%, and DPP-4 inhibitors, 39% Adherence at 1 year: GLP-1 agonists – 11% DPP-4 inhibitors – 18% Other medications – 16%
2016	Alfian et al. [159]	Cross-sectional survey in 91 patients with type 2 diabetes using the eight-item Morisky Medication Adherence Scale (MMAS)	Adherence rates: Low: 49.4% Medium: 29.7% High: 20.9% Higher adherence contributes to improved quality of life
2017	Al-Keilani et al. [160]	Cross-sectional survey to investigate self-monitoring of blood glucose adherence and predictive factors in 1079 patients with diabetes	Adherence rate: 59% Predictors: Insulin use versus oral antidiabetics Previous diabetes education Knowledge about the use of glucose monitors
2017	He et al. [161]	Retrospective analysis of database insurance claims to assess adherence (≥80.0% possession rate) and persistence (no gaps in insulin therapy during ≥90 days) to insulin therapy and associated factors 24,192 patients with type 2 diabetes	Adherence rate: 30.9% Persistence rate: 53.0% Mean time to non-persistence: 230.3 days Patients initiated with analogs were more likely to be adherent compared with patients initiated with human insulin Lower adherence in patients initiated with basal insulin compared with patients initiated with premixed insulin Patients with hypertension and dyslipidemia or treated with prandial insulin or with severe hypoglycemia were more likely to be nonadherent/nonpersistent
	Lin et al. [162]	Retrospective study to assess treatment persistence and associated outcomes in 7320 patients with type 2 diabetes treated with a GLP-1 agonist in combination with basal insulin	Treatment persistence: 16.9% Median time to discontinuation: 133 days Persistent patients had greater A1c reductions, were more likely to achieve A1c <7.0%, were less likely to experience hypoglycemia, had fewer hospitalizations, and were less likely to experience hypoglycemia Total medical charges were significantly lower for persistent patients
	Flory et al. [163]	Retrospective study of a cohort of 11,067 patients from a database including information on more than 120 million commercially insured and Medicare Advantage enrollees Unit to measure adherence: "daily medication possession probability" (MPP): days of supplied prescription/number of patients in the cohort	Clear separation of adherence between drug classes after 90 days Daily MPPs: Sulfonylureas: 0.49 Metformin: 0.46 Basal insulin: 0.39 Glitazones: 0.36 GLP-1 agonists: 0.30 DPP-4 inhibitors: 0.21 Particular attention needs to be paid to adherence issues with newer drug classes. i.e., GLP-1 agonists and DPP-4 inhibitors Substantial differences between rates at which diabetes drugs are prescribed and rates at which patients actually take them

Understanding Adherence Beyond the Medical Perspective

In a lecture "upon medical ethics," Ingelfinger stated that "if you agree that the physician's primary function is to make the patient feel better, a certain amount of authoritarianism, paternalism and domination are the essence of physician's effectiveness [166]." Millions of doctors worldwide still believe that persuasion and mind bending are necessary to be an effective physician [8]. Seven decades of efforts have been devoted to understand adherence from the patients' perspective, starting with the need to change semantics, to move forward from uncooperativeness or noncompliance to adherence as the most accepted but still inaccurate term [167]. Other expressions to designate medication taking are problematic [167]: they imply that physicians have control over patients' behavior, taking medications as they prescribe them is the only means to obtain benefit, and create an unjustifiable distinction between persons who take all the medications as prescribed and those who deviate by any measure, a biased dichotomy clearly distant to the reality, which ignores the existence of different patient behaviors [167]. A new language of medication taking has been required for decades and will be increasingly important, as the role of patients in decision-making and in the successful management of chronic disease is recognized [168]. Steiner and Earnest suggested that to improve the language of medication taking [168]:

1. Terminology has to change; patients have the most important opinion about the best strategy to increase medication taking.
2. Physicians have to ask about medication taking, to be prepared and willing to reply questions.
3. Outcomes have to be emphasized; the importance of medication taking to achieve the results of therapy has to be clearly explained.

Adherence, Compliance, and Concordance: What's Next?

It is still necessary to find an adequate definition that could explain or at least provide an approximate idea about what is involved when patients respond positively to physicians' recommendations, *when they comply or adhere*. "Compliance" has permeated medical science and implies the existence of a medical-centered model of behavior, while "adherence" implies that patients have more autonomy in defining and following the medical treatment [169]. Glasgow and Anderson argued against this claim, based on (1) the counterproductivity of the terms "compliance and adherence;" (2) the uselessness of these approaches when they send the wrong message to patients and health professionals; (3) the multidimensional nature of behaviors leading to adherence, instead of the traditional idea that it is the result of the unitary patient-physician interaction; and (4) the dynamic, always changing nature of treatment [170]. They proposed alternative terms such as self-care or "self-management" to describe the cluster of daily behaviors that patients perform to manage their (personal) diabetes [170].

Table 24.4 summarizes the evolving definitions of compliance, adherence, and concordance.

In conclusion, the story of definitions used to describe a persons' follow-up behavior in response to "medical orders" shows that (1) there is not still a term that accurately describes the behavioral process and personal components leading to patient's performance, albeit "concordance" is probably the best; (2) definitions have evolved from the reductionist view that "it all comes down" to the authority of physicians, to view adherence as a set of interacting behaviors influenced by social determinants and the ecology of healthcare [178]. In his definition of compliance, Wright asked, With what? and criticized the all-inclusive approach to adhere to "everything that is ordered [173]." The complexities of lifestyle and the role of internal and external influences have been recognized, and multiple behavioral strategies have been devised to encourage and support lifestyle changes, including adherence to medications.

Addressing the Challenge of Adherence

The ability of physicians to recognize and measure the magnitude of adherence to medical therapies is still poor, and interventions to improve it have produced unsatisfactory results [3]. The prevalence of primary nonadherence, in which patients did not have their prescription filled within 30 days of receiving the order, has been estimated to range from 7% to 21%, depending on therapeutic class, from 5% to 28.4% with antihypertensives, from 11% to 31.4% with antidiabetics, and from 5% to 28.2% with lipid lowering drugs and is even higher for new medications [158, 179]. In the United States, 3.8 billion prescriptions are written each year, approximately one in five new prescriptions are never filled, and, among those filled, about one half are taken incorrectly, regarding timing, dosage, frequency, and duration [180]. The first survey on adherence sponsored by the National Community Pharmacists Association in 2013 in American adults 40 years and older showed that 24% were completely adherent, with one nonadherent behavior out of nine, 20% were somewhat adherent, and 15% were largely nonadherent (noncompliant using the time-honored term) [181]. In other words, only one in four people expected to take medications for chronic diseases is adherent as expected. Regression modeling identified six predictors of

Table 24.4 Definitions of compliance, adherence, and concordance

Year	Author(s) and reference	Term	Definition
1976	Sackett and Haynes [7]	Compliance	The extent in which the patient's behavior to take medications, following diets, or implementing lifestyle changes coincides with medical or health advice
1982	Dracup and Meleis [171]	Compliance	Extent to which an individual chooses behaviors that coincide with a clinical prescription and achieved through negotiations between health professionals and patients
1987	Meichenbaum and Turk [172]	Adherence	Degree to which a patient follows instructions and prescriptions of his doctor
1993	Wright [173]	Compliance	Compliance with what? It has different meanings Medication taking? Alterations in diet? Advice on exercise or smoking? Keeping appointments?
1996	Urquart [174]	Compliance	Extent to which the patients' actual history of drug administration corresponds to the prescribed regimen
1997	Houston-Miller et al. [175]	Compliance *with medical recommendations*	Extent to which recommendations are followed as defined
2003	World Health Organization [176]	Adherence	Extent to which a person's behavior corresponds with agreed recommendations from a healthcare provider
2005	Balkrishnan [177]	Adherence	Extent to which a patient participates in treatment after agreeing to that regimen
2012	Steiner [178]	Adherence	A set of interacting behaviors influenced by individual, social, and environmental forces

medication adherence: (1) personal connection with a pharmacist or pharmacy staff, (2) affordability of medications, (3) continuity of healthcare, (4) importance for patients to take medications exactly as prescribed, (5) patients' information about their health status, and (6) extent of side effects from medications.

The impact of adherence on clinical outcomes is increasingly recognized and investigated in diseases and health problems in which patients' involvement is essential, from dieting to dermatologic disorders. Nonadherence is associated with higher rates of hospital admissions, poor health outcomes, increased morbidity and mortality, and increased healthcare costs [180]. Nonadherence represents a threat to patient's health and adds huge costs to healthcare systems, estimated at $290 billion annually in the United States [181].

Despite the explosion of research about the effects of medical advice on behaviors, persistence to take medications or to sustain lifestyle changes continues to be low. Instead of considering that resistance to change depends entirely on patients, the way in which physicians talk to them is more important [182]. Addressing needs, negotiation, and collaboration to identify the patients' willingness to change and their personal, family, and social support to harness positive and intrinsic motivation have become new paradigms to improve the participation of patients in their self-management. Patient-centered counseling is essential to improve adherence to recommended treatments, and models for counseling behavior change have become increasingly used, such as the "5As" model proposed by Glasgow et al., which comprises five dominions: Assess, Advise, Agree, Assist, and Arrange [183].

Adherence or compliance is a complex behavioral process strongly influenced by the health beliefs and the environment in which patients live, by the healthcare providers' practice, and by the delivery of healthcare [183]. More than enough evidence exists to support recommendations to improve patient outcomes addressing adherence or compliance and the importance of a multilevel approach including patients, providers, and healthcare organizations [175]. Examples of interventions include the CDC's Data to Care strategy that identifies and reengages nonadherent patients by linking them through the health department, their care providers or both to improve individuals' health and reduce transmission of HIV virus, and the strategies used by Reliant Medical Group to improve adherence to blood pressure medication, including (1) ensuring that patients understand the benefits, (2) choosing lower-cost medications, (3) minimizing medication complexity, and (4) monitoring side effects [180].

In recognition of the importance of adherence in chronic disease management, the World Health Organization published a report in 2003 which identified five influential interacting dimensions: (a) social and economic factors, (b) health system-related factors, (c) condition-related factors, (d) therapy-related factors, and (e) patient-related factors [176]. Multiple system-related factors have negative effects on adherence and clinical outcomes, including deficiencies of health services, poor medication distribution systems, and limited knowledge and training of healthcare providers about

adherence and effective interventions for improvement [176]. Take-home messages from the WHO report reinforce the role of patients to achieve clinical outcomes [176]:

1. Poor adherence to treatment of chronic diseases is a worldwide problem of striking magnitude.
2. The impact of poor adherence will grow as the burden of chronic disease continues to increase.
3. Consequences of poor adherence to long-term therapies include poor health outcomes and increased healthcare costs.
4. Improving adherence also improves patients' safety.
5. Adherence is an important modifier of the effectiveness of health systems.
6. Increasing the effectiveness of adherence interventions may have a greater impact on the health of population than improvements in specific medical treatments.
7. Patients need to be supported, not blamed.
8. Adherence is simultaneously influenced by several factors.
9. Health professionals need to be trained in adherence.

Modified from [176]

A Change of Paradigm Is Needed but Still Waiting

In a classical review by Blackwell in 1973, he stated that "much effort is spent in the study of the effects of drugs, but little attention is devoted (to confirm) if patients take them as directed [184]." He cited a pioneering study in which Porter concluded that the significance and extent of drug defaulting has been largely ignored and that "drug defaulters" are part of every practice [22]. Blackwell recommended that to prescribe effectively, physicians should be aware of the frequency and types of noncompliance and be able to recognize and reduce the factors contributing to poor compliance, including (1) the illness (acute or chronic), (2) the patient (age and gender), (3) the physician's relation to the patient, (4) the complexity of the medication regimen, and (5) the treatment setting (hospital, ambulatory), and proposed three measures to prevent or reduce noncompliance: (1) recognition of patients at risk, (2) treatment planning, and (3) clearly explaining the treatment, instead of facing the consequences [22]. In his conclusion, he stated that "too often a prescription (or a medical visit) signals the end of an interview rather than the start of an alliance [22]."

Poor adherence increases the risks for hospitalization, morbidity, mortality, and overall healthcare costs [154, 180]. The association between poor adherence and outcomes is independent of the pharmacologic effects of drugs and exceeds the benefits demonstrated by clinical trials [185, 186]. Medical interventions are usually based on the mistaken assumption that adherence is a single behavior that can be predicted and that individual clinicians can improve it; counseling has to be complemented by outreach interventions and removal of structural and organizational barriers. Patient involvement and facilitating physician's behaviors are associated with positive outcomes. It has been shown that being treated with dignity and patients' involvement is independently associated with positive outcomes [187]. Many people with diabetes do not see a doctor, and seeking medical care is influenced by a range of social and psychological factors besides the presence or absence of medical problems [188]. Patients' willingness and capacity to "follow doctors' orders" is also a consequence of these factors, and they have potentially negative effects on medical interventions. Involving patients in decisions is important; it is crucial, it is good for them, and it is challenging and fruitful for physicians and health professionals, who need to substitute the paternalistic view to recognize the active role of patients in the teaching process, in the delivery and outcomes of medical care [189]. Medication taking behavior is complex and requires multifaceted strategies to effect improvement; one of the most important is trust [186]. Providers perceived as competent but uncaring would be respected but not trusted, whereas providers perceived as caring but incompetent would be viewed with affection but not trusted. Excellent treatments are not useful if patients do not take them and if physicians are not able to intensify treatment of poorly controlled patients [190].

Conclusion

Treatment and advice for patients with diabetes is complex and includes (1) diet, (2) medication, (3) testing, (4) lifestyle, (5) foot care, (6) attending clinic visits, and (7) integration with priorities of life [191]. Along with lack of integrated care and clinical inertia, poor adherence is one of the contributing factors of poor glycemic control [192]. The reported incidence of poor medication adherence in type 2 diabetes ranges widely according to the methodological approach but nevertheless is highly prevalent, ranging from 28.7% to 93% [191, 192]. In addition to poor glycemic control, lack of adherence increases the use of health resources, medical costs, and mortality rates [193]. Defining adherence in patients with diabetes is difficult for several reasons: treatment and advice are individual, and there are many components to adhere, with different levels of adherence and variability over time and different types of interventions for each component [190]. Research about effective interventions to increase adherence to pharmacological and non-pharmacological modalities of diabetes treatment is essential to improve implementation of evidence-based medicine "in

the real world." In the meantime, clinicians should be aware about the reality of the gap between their clinical advice and the magnitude of patients' adherence with their recommendations and address the interactions of patient, physician, and systemic factors to implement successful diabetes management models [194]. Adherence to prescribed medications is associated with improved clinical outcomes for chronic disease management and reduces mortality [180]. Higher levels of adherence have improvements in clinical and economic outcomes, particularly among patients from poor or minority communities, the most vulnerable segments of the population [180, 195]. Clinical inertia and patient adherence are two largely unrecognized or misinterpreted challenges and opportunities in diabetes management that should be systematically addressed.

Multiple-Choice Questions

1. What is the best term to describe the patients' expected behavior to medical recommendations?
   (a) Obedience
   (b) Compliance
   (c) Adherence
   (d) None of the above
   (e) All of the above
2. Traditional methods to assess adherence include:
   (a) Direct interrogation of patients and their families
   (b) Residual medication counting
   (c) Measurement of drug metabolites
   (d) All of the above
   (e) None of the above
3. More than 30 years ago, it was confirmed that compliance is not related to income, social class, occupation, or education.
   (a) True
   (b) False
4. The word "compliance" implies:
   (a) That patients are obeying as expected
   (b) The effectiveness of treatment
   (c) That patients are willfully disobedient in the face of medical expertise
   (d) That results of controlled clinical trials can be replicated "in the real world"
   (e) All of the above
5. It has been shown that patients are able:
   (a) To self-monitor blood glucose levels and adjust insulin doses
   (b) To self-monitor blood pressure levels and adjust antihypertensive doses
   (c) To self-monitor body mass index to achieve sustained body weight loss
   (d) All of the above
   (e) None of the above
6. Discontinuation of chronic disease treatment is highly associated with:
   (a) Patients' ignorance
   (b) Long waiting times to receive the medical visit
   (c) Deficiencies in doctor-patient relationships
   (d) The economic status of patients
   (e) Insufficient intelligence to understand physicians' orders
7. The "diabetic personality" refers:
   (a) To the consequences of diabetes on mental health
   (b) To the explanation of poor treatment outcomes on the patients' fault
   (c) To the adaptation process to diabetes and its demands
   (d) To the existence of a single, well-defined personality of all people with diabetes
8. Complete adherence to all the areas of diabetes management has been reported at:
   (a) 100%
   (b) 80%
   (c) 50%
   (d) 25%
   (e) 1%
9. Nonadherence to diabetes diet has been reported at:
   (a) 100%
   (b) 75%
   (c) 66%
   (d) 50%
   (e) 25%
10. Errors in insulin dosage by patients have been reported at:
   (a) 100%
   (b) 75%
   (c) 66%
   (d) 50%
   (e) 25%

Correct Answers

1. (d) None of the above
2. (d) All of the above
3. (a) True
4. (c) That patients are willfully disobedient in the face of medical expertise
5. (d) All of the above
6. (b, c)
7. (b) To the explanation of poor treatment outcomes on the patients' fault
8. (e) 1%
9. (b) 75%
10. (d) 50%

Part V

Resources of Support for Persons with Diabetes

Challenges and Opportunities in Diabetes Education

25

Jane K. Dickinson, Melinda Downie Maryniuk, and Margaret Powers

Introduction

Diabetes education started with Elliott P. Joslin's efforts to provide comprehensive care for people with diabetes. In the early insulin era, he developed the role of the diabetes teaching nurse or nurse educator [1]. Diabetes education has grown significantly since that time, with excellent and diverse models evolving around the world. This chapter outlines the components of diabetes education and describes various methods of delivery. This chapter also presents the evidence for diabetes education as a vital resource for people with diabetes in reducing acute and chronic diabetes-related complications and improving other health measures. In addition, existing challenges and future opportunities are discussed.

Definition of Diabetes Self-Management Education and Support

The National Standards for Diabetes Self-Management Education were first developed in the United States in 1995 [2]. These Standards serve as guidance for those providing diabetes education and set the standard for best practice in developing, implementing, and evaluating a diabetes self-management education program. In 2011 a task force representing the American Association of Diabetes Educators and the American Diabetes Association changed the name to National Standards for Diabetes Self-Management Education and Support [3]. In the most recent version, the Standards include the following definition:

> Diabetes Self-Management Education and Support: The ongoing process of facilitating the knowledge, skills, and ability necessary for prediabetes and diabetes self-care, and the activities that assist the person with diabetes or prediabetes in implementing and sustaining the behaviors needed to manage his or her condition on an ongoing basis beyond or outside of formal self-management training. This process incorporates the needs, goals, and life experiences of the person with diabetes or prediabetes and is guided by evidence-based standards. Support (whether behavioral, educational, psychosocial, or clinical) helps implement informed decision making, self-care behaviors, problem solving, and active collaboration with the health care team and to improve clinical outcomes, health status, and quality of life. [4]

Diabetes Canada states the following:

> Access to high-quality self-management education supported by an interprofessional health-care team with specialized knowledge of diabetes, current clinical practice guidelines and best practices has evidence for improvements in the wellness of the person living with diabetes and a decrease in utilization of the health system for ambulatory sensitive conditions. [5]

Other countries have comparable definitions that can often be found on their websites.

Evidence Supporting the Effectiveness of Diabetes Education

Structured diabetes self-management education and support programs lead to reduced A1C [6–11], reduced all-cause mortality in people with type 2 diabetes [12], and improved self-care activity [11] and sometimes result in weight loss [8]. An integrative review that studied pediatric diabetes self-management education and support programs showed that mixed programs containing both self-care aspects and psychosocial aspects, and delivered online, were most likely to

influence psychosocial competencies in children and adolescents [13]. Diabetes self-management education and support has also demonstrated cost-effectiveness [12, 14] and improved quality of life in people with diabetes [7, 15, 16].

Recommendations for Diabetes Education

The American Diabetes Association recommends diabetes self-management education and support for all people with diabetes, as well as those with prediabetes. In their Standards of Medical Care, the American Diabetes Association states that diabetes self-management education and support that is person-centered and tailored to the individual's needs and goals should be delivered at diagnosis and as needed [17]. The International Diabetes Federation also includes "the right to information and education" in their Charter of Rights and Responsibilities for People with Diabetes. In addition, an individualized medical nutrition therapy program, preferably by a registered dietitian, is recommended for all people with diabetes.

Diabetes Australia recommends structured diabetes education to consumers as soon as possible after diagnosis, ongoing, and on request. They also recommend diabetes education that is person-centered, promotes active learning, and has the flexibility to meet individual needs, choices, and learning styles [18]. Diabetes UK published a report titled, Diabetes Education: The Big Missed Opportunity in Diabetes Care, highlighting their view that diabetes education is an essential part of managing diabetes and avoiding long-term complications [19]. According to National Institute for Health and Care Excellence guidelines, structured diabetes education programs should be offered and aimed at empowering people with diabetes to manage successfully [20].

The American Diabetes Association, the American Association of Diabetes Educators, and the Academy of Nutrition and Dietetics recommend diabetes education at four critical times (described later).

The DAWN2 Study sought cross-national comparisons across 17 countries of perceptions on healthcare provision for benchmarking and sharing of clinical practices to improve diabetes care. Results of quantitative surveys of over 15,000 people with diabetes, family members and health care professionals drew attention to the large number of people who feel the burden of the disease, and made the case for improved psychosocial care and diabetes self-management education. Specifically, about half of the people with diabetes surveyed reported diabetes has a negative impact on their physical health and emotional well-being. Just less than half (45%) reported experiencing diabetes-related distress. Education resources are available on the DAWN2 website for healthcare providers to use in facilitating a dialogue-based approach to education and care for people with diabetes [21].

While standards from major diabetes organizations are recognized worldwide, how do these recommendations get interpreted and operationalized? Access to diabetes education and diabetes educators varies greatly around the globe. This section includes highlights from some of the major position papers and practice guidelines, which can be tailored for diverse practice settings.

Standards for Diabetes Education

The process and quality of diabetes education is guided by standards and guidelines. In the United States, the National Standards for Diabetes Self-Management Education and Support [4] define quality diabetes self-management education and support and assist those who educate to implement evidence-based programs and services. The National Standards are reviewed and updated every 5 years by a multidisciplinary group representing the American Diabetes Association and the American Association of Diabetes Educators. The Standards define such things as who can provide diabetes education, content areas to be assessed and taught as needed, importance of providing ongoing support, and quality.

While the National Standards highlight the benefit of a team approach to diabetes education, they also acknowledge that a team is not always possible or available. To meet quality standards, it is recommended diabetes education be delivered by a nurse, dietitian, or pharmacist with relevant background and experience. For example, in the United States, 15 hours of continuing education per year in diabetes-related topics is considered a minimum acceptable level of instruction. Qualification as a Certified Diabetes Educator may be obtained by a wide variety of clinicians within the United States, including nurses, dietitians, pharmacists, physicians, clinical social workers, and master's level exercise physiologists [22]. Based on a survey of the American Association of Diabetes Educators members, in the United States, 50% of diabetes educators are nurses, 35% dietitians, 6% pharmacists, and 6% others, which include exercise physiologists, clinical social workers, master's level health educators, physicians, and podiatrists. In a recent survey of diabetes educators, 86% reported having the Certified Diabetes Educator credential [23].

Eight core content areas are defined within the National Standards. An assessment of each individual's needs determines which elements of the curriculum are required. Content areas include the following:

- Diabetes pathophysiology and treatment options
- Healthy eating
- Physical activity
- Medication use
- Monitoring and using patient-generated health data
- Preventing, detecting, and treating acute and chronic complications
- Healthy coping with psychosocial issues and concerns
- Problem-solving

Other recommended content areas include navigating the healthcare system, self-advocacy, and e-health education.

The National Standards highlight the importance of person-centered, interactive, and evidence-based diabetes education. The most successful approach is one in which patients and providers work together to develop an individualized education plan. Evidence-based communication and behavior change strategies are also recommended, including collaborative goal setting, motivational interviewing, and interactive teaching techniques. In addition the Standards address the need for ongoing support, measuring participant progress, and continuous quality improvement. Within the United States, diabetes education programs and services must be able to demonstrate that each of the standards are met in order to be eligible for payment – both by Medicare, a government insurance plan, and by most private insurers.

Healthcare providers can look for diabetes education standards that may have been written for a country or health system in a specific region, as a variety of them do exist. Notably, the International Diabetes Federation has published a detailed collection of 32 standards that describe not only structure and process standards (recommended elements of a diabetes program similar to those described in the US National Standards document) but also content standards (describing what to assess and teach) and outcomes standards (what to measure) [24].

The roles and expectations for diabetes educators vary greatly around the world. In the United States, many diabetes educators with advanced credentialing work closely with the physician – and other healthcare providers – as a co-manager of the patient's care. This may involve reviewing blood glucose patterns (from meter or continuous glucose monitoring downloads) and making recommendations to the physician for treatment changes and/or adjusting insulin within established guidelines. Some diabetes educators are expected only to deliver information about diabetes to patients, having little interaction with the physician or even input from the patient. The latter is not an ideal model. Instead, collaboration and communication among all team members is most beneficial for the best outcomes.

The American Association of Diabetes Educators has defined five levels of practice for diabetes educators (see Tables 25.1 and 25.2). There are three levels of licensed or certified healthcare professionals (such as a nurse, dietitian, or pharmacist): beginner, intermediate, and advanced. There are also two levels of paraprofessional, which include medical office assistants, community health workers, and peer counselors, who may participate in the formal diabetes education process. For each of these five levels, competencies (minimal skills and knowledge) have been recommended in five domains (see Table 25.3):

Table 25.1 Diabetes educator provider levels

	Diabetes educator level 1	Diabetes educator level 2	Diabetes educator level 3
Educational background	Level 1 educators are healthcare providers who interact professionally with diabetes patients to provide the essential knowledge and skills needed for safe self-care Level 1 designation includes but is not limited to registered nurses (from any accredited entry-level education program), advanced-practice nurses, registered dietitians (licensed or registered), pharmacists (licensed or registered), exercise physiologists, physical therapists, physician assistants, and physicians	Level 2 educators are healthcare providers who have achieved an advanced body of core knowledge and skills related to diabetes education and/or management above that which is required by the profession of origin Level 2 incorporates those providers who meet the academic, professional, and experiential criteria to qualify for and maintain the CDE® credential. A distinction is made between the newly credentialed educator who is competent in all and proficient in some areas of diabetes knowledge and the level 3 educators who are at the highest level of expertise in the field	Level 3 educators are advanced-level experts in diabetes education, clinical management, and/or research Level 3 educator encompasses those involved in integrated, comprehensive, and global management of people with diabetes. This includes but is not limited to clinicians, researchers and academics, program managers, healthcare administrators, and consultants. The educator at this level may hold the CDE® credential; meets the academic, professional, and experiential criteria to qualify for and maintain the BC-ADM credential; and may be recognized as a Fellow of the American Association of Diabetes Educators. This level of practice is characterized by care coordination and management, autonomous assessment, problem identification, planning, implementation, and evaluation of diabetes care Additionally, it involves excellent communication as well as complex critical thinking and clinical decision-making skills. High-level clinical and nonclinical practice is characteristic of this level
Educator/clinician level of practice	Beginner/advanced beginner Basic	Competent/proficient Intermediate	Expert Advanced

(continued)

Table 25.1 (continued)

	Diabetes educator level 1	Diabetes educator level 2	Diabetes educator level 3
Expected and domain-specific knowledge, skills, and adaptation (KSA) for delivery of diabetes education/support	Competencies for diabetes educators Scope of practice, standards of practice, and standards of professional performance for diabetes educators The educator's focus is on transmitting knowledge related to essential skills for safe self-management	Competencies for diabetes educators Scope of practice, standards of practice, and standards of professional performance for diabetes educators The educator/clinician's focus is on both knowledge and skills to create individualized self-management plans, coordinate care, interpret personal data, conduct focused and/or complete educational assessments, and promote successful self-management through adaptation	Competencies for diabetes educators Scope of practice, standards of practice, and standards of professional performance for diabetes educators The clinician/educator's focus is on higher-level counseling, regimen adjustment (as appropriate for scope of practice), recognizing and prioritizing complex data, and therapeutic problem-solving Focused and/or complete clinical and educational assessments are used to guide decision-making
Non-diabetes foundational skills for the delivery of diabetes education	Bloom's taxonomy: remembering, understanding, applying teaching, and learning skills Preprocessed delivery models	Bloom's taxonomy: applying, analyzing, and evaluating teaching and learning skills: Individualized assessment and delivery Educator-facilitated group discussion. Differentiate teaching from learning objectives	Bloom's taxonomy: analyzing, evaluating, and creating teaching and learning skills – creative, individualized teaching for self-management Developing and evaluating new models of education
Novice to expert continuum (Dreyfus model): Expertise develops over time	Entry-level clinician/educator	CDE®/experienced clinician	BC-ADM/CDE®/FAADE/Expert
Years in direct diabetes education and/or management	0–2 years of direct care experience in diabetes (percentage of time devoted to diabetes specialty practice)	3–5 years post achievement of CDE® or more experienced in diabetes clinical/educational care	More than 5 years of direct engagement in the diabetes as a specialty practice

5. Program and business management

Guidebooks, available on the American Association of Diabetes Educators website, are useful for individuals or hospital systems setting up teaching programs for diabetes educators at each different level. Program coordinators can refer to these when defining learning objectives for staff education and tailor them to the specific setting [25, 26].

In the past, there was a lack of clarity regarding when to refer patients for diabetes education. A recent joint position statement between the American Diabetes Association, the American Association of Diabetes Educators, and the Academy of Nutrition and Dietetics defined four critical times for referral to a diabetes educator [27]. These times are at diagnosis, annually (to assess certain situations such as elevated A1C, unexplained highs or lows, or planning a pregnancy), when complicating factors influence self-management (such as a diagnosis of retinopathy or cancer or the occurrence of a stroke) and when transitions in care occur (such as moving to another provider or insurance plan or transitioning from a hospital or rehab stay to home care). The joint position statement defines both what the referring provider needs to do and what may be expected from the diabetes educator. Table 25.5 provides an overview of the referral recommendations (the full algorithm is available at https://www.diabeteseducator.org/practice/practice-documents/position-statements).

Challenges in Meeting Diabetes Education Needs: Addressing the Problem

Each individual with diabetes benefits from initial and ongoing diabetes education and support to address the day-to-day behaviors that impact health and quality of life. One hundred eight million people diagnosed with diabetes worldwide require this intervention, so each can self-manage their diabetes on a daily basis [17, 28]. Diabetes education includes much more than medication teaching; therefore, it is a valuable intervention regardless of when diabetes medications are started. At diagnosis diabetes education involves collaborative discussion and decision-making related to medications, monitoring, physical activity, complications, nutrition, risk reduction, and developing personal strategies to address psychosocial issues and concerns and to promote health and behavior change [27]. A unique comparison of diabetes education and support to metformin highlights the many medical, nutritional, and behavioral benefits of education and support [29] (see Table 25.4).

Challenges in meeting an individual's diabetes education and support needs include knowing what education and support is needed, having qualified staff to engage in this clinical care, and ensuring patients continually access this care as their diabetes care needs change.

Identify Education and Support Needs

There are a number of position statements, consensus papers, standards of care, and curricula that detail topics to address in diabetes care. Many of these highlight the need to offer education in a person-centered, collaborative, engaging, and respectful manner. There are basic needs that should be addressed immediately upon diagnosis by the diabetes care team and then other needs that can be addressed soon after either through a diabetes education program or by dedicated education staff within the clinic [27]. The diabetes education position statement discussed earlier details the breadth of decisions required for daily self-management of diabetes at four critical times (see Table 25.5).

Table 25.4 Scorecard: diabetes self-management education versus metformin

	Benefits rating	
Criteria	Diabetes education	Metformin
Efficacy	High	High
Hypoglycemia risk	Low	Low
Weight	Neutral/loss	Neutral/loss
Side effects	Low/savings	Low
Psychosocial benefits	High	N/A

Table 25.5 Diabetes education and support care at four critical times[a]

Areas of focus and action steps for primary care provider, endocrinologist, and clinical care team
At diagnosis
Answer questions and provide emotional support regarding diagnosis
Provide overview of treatment and treatment goals
Teach survival skills to address immediate requirements (safe use of medication, hypoglycemia treatment if needed, introduction of eating guidelines)
Identify and discuss resources for education and ongoing support
Make referral for diabetes education and medical nutrition therapy
At annual medical visits
Assess all areas of self-management
Review problem-solving skills
Identify strengths and challenges of living with diabetes
When new complicating factors influence self-management
Assess all areas of self-management, and refer for personalized education as required
Review problem-solving skills
Identify strengths and challenges of living with diabetes
When transitions in care occur
Develop diabetes transition plan
Communicate transition plan to new healthcare team members
Establish diabetes education regular follow-up care

Adapted from Powers et al. [27]
[a]See reference for details of action steps and areas of focus for diabetes education

Employ Qualified Staff

Key to successful diabetes education are the method of delivery and engagement of each individual in their care. The focus of diabetes education is to address the clinical, psychosocial, and behavioral needs of individuals. Historically preparation of educators has been more focused on teaching them facts about diabetes rather than emphasizing principles of behavior change. Clinicians who commit to offering diabetes education and support require a unique blend of the art and science of diabetes care as well as resources to meet the needs of each individual.

The diabetes educator's role was developed to address the scope of diabetes self-management education and support needs of individuals with diabetes. In the United States, the Certified Diabetes Educator credential identifies those who meet specific knowledge and practice criteria related to diabetes education [22]. A Certified Diabetes Educator may be a nurse, dietitian nutritionist, pharmacist, social worker, psychologist, nurse practitioner, or other clinician. Different clinics in different locations around the world address the coordination and offering of diabetes education and support in various ways. Research highlights the value of a team-based approach to providing diabetes education; thus the inclusion of a Certified Diabetes Educator or designated diabetes educator on the typical healthcare team is recommended to provide and/or coordinate diabetes education [6, 27].

With this in mind, clinical teams can plan how they address the ever-increasing incidence of diabetes and corresponding need for specialized staff to educate those with diabetes. In the United States, there are 19,484 Certified Diabetes Educators [30]. With over 30 million people in the United States having diabetes [31], each Certified Diabetes Educator would be responsible for the education needs of approximately 1540 people. Worldwide this lack of diabetes educators is likely even more staggering and highlights the need for increased preparation for diabetes educators and other clinicians who accept the responsibility of addressing the initial and ongoing education and support needs of individuals with diabetes.

Ensure Ongoing Access

To address the diabetes education and support needs of people with diabetes, the clinical team can review the needs listed in Table 25.5 (see also Appendix I) and assign staff to each topic. Through discussion and consideration of other resources, teams can identify how to meet the individual needs of patients. In the United States, a referral from a provider is necessary to access a formal diabetes education program. A list of credentialed education programs can be found at www.diabeteseducator.org/deap or www.diabetes.org/erp. In other countries, national diabetes organizations typically list available resources.

It is essential that providers advocate for the education and support needs of their patients. Patients may not be aware of the value and outcomes associated with diabetes education, and some may not understand its necessity in addition to medication they take. It is especially important to highlight the ongoing need for diabetes education and support throughout one's lifetime, including when other complicating factors influence diabetes care and when transitions in care occur. It may be easy to become distracted or focused on a new situation, allowing diabetes care to suffer and become a greater burden on the patient. Diabetes education does not occur in a single session; rather it is an ongoing collaboration with the diabetes team. Lack of follow-up can diminish previous behavior change and successes.

Communication among staff is critical whether or not the team is utilizing the services of a designated, formal diabetes education program. A continuous review of responsibilities, challenges, and successes can lead to many positive outcomes.

Who Are the Diabetes Educators?

The diabetes self-management education and support staff may be a team of professionals representing multiple disciplines, or it may include just one discipline. Often the location and size of the organization determine the size of the leadership and education team. Members of the healthcare team can contribute to an effective diabetes self-management education and support program by collaborating and providing clear communication [27].

In the United States, the first group of diabetes educators started a professional organization, the American Association of Diabetes Educators, which currently has over 14,000 members and represents multiple disciplines [32]. Diabetes education certification (Certified Diabetes Educator or CDE) was first granted in 1986, and the National Certification Board for Diabetes Educators was founded in the same year [33]. Diabetes education is often considered a "specialty" or "specialization"; however, it is not considered its own profession or discipline. Diabetes educators are prepared in their specific discipline and often land in the specialty serendipitously. More recently academic preparation for diabetes educators has become an option.

The American Association of Diabetes Educators has established three levels of diabetes educators and two levels of diabetes paraprofessionals (see Tables 25.1 and 25.2). The practice levels were developed in order to delineate roles and responsibilities, suggest a career path, and clarify the contributions of diabetes educators with different levels of experience, education, and skills in a variety of settings.

The American Association of Diabetes Educators also provides Competencies for Diabetes Educators and Diabetes Paraprofessionals on their website [25]. These competencies were originally developed to provide the minimum knowledge and skills needed for practicing diabetes educators at each level. The competencies are reviewed and revised approximately every 5 years and can be used to develop job descriptions, conduct performance reviews, and create educational curriculum, among other things (see Table 25.3).

Diabetes educators originally assumed this role "on the job" – seeing and responding to a need. Today the need for diabetes education is greater than ever, and there are multiple paths to becoming a diabetes educator. Several universities have certificates and specialties in diabetes, and there is at least one graduate degree in Diabetes Education and Management [34]. Continuing education is available on diabetes topics through several universities and organizations around the world. There are also national and international meetings where people can learn about diabetes education topics (see Table 25.6).

Powers et al. [27]

Diabetes education can range from minimal teaching in a primary or other care provider's office to formal education with a written curriculum and multiple follow-up visits and anything in between. Dietitians, pharmacists, exercise specialists, and other professionals may serve roles separate from or in addition to diabetes education.

Developing a Diabetes Education Program

Diabetes education takes place in a variety of practice settings, including the hospital, clinic, private practice, retail, community, and beyond. There are no limits to where diabetes education can occur. Structured or formal programs typically meet standards for diabetes self-management education.
